The study for groundwater resources system of china with three-rated appraising method of subarea Key word: Water resources; subarea; River valley; Hydrology geology unit; GIS databaseSummary: surface water and groundwater are important constitutes of water resource system. Since the water transport and deposited in a different way within the medium between surface water and ground water, so the modeling and appraising method adopted are different. the first water resources appraising of China, only the one item of national groundwater resources' gross is to 10000 billion tons (occupy 1/8 of all the national groundwater resources or so), this data is equal to the data of the water transported from south to north one time ormore. The author think that the main reasons for the total error of groundwater resource are:1) In the nature, groundwater and surface water frequently conversed and replenished with eachother. It is impossible to appraise them respectively. In the water resources` appraising of China, from one– rated subarea to three-rated subarea, the method of ground water modulus was divided with surface water. So, it can't be reflected clearly that the system of surfacewater and groundwater are oneness. 2) In the water resources` appraising, the computing methods of surface water and ground watersreplenishment and evaporation are not be united, the resource quantities` iteration principleis different, leading to the inconformity of the result. 3) The basic data for water resource's evaluation of china come from the different managementsection respectively. Water conservancy department managed surface water and agricultural water. So relevant water data primarily come from the water conservancy section. Constructed department managed the water for city use. Relevant data mostly come from local constructsection. For a few years, the groundwater was managed by geologic and mining section. Meantime,the section can pursue a part of monitoring work. They have the accumulated data of many years. The data of above three sections are the foundation on which proceed the water resource's evaluations in China. So the problem of data unification should be resolved. The author think that in the first water resources evaluation of China, surface water wasevaluated according to River valley, while ground water was evaluated through Hydrology geology unit, which are the principal reason for the error of water resource's gross. Theconversed relation of four kind of water is complexity, which adopt the evaluation methodof river valley and hydrologic unites respectively. So the gross' error is unavoidable in water resources' appraising. In the thesis, the author brings up the project of three-ratedevaluation and subarea. In the groundwater resources' quantity evaluation, one and two-ratedsubarea method according to river valley are adopted. While three rated subarea according to groundwater unites is used to resolve the problem of the water resources' evaluation error.

ACID RAIN AND GROUNDWATER QUALITY

Roald Gamidovich DZHAMALOV (Water Problems Institute, Russian Academy of Sciences)

The study of the effect of precipitation on acidification processes in groundwater for different combinations of natural and anthropogenic factors that control the response of hydrogeological systems to acidification and the development of methods for the risk assessment of groundwater pollution by acid fallout.On catchment areas in Moscow and Novgorod regions in Central Russia, field observations and analytical determinations were carried out (the sampling of rainwater, meltwater, surface water, soil water, and groundwater, as well as of water-bearing rocks) for the subsequent study and update of the data base on groundwater acidification under individual geological, hydrogeological, landscape, and geomorphological conditions and degree of acid load. The main attention was paid to the study of the hydrochemical regime of spring water and groundwater, which are most liable to acidification. In addition, the mineralogical composition of water-bearing rocks and clayey interlayers was analyzed to assess the degree of interaction between them and percolating acid waters. The data on the hydrochemical groundwater regime within individual catchment areas have been generalized over the period of last 30-40 years. These materials were used for verification and adaptation of the hydrodynamic and physicochemical models for estimating the areal extent and degree of groundwater acidification.The field and experimental studies, as well as simulations, were carried out with a special attention paid to studying the soil and rocks of aeration zone, since they buffer the effect of acid precipitation on groundwater. Stages in leaching the soluble minerals of soil and water-bearing rocks were determined as a function of the acid load and duration of exposure. The relationship was determined between the neutralizing capacity of rocks of aeration zone and amount of carbonate rocks, the rate of infiltration of acid precipitation, as well as the duration of physicochemical interaction in the water-rock system and the solid-to-liquid ratio.Possible forms of migration of constituents of rainwater, meltwater, surface water, and groundwater have been studied under various conditions of their formation and migration, as well as with allowance made for the duration of acidification process in the water-rock system.The analysis of the available criteria of acidification allowed developing new criteria of the degree of acidification of natural waters, which are based on the amount of acid load and its residence time in the water-rock system. Various phases of acidification of soil water and groundwater have been studied under a variety of conditions of their formation and under various hydrogeological regimes.The field and experimental studies, as well as the computer simulation allow us to establish several important particularities of groundwater acidification and contamination under atmosphere fallout.

HYDROGEOLOGICAL ANDHYDROGEOCHEMICAL ASPECTS OF THE NUBIAN SANDSTONE AQUIFER IN EAST OWEINAT AREA, SW EGYPT

Esam EL SAYED[1], K. DAHAB[2], A. M. EBRAHEEM[3] ([1]Geology Department, Faculty of Science, Minia University, [2]Geology Department, Faculty of Science, Menofia Univ, [3]Geology Department, Faculty of Science, Assiut Univ)

East Oweinat area is currently a site of a major reclamation project, which totally depends upon the groundwater extraction from the Nubian Sandstone Aquifer; the only water resource in this area. This aquifer is composed of sandstone beds with minor intercalation of siltstone and kaolinitic sandstone. Groundwater in this aquifer occurs under unconfined conditions, while elsewhere it is under semi confined conditions as a result of the occurrence of clay intercalations within the aquifer materials. Generally, groundwater flow is from southwest to the northeast. The saturated thickness is ranging from less than 100 to 650 meters in the study area. The recent annual recharge to the aquifer system in this area is too low if compared to the present extraction rate and exclusively depends on the transmissivity of the aquifer material and its hydraulic gradient. Groundwater belongs to f resh water class whereas salinity content ranges between 302 and 876 ppm., It is of meteoric origin and belongs to alkali- chloride sulphate water type. Therefore, it is suitable for irrigation purposes for most of the soil types under ordinary conditions.

HS02/07P/C24-033OP Oral-Poster **1504**

A STUDY OF HYDROGEOLOGICAL CONDITIONS OF THE NUBIAN SANDSTONE AQUIFER IN THE AREA BETWEEN ABU SIMBEL AND TUSCHKA, WESTERN DESERT, EGYPT

Esam EL SAYED[1], K. DAHAB[2], A. M. EBRAHEEM[3] ([1]Geology Department, Faculty of Science, Minia University, [2]Geology Department, Faculty of Science, Menofia Univ, [3]Geology Department, Faculty of Science, Assiut Univ)

The Nubian Sandstone Aquifer in the area between Tuschka and Abu Simbil is small portion of the very well known Nubian Sandstone Aquifer System in the Eastern Sahara, which covers the entire area of southwest Egypt, southeast Libya, northeast Chad, and northern Sudan. Tuschka area is currently the site of intensive drilling and development for a huge land reclamation project. The drilling information was used to study the hydrogeological setting of the aquifer in the area. The obtained results indicate that the lithological characteristics and tectonic setting is strongly affecting the groundwater flow pattern as well as the aquifer potentiality of the Nubian Sandstone aquifer in the area. The aquifer potentiality in the study area is low if compared to that of east Oweinat, Dakhla, and Kharga areas. The aquifer is mainly composed of hard ferruginous sandstone with great shale and clay intercalation with a thickness ranging from 140 to 230 meters. T he potionmetric surface is ranging between 102 and 170 meters above mean sea level. Depth to water ranges between 20 and 140 meters from the ground surface.Groundwater in this aquifer belongs to fresh to slightly brackish type (salinity is ranging from 240 to 2370 ppm). The predominant water type is sodium sulhate and sodium chloride. The groundwater is related to meteoric origin. The high concentration of sodium, chloride, and sulfates reflect leaching and dissolution processes of gypsiferous shales and clay as well as long residence time of water. Most of the collected groundwater samples are suitable for irrigation purposes in the study area.

GEOPHYSICAL EXPLORATION FOR GROUNDWATER IN THE TOLON-KUMBUNGU DISTRICT OF GHANA

Jude Simon BAYOR, Aboagye MENYE (HYDROLOGY)

Geophysical exploration for groundwater has been carried out in seven communities the Tolon-Kumbungu District of the Northern Region of Ghana. The communities involved are Gbullung, Woribogu, Gun, Nyorong, Yoggu, Nyankpala-Tuunayili and Nyerishegu. These communities are mostly located in the south-eastern half of Tolon and lie in the Lower Voltaian Sedimentary Basin. The geophysical techniques involved were the Electromagnetic (EM) survey for ground profiling with the EM 34-3 ground conductivity meter and the dipole-dipole configuration in Vertical Electrical Sounding (VES) with the Swedish ABEM SAS 300C resistivity equipment. Results show that major aquifers are confined to hard, fractured sandstone formation. No water was found for weathered zone or fresh rock aquifers. Analysis of data also revealed several thin-bedded sequences of between 4 m and 10 m thickness of sandstone, mudstone shale and their intercalations to be the dominant formations here. Groundwater was confined to between 25 m and 45 m with major aquifers occurring approximately between 34 m and 45 m depths. Groundwater availability to beyond 55 m was not possible. The potential success rate is estimated at 75%. The surveys show conclusively that the EM method and the dipole-dipole array in VES when combined is an effective tool for the location of groundwater in the survey area of the Tolon-Kunbumgu District.

A POLLUTION OF AQUIFERS BY HYDROCARBONACEOUS INCLUSIONS

Nadezhda K. KORSAKOVA, Valentin I. PENKOVSKY (Siberian Division, Russian Academy of Science, Lavrentyev Institute ofHydrodynamics)

Damages of oil-pipe lines, liquid escape from gasoline storage and oil storage, petrol leak from filling station lead to percolation of immiscible with water fluids into water-bearing stratum occurs. At that closed hydrocarbonaceous inclusions are generated inside aquifers. Similar formations ar able to be in dynamic equilibrium with groundwater flow. A water phase partially flows around and partially through such inclusions wich are in stationary positon under the influence of capillary forces. This phenomenon is called ˝internal capillary locking˝. The experiments were realized on transparent fill-up physical models of water-saturated bed contained circle oil inclusions under presence of gravity. It was observed the redistribution of saturation in oil spot under influence of gravity and oncoming flow of water. The limit dynamic equilibrium with water phase flow criterion was obtained for an inclusion. It was demonstrated that equilibrium stationary position was broken under exess over the criterion, and hydrocarbonaceous phase started moving. The mathematical model as a system of differential equations have been formed that allowed to describe in a hydraulic approximation a distribution of oil particles in three-dimensional inclusion been under action of a field of hydrodynamic forces and field of gravitation. A hydraulic pressure have been averaged over vertical component, consequently seepage became two-dimensional. But a distribution of oil particles remained as three-dimensional because of a gravity was taken into account. The condition of phase pressure jump on boundary of phases was taken into consideration too. The finite element method was used for solving of the two-dimensional ground water flow problem with an arbitrary given form of hydrocarbonaceous inclusion. The obtained numerical results are well agreed with the experimental data.

INTEGRATED GEOPHYSICAL INTERPRETATION FOR GROUNDWATER EXPLORATION AT NUKHL AREA, CENTRAL SINAI, EGYPT

Abdel-Rady Ghareeb HASSANEEN[1], Sultan Awad SULTAN[2], Badr Saad MOHAMED[3] ([1]Prof. of Geophysics and head of the geomagnetic and geoelectrical dept., National Research Institute of Astronomy and Geophysics, Helwan, Cairo, Egypt., [2]Lecturer of Geophysics, [3]Geologist (Egyptian geological survey))

Different geophysical tools were carried out on the studied area to define the stratigraphic units, structural elements and the depth to the basement surface. These geophysical tools are geoelectric, magnetic and gravity methods.Quantitative interpretation of the vertical electrical sounding curves was done by using the two layer standard curves and generalized Cagniard graphs (Koefoed , 1960; Orellana and Money, 1966) to determine the thickness and true resistivities for each geoelectrical unit in order to obtain a preliminary models . All VES stations are re-interpreted as a final models using IPI-1D program to compute these final models. The interpretation of the magnetic data started with reduction to the magnetic pole, then depth to the upper surface of the basement was determined applying Eulier deconvolution technique. The quantitative interpretation of Bouguer gravity anomaly map started with separation of residual and regional gravity anomalies applying high and low pass filter technique using Geosoft program (1994). The structural elements can be determined

from the residual gravity anomalies. Also, gravity modeling was carried out along three profiles to define the depth of water bearing Nubian sandstone aquifer and the upper surface of the basement using GM program (1995). The results of the geophysical interpretation show that, the subsurface section consists of six geoelectric units. The depth of upper surface of the Nubian sandstone(aquifer) ranges between 800 to 1000 m. The depth of the basement surface ranges between 1720 m at the northwestern part and 3600 m at the southwestern part of the studied area. There are normal faults whose directions are: N-S, E-W and NE-SW.

STUDY ON REMOVAL OF CADMIUM FROM GROUNDWATER BY ADSORPTION ON GAC , BAC & BIOFILTER

Ramazan ali DIANATI TILAKI (Environmental Health Engineering Department, Mazandaran University of Medical Sciences)

The Contamination of groundwater by toxic heavy metals is a world-wide environmental problem. Rock and minerals containing heavy metals can increase concentrations of these elements in groundwater. Cadmium is a toxic element and can accumulate in the living organisms. Low concentration (below 5 mg/L) of Cadmium is difficult to treat economically using chemical precipitation methodologies. Ion exchange and reverse Osmosis while can guarantee the metal concentration limits required by regulatory standards, have high operation and maintenance costs.The goal of this research was to determination of efficacy of using GAC , Biofilm and BAC columns to treat low concentration Cadmium bearing water streams and was to determination of the effects of temperature and pH on the adsorption isotherms.Studies were conducted to delineate the effect of pH, temperature, initial Cd and adsorbent concentration on adsorption of Cd2+ by GAC , BAC and Biofilm. Breakthrough curves for removal of 0.5 mg/L Cd2+ by GAC; Biofilm and BAC columns at two contact times were plotted. Batch adsorption and column data are compared. pH is shown to be the decisive parameter in Cd removal for GAC but not for BAC or biofilter. Lagergren plots confirms applicability of first-order rate expression for adsorption of Cd by GAC, BAC and Biofilm.The adsorption coeficient(Kad) for BAC were 2 times greater than those with plain GAC. Bed Volumes of water containing 0.5 mg/L Cd2+ treated at breakthrough for GAC , Biofilm and BAC columns were 45, 85 and 180 BV respectively. BAC is more efficient than GAC in the removing of Cd from water environment. Keywords: Cadmium ,adsorption, GAC, BAC , Biofilter.

GROUND WATER ROLE IN THE ARAL SEA REGION PUBLIC WATER SUPPLY

Abdulkhakim SALOKHIDDINOV, Khidoyat VALIEV (Tashkent Institute of Irrigation and Agricultural Mechanization Engineers)

The role of groundwater in public water supply has increased dramatically in many countries during the last decades. Surface water resources contamination (and often depletion) is a reason to use groundwater more intensively. In a number of regions, especially in Central Asia including the Aral Sea region, it reached a catastrophically large scale. At the same time in determining the perspectives of groundwater use, one should consider groundwater not only as a commercial deposit but also and above all as a part of water resources and an important component of the environment. Taking that into account it should be noticed that groundwater in many arid regions is an alternative and often the only possible source for public water supply that can provide terrestrial ecosystems with pure, safe drinking water of high quality. All the above-mentioned apply equally to Central Asia arid regions and in the first place to the Aral Sea basin, where water resources degradation assumed a catastrophic character. According to preliminary results of research it is established that the Aral Sea shrinking has direct impact on change of amudarya and aral complexes higherquaternary and modern sediments groundwater´s level and chemical composition mainly within area of the dried Aral Sea bed.

IMPACTS OF ENVIRONMENTAL CHANGE AND POPULATION GROWTH ON THE WATER QUALITY AND WATER AVAILABILITY IN INDIA

Shadanan K. NAIR (Department of Physical Oceanography, Cochin University of Science & Technology)

Global environmental changes and demands of increasing population make water resources management a difficult issue in many parts of the world. This is especially true for a developing country like India with an exploding population, a weak economy that is related to agriculture and where there are disputes over sharing of water. Life of majority of the population in India depends on agriculture or related industries. Though India is rich in water resources and water resources development projects have helped attaining self-sufficiency in food, the fast increasing population and associated needs pose serious threat to water availability. Overuse, pollution and improper management have been seriously affecting the quantity and quality of water. Global climate models predict a possible change in the rainfall pattern and hence in the water resources of India in the coming decades. In this study, water balances of different States of India have been computed, incorporating the methods of Penman and Thornthwaite, to estimate the water deficiencies, surpluses and the per capita availability. Considering the rate of growth of population and predicted changes in temperature and rainfall patterns, the situation after two decades has been assessed. Study reveals that the present national per capita water availability of 2150m3 will be drastically reduced to 972m3 in few years. Even today, some states have no surplus water from precipitation annually, after meeting the requirements for evapotranspiration and soil moisture recharge. In almost all parts of India, water deficiencies show an increasing trend and surpluses show a decreasing trend. Though some climate models predict an increase in rainfall, it may not be able to compensate for the reduction in soil moisture due to rise in temperature. This will reduce the water level and runoff in rivers. This situation will surely add to the economic crisis. More investment will be needed in domestic supplies, irrigation, national waterways and for finding alternatives for cheap hydroelectric power. If the present

population growth and urbanization continues, the country will find it hard to meet the requirements in domestic and industrial sector and after all in the agricultural sector that may need additional 200MCM water to feed more than 1.5Million population. Guidelines for better management have been provided, considering socio-economic conditions and natural and man made environmental changes on water.

HS02a/07P/D-002   Poster   1545-148

ESTIMATION OF POTENTIAL WATER RESOURCES IN THE LOWER MEKONG RIVER BASIN

NMNS Bandara NAWARATHNA, So KAZAMA, Masaki SAWAMOTO (Department of Civil Engineering, Tohoku University)

Availability of GIS data sets of watershed physical properties and the advancements gained in obtaining distributed meteorological variables with the help of GIS have stimulated the development of physically based hydrological models. The introduction of block wise approach to the TOPMODEL with Muskingum-Cunge flow routing methods (BTOPMC) has enhanced the applicability of TOPMODEL from hundreds of square kilometers to several ten thousands square kilometers. In this research work, BTOPMC is used to simulate hydrological processes in the effective watershed of 277,000 square kilometers from Luang Prabang to Pakse in Loa PDR along the Mekong River. It has becomenecessary to construct reservoirs to meet increasing water demand especially in agriculture and power supply in the lower Mekong river basin. However, with the ongoing debate on environmental aspects of dam constructions, a thorough study from a sound hydrological model is needed to ensure sustainable development. The watershed is divided into four rectangular blocks (250 km*300 km) and the block wise average saturation deficit, which controls the depth to the saturation zone in each grid (1 km*1 km), is calculated in each time step. Upstream observed runoff is used as a boundary condition of the model and four parameters namely, lateral transmissivity under saturated conditions, decay factor, maximum root zone storage, and flood plain Manning coefficient n , are estimated as a function of land use extracted from USGS (United States Geological Survey) global land cover characteristics database. Model parameters were calibrated based on the results at different gauging stations. Reservoir operations are taken into account using simplified ruling curves depending on the purposes of the reservoir. Storages and releases from irrigated crop fields are taken into account by introducing required water level function to the relevant grids. Initially the most sensitive n values for different river reaches were estimated using the shape of simulated hydrographs without any rainfall input. The Mekong River, tributaries and flood plains were differentiated by introducing threshold values for the effective watershed area. Minimum value for the Mekong river basin at Pakse is identified as 0.0015. Annual evapotranspiration was estimated based on a pixel wise methodology related to potential evapotranspiration. The sub basins values ranges from 470 mm to 620 mm. Nash-Sutcliffe coefficient formula was used to evaluate the simulation efficiency. Lowest efficiency value for the year 1993 is 93.5%. Finally, potential water resources distributions at 100 square kilometer grid size were estimated. It has been found that there are sufficient water resources in mountainous area in Laos whereas flat irrigated fields in Thailand need to get water from nearest potential locations for a sustainable development.

HS02a/07P/D-003   Poster   1545-149

CLIMATE CHANGE AND WATER RESOURCES VULNERABILITY IN HEAD AREA OF CHANGJIANG AND HUANGHE

Shao-feng JIA[1], Hua-yun YAN[2], Run-jie LI[3] ([1]Department of Hydrology and Water Resources, Institute of Geographical Sciences and Natural Resource, [2]Bureau of Hydrology and Water Resources Survey of QInghai Province, [3]Institute of Water Resources of Qinghai Province)

The head areas of Changjiang and Huanghe are called as Water Tower of China and have very important significance for water conservation and ecological integrity in Changjiang and Huanghe basins. Although the head area of Changjiang and that of Huanghe are connected together, runoff in two rivers showed different change patterns in recent 50 years. While runoff in head area of Changjiang didn't change evidently (only decreased by 1% compared to 1950's), runoff in head area of Huanghe had decreased by 10% in the same period. It's surprising that the annual precipitation in the head area of Huanghe didn't change obviously. Detail analysis indicated that the main reason of runoff decrease in the head area of Huanghe was the change of time distribution of precipitation i.e. the decrease of precipitation in summer. Perhaps the rising of temperature which may result in the increase of evaporation and transpiration was another reason. But an interesting phenomenon is that the recorded water surface evaporation in head areas of Changjing and Huanghe decreased while temperature rose and sunlight time increased. In fact, this phenomenon occurred in Northwest China universally and so it worth being paid attention to. Because the main two factors influencing fresh water evaporation are temperature and wind, when temperature rising, the sole facto inducing the decrease of water surface evaporation must be slowing of wind. Metrological records in those areas proved this deduction and showed obvious decline of annual average wind speed. So the rising of temperature will not certainly induce evaporation increase while wind speed descending. This make the relation between temperature and evaporation, further the relation between climate change and water resources, more complicated. Two phenomena in the head area of Changjiang and Huanghe—The dissimilar runoff change pattern (Changjiang's vs Huanghe's) in the same region when water and energy balance factors such as precipitation, sunlight time, temperature, wind speed and water surface evaporation are similar, and the complex relationship between temperature, wind speed and evaporation— make it very clear that there is still much uncertainty in the prediction of water resources change in the future in a global changing environment.

AN ESTIMATION OF AVAILABLE WATER RESOURCES

Boris BERAKOVIC[1], Marija BERAKOVIC[2], Ksenija CESAREC[3] ([1]Water Research Department, Faculty of Civil Engineering, Univ of Zagreb, [2]Cratian Waters, [3]Meteorological and Hydrological Service)

Water menagement is a very complex activity and its successfulness depends on many factors and their reliability. In the paper the basic and most influential factors are described. A special attention is given to the estimation of available water resources as one of the basic elements influencing the effectiveness of water management. From the very beginning of water management activities information on water quantity and quality were its basic elements. Today, water balances are made routinely especialy for larger areas, and the results obtained so are not sufficient for efficient water management planing. In the paper approvement possibilities of estimation of available water resources i Croatia are suggested. Successfulness of water management could be improved by simultaneously improving some other influential factors, which are just mentioned in the paper.

CHANGEMENTS CLIMATIQUES, RESSOURCES EN EAU ET SECHERESSES AU MAROC

Mohammed-Said KARROUK (University Hassan II, Centre de Recherche de Climatologie)

En raison du changement climatique, l'environnement climatique actuel au Maroc subi une perturbation due au réchauffement du climat terrestre, qui peut violemment perturber presque tous les systèmes écologiques naturels et de nombreuses structures et institutions dont les marocains ont appris dépendre. Si les climats ne se sont que peu modifiés jusqu'ici, le pays est confront dans les décennies venir, a perspective d'une accélération très forte du changement climatique.Les latitudes marocaines représentent les endroits les plus vulnérables aux effets négatifs de ce bouleversement climatique. Le secteur le plus touch par cette situation au Maroc est l'EAU d aux sécheresses prolongées et répétitives. Et ce en raison de la nouvelle distribution géographique du cycle de l'eau qui s'installe nos latitudes.Les ressources en eau au Maroc, dépendent principalement du retour des précipitations de la saison humide o il pourrait pleuvoir. Cette précipitation qui connaû' dans notre pays une instabilit accrue nous laisse en permanente inquiétude vis-vis de la disponibilit de cette denrée rare sur laquelle se base l'agriculture et la sécurit alimentaire au Maroc.La circulation atmosphérique est le principal mécanisme l'origine des changements dans les variables climatiques dont l'influence se fait sentir l'échelle régionale. Les fluctuations qui affectent nombre de ces facteurs sont fortement interdépendantes, cause des caractéristiques d'ensemble de la circulation atmosphérique et des interactions qui se produisent entre les surfaces terrestres et océaniques.Les précipitations et les températures ont chang au cours des 100 dernières années au Maroc. Au cours de cette période, les précipitations ont connu des variations substantielles et les fluctuations des tendances ont également été relativement importantes.Ces variations ont accompagn les grandes fluctuations des événements extrêmes observés dans la zone intertropicale « ENSO », qui se sont répercutés sur les températures et surtout les précipitations au Maroc travers la circulation atmosphérique dominée par les transferts énergétiques. Un événement négatif « El Niño » se manifeste au Maroc par des sécheresses, et un événement positif « La Niña » par des précipitations. Ces fluctuations extrêmes au Pacifique sont devenues ces dernières décennies plus fréquentes et se manifestent par une violence « exceptionnelle ». Les sécheresses récentes au Maroc ont ét très pesantes et catastrophiques (1983, 1995, 1998), et leur brève interruption s'est manifestée par des inondations (1986, 1996, 1997, 2000 et 2001). Cette instabilit accrue des événements océano-atmosphériques met en péril les ressources en eau au Maroc, l'agriculture et la sécurit alimentaire.Le Maroc, déj sensible une variabilit climatique instable, est soumis aux effets du changement climatique dans plusieurs secteurs, savoir: • Le stress hydrique impos divers systèmes biologiques et secteurs socio-économiques, en raison de l'augmentation de la température et de l'évapotranspiration, entraû<erait un bouleversement du cycle hydrologique.• Les perturbations de l'écoulement de surface qui pourrait être excédentaire en cas de précipitations hivernales, et déficitaire dans les autres saisons.• La rentabilit agricole pourrait être altérée en raison des perturbations du cycle hydrique, ce qui poserait une sérieuse menace pour la sécurit alimentaire du pays.Des mesures draconiennes nécessaires devraient être entreprises pour s'adapter aux éventuels bouleversements, lesquels représentent des facteurs limites pour la continuit en équilibre des écosystèmes et des systèmes socio-économiques.

WORLD MAP OF HYDROGEOLOGICAL CONDITIONS AND GROUNDWATER FLOW

Roald Gamidovich DZHAMALOV, Igor Semenovich ZEKTSER (Water Problems Institute, Russian Academy of Sciences)

The Map was compiled in accordance with special UNESCO Project and printed in the USA in 1999. The methods of groundwater flow assessment and mapping, legend of the map and its main contents were elaborated by Russian scientists (Principal editors Dr. R.Dzhamalov and Dr. I. Zektser). The Map was edited by a special International Editorial Board that included representatives from the Australia, Argentina, Brazil, China, Germany, USA, India, France, Indonesia and numerous other countries.World Map of Hydrogeological Conditions and Groundwater Flow (scale 1:10 mln.) is designed to provide specific and quantitative information for the following practical problems: a) to determine groundwater flow and natural groundwater resources in individual regions of the Earth to characterize water availability and to plan the use and protection of water resources; b) to determine groundwater recharge amounts to establish the regional water balance and existing water resources; c) to determine groundwater contribution to river runoff as it is the most stable portion of total river runoff, as well as to predict changes in river discharges under the effect of large scale groundwater withdrawal; and d) to determine the value of direct groundwater discharge to seas and oceans to establish groundwater contribution to water and salt balances of the seas.The World Map is a special, thematic hydrogeological map whose main content is information on the distribution of several quantitative characteristics of groundwater runoff as well as geological and hydrogeological conditions of groundwater generation. In small-scale mapping of hydrogeological conditions selection of aquifer systems is a severe problem. It is necessary to distinguish principal groundwater flow media - types (subtypes) of rocks with common conditions of generation and spatial distribution of water-conducting properties. Besides of lithological composition of groundwater flow media on the Map the specific values of groundwater flow characteristics (modulus and coefficients) are presented. This combined representation of two quantitative characteristics appreciable improves the informativeness of the Map. Different colors are connected with groundwater flow media types, intensity of each color reflects modulus of groundwater flow or annual specific groundwater discharge values (from less than 0,1 to 10-20 l/s km2), and brown isolines represent coefficients of groundwater flow or ratios groundwater runoff to annual precipitation. The Map gives also information about special conditions of groundwater flow generation connected with human activities, intensive karstification, river channels with surface runoff losing, and rift zones and regional faults, and so on. Firstly in the hydrogeological mapping, the Map presents conditions of direct groundwater discharge to seas together with quantitative characteristics of this global process expressed in specific values.The results of quantitative estimation and mapping of groundwater flow make it possible to solve several problems of groundwater generation under different natural conditions on a completely new basis by introducing quantitative data into the analysis. The carried out research found the principle global and regional regularities and relation between groundwater recharge and the natural and climatic zonality.

ASSESSING THE SUSTAINABILITY OF URBAN WATER RESOURCES

Matthias EISWIRTH (Department of Applied Geology, University of Karlsruhe)

With over 40% of the water supply of Western & Eastern Europe and the Mediterranean region coming from urban aquifers, efficient and cost effective management tools for this resource are essential to maintain the quality of life. Traditional water planning regularly concludes that future water demands will inexorably rise and eventually exceed water supplies available in any given location. However, the increasing concerns about the environmental impacts of water projects and their increasing economic costs mean that traditional planning concepts, which assume unlimited supplies of potable water, must be questioned. This includes the source of the water supplies and its appropriate use. With population densities increasing in urban areas and constraints on funding, it is becoming increasingly evident that the present management of urban water resources and systems will not be suitable models for service provision into the 21st century and that increased emphasis will be placed upon the use of groundwater reserves. Without an adequate knowledge base of the current status of urban water resources, and an understanding of the processes involved, the health and safety of the people who depend on urban groundwater as drinking water can not be assured. In spite of strong efforts initiated by the European Union and other international organisations in the past 20 years, groundwater pollution from industry, traffic, sewers and agriculture is still very high. The complex transport processes of groundwater flow are responsible for the wide distribution of recharged water and contaminants. There is evidence that urban downstream aquifers are contaminated by inorganic, organic and microbial pollution. With population densities increasing particularly in urban areas and the corresponding constraints on funding, it is becoming increasingly evident that present urban water systems will not be suitable models for service provision into the 21st century. The overall objective of a new European Commission funded initiative, called AISUWRS (Assessing and Improving Sustainability of Urban Water Resources and Systems), is to develop an innovative system to quantify and manage the problems from unsustainable urban water systems and assess the impact of pollution on the underlying groundwater resources. The overall scope of the AISUWRS initiative is to assess and improve the sustainability of selected urban water systems and resources with the help of computer tools and thus minimise the impact of pollution on the underlying urban groundwater resources. Parts of these model tools have been already developed to estimate the water flows and contaminant loads within the urban water system. This model represents water and contaminant flows through the existing water, wastewater and stormwater systems, from source to discharge point and have already been applied successfully in selected areas in Australia and Germany.

ASSESSING VULNERABILITY OF WATER RESOURCES TO CLIMATE CHANGE IN MIDWEST

Hua XIE, Wayland J. EHEART (Department of Civil and Environmental Engineering, University of Illinois at Urbana-Champaign)

There exists much scientific evidence showing that our planet is undergoing a global climate change and that the climate change will threaten the status quo of regional water resources that support ecosystem and human society. An assessment was conducted to evaluate the vulnerability of water resources to climate change in the Mackinaw watershed in central Illinios, USA. In this study, the SWAT (Soil and Water Assessment Tool) model was used to predict stream flow and crop yields in a watershed under different future climate scenarios that represent possible climate outcomes predicted by well-known global circulation models. The potential effects of climate change and irrigation incurred by the change, if any, on low-streamflow and profitability of crop growing operations were investigated, for currently customary crops for the region and alternative crops.

THE BASIC FEATURES OF TRANSFORMATION OF A REGIONAL CLIMATIC FIELD OF PRECIPITATION ON UKRAINE UNDER INFLUENCE OF GLOBAL WARMING

Volodymyr M. VOLOSHCHUK, Svetlana G. BOYCHENKO (Department of meteorology and climatology, Kyiv Taras Shevshenko University)

The main aim of this research is to obtain quantitative estimations of the basic tendencies of changes of the monthly sums of precipitation on Ukraine as a result of global warming and to work out scenarios of transformation of a climatic field of precipitation on Ukraine in first half of 21-th century on their basis.In this research were used the following methods: Specific statistical analysis of empirical meteorological data which was worked out by authors specially for revealing very small climatic signal on a background of very large meteorological noise with use mainly of a space-time coordination and connectivity of climate fields; The climatic theory of similarity of processes of formation of an atmospheric precipitation which was worked out by authors for construction of necessary semi-empirical models; Comparison with known materials of regional climatic paleoreconstructions of warm epochs of the past.The following main features of transformation of climatic field of the monthly sums of precipitation on Ukraine under influence of global warming up to 2-3 K are established: Increase of the monthly sums of precipitation for those regions and months of Ukraine for which meteorological norms of precipitation are below 50 mm per month;• Increase of the monthly sums of precipitation for those regions and months of Ukraine for which meteorological norms of precipitation are over 75 mm per month; Decrease of the monthly sums of precipitation for those regions and months of Ukraine for which meteorological norms of precipitation are over 50 mm but below 75 mm per month; Space alignment of a climatic field of the annual sums of precipitation, but averaged on all territory of Ukraine the annual sum of precipitation does not practically change.The important methodological conclusion follows from the obtained results concerning dynamics of a climatic field of precipitation on Ukraine: incorrect averaging on various space-time scales of climatic field of precipitation can result in essential distortion concerning influence of global warming on intensity of regional precipitation. At construction of scenarios of transformation of a climatic field of precipitation on Ukraine two types semi-empirical models are used:• Variability and trends of precipitation as functions of meteorological norms; Meteorological norms, variability and trends of precipitation as functions of seasons, geographical coordinates of a place and its height above the sea level.The scenarios constructed on the basis of such type of semi-empirical models are convenient for using at assessments of influence of global warming in various branches of economy of Ukraine, which are formulated as stochastic space-time functionals from meteorological parameters.

FEATURES OF WATER RESOURCES SYSTEMS IN GEORGIA

Konstantine Kote BZIAVA[1], David Dato GUBELADZE[2] ([1]1. Department of Land Reclamation and Engineering Ecology, [2]Department of Land Reclamation and Engineering Ecology)

The physical-geographical and climatic conditions promoted the large variety of hydrological features both as a whole in all Georgia, and in its separate areas. In Georgia the greatest drain of water (in comparison with the countries of former USSR), exceeding 3000 mm of water per year, however amplitude of fluctuations of this drain depending on territory and river pools is very high. Resources of fresh water of a region are composed from a superficial and underground component of a river drain; underground waters not participating in a river drains and getting directly in the sea; and also water of glaciers, lakes and bogs. The features of water resources of the country are defined by relief and climatic conditions, aridity of territory, mode and geography of a drain of the rivers, and also geographical

isolation of Transcaucasia. All variety of natural resources depending on reproduction can be referred to two groups: renewed and not renewed. Now situation essentially has changed, as water has become scarce, and the former resources do not provide needs for it; besides it its quality considerably has worsened. In this connection there was a necessity besides the operational charges to carry out expenses for production of water accessible to use and on improvement of its quality. For example, at regulation of the river drain in reservoir water resources "sharply grow", and the clearing of water source from pollutants improves its quality, also increasing "water resources" etc. Proceeding from above told, it is possible to note, that in a long-term section "the water resources" as against "of water stocks" are variable size varying as quantitatively, and is qualitatively depending on the requirements showed to water. Now volumes of water used in industrial activity of the man and in a life, continuously grows. As a result of it the necessity of involving in activity of the man of all new and new water sources, i.e. transference "water stocks" in a category "of water resources" has appeared. The present stage of development of a human society is characterized by the tendency of increasing water requirement, and consequently, increasing of water resources. Though in absolute sizes, the specific parameters of water resources of East Georgia are not low in comparison with arid zones of other countries, but the conditions of their use are specific and difficult, since they play a main role in water requirement of neighboring Azerbaijan laying below on current of the river Mtkvari and using a transmitted drain from Georgia. This situation is aggravated also by that as East Georgia, and below laying grounds of Azerbaijan by the climatic conditions are sharply require irrigation up. Proceeding from above mentioned, the problem of water in East Georgia carries not only technical and economic character, but also social, as the development of a national economy of Azerbaijan and indirectly of Armenia depends on its decision, as the growing water consumption by Armenia also increases deficiencies in East Transcaucasia.

STREAMFLOW VARIATION OF FOREST COVERED CATCHMENTS

Zoltán GRIBOVSZKI, Mihály KUCSARA, Péter KALICZ (Department of Forest Opening Up and Hydrology, University of West Hungary)

Rainfall concentration and runoff, otherwise rainfall-runoff processes, which cause river water discharge fluctuation, is one of the basic question ofhydrology. Looking for the answer is important because several social-economy demands have a strong connection with small or bigger rivers fromthe point of view both quantity and quality of the water. Gratification or consideration of these demands is complicated substantially that we have stillpoor knowledge about our stream-flow regime. Water resources mainly stem from upper watersheds. Rivers transported water discharge, which is potential usable, is an integral of streams takeits rise in these small watersheds. These upper watersheds are the basis of the water concentration process, therefore we have to improve ourknowledge about hydrological processes coming up in these territories. In this article we present runoff regime of three small catchments on the basis of one year data. Two catchments have a similar magnitude 0,6and 0,9 km², and one is bigger about 6 km², which has a part other two above mentioned. We have been analyzed indetail from hydrological elements only features of rainfall, discharge, rainfall induced flooding waves, and basic discharge in rainless periods.Variances of these parameters have been analyzed in relation to catchments surface, vegetation coverage and forest management. Result data set well enforce our knowledge about *small catchments hydrological processes*. On the basis of these fundamentals we can plan moreestablished the management of these lands (forest practices, civil engineering works, usage of natural water resources). Global change could change hydrological regime. These results can also utilize on the long term planning ofland use and water demands gratification.

FINGERPRINTING CLIMATE CHANGE DRIVEN DROUGHTS IN WESTERN CANADA

Lawrence Chima NKEMDIRIM (Geography and Earth Sciences, University of Calgary)

Some climate models forecast a higher frequency of drought events in western Canada due to an atmospheric greenhouse gas driven climate change. Because droughts are not uncommon there, it is necessary to differentiate events that are either wholly driven or intensified by climate change from 'normal' events. Two trends currently identified with century-scale climate change appear to adequately fingerprint climate change inspired droughts in the region. They are (a) statistically highly significant increase in surface air temperature and (b) an equally significant decrease in sea level pressure. Fingerprint One (winter droughts- precipitation poor): Based on homogenized data from 114 stations, mean annual temperature rose at a rate of 2.7°C/century between 1953 and 1997. This trend was dominated by increases of about 5 and 6oC in the winter and spring respectively. Paralleling the trend was a highly significant reducing trend in surface air temperature especially during the two seasons. Observation and analysis showed that the Polar High Pressure, which dominates the region's winter climate had weakened and the temperature contrast between the Arctic and polar airmasses had declined. The resulting 'softening' of the polar front correlated well with negative winter precipitation anomalies. Precipitation more than 2 standard deviations below normal were 20 percent more frequent in post 1975 winters than in pre-1975 ones and the difference was statistically significant at 95% confidence level. Additionally, the post-1975 two standard deviation events correlated well with both pressure anomalies and change in mean surface temperature. Fingerprint Two (summer droughts-precipitation rich): The Canada Climate Center model predicted increases in precipitation for the region ranging from 15mm/year to 45mm. An energy balance model, in which all sources of energy including a strong advective component due to the Chinook (a mountain wind, which significantly impacts the temperature regime in the region) were fully specified, enabled a realistic assessment of the region's water balance under the present warmer regime. Water deficit ranging from 250mm above normal in the driest areas to 45 mm in the wettest parts was indicated for the post-1975 period. The Palmer Drought Index was used to identify recent drought events that were severer than they would have been under similar summer and rainfall and antecedent moisture. The frequency of such events increased 35% in the post-1975 period.

THE CONCEPT OF MODERN ARID ZONES OF HYDROGEOLOGY OF CENTRAL ASIA AND ITS PROBLEM

Nasirdjan -TAKHIROV, Shukhrat Saifullaevich RADJABOV (Department of hidrogeology, National University of Uzbekistan)

The hydrogeology as a science intensively developed within last century and its fundamental positions are already formulated.Especially, after 60th of the last century, the accomplishing of any type of hydro-geological researches was accompanied with the decision of a problem to manage the dynamics (changes) and chemical compound of underground waters within the limits of concrete borders.The requirement to a hydro-geological science after 70th has got rather complex character. These requirements follow from an ecological problematic of the regions. The underground hydrosphere is considered (examined) as the mainframe of the geoecological environment and is one of the components for eco-system. So, it occurred

the new situation connected to an intensification of technogenesis and gradually, the concept of a hydro-geological science has got the new maintenance (contents), providing an ultimate goal – management of underground hydrosphere within the framework of ecological requirements. The decision of hydro-geological problems in volume of its new concept demands the preliminary system analysis of hydro-geological situation. This work is feasible only in development of the further researches on a new scientific direction – technogenetic evolution of hydro-geological conditions of arid zones, rational use and resource management of underground waters: an ecological policy, balance, preservation, protection and the forecast.The object of research is underground water of hyper genesis zones, that is on a part of lytosphere where the active and slowed down water exchange is observed. Thus, the purpose of maintenance of the uniform concept, system, methodology and methods of management and operation of underground waters for needs of a national economy is pursued within the framework of ecological requirements.On the faculty of hydrogeology of National University of Uzbekistan, researches on the mentioned above new direction on Arid zones – Ustyurt, Aral Sea Region, Kyzylkum, Amu-Darya and Fergana artesian pools - are conducted.Researches on the given direction provide the following:- Revealing of scientific bases for development of underground waters under difficult ecological conditions in the arid zones of Uzbekistan and definition of their role in development of geo-ecological processes;- Identification of water problems and problems of social and economic development- Development of criteria for estimation of opportunities to use the resources of underground waters for social - ecological and technical needs- Development of long-term program to develop the water supply for drink, animal industries, technical needs and for infrastructures- Scheduling of the work on protection, management and rational use of underground waters according to the ecological requirements.

THE GLOBAL WATER SYSTEM PROJECT OF IGBP*, IHDP*, WCRP*, DIVERSITAS

Holger H. HOFF[1], Holger HOFF[1], Carlo JAEGER[1], Denis LETTENMAIER[2], Christian LEVEQUE[3], Harry LINS[4], Michel MEYBECK[5], Madiodio NIASSE[6], Charles VOROSMARTY[7] ([1]PIK, [2]University of Washington, Seattle, USA, [3]Programme Environnement, Vie et Sociétés, Meudon Cedex, France, [4]U.S. Geological Survey, Reston, Virginia, USA, [5]Université Paris 6, France, [6]IUCN-BRAO, Ouagadougou, Burkina Faso, [7]University of New Hampshire, Durham, USA)

The Global Water System (GWS) plays a central and integrative role in the dynamics of the Earth system. It is a regulator of biogeophysical and biogeochemical processes, and it is also essential for sustenance of human societies. The GWS is increasingly modified by humans and through climate effects (facets of it have moved well outside the range of natural variability) , without adequate understanding of how the system works. For understanding the changes, feedbacks and potentially critical thresholds within the Earth system, and eventually for better managing the GWS, new synthetic knowledge is required. The Global Water System Project (GWSP) is a new activity being undertaken jointly by the World Climate Research Programme (WCRP), International Geophshere-Biosphere Program (IGBP), International Human Dimensions Program (IHP), and Diversitas. It will address the GWS in a comprehensive fashion at the global scale, building upon the emerging new consolidated Earth systems data sets, global monitoring tools, and predictive and coupled modeling capabilities. The central scientific question that motivates the GWSP is: ˝How are humans changing the global water cycle, the associated biogeochemical cycles, and the biological components of the GWS, and what are the social feedbacks arising from these changes?˝ GWSP will be structured around three ˝framing questions˝: a) What are the relative magnitudes of global-scale changes in the global water system that are attributable to changing human activities, and to environmental factors such as climate variability and change?; b) What are the main mechanisms by which human activities are affecting the global water system; and c) To what extent is the global water system resilient to global change? Examples of issues that might be addressed under each of these questions are provided.

HS02a/07P/D-015 — Poster — 1545-161

MODELLING OF WATER AVAILABILITY IN GRASSLAND ECOSYSTEMS OF ARID ZONE DELTA PLAINS

Natalia V. PENKOVA[1], V.P. SINGH[2], V.A. KHAYDAROVA[3], N.M. NOVIKOVA[4] ([1]State Hydrological Institute, [2]Louisiana State University, [3]Water Problems Institute, Academy of Sciences of Uzbekistan, [4]Water Problems Institute, Russian Academy of Sciences)

For successful long-term planning and ecosystem management in river deltas of drought-prone regions, it is desirable to develop sufficiently rigorous but not very complex and data-extensive models which are easy to understand and can be used by a wide range of specialists and experts, not sophisticated in purely hydrological, ecological or biological scientific knowledge, for real decision-making. In the contribution, the most simple version of conductance-type combination equation (Budyko´s combined method) is used to calculate within-the-year and long-term variations and trends in water availability (evapotranspiration and soil water content) for grassland ecosystems in Syrdarya and Amudarya river deltas (Aral Sea basin), Volga and Terek river deltas (Caspian Sea basin) and Mississippi delta plain. The biological response to environmental conditions (atmospheric demand, precipitation intensity, ground water table, soil water properties), and to agrotechnology (fertilization, irrigation) by using non-linear multi-dimentional cubic splines approximations for ˝biological˝ parameter of the Budyko´s equation is estimated for annual grass crops and perennial herbs, with particular emphasis on the vegetation condition (closed and sparse canopy, high and low productivity, etc.) (Khaydarova, Kucherova and Penkova, 1998). A comparison is made of the results with ones obtained by applying mechanistic volume type models (Singh, 1989), and resistance-type combination techniques (Penman-Monteith equation). The advantages and shortcomings of the models under analysis are highlighted. An application of the models for historical formation of water availability patterns and for possible climatic and economic conditions in the future is presented. The ecosystems of the deltas represent different natural self-development and man-induced stages - from the stage of drying, increasing of soil salinization and decreasing of meadowlands productivity (Aral basin) to the stage of humid-meadow lands restoration conditioned by rising the Caspian sea-level. Vegetation changes in the territories are of long-term cyclic nature, depending on climatic fluctuations and superimposed anthropogenic influences (Novikova, 1997). The superimpositions are investigated for different periods of economic development of states.

HS02a/07P/D-016 — Poster — 1545-162

CLIMATIC VARIABILITY AND LAND RESOURECS VULNERABILITY IN THE FORCADOS RIVER ESTUARY

Mayowa FASONA (University of Lagos)

The current climatic fluctuations and shift from global climatic normals is causing apprehensions across the blue planet. Data on global climatic indicators show that there has been a net increase in global surface temperature by between 0.30c and 0.50c over pre-industrial periods. Evidences of global warming have already been noted in glacial margin retreat, a rise in snowline, a rise in sea level, northward recession of the tundra margin in the

arctic and the ferocious southward march of the Sahara in the tropics. It has also been estimated that an increase of between 10c and 4.50c over the current global temperatures is expected to trigger off accelerated sea level rise of between 0.2m and 1.4m, which have lots of catastrophic implications especially for the coastal ecologies and other low-lying areas of the world. This paper utilizes Remote Sensing and GIS techniques to assess likely implications of accelerated sea level rise on water and land resources of the areas around the estuary of the Forcados River. Current ecological and land resources data on the study area was generated from remotely sensed satellite imagery. This was overlayed with spatial data on elevation, soil, geology and water resources to generate floodable areas sensitivity map for this coastal environment. The implication of this for food security, sustainable water resources management and coastal resources management is also discussed.

HS02a/07P/D-017   Poster   **1545-163**

INFLUENCE OF CLIMATE WARMING ON ASIAN LAKES FROM VIEW POINTS OF WATER RESOURCES

Hiroji FUSHIMI (The University of Shiga Prefecture)

Due to the climate warming, glaciers are rapidly melting and lakes are extremely expanding in the Nepal Himalayas, and the region faces further natural disasters including the glacial lake outburst flood and the related landslide phenomena. The water level of Lake Hovsgol in Mongolia has risen 60cm for the recent 20 years, so that the surrounding forests, pastures and the lakeshore town have been inundating year by year. Three causes of the water level rise could be noticed as follows: 1) the formation of a natural dam at the end of the lake caused by the sedimentation of sand and gravel which were transported from the tributary river at the time of heavy rain; 2) the thaw of permafrost around the lake where the ground temperature becomes higher with increases of the incoming radiation due to deforestation owing to the anthropogenic expansion of pasture and fired forest; 3) the thaw of permafrost caused by the global warming. When the average air temperature rises by 3.5 degrees Celsius in Lake Biwa basin in Japan, the amount of snow cover would significantly decrease to 60% of the average (1 billion tons) even if the precipitation exceeds by 20%. When the amount of snow cover is more than the average, the lowest dissolved oxygen concentration in the deep layer of Lake Biwa increases due to the density current of the oxygen-rich snowmelt. However, the dissolved oxygen concentration rapidly decreases, when the amount of snow cover is less than 1 billion tons. The climate warming will significantly decrease the amount of snow cover in Lake Biwa basin and the dissolved oxygen concentration in the deep layer of the lake, leading to further enhancement of eutrophication in the 21st century. There are numerous lakes in the inland mountainous regions and the coastal lowlands of Asia where the mighty rivers, such as Rivers Yellow, Yangtze, Mekong, Ganges and Indus, originate from and flow down to the megalopolises with the rapid population growth in the river mouth areas. At the first stage of the global warming, glaciers and permafrost layers melt, and the lake water increases. However, there comes the shortage period of water resources in the later stage of the global warming due to the shrinkage of glaciers and permafrost layers and this may lead to the serious environmental issues in Asia, when the water resources become scarce especially in the dry seasons. So, there is a need to create a new management system for the rational use of water resources taking into account the recent changes in glacial as well as limnological phenomena due to the climate warming.

HS02a/07P/D-018   Poster   **1545-164**

APPLICATION OF WATER BALANCE MODEL FOR REVEALING OF HIDDEN CYCLES IN THE CHANGES OF CHARACTERISTICS OF ENCLOSED LAKES (CASPIAN SEA AS A CASE STUDY)

Alexey Vladimirovich BABKIN (Lab. of Hydroecological Research of Inland Water Bodies, State Hydrological Institute)

The specific inter-year variations of level, area and water balance components of large closed lakes are caused by quasi-periodical dynamics of global and regionalnatural processes. The global factors are directly or through Earth climatic system affect the water regime of the lakes and their catchment areas. The revealing of hidden cycles in the variation of lake's characteristics is acute for exploration of their relationships with global factors and for forecast of their possible changes in the future. The solution of differential equation of lake water balance permitted to elaborate a mathematical model, where dynamics of the mutually related Caspian Sea characteristics (level, water surface area, evaporation and flow of water to Kara-Bogaz-Gol gulf) are the response of inflow (river run off, precipitation and ground-water run off) oscillation. The oscillation of water inflow causes the variation of sea level, area and water balance components. The extremes of sea characteristics have a time lag, if compared with impact extremes. The amplitudes of variations of sea characteristics and the time of their delay from inflow were calculated for different values of inflow and for the large number of periods. The dependencies of amplitudes of sea characteristics and the time of their delay to inflow from period of variations are exposed on the special nomographs. The observation data on water inflow and sea level were approximated by periodic functions. The least sums of quadrates of differences of approximating sinuses and the values of time series of level and water inflow were computed in dependence with the length of period. The cyclic qualities in variation of lake's characteristics are revealed near the periods where there are the minimums of sums of quadrates of differences of approximating sinuses and values of time series of level and water inflow, and where the time delay of level to inflow and relation of their amplitudes of approximating functions are close two the model results. The application of water balance model for analysis of cyclic qualities in dynamics of lake's characteristics make its results more reliable and physically based thenthe use of statistical approaches only. The resemble research and modeling of dynamics of lake characteristics may be fulfilled for another large enclosed water bodies of the Earth.

INDUSTRIAL WASTE WATER IMPACT ON WATER QUALITY OF ZARAVSHAN RIVER, UZBEKISTAN

Marina Stanislavovna MOLODOVSKAYA[1], Raisa V. TORYANNIKOVA[1], Nariman M. UMAROV[2] ([1]Central Asian Res. Hydrometeorological Inst., Dept. of Res. and Forecasts of Environmental Pollution, [2]State Spec. Inspection of Analytical Control of the State Com. for Nature Prot. of Uzbekistan)

Zaravshan River valley is one from the most important economical areas of Uzbekistan. The catchment area of Zaravshan River includes territories of several industrially developed areas of republic with the number of largest cities - Samarkand, Navoi, Bukhara, etc. In past, Zaravshan had been the confluent of Amu-Darya River (which is currently the main tributary of Aral Sea) but along with irrigation network development later it became the separated river system. Zaravshan belongs to rivers with the snow-glacial type of feeding. The Height of Flow Formation Zone is 2829 m.a.s.l; Total Length is 2342 km; Total Catchment Area is 12,300 km². In its low stream Zaravshan River is intensively withdrawn by channels network. The Average Annual Discharge is 169 m³/s. About 96% of Total Runoff is used for

---

agricultural irrigation. There are also 93 Industrial Enterprises, 52 Sewage Disposal Plants at the territory of river basin; 46 Water Intake and 46 Water Release points along the middle stream of Zaravshan River. Specific Human Water Demand in this region has increased in 1.5 times since 1975. Industrial and Domestic Wastes Inflows into Zaravshan River pose a serious threat for Water Quality and Public Health especially in urban zones with high population density. The ecological situation in region has been considerably deteriorating for recent years due to increasing fresh water demands for industrial and agricultural needs. In turn, it has led to the large-scale contamination of surface and ground water of Zaravshan River basin. The Water Quality Assessment after exposure by Waste Water is carried out using the comparison of hydrochemical data obtained from different points of Zaravshan River body with the Admissible Limits. The choice of Representative Hydrochemical Indexes was done with considering wastes composition and pollutants transformation. The main principles were formulated as following: • Representative Compounds(RC) must be specific about prevalent wastes composition;• RC must have Maximum Admissible Concentration (MAC) exceeding maximal over the other compounds;• Velocity of RC transformation after coming into water flow must be minimal. For Zaravshan there were chosen two groups of the RC. The first group is common for any type of water system:.1)BOD; 2)COD; 3)Dissolved Oxygen;4)TDS; 5)Ammonium Ions; 6)Surface Active Substances (SAS); 7)Phenols. The second group is specific one and caused by the character of wastes: 1)Oil Products; 2)Fluorides; 3)Phosphates; 4)Nitrates; 5)Nitrites; 6)Copper; 7)Chromium; 8)Lead; 9)Cyanides; 10)Arsenic, etc. The Hydrological Indexes of Average Contamination and Total Loading of River Flow were calculated with using the average concentration of pollutants in river flow at the point lower than waste water release had been done. The duration of periods of Contaminated and Pure Runoff and their volumes (in shares of Annual Average Runoff or directly in m3/year) also were calculated using Representative Indexes. This methodology can be applied either to single observing point, or river section, or water subject as a whole.

HS02a/07P/D-020   Poster   **1545-166**

STATUS, TENDENCY AND PROBLEMS OF TRANSBOUNDARY WATER QUALITY MANAGEMENT IN ARAL SEA BASIN

Raisa V. TARYANNIKOVA, Marina S. MOLODOVSKAYA (Central Asian Res. Hydrometeorological Inst., Dept. of Res. and Forecasts of Environmental Pollution)

The system of water use exploited in Aral Sea Basin for the last decades, had led to water deficiency, deterioration of surface and ground Water Quality (WQ) along with corresponding social and ecological disasters. It became one of constraining factors of region stable development. Moreover, many water subjects have lost their ecological and biotic functions as environment of aquatic flora and fauna; landscape-aesthetic shape and recreation abilities. The situation is typical one not only for Zones of Intensive Water Consumption (ZIWC) with the highest antropogenic stress on reservoirs, but also for Water Formation Zone (WFZ) where Surface Water Quality (SWQ) has been always considered satisfactory. The analysis of long-term WQ information has shown the dangerous tendency of intensification of biological productivity, i.e. there is eutrophication and, as a result, deterioration of WQ in WFZ reservoirs. The tendencies of Surface Water Quality for the last ten years are indicated. The antropogenic changing of surface runoff, disregarding the buffering water ecosystems and necessary ecological minimum of river water discharge negatively influence on their social and ecological features. Decreasing water discharges lower than Ecological Allowable Level infringes ecological equilibrium and WQ. The water warming-up increases and contents of Dissolved Oxygen reduces. The pollution density grows up even without their additional coming from outside and ˝hydrological˝ eutrophication and secondary contamination take place. In Central Asian region practically all large and numerous small-sized rivers are transboundary, i.e. they coincide with or intersect the boundaries between two or more States. Currently, the WQ management in region is represented as Complex Regional Program of interacting political, economic, technical and legal operations. That ensures the fulfillment of rules regulating and limiting harmful effect on water environment. The solution of such complicated and actual problems is possible only with coordination efforts of all Regional States, with mutual obligations on realization adequate both of water economic and water-security policies and responsibility of States for Transboundary Waters (TW) Quality state. However, nowadays in region there is not any regulating system of TW Resources Quality. Measures on protection and rehabilitation of Water Resources should be based on ecosystem approach with new understanding WQ problems. All water basins should be considered as single whole ecosystem, concerning which water economic activity is carried out. Just on the base of ecosystem approach it is possible to resolve the primary and challenge task of TW management – definition of quotas of dumping pollutants in TW for each State, appropriate agreements and responsibility for their fulfillment. In future, along with further population growth, urbanization of landscapes, social-economic development of region, antropogenic influence on WQ will be increasing, especially within low-water years. It makes us fall to thinking about the preventive measures just now, not putting off until ˝afterwards˝, and to direct efforts for restoring and preservation of Natural Water Resources.

STUDY ON THE MODELING METHOD OF LAND WATER QUANTITY AND QUALITY AND ECOLOGY COUPLING SYSTEM

Ge TAN[1], Qiting ZUO[2], Jun XIA[1] ([1]Hydrology Studio, Institute of Geographical Sciences and Natural Resources Research, CAS, [2]College of Water Resources and Environment, Zhengzhou University)

As the basic content of quantitative study on Management of Sustainable Water Resources, it is necessary, and difficult as well, to build water quantity and quality and ecology coupling system model. On the basis of application study, this paper puts forward a new method called "Multi-Box Modeling". This method's clue is definitude, calculation is simple, and model is reliable. It is confirmed by the authors that the built model can stand for "land water resources system construction connection" and can be used in quantitative study on Management of Sustainable Water Resources.

SOIL DEGRADATION OF JAVA ISLAND

Seno ADI (BPP Teknologi)

The rapid population growth in Java island has caused the pressure to natural resources through intensive agriculture activity. Especially in the upstream region, this situation caused the soil degradation by heavily erosion lead to sediment deposition in the lower region as indicated by the sediment carried of over 10 million ton/year in one river basin in central Java. The land degradation in Java island is not only cause unproductive soil for agriculture development but also cause the disaster such as flooding as well as water crisis. The soil and water conservation activities have been introducing to carry out the land degradation. The Indonesian government under Forestry Departement has such a program called reforestation and regreening, however the farmers have their own interest for land management in relation to the farming commodity that may not take care the soil and water conservation. The research institute has an important role to link and correspond the

farmercommodity interest with the government program in such away the soil and water conservation could be implemented by conducting the appropriate technology thatfacilitate economic development for the farmers.

ASSESSMENT OF THE IMPACT OF INDUSTRIAL EFFLUENTS ON WATER QUALITY IN KORBA AND ENVIRONS, CHHATISGARH, INDIA

L.P. CHOURASIA (Department of Applied Geology,Dr. H.S. Gour Univ)

The effects of multiple industrial pollution sources on the groundwater system were evaluated in the industrial complex at Korbe of Chhatisgarh State of India. The quality of groundwater in the region has been affected negatively due to the discharge of effluents on open and land into ponds, tanks and streams. Water samples from surface water bodies and dug wells were analyzed for their major ion concentrations. The high values of electrical (EC) and concentrations of Na^+, Ca^{2+}, Cl^- and HCO_3^- indicate the impact of industrial effects on water quality. Based on the hydro chemistry, the groundwater is classified into various types such as sodium chloride, sodium-bicarbonate calcium chloride, and magnesium-chloride etc. Its suitability for drinking and irrigation purpose has been assessed. The groundwater quality in around Korba has became hazardous. Some possible remedial measure are suggested.

WATER QUALITY IN NORTHERN KARNATAKA, INDIA - A CASE STUDY

Ramaraju Hanumanahalli KAMBADARANGAPPA[1], Rajkamal[2], Prasanna Kumar N. S.[2], Ranganna G.[1] ([1]Dept. of Civil/ Environmental Engineering, Bangalore Univ., [2]Karnataka Rural Water Supply & Sanitation Agency, Rural Development & Panchayat Raj Dept.)

Of all kinds of pollution that are steadily degrading man's physical, environment. Probably the least recognised is the hidden deterioration in the quality of ground water. Diseases related to the use of contaminated ground water may be divided into those, which are caused by microorganisms, a biological agent (a pathogen), and those, which are caused by chemical substances those that are caused by chemical substances. However, these latter diseases are over shadowed in developing countries by the former, which are the main causes of disease and death. As a part of the preparatory work for the **JAL NIRMAL** Project, a Water Quality Analysis study was undertaken. The objective of this study was to access the nature, extent and severity of Water Quality problems in the project area and the underlying causes thereof. The study was under taken in three pilot districts viz. Belgaum, Dharwad, Gulbarga (and Gadag district as a special case study due to fluoride problem) and the primary data was generated on water quality. There are 281 existing water sources in the 24 villages (10 GP's), out of which 212 sources are in use. Some are not in use due to inadequate quantity and some due to meager quality. 204 samples were collected from all the sources in use and additional 26 samples were collected for analysis of pesticides. The results reveals 174 samples (85%) were found to be non potable. The full-length paper presents the Water Quality status and mitigative measures.

INTEGRATING HIGH RESOLUTION SATELLITE IMAGERY AND WATER QUALITY STATISTICS FOR WATER RESOURCE MANAGEMENT

Nandani Dhammika Kumari DAYAWANSA (Department of Agricultural Engineering, University of Peradeniya)

Water is an important natural resource and is a vital component of plant and animal life with two thirds of the earth being covered with water. Proper management of water resources is of paramount importance as the water quantity and quality deterioration is being widely reported all over the world. Scarcity and the low quality of water are serious problems that are faced by the disadvantageous communities in the less developed countries. With the above background, this study focussed on the use of multidisciplinary approach to handle the water-related issues in a cost effective and sustainable manner. The seasonal variations of the water availability in the reservoirs in a part of the dry zone of Sri Lanka are predicted with high-resolution (IRS LISS III) satellite imagery. At the same time the command areas of the reservoirs/ tanks are identified with the help of the same imagery. The water samples from the water bodies are selected to monitor the water quality status and the crop management information are gathered to be coupled with the water quantity data during different seasons of the year. The extracted information from remote sensing sources and field sampling is used to quantify the extent of water pollution and the contribution of agricultural and other anthropogenic activities on water quality deterioration. The output of the study can be used for policy formulation and determining guidelines for fertiliser and agrochemical use with a proper understanding of the uncertainty coupled with the information. The synoptic viewing capability and the quickness of gathering spatial information in remote sensing approach compared to the field surveying will be economically and technically feasible in sustainable water resource management in a rapidly changing environment.

SEASONAL VARIATION IN WATER QUALITY IN ORLE RIVER BASIN, S.W. NIGERIA 2 CHEMICAL HYDROLOGY

Catherine Imhangulaya IKHILE[1], Stella Maris AKHIONBARE[2] ([1]Department of Geography and Regional Planning, [2]New Grass Technologies)

An investigation of the chemical conditions of water bodies in the Orle River Basin in Edo State, Nigeria was carried out in 1987 and 1997. The quality of the water in the drainage basin was compared between this ten years period for any possible variation due to global changes in climate and population pressure. The results reveal that in 1987, chloride, sodium, biochemical oxygen demand (BOD5) and dissolved oxygen (DO) varied significantly with the seasons. While chloride, DO, BOD5 and COD show increase in the wet season, sodium, potassium, calcium, magnesium, iron, aluminium, silica, nitrate, sulphate and total hardness increased in the dry season and decreased in the wet season. In 1997, while total hardness, silica, nitrate iron and COD increased in the wet season, chloride, calcium, magnesium, DO and BOD5 increased in the wet season and decreased in the dry season. The values of some of the parameters are beyond tolerable limits. The degree of pollution observed in the rivers constituting Orle River Basin is sufficiently significant to necessitate pre-treatment of the basin water prior to domestic and industrial uses. Presently, the natives treat the water with alum before use, but this practice is not sufficient chemical treatment required to make the water safe for consumption.

CONCENTRATONS OF URANIUM IN SURFACE WATER IN QINGHAI-TIBET PLATEAU

Yuefang LI, Tandong YAO, Lide TIAN, Wusheng YU, Jianchen PU (Key laboratory of Ice Core and Cold Regions Environmental Research, CAREERI, CAS)

U is not also a natural radioactive element but a heavy metal. It has radio-activity and also do harmful to human health just like lead. So many studies pay attention to this element in recent years. Study showed that human mainly intake uranium from water. So it is important to know the content of uranium in natural water. In other hand, the distribution of uranium in water has signifi-cance in geochemistry exploration of uranium and water quality assessment. The Qinghai –Tibet plateau is affluent in water resources and some big rivers are the headwaters of some world rivers such as the Changjiang River and the Brahmaputra river etc. So it is important to know the distribution of U concen-trations in waters in the plateau. We present here data on the dissolved U in surface waters as well as some ground waters in the plateau for the first time in most sites of Qinghai-Tibet plateau. The primary objective of our study is to identify the spatial distribu-tion of U concentrations and establish the background value of uranium concen-tration in the water in the plateau. This study contributes new data on the U content in waters in China. Sampling equipment were pre-cleaned in clean room and concentrations of U were determined by the ultrasensitive inductively coupled plasma sector filed mass spectrometry (ICP-SFMS) technique in clean room conditions. The data show that the concentrations of dissolved U in surface waters are in the range of 0.17 to 6.53µg/L, with a mean value of 2.56µg/L. That is higher than that of World Rivers. The concentrations of U are changeable not only in the same water system but in the different water system and show an obvious spatial variations.The highest concentration was observed in a glacial melt water comes from Xixiabangma mountain located in Himalayan region,the southern part of the plateau.The lowest concentration was found in the west-middle part of the plateau.

ISOTOPIC EVALUATION OF GROUNDWATER SYSTEMS FOR RISK ASSESSMENT AND MANAGEMENT DURING EXTREME EVENTS

Partha Sarathi DATTA, Sunil Kumar TYAGI (Nuclear Research Laboratory, India Agricultural Research Institute)

In different parts of the world, increasing population, urbanization, and competition for economic development induced indiscriminate exploitation of groundwater and its contamination hamper groundwater management programs. Management strategies require scientific evaluation of groundwater vulnerability to depletion and pollution, and risk assessment, in relation to changes in landuse and other environmental conditions. In this context, the groundwater system in Delhi region has been described, using stable isotopes (^2H, ^{18}O) distributions in groundwater and rainfall. The isotope signatures of Delhi rainfall (^{18}O: -15.3 to +8.0‰ and ^2H : -120 to +55.0‰) generally fall along the world meteoric line, depleted ^{18}O is generally associated with heavy rainfall, and the rainfall deficient years are generally associated with relatively enriched ^{18}O in monthly rainfall. Changes in landuse result in variation in recharge from location to location, both in space and time, with a wide range of ^{18}O signatures in groundwater (^{18}O: -2.8 to-8.6‰), both laterally and vertically, suggesting occurrence of an inhomogeneous stratified system. Groundwater renewal has a selection effect in favor of isotopically depleted rainfall, with most parts receiving less than 5% recharge. Imbalance in recharge with withdrawal resulted in decline in groundwater levels by 8-10m during the last decade. Distribution of ^{18}O and Cl in groundwater suggest occurrence of two main flow systems vertically: (i) Uppermost local flow, rapidly circulating, low salinity, more vulnerable to overexploitation, and (ii) Relatively slow circulating intermediate zone and more vulnerable to salinisation and depletion. The groundwater in different parts has also become considerably vulnerable to pollution, with a wide range of nitrate (30-1600 mg/l), fluoride F (1-16.0 mg/l), Zn (3-41 Mg/l), Cu (5-182 Mg/l), Fe (279-1067 Mg/l), Pb (31-622 Mg/l), Ni ($<$1-105 Mg/l), Cd ($<$1-202 Mg/l). Increase in groundwater contaminants levels, associated with enriched ^{18}O isotope, clearly suggests increasing risk of groundwater to pollution from localized infiltration of isotopically enriched (^{18}O: -3 to -5‰) and highly contaminated agricultural and urban surface run-off water, through stagnant water pools. Governed by the zonal disparity in water supply and groundwater abstraction, many flowpaths of inter-mixing of contaminated water with fresh water bodies can be visualized from ^{18}O and Cl relationships. Risk of groundwater depletion and contamination are governed by rainfall pattern, recharge, withdrawal, and surface run-off characteristics, groundwater-surface water interactions, and sorption/desorption processes in the soil. For comprehensive assessment of risk associated with extreme events, more field research and scientific knowledge is needed on isotopic responses and dynamics of pollutants in the groundwater flow, aquifer´s attenuation capacity for contaminants, under natural and exploited conditions, in relation to land use, wastes disposal and other environmental changes. Risk can be partly minimized or controlled by restricting migration of population from surrounding states, unplanned groundwater abstraction, and eliminating wastes disposal within the protection zones, through strict enforcement of regulatory measures.

GROUNDWATER ISSUES IN PONDICHERRY COASTAL ZONE , INDIA

S.S.Sundarvel RAGASAKTHI (IAHS)

The intense use of ground water has caused major water-level declines and significantly decreased the saturated thickness of aquifers in some areas. In many semi-arid to arid regions, ground water has been withdrawn at rates far in excess of recharge, leading to ground-water "mining" This is often accompanied by detrimental environmental side effects, such as reduced ground-water discharge to springs, streams, and wetlands, and land subsidence. Land drainage is a source of ground-water depletion, as the construction of drainage ditches and canals in surficial systems can lead to regional lowering of the water table. A significant component of the total depletion may come from low-permeability confining layers, but they are rarely monitored and usually overlooked. The magnitude of worldwide depletion of ground water in storage may be so large as to constitute a measurable contributor to sea-level rise. But the magnitude of depletion is poorly documented worldwide, particularly in developing countries. The management concept of "sustainable development" may offer a viable approach to dealing with overexploitation of ground-water resources, but its implementation has been largely subjective and sometimes arbitrary. The purpose of this paper is to document methods and examples that would help define the magnitude of the problem in Pondicherry Coastal Zone,India and explore local and regional management approaches to mitigate the problem or assure sustainable development.

THE STUDY FOR GROUNDWATER RESOURCES SYSTEM OF CHINA WITH THREE-RATED APPRAISING METHOD OF SUBAREA

huajun hua LOU, Hong Hong WANGHONG, Jun Jun XIAJUN, XianFang Xian SONG (institute of geographic sciences & natural resources research,chinese academy of sciences(cas))

Surface water and groundwater are important constitutes of water resource system. Since the water transport and deposited in a different way within the medium between surface water and ground water, so the modeling and appraising method adopted are different. The first water resources appraising of China, only the one item of national groundwater resources' gross is to 10000 billion tons (occupy 1/8 of all the national groundwater resources or so), this data is equal to the data of the water transported from south to north one time ormore. The author think that the main reasons for the total error of groundwater resource are:1) In the nature, groundwater and surface water frequently conversed and replenished with eachother. It is impossible to appraise them respectively. In the water resources' appraising of China, from one– rated subarea to three-rated subarea, the method of ground water modulus was divided with surface water. So, it can't be reflected clearly that the system of surfacewater and groundwater are oneness. 2) In the water resources' appraising, the computing methods of surface water and ground watersreplenishment and evaporation are not be united, the resource quantities' iteration principleis different, leading to the inconformity of the result. 3) The basic data for water resource's evaluation of china come from the different managementsection respectively. Water conservancy department managed surface water and agricultural water. So relevant water data primarily come from the water conservancy section. Constructed department managed the water for city use. Relevant data mostly come from local constructsection. For a few years, the groundwater was managed by geologic and mining section. Meantime,the section can pursue a part of monitoring work. They have the accumulated data of many years.The data of above three sections are the foundation on which proceed the water resource's evaluations in China .so the problem of data unification should be resolved. The author think that in the first water resources evaluation of China, surface water wasevaluated according to River valley, while ground water was evaluated through Hydrology geology unit, which are the principal reason for the error of water resource's gross. Theconversed relation of four kind of water is complexity, which adopt the evaluation methodof river valley and hydrologic unites respectively. So the gross' error is unavoidable in water resources' appraising. In the thesis, the author brings up the project of three-ratedevaluation and subarea. In the groundwater resources' quantity evaluation, one and two-ratedsubarea method according to river valley are adopted. While three rated subarea according to groundwater unites is used to resolve the problem of the water resources' evaluation error.

ACID RAIN AND GROUNDWATER QUALITY

Roald Gamidovich DZHAMALOV (Water Problems Institute, Russian Academy of Sciences)

The study of the effect of precipitation on acidification processes in groundwater for different combinations of natural and anthropogenic factors that control the response of hydrogeological systems to acidification and the development of methods for the risk assessment of groundwater pollution by acid fallout. On catchment areas in Moscow and Novgorod regions in Central Russia, field observations and analytical determinations were carried out (the sampling of rainwater, meltwater, surface water, soil water, and groundwater, as well as of water-bearing rocks) for the subsequent study and update of the data base on groundwater acidification under individual geological, hydrogeological, landscape, and geomorphological conditions and degree of acid load. The main attention was paid to the study of the hydrochemical regime of spring water and groundwater, which are most liable to acidification. In addition, the mineralogical composition of water-bearing rocks and clayey interlayers was analyzed to assess the degree of interaction between them and percolating acid waters. The data on the hydrochemical groundwater regime within individual catchment areas have been generalized over the period of last 30-40 years. These materials were used for verification and adaptation of the hydrodynamic and physicochemical models for estimating the areal extent and degree of groundwater acidification.The field and experimental studies, as well as simulations, were carried out with a special attention paid to studying the soil and rocks of aeration zone, since they buffer the effect of acid precipitation on groundwater. Stages in leaching the soluble minerals of soil and water-bearing rocks were determined as a function of the acid load and duration of exposure. The relationship was determined between the neutralizing capacity of rocks of aeration zone and amount of carbonate rocks, the rate of infiltration of acid precipitation, as well as the duration of physicochemical interaction in the water-rock system and the solid-to-liquid ratio.Possible forms of migration of constituents of rainwater, meltwater, surface water, and groundwater have been studied under various conditions of their formation and migration, as well as with allowance made for the duration of acidification process in the water-rock system.The analysis of the available criteria of acidification allowed developing new criteria of the degree of acidification of natural waters, which are based on the amount of acid load and its residence time in the water-rock system. Various phases of acidification of soil water and groundwater have been studied under a variety of conditions of their formation and under various hydrogeological regimes.The field and experimental studies, as well as the computer simulation allow us to establish several important particularities of groundwater acidification and contamination under atmosphere fallout.

HS02a/07P/D-032 Poster 1545-178

HYDROGEOLOGICAL ANDHYDROGEOCHEMICAL ASPECTS OF THE NUBIAN SANDSTONE AQUIFER IN EAST OWEINAT AREA, SW EGYPT

Esam EL SAYED[1], K. DAHAB[2], A.M. EBRAHEEM[3] ([1]Geology Department, Faculty of Science, Minia University, [2]Geology Department, Faculty of Science, Menofia Univ, [3]Geology Department, Faculty of Science, Assiut Univ)

East Oweinat area is currently a site of a major reclamation project, which totally depends upon the groundwater extraction from the Nubian Sandstone Aquifer; the only water resource in this area. This aquifer is composed of sandstone beds with minor intercalation of siltstone and kaolinitic sandstone. Groundwater in this aquifer occurs under unconfined conditions, while elsewhere it is under semi confined conditions as a result of the occurrence of clay intercalations within the aquifer materials. Generally, groundwater flow is from southwest to the northeast. The saturated thickness is ranging from less than 100 to 650 meters in the study area. The recent annual recharge to the aquifer system in this area is too low if compared to the present extraction rate and exclusively depends on the transmissivity of the aquifer material and its hydraulic gradient. Groundwater belongs to f resh water class whereas salinity content ranges between 302 and 876 ppm., It is of meteoric origin and belongs to alkali- chloride sulphate water type. Therefore, it is suitable for irrigation purposes for most of the soil types under ordinary conditions.

HS02a/07P/D-033 Poster 1545-179

A STUDY OF HYDROGEOLOGICAL CONDITIONS OF THE NUBIAN SANDSTONE AQUIFER IN THE AREA BETWEEN ABU SIMBEL AND TUSCHKA, WESTERN DESERT, EGYPT

Esam EL SAYED[1], K. DAHAB[2], A.M. EBRAHEEM[3] ([1]Geology Department, Faculty of Science, Minia University, [2]Geology Department, Faculty of Science, Menofia Univ, [3]Geology Department, Faculty of Science, Assiut Univ)

The Nubian Sandstone Aquifer in the area between Tuschka and Abu Simbil is small portion of the very well known Nubian Sandstone Aquifer System in the Eastern Sahara, which covers the entire area of southwest Egypt, southeast Libya, northeast Chad, and northern Sudan. Tuschka area is currently the site of intensive drilling and development for a huge land reclamation project. The drilling information was used to study the hydrogeological setting of the aquifer in the area. The obtained results indicate that the lithological characteristics and tectonic setting is strongly affecting the groundwater flow pattern as well as the aquifer potentiality of the Nubian Sandstone aquifer in the area. The aquifer potentiality in the study area is low if compared to that of east Oweinat, Dakhla, and Kharga areas. The aquifer is mainly composed of hard ferruginous sandstone with great shale and clay intercalation with a thickness ranging from 140 to 230 meters. T he potionmetric surface is ranging between 102 and 170 meters above mean sea level. Depth to water ranges between 20 and 140 meters from the ground surface.Groundwater in this aquifer belongs to fresh to slightly brackish type (salinity is ranging from 240 to 2370 ppm). The predominant water type is sodium sulhate and sodium chloride. The groundwater is related to meteoric origin. The high concentration of sodium, chloride, and sulfates reflect leaching and dissolution processes of gypsiferous shales and clay as well as long residence time of water. Most of the collected groundwater samples are suitable for irrigation purposes in the study area.

HS02a/07P/D-034 Poster 1545-180

GEOPHYSICAL EXPLORATION FOR GROUNDWATER IN THE TOLON-KUMBUNGU DISTRICT OF GHANA

Jude Simon BAYOR, Aboagye MENYE (HYDROLOGY)

Geophysical exploration for groundwater has been carried out in seven communities the Tolon-Kumbungu District of the Northern Region of Ghana. The communities involved are Gbullung, Woribogu, Gun, Nyorong, Yoggu, Nyankpala-Tuunayili and Nyerishegu. These communities are mostly located in the south-eastern half of Tolon and lie in the Lower Voltaian Sedimentary Basin. The geophysical techniques involved were the Electromagnetic (EM) survey for ground profiling with the EM 34-3 ground conductivity meter and the dipole-dipole configuration in Vertical Electrical Sounding (VES) with the Swedish ABEM SAS 300C resistivity equipment. Results show that major aquifers are confined to hard, fractured sandstone formation. No water was found for weathered zone or fresh rock aquifers. Analysis of data also revealed several thin-bedded sequences of between 4 m and 10 m thickness of sandstone, mudstone shale and their intercalations to be the dominant formations here. Groundwater was confined to between 25 m and 45 m with major aquifers occurring approximately between 34 m and 45 m depths. Groundwater availability to beyond 55 m was not possible. The potential success rate is estimated at 75%. The surveys show conclusively that the EM method and the dipole-dipole array in VES when combined is an effective tool for the location of groundwater in the survey area of the Tolon-Kunbumgu District.

HS02a/07P/D-035 Poster 1545-181

A POLLUTION OF AQUIFERS BY HYDROCARBONACEOUS INCLUSIONS

Nadezhda K. KORSAKOVA, Valentin I. PENKOVSKY (Siberian Division, Russian Academy of Science, Lavrentyev Institute ofHydrodynamics)

Damages of oil-pipe lines, liquid escape from gasoline storage and oil storage, petrol leak from filling station lead to percolation of immiscible with water fluids into water-bearing stratum occurs. At that closed hydrocarbonaceous inclusions are generated inside aquifers. Similar formations are able to be in dynamic equilibrium with groundwater flow. A water phase partially flows around and partially through such inclusions which are in stationary positon under the influence of capillary forces. This phenomenon is called ˝internal capillary locking˝. The experiments were realized on transparent fill-up physical models of water-saturated bed contained circle oil inclusions under presence of gravity. It was observed the redistribution of saturation in oil spot under influence of gravity and oncoming flow of water. The limit dynamic equilibrium with water phase flow criterion was obtained for an inclusion. It was demonstrated that equilibrium stationary position was broken under exess over the criterion, and hydrocarbonaceous phase started moving. The mathematical model as a system of differential equations have been formed that allowed to describe in a hydraulic approximation a distribution of oil particles in three-dimensional inclusion been under action of a field of hydrodynamic forces and field of gravitation. A hydraulic pressure have been averaged over vertical component, consequently seepage became two-dimensional. But a distribution of oil particles remained as three-dimensional because of a gravity was taken into account. The condition of phase pressure jump on boundary of phases was taken into consideration too. The finite element method was used for solving of the two-dimensional ground water flow problem with an arbitrary given form of hydrocarbonaceous inclusion. The obtained numerical results are well agreed with the experimental data.

INTEGRATED GEOPHYSICAL INTERPRETATION FOR GROUNDWATER EXPLORATION AT NUKHL AREA , CENTRAL SINAI, EGYPT

Abdel-Rady Ghareeb HASSANEEN[1], Sultan Awad SULTAN[2], Badr Saad MOHAMED[3] ([1]Prof. of Geophysics and head of the geomagnetic and geoelectrical dept., National Research Institute of Astronomy and Geophysics, Helwan, Cairo, Egypt., [2]Lecturer of Geophysics, [3]Geologist (Egyptian geological survey))

Different geophysical tools were carried out on the studied area to define the stratigraphic units, structural elements and the depth to the basement surface. These geophysical tools are geoelectric, magnetic and gravity methods.Quantitative interpretation of the vertical electrical sounding curves was done by using the two layer standard curves and generalized Cagniard graphs (Koefoed , 1960; Orellana and Money, 1966) to determine the thickness and true resistivities for each geoelectrical unit in order to obtain a preliminary models . All VES stations are re-interpreted as a final models using IPI-1D program to compute these final models. The interpretation of the magnetic data started with reduction to the magnetic pole, then depth to the upper surface of the basement was determined applying Eulier deconvolution technique. The quantitative interpretation of Bouguer gravity anomaly map started with separation of residual and regional gravity anomalies applying high and low pass filter technique using Geosoft program (1994). The structural elements can be determined

from the residual gravity anomalies. Also, gravity modeling was carried out along three profiles to define the depth of water bearing Nubian sandstone aquifer and the upper surface of the basement using GM program (1995). The results of the geophysical interpretation show that, the subsurface section consists of six geoelectric units. The depth of upper surface of the Nubian sandstone(aquifer) ranges between 800 to 1000 m. The depth of the basement surface ranges between 1720 m at the northwestern part and 3600 m at the southwestern part of the studied area. There are normal faults whose directions are: N-S, E-W and NE-SW.

STUDY ON REMOVAL OF CADMIUM FROM GROUNDWATER BY ADSORPTION ON GAC , BAC & BIOFILTER

Ramazan ali DIANATI TILAKI (Environmental Health Engineering Department, Mazandaran University of Medical Sciences)

The Contamination of groundwater by toxic heavy metals is a world-wide environmental problem. Rock and minerals containing heavy metals can increase concentrations of these elements in groundwater. Cadmium is a toxic element and can accumulate in the living organisms. Low concentration (below 5 mg/L) of Cadmium is difficult to treat economically using chemical precipitation methodologies. Ion exchange and reverse Osmosis while can guarantee the metal concentration limits required by regulatory standards, have high operation and maintenance costs.The goal of this research was to determination of efficacy of using GAC , Biofilm and BAC columns to treat low concentration Cadmium bearing water streams and was to determination of the effects of temperature and pH on the adsorption isotherms.Studies were conducted to delineate the effect of pH, temperature, initial Cd and adsorbent concentration on adsorption of Cd2+ by GAC , BAC and Biofilm. Breakthrough curves for removal of 0.5 mg/L Cd2+ by GAC; Biofilm and BAC columns at two contact times were plotted. Batch adsorption and column data are compared. pH is shown to be the decisive parameter in Cd removal for GAC but not for BAC or biofilter. Lagergren plots confirms applicability of first-order rate expression for adsorption of Cd by GAC, BAC and Biofilm.The adsorption coeficient(Kad) for BAC were 2 times greater than those with plain GAC. Bed Volumes of water containing 0.5 mg/L Cd2+ treated at breakthrough for GAC , Biofilm and BAC columns were 45, 85 and 180 BV respectively. BAC is more efficient than GAC in the removing of Cd from water environment. Keywords: Cadmium ,adsorption, GAC, BAC , Biofilter,

GROUND WATER ROLE IN THE ARAL SEA REGION PUBLIC WATER SUPPLY

Abdulkhakim SALOKHIDDINOV, Khidoyat VALIEV (Tashkent Institute of Irrigation and Agricultural Mechanization Engineers)

The role of groundwater in public water supply has increased dramatically in many countries during the last decades. Surface water resources contamination (and often depletion) is a reason to use groundwater more intensively. In a number of regions, especially in Central Asia including the Aral Sea region, it reached a catastrophically large scale. At the same time in determining the perspectives of groundwater use, one should consider groundwater not only as a commercial deposit but also and above all as a part of water resources and an important component of the environment. Taking that into account it should be noticed that groundwater in many arid regions is an alternative and often the only possible source for public water supply that can provide terrestrial ecosystems with pure, safe drinking water of high quality. All the above-mentioned apply equally to Central Asia arid regions and in the first place to the Aral Sea basin, where water resources degradation assumed a catastrophic character. According to preliminary results of research it is established that the Aral Sea shrinking has direct impact on change of amudarya and aral complexes higherquaternary and modern sediments groundwater´s level and chemical composition mainly within area of the dried Aral Sea bed.

IMPACTS OF GLOBAL WARMING ON SEMI-LARGE SCALE LAKES

Michio Dalai KUMAGAI[1], Kanako ISHIKAWA[2], Naoko ISHIGURO[3] ([1]Lake Biwa Research Institute, [2]Kyoto University, [3]Limoges University)

Global warming is now bringing serious problems on the semi-large scale lakes (100 –1000 km2 in area), because these sizes of lakes are not so much sensitive as small lakes and more reactive than great lakes over 1000km2 in area. We have been studying such scale of lakes in the world, and found that some lakes are facing very much serious situation. Lac Leman of Swiss and France has lost oxygen in the hypolimnion, and it is rarely supplied now even if eutrophication stopped. Annual mean dissolved oxygen is less than 1mg/L for several years, and suddenly the level was recovered by winter overturning. This is clearly controlled by global climate change. Lake Huxian in Yunnan Province of China is also suffering from insufficient oxygen recovery in winter, and the local government is wondering what action they should take. As fresh water resource in China is very much limited, the deterioration of Lake Huxian is getting social problem now. Lake Biwa, the largest lake in Japan, looks still fine, but actually benthic ecosystem and water quality are getting worse year by year. The depletion of dissolve oxygen in Lake Biwa is caused by both decrease of oxygen supply in winter and increase of oxygen consumption in summer. As Lake Biwa is supplying drinking water to more than 13 million people in Osaka, Kobe, Nara, Kyoto and Shiga area, the well management of this lake is a big social demand. Even Lake Tahoe, which is one of most beautiful lakes in the world, is loosing oxygen now in a deeper layer, and it depends on the deficiency of overturning due to global warming. When we compare the apparent oxygen consumption rate among several semi-large scale lakes, we found that Lake Biwa has highest value, and is most productive. Thus global warming is definitely changing water quality and ecosystem of semi-large scale lakes as well as eutrophication. In this study, we present current information of such lakes, and discuss what are happing at present and will occur in the future. As semi-large scale lakes play more important role to

---

maintain the human being society than others, those should be carefully monitored and managed wisely.

ANALYSIS OF WATER RESOURCES IN THE YELLOW RIVER BASIN USING THE DISTRIBUTED HYDROLOGICAL MODEL

Dawen YANG[1], Toshio KOIKE[1], Katumi MUSIAKE[2], Tetsuya KUSUDA[3] ([1] Department of Civil Engineering, Univ of Tokyo, [2]Institute of Industrial Science, Univ of Tokyo, [3]Faculty of Engineering, Kyushu University)

The Yellow River basin is the second largest basin in China. Due to recently fast development of economics, water shortage is becoming a serious problem. For better management of water resources in the Yellow River basin, water resources assessment is firstly important. This research develops a distributed hydrological model to simulate the spatial-temporal characteristics of hydrology in the Yellow River basin. Land uses, topography, geology and soil conditions, and artificial water uses (mainly agricultural irrigation) determine the complexity of hydrological characteristics in this basin. With the limited observation of the river discharge, it is impossible to develop a simple model for simulating hydrology in different sub-basins. Present research attempted to incorporate all available spatial information into the hydrological model by a distributed approach. Based on the physical governing equations, a comprehensive hydrological model has been developed. Using a 10-years metrological data set, the hydrological characteristics and distribution of water resources are discussed in the paper. Because the majority of water use is for agriculture irrigation, this research also tried to incorporate the irrigation water use with the hydrological model for exploring irrigation management.

PATTERNS OF RUNOFF CHANGE IN BULGARIA

Marin Gospodinov GENEV (National Institute of Meteorology and Hydrology)

We consider the geographical location of Bulgaria on the Balkan Peninsula and the impact of the complex mechanism of atmospheric circulation. We make statements regarding the cyclonic activity related to the rainfall situation in the country. We emphasise the importance of the Mediterranean cyclones, their formation and evolution, to rainfall. An overall climatic division of the country is also outlined. River runoff formation principles are also considered. The evolution of the runoff (a probabilistic process) is derived in terms of certain hypotheses introduced in the paper. Two approaches are employed in the analysis of river runoff pattern changes: determination of internal structural changes and of patterns in annual runoff change. For the purposes of the current investigation the country is divided into three runoff regions: Danubian, Black Sea and Aegean runoff basins. The climatic features of each of the basins are as follows: Danubian basin - moderate continental climate; the larger part of the Black Sea basin (its northern part) - Black Sea-influenced climate, its southern part is with a dominating Mediterranean climate (falling within a transitional zone); the northern part of the Aegean runoff region – a mixture of moderate continental and mountain climate, its southern part – under the influence of the Mediterranean climate. Each of these runoff basins had been formed by a raft of catchment basins, and can be characterized by the details of its temperature, precipitation and runoff changes. The patterns of runoff change are established by means of a complex approach allowing the combined determination of the principal climatic elements – temperature and precipitation. The raft of 1st and 2nd class meteorological stations enables us to set a space step, on a relatively uniform grid, of 25.6 km for the temperature, 19.2 km for the precipitation, and 27.3 km for the runoff. The analysis of the thus determined temperature, precipitation and runoff complex indicates the presence of specific structures giving rise the main phases of the main variation cycles. A trend analysis then determines the annual change patterns in the complexes. We observed a clear-cut phase of reduced rainfall and runoff beginning after 1981-82 and which has been active ever-since (2001). This shortage of precipitation caused droughts in each of the runoff basins. We assess this phase for each one of the complexes with respect to the recommended by the WMO norm. For the Danubian region the total decrease in runoff is in the order of 30-32 %, for the Black Sea of 43-46 % and for the Aegean – 35-39 %. It has to be noted that no such phase in the annual changes of river runoff and precipitation has previously been witnessed in Bulgaria.

HS02/08A/C24-004   0915

LONG TERM VARIATIONS IN RUNOFF AND CLIMATE IN SWEDEN

Göran Johannes LINDSTRÖM, Sten BERGSTRÖM (Swedish Meteorological and Hydrological Institute)

Sweden, and many other countries, has experienced a large number of floods in recent years, e.g. in 1995, 2000 and 2001. The objective of the present paper is to study long term variations in runoff in Sweden, now that data from the whole 20th century is at hand. The runoff from the whole country, for the period 1901-2000, was estimated. The runoff during the period 1981-2000 was about 8 % higher than during the rest of the century. This wet period followed after the dry 1970s, which was the decade deviating the most from the rest of the century. The high runoff in recent years was most pronounced in the north. A substantial part of the increase in recent years occurred in the period January-June. However, the runoff in the 1920s was also high, and if isolated, the period 1920-1980 could be interpreted as having a falling tendency, whereas an increasing tendency appears from about 1950 to 2000. Seen over the whole century no significant changes were found. Extreme floods show a similar tendency as that of annual runoff, with many recent flood events, particularly in the northern part of the country. On the other hand, observations from the 19th century show that the runoff was even higher then. Trend tests suggest downward trends for two out of three of the long series in the analysis, the longest starting in 1807. The long records of runoff were analysed jointly with recorded precipitation, temperature and the NAO index. For the whole country, the latest ten years have been the wettest for more than 100 years and very warm. For southern Sweden, and in a longer time perspective, the high temperatures are more impressive than river runoff. The combination of high temperatures and high river runoff in recent years is quite different from the high runoff records in the 19th century, when temperatures were lower. The recent wet years have often been connected to winter periods with westerly winds. The past 20 years have undoubtedly been wet. It is nevertheless difficult to extrapolate a possible trend starting at about 1950 into the future.

HS02/08A/C24-005   0930

THE IMPACTS OF HUMAN ACTIVITIES ON THE HYDROLOGICAL PROCESSES IN THE ARID ZONES OF NORTHWEST CHINA IN RECENT 50 YEARS

Genxu WANG, Guodong CHENG, Mingyuan DU, Yongping SHEN (Department of Water &Soil resources Research, Cold & Arid Regions Environmental and Engineering Research Insitute, CAS)

Unlike other drylands in the world, arid zones in northwest China are characterized by

alternately distributed high mountains and plains. The mountain areas have abundant precipitation and glacier which forms surface water flow to plains and form numerous inland river systems. There were no runoff occurred in plains with precipitation of lower than 200mm, but complex transformation between surface water and groundwater. The hydrological regimes of groundwater and spring water, in a large extent, depend on the surface runoff. From several points of view, such as surface runoff dynamic changes out from mountain mouth and in lower reaches both in annual and inter- annual, the changes of groundwater table and the spring water volume, and temporal and spatial hydro-chemical regimes etc. were discussed in this paper for revealing the characteristics of hydrological changes resulted from human activities in recent 50 years. The inter-annual outflow of most rivers out from mountains exhibited an increase trend in recent 50 years, especially in the rivers that the recharges of the glacier and snow milt-water taken an important role by the component rate over 10.0%. However, river discharge in the lower reaches is decreasing, terminal lakes are contracting or drying up and water quality is getting worse due to expanding large-scale exploitation of water resources. Many small rivers disappear soon after flowing from mountain valleys, river courses are shortening, the spring water volume is continually reduced, and the groundwater table is falling in most parts of middle and lower reaches. These hydrological changes enhanced the water supply-demand paradox, and resulted to serious environmental problems. Understanding the characteristics of hydrological processes and regimes changes was important for driving the solutions of rational use of the limited water resources and the limiting of environmental degradation in the northwest China. Key word: Arid zone, hydrological process, water exploitation, impact, hydrological change

VARIATION FEATURES OF THE CLIMATE AND GLACIERS IN CHINA'S MONSOONAL TEMPERATE-GLACIER REGION SINCE THE LITTLE ICE AGE

Yuan Qing HE[1], Zhonglin ZHANG[2], Tuo CHEN[2], Tandong YAO[1], Hongxi PANG[2] ([1]professor, [2]Dr.)

The collected climatic observation data, ice core records, tree ring index and recordation of glacier variations have been used and compared, to reconstruct the detailed history of climatic and glacial changes in the monsoonal temperate-glacier region of southwestern China during the past 400 years. All results indicate that the temperature in the region has increased in a fluctuating way since 20th century after the two cold stages of the Little Ice Age during the 17-19 century, corresponding to most of the retreating glaciers in a background of global warming. Differentially, the amount, variation amplitude and trend of precipitation in the region vary in different parts of the region. The climatic records in Dasuopu ice core, located in the Himalaya area and the western part of this region, show that the precipitation has trended to decrease since 1950's, in comparison with the tendency of increasing temperature during the same period. However, precipitation in Hengduan Mountains and other districts of this region display a rising and similar trend with that of temperature change. The different climatic variation feature may be associated with the varied atmosphere circulations over the region. As indicated by the analyzed data, the southwestern monsoon, which mainly controls China's temperate-glacier region, can be classified into two sections. One is called Indian Monsoon from Arabian Sea, passing through the Indian Peninsula, which mainly carries the vapor for precipitation to Himalaya district, the western part of region; the other is called Bengal monsoon from Bay of Bengal, passing over Bengal and Burma, which is the major source of precipitation in Hengduan Mountains and other areas, the eastern part of the region. Moreover, the eastern part of this region is also controlled by the southeast monsoon deriving from the western Pacific and in the west is manipulated by the southern branch of westerly circulation in winter. This complex atmospheric situation results in the variable patterns of precipitation in different parts of the region. The temperate glaciers distributed in the region is very sensitive to climate warming after the Little Ice Age and most of glaciers have been retreating successively since 20th century and the speeds have accelerated after 1980's and speeds of few advancing glaciers are alleviating. Although both temperature and precipitation influence the change of glaciers, further work is needed to confirm which one is major factor to affect present glacier change.

PREDICTION OF RIVER RUNOFF BY THE THE NORTH ATLANTIC OSCILLATION INDEX

Joanna K. POCIASK-KARTECZKA, ZENON NIECKARZ, Danuta LIMANOWKA (Hydr. Dept., Institute of Geography, Jagellonian University)

The North Atlantic Oscillation has been identified as one of principal factor controlling the weather conditions over the middle and high latitudes of the Northnern Hemisphere. It has controlled the regional temperature and precipitation variability (Bonsal *et al.* 2001, Hurrell & Van Loon 1997, Shabbar et al. 1997). The meteorological conditions in Poland are influenced also by the NAO (Wibig 2000). Therefore, it creates a posssibility of a non-directly influence of NAO on the river runoff. This relationship has not received enough of scientific attention. Three river basins runoff was analysed: Skawa (835 km^2), Dunajec (4 341 km^2) and Wistula (31 846 km^2). All basins are located in the Carpathian Mts. Data sets of long-term mean monthly, seasonal, minimum and maximum values of river discharge were available for 1951-2000 and taken into consideration. And, the winter Hurrell's NAO index and the Rogers's NAO indexes respectively. The NAO conditions over the period 1951-2000 were very differenciated, and two particular air-circulation epochs was analysed separately also: 1951-1970 and 1971-1995 (Marsz, Styszyńska 2001). On the base of analysis of the Rogers's and Hurrell's indexes and the Carpathian river discharge, some relationships were identified. The present analysis of the NAO Hurrell's and Roger's indexes and the Carpathian rivers discharge demonstrates very interesting large-scale connections: the positive NAO episode in winter are associated with low discharge in the summer and in the beginning of the autumn. The most remarkable relationships were obtained in the analysis performed over the atmospheric circulation epochs: mean annual NAO index explains 41% of variability of mean river discharge in summer and 30% of variablity of mean annual river discharge. There is a relationship between the winter NAO index and river discharge in August. Styszyńska (2002) stated similar relationship concerning NAO and the Warta Riv. (western Poland) discharge. She found also a link between winter NAO index and precipitation during late summer: the winter NAO index explains about 30% of precipitation variability in August next year (Styszyńska 2001). This delay of reaction of this part of Central Europe is noticeable. The article describes the possibilities of prediction of the river runoff in summer. Models of linear regression for estimation the river runoff in August were calculated. It may facilitate a prediction the August river runoff with a few months preceding. It may be stated that NAO plays an important role as indirect factor influencing river discharge.

UTILISATION COUPLEE DE MODELES HYDROLOGIQUES DE BILANS ET DE SIG POUR EVALUER LES RESSOURCES EN EAU MOBILISABLES ET LEUR EVOLUTION SPATIO-TEMPORELLE. APPLICATION A L'AFRIQUE DE L'OUEST

Jean-Emmanuel PATUREL, Eric SERVAT, Gil MAHE, Alain DEZETTER, Mahaman OUEDRAOGO (Institute of Research for Development (formerly ORSTOM))

L'Hydrologie Régionale vise et permet de répondre aux besoins de ceux qui, gestionnaires de projet, d'aménagements, décideurs et autres, travaillent généralement une grande échelle d'espace. Celle-ci est, en effet, celle de la mobilisation et de la planification en termes de ressources en eau. Le travail présentici couple des modèles hydrologiques un Système d'Information Géographique, afin d'analyser l'impact de la pèjoration climatique observée depuis plus de 30 ans en Afrique de l'Ouest sur ces lames d'eau écoulées et donc sur la ressource en eau disponible et mobilisable. En fonction de l'objectif vis une grille réguliese de mailles de dimension 0.5°x0.5° et un pas de temps mensuel ont étretenus. Un travail préparatoire a abouti la sélection de modèles Pluie-Débit de bilans simples et robustes (GR2M, Water Balance Model modifiet Yates) nécessitant des données d'entrée peu nombreuses et assez facilement disponibles en Afrique : précipitation, évapotranspiration potentielle et des valeurs de capacitde rétention en eau des sols. On simule alors, pour chaque maille et indépendamment les unes des autres, et pour chaque pas de temps, la lame d'eau écoulée totale. Les modèles de bilan hydrologique sélectionnés permettent d'atteindre des niveaux de performance très satisfaisants. Dans les tests réalisés, aucun des modèles ne présente une supérioritnette par rapport aux autres. Cependant, pour les modèles GR2M et WBM, les résultats obtenus sur certains bassins versants se révèlent difficilement transposables d'autres, non jaugés, et pour lesquels on ne dispose d'aucune information. Le modèle de Yates permet, quant lui, de prédéterminer les valeurs de ses paramètres sans aucune procédure de calage et validation. Il s'appuie sur le schéma de classification "climat-végétation" de Holdrige qui autorise une prédetermination des paramètres l'aide d'une une méthode empirique précédemment appliquée la région étudiée. La cartographie des lames d'eau écoulées mensuelles et annuelles rend possible, d'une part, de dresser une répartition spatiale des écoulements l'échelle régionale et, d'autre part, d'apprécier l'impact de la variabilitdu climat sur les ressources en eau. En superposant ces grilles les contours des bassins versants, l'écoulement total l'exutoire d'un bassin est, en effet, obtenu par l'addition des contributions élémentaires pondérées des différentes mailles qui les constituent. Ce travail a permis de s'intéresser la sélection de modèles pluie-débit opérationnels en Afrique de l'ouest. Il a également conduit mener un travail de fond quant l'influence des données disponibles sur les résultats obtenus en aval d'une modélisation hydrologique. Cette étude a aussi sou'signl'évolution des ressources en eau en Afrique de l'ouest durant les dernièses décennies, mettant l'accent sur la baisse des ressources mobilisables, ce qui est particulièsement pénalisant dans des pays du Sud ol'économie repose principalement sur l'agriculture.

GLOBAL WATER RESOURCES ASSESSMENT UNDER CLIMATIC CHANGE USING TRIP

Taikan OKI[1], Yasushi AGATA[2], Shinjiro KANAE[3], Katumi MUSIAKE[3], Takao SARUHASHI[4] ([1]Reseach Institute for Humanity and Nature, [2]JST/CREST, [3]Institute of Industrial Science, U of Tokyo, [4]The NEWJEC, Inc.)

Anticipated water scarcity in the first half of this centuryis one of the most concerned international issues to be assessedadequately. However, even though the issue has an international impactand world wide monitoring is critical, there are limitednumber of global estimates at present.In this study, annual water availability was derived fromannual runoff estimated by land surface modelsusing Total Runoff Integrating Pathways (TRIP)with 0.5 degree by 0.5 degree longitude/latitude resolution globally.Global distribution of water withdrawal for each sector in the samehorizontal spatial resolution was estimated based on country-basestatistics of municipal water use, industrial water use, andagricultural intake, using global geographical information system withglobal distributions of population and irrigated crop land area. The total population under water stress estimated for 1995correspondedvery well with former estimates, however, the number ishighly depend on how to assume the ratio how much water from upstream of the region can be considered as ``available´´ water resourceswithin the region. It suggests the importance of regional studies evaluating thethe water quality deterioration in the upper stream,the real consumption of water resources in the upper stream,and the accessibility to water.The last factor should be closely related to how many large scalewater withdrawal schemes are implemented in the region.Further studies by an integrated approach to improve the accuracy offuture projections on both the natural and social sides of the waterresources should be promoted. About the future projection of the global water resourcesassessment, population growth, climatic change, and theincrease of water consumption per capita are considered.Population growth scenario follows the UN projection in eachcountry. Change in annual runoff was estimated based on theclimatic simulation by a general circulation model by theCenter of Climate System Study, U of Tokyo, and the NationalInstitute for Environmental Studies, coupled with TRIP. The increasein unit consumption of water was related to the predicted growth of GDP.With the increase of population only, future population understrong water scarcity, with water scarcity index is larger than 0.4,will increase by 90% in 2050 compared to the current situation in 1995.Consideration of the climatic change due to the global warming willrelax this situation, and only 74% will be under the strong waterscarcity according to the future projection used in this study.

FORECASTING RUNOFF WITH COMBINED MODELS OF ATMOSPHERIC BEHAVIOUR AND RIVER BASIN RESPONSE: A CASE STUDY FROM SOUTHERN BRAZIL

CARLOS E.M. TUCCI[1], Walter COLLISCHONN[1], Pedro L. DIAS[2], Robin T. CLARKE[1] ([1]Instituto de Pesquisas Hidraulicas, [2]University of São Paulo, Brazil)

Over 90% of Brazil´s energy demand is supplied at present by hydropower. It is therefore essential for purposes of future planning to have good estimates of reservoir inflows, and the longer the lead-time of streamflow forecasts, the more distant is the planning horizon for decisions concerning the costing, production and distribution of power. Whilst it is relatively easy to forecast river basin response to precipitation that has already fallen, forecasts for periods beyond this immediate response time must be based upon estimates of future precipitation. This paper describes the results of work which combines forecasts of future rainfall given by a model of global climate with a detailed, distributed model of river basin response in the Brazilian part of the River Uruguay basin, an area of intensive hydropower production. The work required close collaboration between meteorologists and hydrologists. Comparison of predicted and observed rainfall over the period of model calibration showed that it was necessary to apply a statistical correction to eliminate a spatial trend in predicted rainfall. Data from a two-year period was set aside for model validation. Results show that the combined use of models of climate and river-basin response has been successful for the River Uruguay basin, in that the root-mean-square error (RMSE), between observed flows

and flows predicted by the combined model, is substantially less than the RMSE between observed flows and the historic mean monthly flows.

HS02/08A/C24-011   1130

INVESTIGATION OF FEEDBACK MECHANISMS BETWEEN SOIL-MOISTURE, LAND USE AND PRECIPITATION IN WEST AFRICA

Harald G. KUNSTMANN, Gerlinde JUNG (Institute for Meteorology and Climate Research, Karlsruhe Research Center)

The ongoing intensification of agriculture in West Africa leads to a change in surface and subsurface characteristics, which directly affects evapotranspiration rates. If these changed evapotranspiration rates in turn affect regional rainfall patterns, rainfed and irrigated agriculture in West Africa may face changed boundary conditions because rainfall can decrease in specific areas due to feedback mechanisms between land use change, soil moisture change and subsequent precipitation change. To identify the feedback mechanisms between land surface (soil and vegetation) and atmosphere, an extensive numerical experiment was carried out. We applied the mesoscale meteorological model MM5 for the investigation of soil-moisture-precipitation and landuse-precipitation feedback effects in West Africa and in particular the Volta Basin (which covers 400,000 km2 and extends from Burkina Faso to Ghana, Togo, Ivory Coast). For that purpose, MM5 was prepared for runs in West Africa; optimal parameterisations for microphysics, cumulus parameterisations and radiation scheme were determined and validation was performed for a 30 day period. Great differences in the ability to quantitatively describe the observed meteorological data were found between different model parameterisations. The determined optimal parameterisation was found to reproduce observations well. The main research question was to what extent regional (intra-domain) evapotranspiration determines rainfall within the domains. We concentrated on the estimation of lumped precipitation recycling ratio and precipitation efficiency. The effect of decreased and increased initial soil moisture on the total rainfall after a four weeks period in summer 1998 was investigated. Scale dependent, positive as well as negative feedback mechanisms were found: while in the Volta Basin itself, an increase in initial soil moisture led to decreased precipitation, in West Africa as a whole, an increase led to increased total precipitation. Moreover, nonlinear effects were observed. Sensitivity of precipitation with respect to soil moisture was found very variable over space and takes on negative as well as positive values. Recent research revealed that land use change in the Volta Basin is basically characterised by a transition from cropland woodland mosaic into shrub land and finally into grassland. To investigate the effect of such a transition for the simulation period, we computed the total rainfall distribution under the assumption of the proposed land use substitution for the simulation period, *ceteris paribus*. Similar to initial soil moisture sensitivity, the precipitation change response was found to be very variable over space. Investigation of a locally differentiating precipitation ratio, determined from an iterative algorithm, showed much larger values for the recycling ratio than the lumped approach. This discrepancy shows the current research need for concepts which do not assume perfect vertical mixing of water molecules. The approach we follow for this task is the ″Evapotranspiration tagging″ which follows the path and the phase transitions of water molecules from its origin as evapotranspiration to their ″final″ return to the surface as precipitation. Preliminary results of the approach are presented.

HS02/08A/C24-012   1145

THE EFFECT OF DOWNSCALING TECHNIQUES ON WATER RESOURCE SCENARIOS FOR CLIMATE CHANGE

Johan ANDRÉASSON, Sten BERGSTRÖM, Bengt CARLSSON, L. Phil GRAHAM, Göran LINDSTRÖM (Swedish Meteorological and Hydrological Institute)

The prospect of climate change is an issue of high importance regarding future water resources. About 50% of Sweden's electric power production is generated by hydropower, which raises questions about how a future climate will affect both the frequency of extreme runoff events and the seasonal river runoff. During the last decade there seems to have been more floods than experienced before, which furthermore adds to the question AEls this a result of climate change that we can see already today?   Global Climate Models (GCMs) are used as a tool to create scenarios on what kind of changes in the future climate we might expect. However, the typical horizontal resolution of GCMs is 200-300 km, which tends to greatly smooth the geographical features of the earth's surface. There is therefore a need for more detailed information when studying the climate change effects on a regional scale, as is the case when one wants to estimate the effects on single catchments. Downscaling of GCMs, to increase the resolution over a limited region, can be done either by use of a regional climate model (RCM) or by statistical downscaling of the GCMs. Although all of these techniques are common, they are seldom compared. In this paper, water resources simulations are presented for three Swedish catchments, ranging in size from 3 665 km2 to 4 646 km2. The simulations were based on direct GCM model output, dynamical downscaling and statistical downscaling. The GCMs used were the HadCM2 and ECHAM4. The regional climate model, RCA, was developed at the Rossby Centre of the Swedish meteorological and Hydrological Institute. The hydrological model used was the HBV model. The statistical downscaling used long time series of sea level pressure, temperature and precipitation to find relationships between the GCM control run (present climate) and apply them on the GCM scenario simulations to obtain a more regionally oriented future climate result. Preliminary results indicate that the orographic influence of especially high mountains described in the dynamical downscaling has an effect on the outcome of the water resources studies. The ensemble of simulations further provides a measure of the uncertainty in assessing the future water resources in a changing climate. **Acknowledgements** The authors are active participants in the Swedish Regional Climate Modelling Programme (SWECLIM), which is funded jointly by the Swedish Foundation for Strategic Environmental Research (MISTRA) and the Swedish Meteorological and Hydrological Institute (SMHI).

HS02/08A/C24-013   1200

GENERATION OF RAINFALL SCENARIOS USING DAILY PATTERNS OF CHANGE FROM GENERAL CIRCULATION MODELS

Timothy Ives HARROLD (CSIRO Atmospheric Resarch)

Climate change under global warming conditions can be simulated using General Circulation Models (GCMs), which give results at regional scales, with a grid square resolution typically of the order of 200km in each direction. However, it is changes in local climates, below the resolution of the GCM outputs, that will determine the impacts on water resources. Downscaling of the GCM outputs is therefore required to produce rainfall scenarios at scales relevant to hydrological impact studies. One of the simplest, and most widely used, techniques for generation of ″climate change impacted″ rainfall is to perturb observed records of point rainfall by the average change in GCM grid square rainfall from current to future conditions, calculated on a monthly basis. In this simple approach, all of the daily values occurring in a given month are scaled by the same percentage, regardless of the magnitude of the rainfall. This paper proposes a modification of the perturbation approach, that uses a daily pattern of change in the ranked rainfalls from the GCM, and then scales the

ranked point daily rainfall by this pattern of change. This new approach can produce sequences of ″climate change impacted″ point daily rainfall that are very different in magnitude to sequences that are produced by simpler perturbation methods, especially in terms of rainfall that will produce runoff. We argue that the proposed method is superior, because it produces sequences that are consistent with what the GCM is saying about changes in extreme daily rainfalls and changes in the frequency of wet days.

CAUSAL RELATIONSHIPS BETWEEN LAND USE CHANGES AND WATER QUALITY – A CASE STUDY FROM NIAH CATCHMENT, SARAWAK, EAST MALAYSIA

Tina Svan HANSEN (Institure of Geography, University of Copenhagen)

Over the past decades, successive waves of land use changes have taken place in the coastal zone of Sarawak, Malaysia. Large forest areas have been logged and gradually the same land areas have been converted into oil palm plantations.This paper presents results from an ongoing Ph.D. study in the Niah River Catchment, which is located in the northern part of the coastal zone of Sarawak.The study aims to relate different types of land use changes to water quality changes in the same catchment area. Land use changes are identified by means ofsatellite images, plantation maps and logging concession maps from the past thirty years. These land use data are related to historical data on water quality, which are provided by the institutions collecting data on water qualityin Sarawak, i.e., Public Works Department, Department of Environment and the Natural Resources and Environment Board. The long-term historical data are supplemented with recent water quality data from individual local oil palm plantations in the catchment. In addition, water quality data are currently being collected from the major land use types in the area i.e. oil palm plantations, logged forest and shifting cultivation. Preliminary results show that over the past thirty years large forest areas have been logged and gradually replaced by oil palm plantations in the interior areas of the catchment. In 2001, oil palm plantations occupied more than 40% of the catchment area upstream of the local water treatment plant. In the same time period, the agricultural production in the local shifting cultivation and small scale farming systems have been intensified with the consequence of increased and more frequent use of fertilizers and herbicides. Preliminary results on changes in water quantity and quality indicate heavier and more frequent flooding down-stream after the 'emergence' of large oil palm plantations upstream in the mid eighties. In addition, a trend can be identified towards a decreasing pH-value and increased TSS and nutrients levels.

HS02/08P/C24-002   1415

CHEMICAL CHARACTERISTICS OF SURFACE WATER IN ORAMIRIUKWA AND ONUKWU RIVERS AZARAEGBELU, OWERRI

Ibe Kasimir MADUABUCHI, A.I. EGBUJOR (Department of Geology, Federal University of Technology)

The catchment area of the Oramiriukwa and Onukwu Rivers are within the sandy formation of the coastal plain sands of the Benin formation (Miocene - Recent). Soil type is lateritic sand. The study has been carried out by conducting a short term hydrochemical analysis of the surface water (Oramiriukwa and Onukwu Rivers) and land pollution survey around the rivers. The partial distribution of contaminants/pollutants due to poor land use systems and human activities were investigated, thus emphasizing integrated planned development as a preventive measure for arresting pollution levels in fast-growing urban centers. Metallic, non-metallic ions, total dissolved solids, chemical oxygen demand and physical parameters were analysed for the surface water samples and the results were evaluated in the light of World Health Organisation standard (WHO) and found good/admissible for human consumption. They are also good for irrigation purposes.

HS02/08P/C24-003   1430

MODELING NITROGEN DYNAMICS IN AN AGRICULTURAL-FORESTED CATCHMENT

Baolin SU[1], So KAZAMA[1], Minjiao LU[2], Masaki SAWAMOTO[1] ([1]Department of Civil Engineering, Tohoku University, [2]Department of Civil and Environmental Engineering, Nagaoka University of Technology)

A spatially distributed nitrogen simulation (DNS) model has been developed to simulate nitrogen dynamics in catchments. The model can simulates hydrological process and various nitrogen processes in grid cell level continuously by considering plant uptake, atmospheric wet depositions, fertilizer application, mineralization, nitrification and denitrification, and point sources if any. The hydrological component of DNS model is based on the distributed Xinanjiang (DXAJ) rainfall-runoff model, in which the whole catchment is divided into square grid cells and runoff generation component of the Xinanjiang model is applied to estimate the surface and sub-surface runoff in each grid cell. Rainfall input is distributed to each grid cell using distance-weighted rainfall, and evapotranspiration is adjusted to each grid cell considering air temperature variation depending on elevation. Parameters for runoff calculation are specified to land use level. An optimal routing order approach is used to implement the distributed routing through a routing order sequential file, which consists of information necessary for routing calculation, such as routing order, hydraulic attributes and hydrological connectivity of each grid cell. The nitrogen component of DNS model simulates daily average nitrate- and ammonium-nitrogen concentration of stream water considering key sources and sinks which are represented by a series of first order kinetic equations and various external inputs. In particular, plant growth indexes for land use class forest and agricultural lands are incorporated to simulate the plant uptake variation in according to seasonal vegetation cover variations. Model calibrations showed that there is a good agreement between simulated and observed stream nitrate-nitrogen concentration. Sensitivity analysis showed that the plant uptake is the key sink of nitrogen, whereas the agricultural fertilizer application is the key source of nitrogen during the fertilizer addition period. Wet deposition makes a small contribution to the stream nitrogen concentration.

HS02/08P/C24-004 — 1445

ASSESSMENT OF GROUNDWATER QUALITY AND CLIMATIC WATER BALANCE STUDIES IN PAGERU RIVER BASIN, ANDHRA PRADESH, INDIA

Shakeel AHMED (I.F.C.G.R.,NATIONAL GEOPHYSICAL RESEARCH INSTITUTE,)

Pageru River is located in Cuddapah district, Andhra Pradesh, India. Cuddapah is a chronically drought prone area in terms of water resources with inadequate and highly erratic rainfall resulting poor groundwater potential. The scanty surface water resources for drinking and agriculture, has made no dispute to rely more on groundwater resources in the district. Total annual rainfall and its distribution in space and time of the season are responsible for a success. This means the intensity of rainfall and its variability both in kharif (June to September) and Rabi (October to January) seasons are guiding factors. Climatic water balance and droughts of Pageru River Basin has been prepared by using rainfall data of eight rain gauge stations located in and around the basin. The values of rainfall and temperature have been collected and the water balance parameters have been computed on the basis of Thornthwaite and Mather method. In addition 99 water samples were collected for both pre and post-monsoon seasons and analysed for major ions to assess the water quality in relation to agriculture and domestic uses in the basin. Total area of the basin is 480 Km2 lies between Lat 14o 39´04″ and 14o 39´ 51´´N and Long 78o19´12´´ and 78o41´32´´E The drainage pattern of the basin is dendritic in nature. The rock formations of the study area are classified as Cuddapah super group and Kurnool group. The important rocks consist chiefly of quartzite, limestone and shale. The general climate of the basin is hot and semi-arid in nature. The temperature reaches high in the month of April and decreases gradually and reaches minimum in the month of December. The River Basin receives an average annual rainfall of 581mm with significant seasonal variations. The rainfall data for 105 years (1891-1995) of Kamalapuram station, which is located within the basin area, has been used to compute yearly water balance parameters, while for the remaining 7 stations monthly averages are used to compute the water balance parameters of the region. Based on computation of climatic water balance analysis indicates that the annual water deficit of the basin is 821mm. The maximum water deficit is observed during March and June months and it is minimum in the month of September. The analysis of the data revealed that the annual distribution is more controlled by the physiography of the region. A comparison of water balance and cropping pattern adopting in the villages indicate that the area under basin is only suitable for cultivation of drought resistant crops such as jowar (Sorgum Bicolor), ragi (Eleusine Coracana), bajra (Pennisetum Typhoides). Assessment of water samples from various methods proved that majority of the water samples is good either for drinking or for agriculture in both seasons.

EFFECT OF IRRIGATION ON GROUND WATER CHEMISTRY IN LOWER CHAMBAL COMMAND AREA, MADHYA PRADESH, INDIA

L.P. CHOURASIA (Department of Applied Geology,Dr. H.S. Gour Univ)

The study area is a part of the Chambal and Sind river basin and falls Bhind and Morena districts of Madhya Pradesh, India. It is irrigated by the Chambal canal system. The area comprises of alluvium in which groundwater occurs under unconfined and semi-confined conditions. To determine the effect of irrigation on groundwater chemistry, forty-five ground water sample from non-irrigated area and forty five samples from irrigated area have been collected during. May June 1998 from the existing dug wells of the study area. The major cations and antons have been determined from the samples. The statistical analysis of these data suggests that the irrigations does have an effect on groundwater chemistry. At the 99% confidence level, the concentrations of the chemical constituents are much higher in irrigated area that the non-irrigated area. These areas are identical except in their agricultural development. Though most of groundwater of samples come under good water class for irrigation but some of them are unsuitable for irrigation. The processes associated with surface water irrigation involved in modifying the concentration of chemical constituents in groundwater are evaporation and transpiration, mineral dissolution, dissolution of fertilizers, mixing with existing groundwater, CO_2 uptake and ion exchange. In addition, Calcite precipitation is likely to be a control on Ca and HCO_3 concentrations at several stages. Although the method has only examined one "Snap Slot˝ in time, the approach to data analysis adopted here is simply enough to be incorporated as routine following field collection of data but it is representative of a longer-term average.

HS02/08P/C24-006 — 1515

THE ORIGIN OF WATER SALINITY OF THE ANNABA COAST (N.E ALGERIA)

Larbi DJABRI, R. LAOUAR, A. HANI, J. MANIA, J. MUDRY (11, Rue Asla Hocine, Annaba 23000, Algérie)

Water of wells located at the Annaba city coast are characterised by high salinity. The origin of this may be attributed to several factors such as the geological features of the region, the climate and the salted bevel. A number of analyses have been carried out during October 1990, November 1998, December 1998, January 1999 and February 1999, in order to locate the origin of this high salinity. Principal component analysis show that the chloride-riche, Na-rich water is located nearly the sea. This indicate that seawater is the most likely contaminant of freshwater and that the sand can contribute highly to the observed high chloride contents. Our results also indicate that the salinity increases steadily when approaching the sea, and this indicates again the influence of marine water. Away from the coast, the observed Sr/Ca ratios ($<$ 1) is due to the absence of the evaporitic formation which outcrops further south of the region.

LOWER NIGER DREDGING AND CUMULATIVE ENVIRONMENTAL CHANGE

Shakirudeen Sule ODUNUGA, Tejuoso OLUFEMI, Fasona JOHNSON (University of Lagos)

The Niger-Benue waterway, with a cumulative water route distance of about 2,200km, provides a natural artery and has great potential for water transportation from the coastal area of Warri and port-Harcourt to the middle belt and from thence to the north-easter and north-wester frontiers of Nigeria. The long period of the neglect of the lower Niger has resulted in the blockage of the channel of the waterway. The blockage and seasonal fluctuation of the river has confined effective service of even small ferry to particular area and period of year. In view of theses, the present project of dredging was conceptualized to improve the navigability of the water route so as to promote both local and international economic integration. Statistical measure of moments, regression and trend analysis were adopted for the understanding of the water resources dynamic of the lower Niger, while uncertainly in the water resource, processes as a result of large scale deforestation due to dredging activities was reduced through the adoption of water balance approach for the local catchment of the three selected stations (Onitsha, Lokoja and Baro). Ranges of parameters from about 20% to 15% reductive in Evapo-Transpiration contribution to rainfall at onitsha to

about 15% to 10% reductive ot Baro were assumed. The response of the water resource to the expected change was estimated and the trend in water resources potential was properly determined. On the most critical issue of Least Available Depth (LAD´s) for large scale shipping the water level duration analysis was adopted. The expected depths for the lower Niger at the three selection station were calculated / forecasted spation-temporally and the freight movements for the forecasted water depth were suggested. The implication of the dredging on water demand, use and supply for the teaming population along the Niger valley was examined and suggestion were made for sustainable use.

IDENTIFYING HUMAN INDUCED PRESSURES AND THEIR IMPACT ON WATER RESOURCES - THE ASSESSMENT OF THE HYDROLOGICAL QUALITY IN RIVER BASINS

Michael EISELE, Andreas STEINBRICH, Christian LEIBUNDGUT (Institute of Hydrology, University of Freiburg)

To maintain or establish a sustainable use of water resources the identification of human induced pressures on the hydrological system has to be combined with an assessment of its vulnerability. For this purpose assessment procedures, which integrate all relevant hydrological criteria on the catchment scale, are needed. The assessment procedure Hydrological Quality is a combination of tools, by which identification and quantification of human impacts on quantity and quality of water resources within a catchment can be carried out. Pressures on the hydrological system are assessed using criteria which are derived from commonly available data sets. Quantitative pressures on water resources are identified using criteria of land use structure, water use, water abstraction and transfer, storage volume of dams and reservoirs and river morphology. Pressures on water quality are characterized using criteria for land use, agricultural intensity, population density, sewage system and urban runoff. The vulnerability of the hydrological system towards quantitative pressures is described using stream flow coefficients and a spatially differentiated estimation of groundwater recharge. Additionally human induced alterations of runoff dynamics are evaluated using statistical methods and taking into account climatic effects. To link pressures on water quality with the chemical situation in surface and groundwater a spatially differentiated water and nutrient balance is calculated. Calibration and validation of parameter values (e.g. for nutrient losses) and model results (e.g. total runoff and concentration levels) are achieved using stream flow data and measured concentrations from rivers and groundwater wells. The procedure is applied in a set of meso-scale river basins (15 to 3000 km³) in South-West Germany. To examine the human impact, different scenarios (potential natural status, land use change, urban development) are calculated and compared to the actual status. To estimate the potential range of error in the predictions an uncertainty analysis is carried out based on the sensitivity of calibrated parameter values. In the paper an overview on the methodology and the results of the procedure will be presented. With the application of the assessment procedure Hydrological Quality a reliable estimation of the human impact on water resources can be achieved. Individual pressures on different parts of the hydrological system can be identified and quantified. Subsequently this information can be used to define options for the improvement of water resources management in a river basin.

ESTIMATING LAND COVER CHANGES AND ASSOCIATED ENVIRONMENTAL IMPACTS ON WETLANDS, BY COUPLING REMOTE SENSING AND HYDROLOGIC MODELING

Ierotheos Z. ZACHARIAS, Elias DIMITRIOU, Theodoros KOUSSOURIS (NCMR)

Significant degradation occurred worldwide in ecologically significant wetland areas during the last century. Land use changes and associated hydrologic disturbances, mainly caused by human activities, is a common reason for this evolution. Thus, there is a need to identify and quantify potential impacts on wetlands from specific land use alterations in order to facilitate future environmental management and preservation activities. The particular scientific effort utilized remotely sensed data, GIS techniques and hydrologic modeling to estimate land use alterations during a 40-years period and simulate respective changes in hydrologic parameters such as overland and underground flow, infiltration, evapotranspiration and water storages on ground surface. Aerial photos of an intensely modified area from various human activities have been acquired concerning the years 1947 and 1986, elaborated with a GIS package and provided the land use maps for each period. These maps have been imported to MIKE SHE hydrologic model and two simulations have been developed (one for each period) by utilizing the same meteorological data so as to estimate and compare the differences in the aforementioned hydrologic parameters caused by the quantified land use changes. The results indicated significant variations in the hydrologic regime such as a considerable increase of agricultural land which caused a 6% increase in the annual evapotranspiration and a 10% increase in the water deficit of the soil profile. The urban development during the examined period, directed to an 11% increase in the annual overland flow and a 2% decrease in the underground flow towards wetland area. These indicative results together with the detailed modeling outputs illustrated substantial impacts on the regional hydrology and consequently on the wetland areas due to the observed land use changes.

HS02/08P/C24-010 — 1645

A COMPARATIVE STUDY ON FLOW GENERATION MODELS FOR WATER RESOURCE PLANNING

Seung Yup RIEU[1], Young-Oh KIM[1], Dong Ryul LEE[2] ([1]School of Civil, Urban & Geosystem Engineering, Seoul National University, [2]Water Resource & Environmental Division, Korea Institute of Construction Technology)

The long-term water resource planning in Korea has been updated typically every 10 year based on so-called 'the water balance analysis. Predicting the water supply and demand for the basin being considered in a target year, the analysis simply estimates the possible water deficits within the basin, using a simulation model such as MODSIM. The common water resource performance criteria such as reliability, resiliency, and vulnerability can be calculated as the model output to assess the water deficit severity. The previous studies showed that the performance criteria were very sensitive to the choice of the future water demand and supply scenarios, especially the future streamflow scenario. Two approaches have been commonly used for the streamflow scenario in Korea. The first approach selected the driest year among the available 30-year historical data and calculated the performance criteria using this single series. For most of the Korean river basins, the lowest flow occurred in 1968. The second approach used the entire 30-year record and searched the worst criteria. For both approaches, the calculated criteria were considered as the 30-year water deficit indices but their uncertainties have been recognized to be large because the 30-year record is not long enough to overcome the sampling variability. Therefore, it becomes necessary to generate a large number of synthetic flow data in order to obtain reliable values of the performance criteria though the water balance analysis. In this study, we compare a

parametric and a nonparametric flow generation models, which can effectively reproduce the long-term persistence of observed flows as well as other flow characteristics. As the parametric model, a FARIMA (Fractionally Differenced ARIMA) model is selected. Allowing the differencing order to be fractional, FARIMA has flexibility in the choice of short memory autocorrelation structures by varying autoregressive and moving average components. Therefore, FARIMA has been recognized as a powerful generation tool that can model both short and long memory in a time series. As the nonparametric model, on the other hand, a post-blackening hybrid model is selected. This model requires a minimum assumption of the stochastic process and generates flows using the residual resampling scheme with moving blocks bootstrap. Nonparametric approaches are known to capture the linear and nonlinear dependence of observed flows without any prior assumption. The proposed generation models are compared in terms of reproducing the Hurst coefficient of observed flows. The drought statistics and the water performance criteria are also calculated from the generated flow data and compared with those using a simple ARIMA model. Finally, a large number of the generated flow data allows us to present uncertainties in the performance criteria as an output of the water balance analysis for the long-term water resource planning.

RIVER FLOW PREDICTION: A HYBRID NEURAL NETWORK APPROACH

A.W. JAYAWARDENA, T.M.K.G. FERNANDO (Department of Civil Engineering, The University of Hong Kong)

Prediction of river flow is an important topic in management of water resources. The topic is however a difficult one because of the complexity of the physical processes involved in the generation of river flows. Recently, artificial neural network methods have emerged as an alternative modelling tool for river flow prediction with promising results. In this study, artificial neural network and multivariate statistical analysis techniques are incorporated to predict the daily river flow at the Kitamatsuno gauging station in the Fuji River in Japan. The original data set consists of daily discharges at the Kitamatsuno gauging station and rainfall and temperature data collected from 10 weather stations in and around the Fuji River basin. From the available weather data, rainfall from 4 stations and temperature from 2 stations together with the river flow were selected as input variables. The principal component analysis, a standard procedure used in multivariate statistical analysis to obtain the set of uncorrelated variables, each of which is a linear combination of the original variables was used to pre-process the input data. The rationale for using the uncorrelated inputs was to reduce input space while improving the convergence of the learning and generalisation capabilities of the trained network. The first 3 principal components represent about 93% of the data variance and there is an elbow occurs in the scree plot (plot of magnitude of an eigenvalue versus its number) at about 3. Therefore the first 3 principal component scores were selected as the orthogonalized input variables for multi-layer perceptron neural network with back propagation algorithm. The predictions were made with 1-day lead-time and the results were compared with the results obtained from the neural network with original input variables as inputs. The principal component scores and original inputs with time lags from 1 to 7 days were used as input variables to obtain the optimal number of lagged data to be considered. Four error indicators, the root mean square error, the mean absolute error, the correlation coefficient and the coefficient of efficiency are computed for each simulation to assess the performance of the models. These error measures lie within acceptable limits for both training and testing data for most of the models. The results are encouraging and suggest that the use of pre-processed data as input variables would enhance the generalisation capabilities of the trained network.

HS02/08P/C24-012   1715
LONG-TERM ESTIMATION OF EVAPOTRANSPIRATION FROM A TROPICAL RAIN FOREST IN PENINSULAR MALAYSIA

Makoto TANI[1], Abdul Rahim Nik[2], Yukio YASUDA[3], Shoji NOGUCHI[4], Siti Aisah SHAMSUDIN[2], Mohd Md SAHAT[2], Satoru TAKANASHI[1] ([1]Graduate School of Agriculture, Kyoto University, [2]Forest Research Institute Malaysia, [3]Forestry and Forest Products Research Institute, [4]Japan International Center for Agricultural Sciences)

Limited information is available on influences of climate change on evapotraspiration from tropical rain forest. In view of the increasing population in the region and a long-term effect of climate change on water supply, it warrants a rigorous scientific study on this aspect. An observation study for estimating long-term evapotranspiration from a tropical rain forest was conducted in Pasoh Forest Reserve, Peninsular Malaysia. The Penman-Monteith-Rutter model was applied to four-year meteorological records monitored at the top of a 52-m tower to estimate evapotranspiration in both dry and wet canopy conditions. Characteristics of aerodynamic and surface resistances necessary for the model application were evaluated from flux records measured in the daytime of rainless days by a closed-path eddy covariance system as well as by a pair of ventilated psychrometers for the Bowen ratio method. Water storage on the canopy was estimated from measurements of throughfall and stemflow to separately calculate evaporation from the wet canopy and transpiration from the dry canopy. The estimation showed that the annual average of total evapotranspiration, transpiration and evaporation from the wet canopy, for 1996 to 1999 were 1548 mm, 1218 mm and 331 mm, respectively, against the rainfall of 1571 mm and the net radiation of 1744 mm (water equivalent). The fact that the rainfall amount was very small compared with that of a normal year, about 1800 mm, was largely attributed to a clear and long dry condition responding to a strong El Nino in 1997 and 1998. Even under this dry climate in our observation years, the transpiration constantly represents a large portion of the net radiation on rainless days, suggesting that soil moisture deficit has little influence on transpiration. However, further continuous monitoring is necessary in order to examine a tendency of unlimited large evapotranspiration from the tropical rain forest in Pasoh would be maintained under the progressing climate change.

HS02/08P/C24-013   1730
EVAPORATION OF INTERCEPTED PRECIPITATION IN UNLOGGED AND LOGGED FOREST AREAS OF CENTRAL KALIMANTAN, INDONESIA

Chay ASDAK (Institute of Ecology, Padjadjaran University)

The effect of logging practices on rainfall interception loss were monitored for twelve months and related to vegetation and rainfall characteristics at the Wanariset Sangai on the upper reaches of the Mentaya river, Central Kalimantan. The traditional volume balance method was used to measure throughfall, stemflow and interception loss. The results show that evaporation of intercepted rainfall is higher in the unlogged forest (11% of total gross rainfall) than in the logged forest (6%). These results were closely associated with the reduction in number of trees per hectare from 581 in the unlogged plot to 278 (52%) in the logged plot or a reduction in terms of basal area from 38.6 to 13.8 m^2 ha^1 (65%). The evaporation rate during and after rainfall has ceased in canopy-saturated conditions was calculated by an energy balance method, which relied on the modified Penman equation using directly determined microclimatic and canopy structure variables as inputs. The results obtained showed that the evaporation from wet canopies in this research area is driven more by

advected energy than by radiative energy. In the unlogged plot, advective energy accounted for 0.38 mm h^{-1} of the 0.50 mm h^{-1} of evaporation, whereas radiative energy accounted for only 0.13 mm h^{-1}. A similar relationship between the major driving variables and the rate of evaporation was also found in the logged plot and this implies that logging activities did not change the proportion of energy used for interception loss.

HS02/09A/C24-001   0900
ESTIMATION OF A SNOW DISTRIBUTION IN SUBALPINE REGION: USING A DISTRIBUTED SNOWMELT MODEL

Kentaro MATSUI[1], Takeshi OHTA[1] ([1]Graduate School of Bioagricultural Sciences, Nagoya University, [2]Faculty of Agriculture, Iwate University)

Estimating the snow distribution in subalpine region is important to for waterresources management. Recently, many methods using remote sensing technology,such as an interpretation of aerial photographs or satellite images, areproposed to observe a snow distribution. These methods are effective in theplace where vegetation density is low. However, when such a technique is usedfor dense forest, it is difficult to know the snow distribution on the groundbelow the forest canopy and to grasp the temporal change of the snow properties.In order to avoid these problems, we used the heat-balance method for simulatingsnow accumulation and melt. Considering the balance of snow accumulation came ofprecipitations and snowmelt runoff gained with the use of the heat balancemethod, estimation of the snow water equivalent and judgments about theexistence of the snow coverage are attained in arbitrary points. In this study,we used mainly the distributed snowmelt model designed by Ohta (1994). This one-dimensional model considers the snowpack as a single bulk layer. The influence of the forest canopies for snow accumulation and melt processes is given through means of making each meteorological element into the function of the rate of vegetation covering. Consequently, we can use a single procedure both open and forest site. For derivation of vegetation coverage, we used the aerial photographs taken during the analysis period. Our study site is Akagawa catchment located in Hachimantai semi-national park, northern Japan. The area of the catchment is 16.7 ha and the elevation ranges from 480 to 1578 m a.s.l. The catchment is covered by evergreen conifers in upper region than about 1100 m a.s.l. or more, and by deciduous trees in lower than it. While the maximum snow water equivalent in the catchment exceeds 1000 mm annually, in the end of May the snow coverage is mostly wiped out all over the districts owing to the intensive snowmelt beginning at the middle of April. In the two winter seasons of 1998-1999 and 1999-2000, we had the intensive observation period to measure the meteorological element and snow depth and density. Therefore, we have simulated the snow distribution for these two seasons. A comparison between the observed and estimated snow distribution gave the following results: in the early days of snowmelt seasons, beginning of May, thismodel has relatively a good performance. But the model performance had gone down as snowmelt was progressed. Especially, it was found that the calculated snow area in open and high site was smaller than observed. As one of the cause of this, it is considered that the wind speed in open and high sites was higher than in forest or low sites. Since the snow is carry away due to the higher wind speed, snow water equivalent may decrease there.

HS02/09A/C24-002   0915
THE INFLUENCE OF SNOW DEPTH ON THE VARIATION OF VEGETATION ACTIVITY AND EVAPOTRANSPIRATION

Yoshihiro ASAOKA, So KAZAMA, Masaki SAWAMOTO (Department of Civil Engineering, Tohoku University)

The influences of snow depth on vegetation activity and evapotranspiration in the Tohoku district, which is about 780,000 square kilometers and is famous for heavy snow, were discussed. Firstly, some datasets consisting of snow depth distribution, NDVI (Normalized Differences Vegetation Index) distribution, Warm Index distribution and Evapotranspiration distribution are composited in little snow season, normal snow season and heavy snow season. Snow depth distribution is estimated based on snow depth dependency of elevation distribution of snow depth by using NOAA/AVHRR, GIS, and observation data. It is known that NDVI indicates vegetation activity and Warm Index have good correlation with the distribution of potential vegetation. Evapotranspiration is estimated by using NDVI. Secondly, The relationships among snow depth, NDVI, and WI are individually investigated in the forest area by using these datasets. Thirdly, evapotranspiration in summer was evaluated by each snow amount condition in winter. As the results, vegetation activities in summer are related to snowdepth and the period of snow cover. Especially, adequate snow depth in winter effects growth of vegetation in summer. Moreover, overabundant snow depth constricts growth of vegetation. Therefore, heavy snow season constricts vegetation growth in wide area. It is shown that snow quantities in winter have influence to vegetation activities and evapotranspiration. These results are useful for water resources planning considering climate change.

HS02/09A/C24-003   0930
EFFECT OF SNOW INTERCEPTION ON THE ENERGY BALANCE ABOVE DECIDUOUS AND CONIFEROUS FORESTS DURING A SNOWY WINTER

Kazuyoshi SUZUKI[1], Yuichiro NAKAI[2], Takeshi OHTA[3], Tsutomu NAKAMURA[4], Tetsuo OHATA[5] ([1]Frontier Observational Research System for Global Change, [2]Hokkaido Center, Forestry and Forest Products Research Institute, [3]Nagoya University/ Frontier Observational Research System for Global Change, [4]Iwate University, [5]Institute for Low Temperature Sciences, Hokkaido University/ Frontier Observational Research System)

In northern Japan, mountain watersheds are covered mostly by forests with a seasonal snowpack. During thaw periods, melt water is an important water resource, and it is necessary to estimate the net snow water equivalent under the forest canopy in mountain regions. Some of the snowfall is intercepted by the forest canopy and evaporates or melts. The amount of snow intercepted by the canopy depends on the tree species and affects the

water and energy balances in mountain watersheds. However, the dependency of snow interception on tree species and the differences in the influence of snow interception on the energy and water balances are not well understood. In this paper, we discuss how intercepted snow above deciduous and coniferous forests affects water and energy balances.Intensive micrometeorological observations above and below the canopy were carried out in a deciduous (DF) and coniferous (CF) forest in mid-winter 1996-97 near Sapporo, on Hokkaido Island, Japan. The energy balances were analyzed based on the observations. The DF was composed mainly of ash and oak trees, and had a plant area index (PAI) of 0.9. The CF consisted of Yezo spruce, Akaezo spruce, and Todo fir, and the PAI was 5. The sensible heat fluxes above both the DF and CF were measured using the eddy correlation method, while the latent heat flux was evaluated using the band-pass eddy covariance method in the CF and the energy balance method in the DF.Since the amount of intercepted snow was large in the CF, but insignificantly small in the DF, the latent heat flux above the CF was larger than that above the DF, especially just after a snowfall. This demonstrated that variation in the amount of snow on a canopy due to differences in forest conditions affects the water and energy balances above the canopy. Furthermore, intercepted snow above the CF increased albedo, while the net all-wave radiation above the DF was larger than that above the CF. The effect of intercepted snow on the canopies caused more of the net all-wave radiation above the CF to be partitioned into the latent heat flux than into the sensible heat flux. Conversely, the net all-wave radiation at the DF was partitioned mostly into the sensible heat flux and snowmelt energy. This might cause differences in the location of energy exchange in CF and DF.

SOME PROBLEMS IN REGIONALIZATION OF INDIANA WATERSHEDS

A. Ramachandra RAO[1], A. Ramachandra RAO[1] ([1]School of Civil Engineering, Purdue University, [2]Department of Civil Engineering, Indian Institute of Science, Bangalore - 560012, INDIA)

Because of the paucity of flood data, it is not always possible to use traditional methods of frequency analysis to arrive at estimates of flood values corresponding to specified recurrence intervals. Engineers use methods that are based on data from nearby stations. As watersheds in a region may have different responses to rainfall, hydrologists have sought to identify groups of watersheds that have similarity in flood producing mechanisms. The group of watersheds with similar hydrologic response constitutes a hydrologically homogeneous region. The procedure of identifying such regions is traditionally referred to as Regionalization. The basic objective of this paper is to address some problems concerning the use of cluster analysis methods for regionalization of watersheds. As no single procedure has been demonstrated to yield universally acceptable results, several methods of regionalization are in use. No information is available about the performance of these methods. In particular, problems which arose in the use of the Hybrid Cluster Analysis are discussed in this paper. Three hybrid-cluster algorithms, which are a blend of agglomerative hierarchical and partitional clustering procedures, were tested in this study to determine their potential in delineating watersheds in Indiana, U.S.A., into regions that are homogeneous in hydrologic response. The hierarchical clustering algorithms considered for hybridization were Single linkage, Complete linkage and Ward´s algorithms, while the partitional clustering algorithm used is the hard K-means algorithm. The details concerning the data used for the study region are provided. The results from the hybrid cluster analysis models are reported and the problems encountered in deriving the final regions from the clusters are discussed. The results of the study are discussed and a set of conclusions is presented.

HS02/09A/C24-005   1000

AN APPROACH TO CREATING LUMPED-PARAMETER RAINFALL-RUNOFF MODELS FOR CATCHMENTS EXPERIENCING ENVIRONMENTAL CHANGE

William Earl BARDSLEY[1], Suxia LIU[2] ([1]Earth Sciences. University of Waikato, [2]Chinese Academy of Sciences.)

Many stream and river catchments are presently experiencing progressive hydrological change as a consequence of land use modification. The single-calibration approach to rainfall-runoff models is not appropriate in such circumstances because, in reality, the model parameter values will themselves be undergoing change through time. Such parameter trends can be incorporated readily in empirical statistical catchment models, but progressive recalibration of nonlinear lumped rainfall-runoff catchment models can be cumbersome because nonlinear model calibration remains something of an art. While still maintaining a link to physical hydrological processes, we present an approach to straightforward progressive model recalibration by way of a lumped-parameter finite-mixture distributional model for simulating hydrograph generation from rainfall events. The model contains just two nonlinear parameters and a large number of linear parameters. A single manual calibration is carried out to fix the values of the nonlinear parameters, with the linear parameters thereafter being progressively re-estimated over time by a standard automated procedure. This allows reliable convergence during recalibrations which implicitly incorporate the effects of catchment environmental changes via the linear parameter adjustments. The model might be applied, for example, as a flood warning technique for catchments with progressive land use change. Application of the model is illustrated with examples from river catchments in New Zealand and China which have experienced time-varying hydrological responses.

HS02/09A/C24-006   1045

THE IMPACT OF CLIMATE VARIABILITY ON FLOOD RISK

Anthony S. KIEM, Stewart W. FRANKS (Department of Civil, Surveying and Environmental Engineering, University of Newcastle)

Recent research has highlighted the persistence of multi-decadal epochsof enhanced/reduced flood risk across New South Wales, Australia. Recentclimatological studies have also revealed multi-decadal variability inthe modulation of the magnitude of El Nino/Southern Oscillation (ENSO)impacts. In this paper, the variability of flood risk across NSW isanalysed with respect to the observed modulation of ENSO eventmagnitude. This is achieved through the use of a simple index ofregional flood risk. The results indicate that cold ENSO events (LaNina) are the dominant drivers of elevated flood risk. An analysis ofmulti-decadal modulation of flood risk is achieved using theinter-decadal Pacific Oscillation (IPO) index. The analysis reveals thatIPO modulation of ENSO events leads to multi-decadal epochs of elevatedflood risk, however this modulation appears to affect not only themagnitude of individual ENSO events, but also the frequency of theiroccurrence. This dual modulation of ENSO processes has the effect ofreducing and elevating flood risk on multi-decadal timescales. Theseresults have marked implications for achieving robust flood frequencyanalysis as well as providing a strong example of the role of naturalclimate variability.

COULD THE GLOBAL WARMING CAUSE THE LAST FLOODS OF TISZA RIVER?

Istvan KONTUR[1], Andras BARDOSSY[2], Balazs CZENTYE[1] ([1]Technical University of Budapest, [2]University of Stuttgart)

The last 4 years on the Hungarian part of the Tisza river there experiencedthe highest ever flood peaks of the more then 100 years of observations series. The purpose of this paper is to analyze the possible causes of these floods and establish methodologies for the assessment of design floods. The water system of Tisza has two main typical properties: its system is forked and has several subsidiary streams and the other is when the river gets on plain area the slopes of the riverbed reduces to a few centimeters on each kilometer. The watercourses forming a fan leant against the east-north-eastern crags of Carpathians collect precipitations water of fronts coming from south and west. A large amount of extreme situations is conceivable because each cyclone effects each part of catchments differently. The first task is to identify the common meteorological features occurring prior to floods. Large-scale atmospheric circulation patterns and specific humidity are considered for this purpose. The time series of these variables shows non-stationary behavior. On the other hand the Tisza river basin experienced major changes due to anthropogenic influences during the last 150 years. Substantial changes in the river course affected the flow times and the interactions of the flood waves coming from different subcatchments. Land use changes have also affected the flood production. The effects of these changes are quantified using simplified models. The time series of circulation patterns is investigated for the frequencies of the patterns and their durations. Further the Markov transition matrices are investigated to see if changes in typical circulation pattern sequences occurred. The relationship of the circulation patterns and discharge changes helps to identify the amount to which climate change or climate fluctuations are responsible for the unusual behavior of the Tisza river.

HS02/09A/C24-008   1115

EXTREME PRECIPITATION AND FLOODS IN THE CHANGING WORLD

Zbigniew W. KUNDZEWICZ (Research Centre of Agricultural and Forest Environment, Polish Academy of Sciences, Poznan, Poland)

In recent decades, flood losses have shown a rapid rising tendency worldwide, which can be linked to socio-economic and climatic factors. Increase in the flood risk is also foreseen in the future. In the present contribution, existing information on changes in extreme precipitation and river flow has been reviewed, in the context of the past-to-present records and future scenarios.Several non-climatic factors exacerbate flood hazard, such as the land-use changes: deforestation and urbanization; and river regulation, which reduce the available water storage capacity. Demographic pressure causes encroachment of informal settlements into hazardous locations in floodplains, e.g., around mega-cities in developing countries. Over-reliance on the safety provided by flood control works enhances accumulation of wealth in endangered areas. However, when a levee breaks, flood losses are higher than they would have been in a levee-free case. Climate impacts contribute considerably to the increase of flood exposure. As the atmosphere's water holding capacity grows with temperature, the possibility of intensive precipitation also increases. Higher and more intense precipitation has been already observed in many areas of the globe and this trend is expected to be even more pronounced in a future, warmer world. In a number of studies, floods have been found to become more frequent and intense, and continuation of this tendency is foreseen for the future. Yet, it would be a gross oversimplification to state that floods have uniformly exhibited growing trends everywhere. Results of some well documented studies demonstrate reduction of flood flows in several locations, or else reduction in some amplitude categories, leading to the conclusion ˝generally wetter but less extreme˝.Adverse effects on floods have already been observed due to changing climatic variability, and they are also projected to amplify. The frequency and intensity of El Niño-Southern Oscillation (ENSO) have been unusual over the last decades. Warm phase of ENSO, i. e. El Niño, during which precipitation and floods in several locations occur more frequently, has become more frequent, persistent and intense. In general, changes in flood frequency are complex, depending on the generating mechanism, e.g., rainfall vs snowmelt. It is a robust finding that seasonality of floods has changed in the warmer world. Increase in floods in mid and high latitude winters (due to more frequent, and more intense, wet spells; with rain rather than snow), earlier high spring flows e.g., in Europe, and decreasing ice-jam-related floods have been observed. Despite the considerable investments into flood protection, in many countries there is a rising vulnerability to floods, as the increase of exposure to floods is faster than the growth of the adaptive capacity.

TESTING TRENDS IN ANNUAL PEAK DISCHARGE SERIES IN ISRAEL

Arie BEN-ZVI[1], Benjamin AZMON[2] ([1]Israel Hydrological Service, [2]Israel Hydrological Service, Haifa, ISRAEL)

It is commonly presumed that development enhances flood discharges. Therefore, use of statistical properties of past records, for flood predictions in areas under development, might underrate the predicted values. This may be particularly important for arid and semiarid regions, where the discharges are sensitive to land use changes. However, temporal variations in the statistical properties of high discharges are little dealt with in the scientific literature. In this respect, Israel, which is located in such a region and underwent a widespread development during the recent decades, can provide a suitable case study. Results of this study are presented here.The study encompasses annual peak discharges at 64 hydrometric stations whose period of available records is between 24 and 57 years, and on average it is 47 years. Effects of abrupt major changes in watersheds of a number of stations, such as construction of dams and transferring lake and swamp areas into an arable land, were excluded from the study by ignoring the records prior to the appropriate change.Values of the coefficient of variation, for annual peak discharge series in Israel, are about a unity. Such high values hinder distinction between random and systematic changes in magnitudes of peak discharges. To gain reliable conclusions, the data underwent a variety of parametric and non-parametric tests. These include trend analysis with respect to time and comparisons between statistical values computed for the first and the second half of the period of observation at each station.No general trend is found for annual peak discharges in most areas of Israel, although a few local trends are observed. An exception appears for the Upper Jordan Watershed, where an overall decline is found. This trend is statistically significant for a number of stations located in that watershed. The decline is conceptually attributed to changes in the meteorological causes of high discharges and to the intensified water use within the State of Lebanon, where major tributaries of the Jordan River are originated. Another general result is the lack of relatively high discharges from 1970 to about 1985, vs. the very frequent occurrences of floods during the 1990s. Consequently, the variability of annual maximum discharges during the 1970s-1990s is substantially larger than during the 1940s-1960s. This effect is assumed resulting from fluctuations in meteorological conditions that generate high discharges. Another effect, attributed to a shift in cloud tracks, is the appearance of opposite trends in two neighboring stations.

HS02/09A/C24-011   1145

REGIONAL FLOOD RISK - WHAT ARE THE DRIVING PROCESSES?

Ralf MERZ (Institute of Hydraulics and Hydrology, TU Vienna)

The assessment of flood risk under changed conditions, such as changed land-use, climate, and hydropower operation, is difficult as traditional flood frequency analysis relies heavily on black-box statistical methods that use observed historic flood peak data alone. Under changed environmental conditions it is likely that these simple methods will fail to provide realistic estimates. An alternative is to use a process based approach. The main advantage of a process based approach is that it allows to factor in the various controls on flood risk and to examine changed controls explicitly. However, at the regional scale the identification of flood processes is hampered by data limitations. Also, in the same catchment extreme floods can result from different processes. We propose an event based flood process classification method that combines a number of data sources to address the data problem. Maximum annual flood data are combined with event based information on the atmospheric forcing and the catchment state. The latter is estimated by running a soil moisture accounting scheme for all the catchments over the entire study period. The procedure allows us to identify five catchment-scale flood driving processes. These are: synoptic rainfall, short duration rainfall, flash floods, rain-on-snow, radiation melt. The identification procedure is manual based on expert judgment. For each event, the expert decides the process type, based on an examination of synoptic maps of the state variables and the atmospheric forcing, and a set of rules. For example, the rule for radiation melt is of the form ˝snow water equivalent > 10 mm and snow melt > 3 mm/day and rainfall < 1 mm/day˝. We applied the new method to 500 catchments in Austria. The catchments exhibit very diverse climate and land-use characteristics, from low-land to alpine characteristics. The data set consisted of up to 30 years of data which led to a classification of a total of 10 242 flood events. The method classified 43, 27, 4, 21, 3% of the events into synoptic rainfall, short duration rainfall, flash floods, rain-on-snow, and radiation melt, respectively. We analysed the severity of the floods belonging to each process type with respect to flood seasonality, event characteristics (e.g. precipitation depth, runoff coefficient) and catchment characteristics (e.g. land-use, scale). This analysis provided useful information on the regional behaviour of floods of different magnitudes. The process classification can also be used in a more quantitative way by constructing compound flood frequency curves. The results indicate that the compound curves that use information on both the flood peaks and the process types extrapolate more accurately to large return periods than curves that use only information on the flood peaks. Ongoing work examines the potential of an automated method of process classification based on fuzzy rules. Preliminary analyses suggest that the automated method can mimic the manual process classification well. It is suggested that the automated method is also applicable to flood regimes in other regions.

HS02/09A/C24-012   1200

MAXIMUM PRECIPITATION VALUES?

Gerd TETZLAFF, Michael BOERNGEN, Manfred MUDELSEE, Armin RAABE (Institut of Meteorology, University of Leipzig)

Recent flood events in Germany initiated an debate on the causalities. In many opinions the climatic change effects were held responsible for the clustering of catastrophes as recorded in the media. Looking at central European historic flood events exhibited that major floodings are not restricted to recent periods. However, there is very little material available on the frequency and its changes through times, including even the actual times. Indirectly, it was often postulated to suppress flood totally. This however means to estimate a maximum catchment areal precipitation. There are published methods to achieve such an estimation. For the river Main these results were compared against the major flood event of 1342, the highest flood recorded in central Europe since the medevial ages. From the river levels the precipitation was estimated in several steps, applying a precipitation model as well. Finally, the average precipitation for the catchment ares of more than 20000km2 amounted to about 200 mm. This value is somewhat larger than the ones found in the recent river Elbe floodings.

HS02/09A/C24-013   1215

THE SCENARIOS OF CHANGE OF REPEATABILITY OF THE CATASTROPHIC PHENOMENA IN UKRAINE UNDER INFLUENCE OF GLOBAL WARMING (ON THE BASIS OF HISTORICAL RECORDS AND ANNALS)

Svetlana G. BOYCHENKO (Department of meteorology and climatology, Kyiv Taras Shevshenko University)

The main aim of this research is to obtain quantitative estimations of the basic tendencies of change of repeatability of the catastrophic phenomena in Ukraine as a result of global warming and to work out scenarios of possible increase or decrease of their repeatability in first half of 21-th century on their basis.In this research were considered data, which obtained on the basis of the analysis of various historical records and annals (manuscripts). These records were very carefully conducted and described in monasteries, which were placed, in particular, on all territory of Russian plain. The following phenomena were considered: droughts, rainy summers, floods and high waters, cold winters, late springs, colds at the beginning of a summer, catastrophic thunderstorms, catastrophic storms etc. Therefore we use the names of these events, which have accepted in historical records and annals (manuscripts). But most sharply expressed events both on space scales and ecological and social consequences were selected. For reduction of the mistake caused mainly with the psychological factor at records and statistical sample of the data methods of a respective centering and normalization of empirical time series of repeatability of the climatic catastrophic phenomena were used.The statistical analysis of these data shows that the long-term dynamics of repeatability of the climatic catastrophic phenomena in the territory of Ukraine was not an ordinary stationary Poissons's flux of events. For example, grouping of events is precisely traced for some periods. It means that there is a factor, which essentially influences repeatability of the considered events. The hypothesis was proved that the fluctuations of temperature of Europe possibly could be such factor. These fluctuations are closely connected to fluctuations of the global thermal regime of our planet. Therefore this hypothesis means that a global warming or a global cooling can essentially influence the repeatability of climatic catastrophic phenomena on the territory of Ukraine. It is found that the repeatability of the considered events is a non-monotonic function of temperature fluctuations, namely: repeatability (frequencies) of catastrophic climatic phenomena in the territory of Ukraine was higher, when the global temperature was deviating in either direction from some optimum level (at global warming or cooling from some optimum level of global temperature).In this research are constructed semi-empirical model for rating of intensity of climatic catastrophic phenomena in Ukraine as function of index of climatic anomality.This semi-empirical model can be used as a scenario of possible dynamics of repeatability of climatic catastrophic phenomena in the territory of Ukraine at the further global warming.Unfortunately there is no certainty that global warming caused by various physical mechanisms will lead to analogous environmental consequences (it is possibly that the present global warming is caused by anthropogenic amplification of the global greenhouse effect).

HS02/09P/C24-001   1400

DATA ASSIMILATION IN THE MIKE 11 FLOOD FORECASTING SYSTEM USING KALMAN FILTERING

Dan ROSBJERG[1], Jesper DAMGAARD[1], Frands Søbjerg HANSE[1], Henrik MADSEN[2] ([1]Environment & Resources DTU, Technical University of Denmark, [2]DHI Water & Environment, Agern)

In recent years major floodings have occurred in a number of countries world-wide, e.g. Poland, Czech Republic, Germany, UK, China, Bangladesh and Mozambique. To reduce the loss of life and the damage to property hydrological models to forecast flow and water level in the river systems are often implemented. Usually measurements of water level or flow are available at different locations throughout the river system. By using these measurements it is possible to update the model results and obtain a better estimate for the initial conditions in the river system at the time of forecast. The updating procedure in the 1-D hydrological model MIKE 11, developed by DHI Water & Environment, was examined. The existing iterative flood forecasting updating procedure (FF) was compared with a newly developed ensemble Kalman filter updating procedure (KF). Unlike the FF the KF pays respect to the uncertainty associated with the model results and the data used for updating. The user provides MIKE 11 with estimates of model and measurement uncertainty and KF weights the information to obtain an optimal result in the least square sense. Using data from the extreme flooding event in 1999 in the Sesia catchment in the Piedmonte region in the north-western part of Italy, FF and KF were compared with respect to their ability to assimilate and forecast water levels. It was verified that both methods produced similar results at and downstream of the measurement stations, but that the KF was also capable of correcting the flow upstream the measurement stations. In most cases the model results were improved upon using KF, but at the expense of significantly higher computational costs. The model uncertainty in the KF was placed on the catchment runoff determined from the deterministic, lumped, conceptual rainfall runoff model NAM. To get realistic estimates of the model uncertainty, studies of the catchment runoff from the NAM model as a function of the uncertainties in input data (precipitation and temperature) and model parameters were conducted using Monte Carlo simulations. Due to the highly heterogeneous geology and varying topography in the model area the study was conducted on both a low land and a mountainous sub-catchment within the Sesia catchment. It was found that the coefficient of variation of the uncertainty on runoff from a mountainous catchment was 25-35 % whereas the value was somewhat lower, 15-25 %, in a low land catchment due to the higher response time. Using these values in MIKE 11 reasonable uncertainty estimates of the predicted water levels in the river system were obtained.

HS02/09P/C24-002   1415

A CONSENSUS REAL-TIME RIVER FLOW FORECASTING MODEL FOR THE BLUE NILE RIVER

Asaad Y. SHAMSELDIN[1], Kieran M. O'CONNOR[2] ([1]Department of Civil Engineering, University of Birmingham,, [2]Department of Engineering Hydrology, National University of Ireland, Galway, Galway)

The Blue Nile, one of the main tributaries of the River Nile, which is the longest river in the world, is a trans-boundary river. Originating in Lake Tana in the Ethiopian plateau, which is located in East Africa, it has a basin area of 324,530 km2. Contributing about 59 % of the annual flow of the River Nile, it is regarded as the main source of floods on that river. Such floods cause loss of life and massive scale damage to the agricultural sector and to property near the river. In the present paper, a consensus real-time river flow forecasting model for the Blue Nile River is presented. The essence of the consensus model concept is that the synchronous outputs (i.e. discharge forecasts) of a number of structurally different river flow forecasting models are combined to provide an overall ´consensus´ discharge forecast that would be more accurate and reliable than that of the best of the individual models contributing to the combination. The consensus model developed in the present paper uses the river flow forecasts of two individual real-time multiple-input single-output river flow routing models, the first of which is based on the structure of the linear transfer function model, the second having the structure of the multi-layer feed-forward neural network. Each of these two individual models uses the upstream inflows on the Blue Nile and the outflows of its major tributaries as inputs and has an in-built forecast updating procedure. The final outputs required are the real-time river flow forecasts on the Blue Nile upstream Khartoum, the capital city of Sudan. Both the weighted average method and the neural network method are used to combine the forecasts of these two models in order to produce the consensus real-time river flow forecasts. Nineteen years of daily flow data are considered in the study; the first thirteen years being selected for model calibration/training, while the remaining six years are used for model verification. The results indicate that the consensus model can successfully be employed for real-time river flow forecasting on the Blue Nile River, at Khartoum. The results also confirm that the forecasts of the consensus model are indeed better than those of the best individual model used in producing the consensus forecasts, thereby vindicating the consensus concept. Thus, the consensus model can be used as an effective tool for flood forecasting and hence as a component of a decision support system for the mitigation of the hazardous impacts of the floods of the River Nile.

PLICATION OF DYNAMIC-STOCHASTIC MODEL OF RUNOFF GENERATION FOR ESTIMATING OF EXTREME FLOOD RISK IN A BASIN WITH LAND-USE CHANGE

Lev S. KUCHMENT, A.N. GELFAN, V.N. DEMIDOV (Water Problems Institute of Russian Academy of Sciences)

A coupling of a physically based model of runoff generation with the Monte-Carlo simulation of the model inputs is applied to obtain flood series and estimate flood characteristics frequencies for a river basin with changing land -use. The model of runoff generation is based on the finite-element schematization of river basin and includes the description of the following hydrological processes: snow cover formation and snowmelt, freezing and thawing of soil, vertical soil moisture transfer and evaporation, overland and channel flow. The Monte-Carlo simulation of snowmelt runoff is based on stochastic models of daily precipitation series, daily air temperature and daily air humidity deficit (for continuous modeling during autumn-winter-spring seasons) or statistical distributions of snow water equivalent, depth of frozen soil, and soil moisture content before snowmelt (for modeling during only snowmelt flood events). The daily precipitation consists of a model of daily precipitation occurrence (a first-order Markov chain is applied) and gamma distributions of daily precipitation amounts. Because of the strong autocorrelation in the air daily temperature series, for modeling the daily temperature the fragment method was applied. The histogram of daily air humidity deficit values was fitted by lognormal distribution. The distributions of snow water equivalent, depth of frozen soil, and soil moisture content before snowmelt were constructed on basis of calculations which were carried out with help of the

physically based model of snowmelt runoff generation. To simulate the rainfall runoff, the statistical distributions of precipitation amounts, precipitation durations, durations of dry periods, and mean air humidity deficit for dry periods were used. The case-study carried out for the Seim River basin situated in the south-western part of Russia (the catchment area is 7460 km2). The 20-years hydrometeorological measurement series have been used for calibration and verification of the dynamic part of the model (5 parameters have been calibrated); the 34-years series have been used for construction of the stochastic part. The calculated exceedance probabilities of the peak discharge were compared with ones calculated using 61-years runoff data. The good correspondence of the measured and calculated values have been obtained. The developed dynamic-stochastic model was applied for estimation of changing exceedance probabilities of runoff characteristics at three scenarios of land use in the Seim river basin (for the beginning of the twentieth century, for the present time, for future). Problems of uncertainty in estimating of extreme snowmelt flood characteristics have been investigated for continuous modeling of flood series and for event flood approach.

HS02/09P/C24-004   1445

DECISION SUPPORT SYSTEM FOR FLOOD CONTROL AND ECOSYSTEM UPGRADING IN RED RIVER BASIN

Martijn J. BOOIJ, C.B. VREUGDENHIL (Department of Civil Engineering, University of Twente)

Flood disasters cause massive losses of human lives and immense damage to the infrastructure and economic activities in the Red River basin in Vietnam and China. These disasters result not only from the climatological circumstances, but are also caused by human development. The ecosystem has been seriously disrupted by the rapid population growth and by the uncontrolled development of industrial and urban centres. This has led to deforestation and changes in the ecosystem, which in turn increased the flooding risk. The severity of the floods can be mitigated by adopting suitable measures for flood control and for preservation and sustainable upgrading of ecosystems. These measures should take into account the social, economical and ecological consequences. Short term measures include flood diversion, rescue actions and prevention of unexpected dyke break and inundation in important urban and industrial zones. Here, the emphasis is on the long term, with measures such as reforestation, the construction of reservoirs in upstream areas and a controlled development of urban and industrial centres. The objective is to develop and apply a system to support decisions concerning the selection of a suitable combination of measures, considering all important consequences. This objective is achieved by carefully selecting the most appropriate model environment for the decision support system (DSS). Next, the hydrological, hydraulic and socio-economic models were constructed in a consistent way taking into account the characteristics of the measures, spatial and temporal scales, future scenarios and the project objectives. The thus obtained DSS and its components were tested for a number of scenarios and time periods. Meteorological, hydrological, hydraulic and socio-economic data from several sources in Vietnam and China were used for this purpose. The main advantages of the chosen model environment are the spatial-temporal character, the built-in capabilities, the flexibility and the possibility to construct user interfaces appropriate for the model user. The DSS has a variable spatial resolution with a more coarse scale in the upstream part of the basin and a finer scale downstream, to account for example for the large spatial variability in flood damage in the river delta. The hydrological model is based on the concepts of the HBV model, while the hydraulic inundation model is a statistical parameterisation taking into account the elevation pattern, land use, dike location and water level. The socio-economic model is a conceptualisation of the socio-economic flows, allowing for migration between the economic sectors based on net revenues and land use. The appropriate measures are selected and optimised by evaluating their effects in the DSS and applying a simple linear programming model. Preliminary results suggest that a combination of measures in the upstream part together with dike heightening will be most preferable. However, large uncertainties complicate the distinction to be made between different measures.

HS02/09P/C24-005   1500

FLOOD CONTROL - ENVIRONMENTAL AND SOCIO-ECONOMIC ISSUES: A CASE STUDY IN THE DAY RIVER REGION IN VIET NAM

Dao Thi Anh PHAN[1], Kaoru TAKARA[2] ([1]Institute of Meteorology and Hydrology, Hydro-Meteorological Service, Viet Nam, [2]Disaster Prevention Research Institute, Kyoto University, Japan)

Viet Nam has large systems of rivers and is one of the most disaster-prone countries in the world including river flooding. Viet Nam has appropriate policies, strategy and action to control floods and mitigate its damage and help people to recover after floods. Viet Nam also builds hydraulic works to prevent important zones of Viet Nam from floods. It leads to impact on changes of hydrological regime and water resources in some areas. Many researches on flood control have been done in Viet Nam. However, it is important to recognize that flood control has not been attached to the environmental and socio-economic issues in areas suffering from flood yet. This paper explores the environmental and socio-economic issues in areas suffered by floods including policy/strategy analysis related to flood control. Questions focused are: How floods affect the living, socio-economic development and environment? And how societies respond and adapt to the above problems? Based on these points, a case study in the Day River region, which belongs to the Red River Delta of Viet Nam will be discussed. The Day River region has an important position for socio-economic development in the Red River Delta. The area borders the capital city of Hanoi and many important cities, towns and economic, politic centers of the country. Therefore, a project on flood diversion in the Day River region was approved by the Viet Nam Government in 1999. The findings would provide comprehensive understanding about the environment and socio-economic condition based upon an integrated approach for the decision-makers and managers in planning/management and reasonable use of water resources and in the flood control in this region.

HS02/09P/C24-006   1515

RISK ASSESSMENT FOR DIVERSION OPEN CHANNEL CLOSURE OF THE THREE GORGES PROJECT IN THE YANGTZE RIVER

Caijun WANG[1], Shenglian GUO[1], Xiangrong TIAN[1], Yonghua ZHU[2] ([1]College of Water Resources and Hydropower Engineering,WUHAN University, [2]College of Mathematics and Statistics, Wuhan University, Wuhan 430072 CHINA)

Three Gorges Project (TGP) located on the Yangtze River is the largest hydraulic project in the world. TGP commenced construction in 1994 and the diversion open channel will be closed in November 2002. The final closure will begin when the gap through which the river flows has been reduced along the axis of the fill to 120m by simultaneously dumping rock-fill from both banks. This paper mainly focuses on the assessment of the hydrologic and construction risks of the diversion open channel final closure. On the basis of daily flow data of Yichang hydrological station during 1877~2000 with 124 years of records and the different sampling methods, the Pearson type-III distribution, flow duration curve and Poisson procedure are proposed and applied to determine design flow discharge and assess the

hydrologic risks. The design flow discharges with 10300m³/s or 12200m³/s are finally recommended for diversion open channel closure. It is found that the maximum hydrologic risks are 15.47% (Nov. 23rd, 2002) and 14.31% (Nov. 16th, 2002) under the design discharge 10300m³/s or 12200m³/s respectively. The construction risk of the final closure is resulted from the randomness and uncertainty of some hydraulic variables, such as water head, flow velocity and discharge. The water head of the gap is regarded as the primary factor of the construction risk and a corresponding model is proposed and developed. One dimensional unsteady flow hydraulic model based on discharge and energy conservation laws are established and the value of water head, flow velocity and discharge is obtained for given design flow discharge. The water head of the gap is assumed as a random variable with normal distribution, and the construction risks of point and 95%-confidence interval estimate are calculated. The results show that the construction risk increases with the reduction of the gap width or water head increase. For 10300m³/s or 12200m³/s design flow discharges, the maximum construction risks (when the gap is 20m wide) are 18.6% or 13.6% respectively. These estimated hydrologic and construction risks are all satisfied Chinese guidelines of the Construction Design of Hydraulic and Hydropower Engineering. It is suggested the final closure be completed after Nov. 23rd, 2002 or during Nov. 16th to 23rd with 10300m³/s or 12200m³/s design flow discharge respectively. These recommendations have been adopted by the Three Gorges Project Development Corporation and used for the diversion open channel closure of TGP decision-making.

HS02/09P/C24-007   1530

GLOBAL CHANGE--RISK ASSESSMENT AND REAL TIME HYDROLOGICAL FORECASTING OF FOREST CONFLAGRATIONS FOR WATER MANAGEMENT

S. LOBANOV[1], S. LOBANOV[1], V. KULIK[2] ([1]Far Eastern Regional Hydrometeorological Research Institute (FERHRI), [2]CYPUM PTY LTD , P.O. Box 863, Canberra City, ACT , AUSTRALIA 2601)

The global change makes irrelevant many methods of risk assessment andforecasting. In particular, changing climate means a greater probabilityof forest conflagrations. This results in disabling of water supplywatersheds and reservoir contamination. Old methods of meteorologicalforecasting of conflagrations will become less reliable, being based oncorrelations, obtained for a period of stable climate. EXISTINGhydrological networks can be used for wild conflagration prediction. Runoffdata allows the prediction of high fire danger earlier, with less overcaution, highlightsthe most dangerous watersheds and makes forecast more foolproof. In somecases hydroforecast improves the likelihood of prevention of a majordisaster. This technique has certain DIFFERENCES from the standardmeteorological methods: (1)It predicts bushfires not for an administrativeor geographical region, but for a watershed-- so, a bushfire can beforecast for certain water supply reservoirs; (2) It allows forecast ofthe bushfire danger earlier and estimates of the amount of time availablefor active measures; (3) It is less overcautious, thus excluding most falsealarm situations;(4) It is more accurate, simply because it uses hydrographicaldata, which is more representative than meteorological data;(5)It is morefoolproof and less dependent on the errors of observations; (6) Itdepends less on the stochastical nature of summer rains and othermeteorological elements.(7) It is simpler than any other method.There aretwo groups of PREDICTORS. (A) Early Predictors:(A1) Low flow; (A2) Changeof the curvature of the recession curve from concave to convex (semi logpaper);(A3) Accelerated recession. These early predictors can be used toestimate how many days there are before the critical fire danger starts(by an extrapolation of the recession curve). (B) Later Predictors: (B1)Stabilization of the runoff to a ″zero flow″ value; (B2) Steep rate of therecession after intermediate minor rains;(B3) Convex recession afterintermediate rains.(B4) Abrupt stabilization of the runoff to ″zero flow″several days after a minor rain. The manifestation of these latepredictors means that the probability of a bushfire has increaseddramatically. This method allows a forecast of the CRITICAL fire danger, when a bushfire isalmost inevitable. Experimental risk assessment and real time forecastwere successful for for water supply watersheds of Russia and Australia. Quitedifferent tools may be used in any particular case, due to local customs,hardware and software. For example, in some cases a deviation from normalrainfall-runoff relationships (runoff-rainfall or water balance models)could be a good indicator. A conflagration is a very rare phenomenon andto collect sufficient amount of information for any development of theforecasting technique it is necessary simply to analyze more cases.We askeverybody who has in their disposal data on watersheds, affected by anintense bushfire, to try this simple technique, to develop it and tocommunicate their results.

HS02/09P/C24-008   1615

SUSTAINABLE GROUND-WATER EXPLOITATION

Hugo A. LOAICIGA (Department of Geography / UCSB Santa Barbara California 93106-4060 USA)

Sustainable ground-water exploitation defines indefinite extraction of potable ground water that preserves its quality, maintains its natural ecological functionality, and provides water for human use without creating environmental or geologic hazards. Sustainability is a difficult goal in view of local and global climate changes that might effect the rates of ground-water recharge and of population and economic growth that may change the rate of water exraction. Climate variability -and, in particular, protracted drought- pose additional challenges to sustainable ground-water exploitation. Several factors most coalesce in order to achieve sustainable ground-water management: (1) knowledge of the climate-recharge linkages that determine the status of storage in an aquifer; (2) understanding of the evolution of ground-water chemical, biological, and physical characteristics as a result of ground-water pumping; (3) development of alternative and substitute water sources to replace and supplement ground water; (4) creation of institutional and cultural practices of water use that are flexible and adaptable to changing conditions. This article provides examples of sustainable ground-water exploitation strategies in the United States. The examples cover physical (e.g., pumping, recharge) and non-physical (pricing, conservation) measures that have been implemented in stressed aquifers to maintain their integrity and yield in the long term.

HS02/09P/C24-009   1630

SUSTAINABLE WATER RESOURCES MANAGEMENT IN DRAGONJA CATCHMENT, SLOVENIA

Mitja BRILLY[1], Lidija GLOBEVNIK[2] ([1]Faculty of Civil and Geodetic Engineering, University of Ljubljana, [2]Water Management Institute)

The Dragonja river catchment extends over two countries, Slovenia and Croatia. Historically, the area was important food supply area for the cities on the Trieste Bay shoreline. Due to intensive land use, erosion processes have been intensive. There have been more than 60 water mill on the area. Due to its weak socio-economic potential after the WWII, the area has been depopulated and agriculturally abandoned until recently. In 1991, the river Dragonja became the state border. Today, the area is developing again. There are a lot of conflict situations due to three doctrines that are being promulgated by different parties. The first doctrine is development of the area as drinking water supply and food production resource on sides, Slovenian and Croatian. The second is tourist development (airport extension, golf resort) of the valley. At the same time, the area is being planned to be

protected as Landscape Park. Though the processes of natural overgrowing have been intensive lately, the area still has not lost its traditional agricultural landscape character. There is a strong process of natural forestation on the abounded agricultural lands on hill slopes. The hydrology of river change tremendously due landscape changes as impact of economical and social processes on the catchment. The river gained natural character due to abandonment of water mills and lack of any regulatory measures. At the same time there was strong impact of change of hydrological regime and lowering of erosion processes on the catchment surface and riverbank. The hydromorphological processes are different today due to past human involvement. Physical planning and use of natural resources should take into consideration trend analysis of river morphological character. This is even more important because the river is a bordering river between two countries. There are two main goals for promotion of sustainable development of water resources: analysis of scientific questions and development of national and international institutional and human resources capacities. The questions are long term impact of existing processes and impact of new development of the area, increasing of population and economical development. The issues are: 1) How to preserve the area as an important natural and cultural heritage area, manage sustainable development and protect the water resources. 2) How to manage river corridors and erosion spots to reasonably control hydrological characteristics and to protect endemic and other important flora and fauna species. 3) How to streamline and fulfil water demands in Slovenia and Croatia. 4) How to manage flood protection of coastal areas under development. and 5) How to propose suitable land use practices. The Slovenian and Croatian IHP Committees propose the Dragonja catchment for HELP initiative of UNESCO.

CHANGES OF WATER RESOURCE AND COUNTERMEASURES IN CHINA

Yongjian DING, Jianping YANG, Rensheng CHEN (Cold and Arid Regions Environmental and Engineering Research Institute, Chinese Academy of Sciences)

As a country of monsoon climate, water resource supply depends on precipitation in the majority of China. General distribution of water resource is more south and less north in China. In ordinary monsoon and strong monsoon years, precipitation is plenty in north China. After the end of 1970s, due to remarkable climate warming, rapidly economic development after carrying out the reform and open policy, increasing population, quick urbanization process and so on, water resource in north China is in severe shortage conditions. Contradiction between supply and need of water resource is even worse. Economic loss took the shortage of water resource is significant Moreover the loss multiplies year after year. On the contrary, there occur flood disasters frequently because of excessive precipitation. In the face of the above conditions, on the one hand, measures took is as follows: to economize on water in everyday life, to develop saving rainfall style agriculture, and to utilize saving water technique in industry. On the other hand, surplus water in south China is transferred into north China to mitigate tense water resource in north China. At present the east line of the project of South Water North Transfer is constructing. The middle and west lines is discussing. Except for above the countermeasures, it is essential to pay attention on scientific management. If management and countermeasures took is inconsistent, the countermeasures cannot bring into play practical utility. So based on active assessment of water resource changes, effective countermeasures took, and enforcement of scientific management, limited water resources can be only used rationally and economic loss gave rise to by the shortage and the excessiveness of water resources can be only decreased as large as possible.

MANAGEMENT OF INTERNATIONALLY SHARED GROUNDWATER RESOURCES IN SEMI-ARID AND ARID REGIONS ?ETHE NORTHERN AFRICAN AQUIFER SYSTEM

Tobias U. SIEGFRIED (Institue of Hydromechanics and Water resources Management)

Population growth, extension of irrigated agriculture, pollution of surface and groundwater and inefficient allocation are amongst the most prominent factors contributing to water shortage. The resulting stress on societies is multidimensional - from a non-equal distribution of water on the communal level to centre-periphery issues on the national level and up to international disputes over shared resources. What is needed is an intelligent management strategy of the water resources in order to prevent an escalation of existing and future conflicts of interest. This research project focuses on the Northern Saharan Aquifer System (SASS) shared between Algeria, Tunisia and Libya. In these countries agricultural policy in the last fifty years was largely determined by considerations of food security, self-sufficiency and import substitution practices. That, in addition to lacking political will to jointly manage the aquifer system as well as inadequate monitoring tools and sparse data have led to the present situation where global abstraction exceeds recharge approximately three times. According to planning provided by the individual states, this imbalance of the hydrological state of the system will further accentuate until 2050 where the ratio abstraction / recharge is estimated to surpass a factor of 15. With regard to quantity a simple "back of the envelope" calculation shows that the SASS constitutes a resource for exploitative use for many centuries to come. However any adherent of this position has to be aware that the approach of pursuing purely exploitative strategies comes at a price economically, environmentally and socially speaking. Therefore a systemic approach based on a basin-wide collaboration to achieve optimal allocation is presented. Within that, a physical quantification of the resource was combined with an economic quantification of costs and benefits and the evaluation of tradeoffs involved in different courses of action. It's objective is to maximize benefits resulting from groundwater abstraction while taking into consideration spatially distributed quantity and quality constraints. These constraints include: head constraints, gradient switching constraints in areas sensitive to backflow of brine from Chotts and Sebkhas and finally quantity constraints. A globally optimal allocation strategies will be presented that can be considered as a benchmark for differing strategies. However, such a strategy is not likely to be pursued by the three riparian states if the negative externalities associated with alternative management cannot be better understood and quantified and the potential of tradeoffs investigated. Previous research within the framework of non-cooperative differential games has extensively covered situations where symmetry between the player's interests existed. With regard to the highly diverse productive systems and greatly varying aquifer properties as well as economic potential of the three riparian states it is questionable whether this approach is appropriate. We follow a more natural method by representing the differential game with asymmetric economic players that act upon the SASS aquifer model. Results will be presented utilizing empirical data supplied from Algeria, Tunisia and Libya putting the Gisser-Sachez-effect in new light.

WORLD WATER USE: TRENDS, SCENARIOS, CONSEQUENCES

Igor Alexeevich SHIKLOMANOV (Director of the State Hydrological Institute)

New results of the prognostic assessment of the world water use obtained at SHI in 2001 during the research made to improve the dynamics of the world water resources are presented. Using the materials which are being published in the monograph "World Water Resources at the Beginning of the 21st Century", prepared by SHI, as well as a new data on water use all over the world a new scenario has been developed and validated on the global water use before 2025, i.e. scenario of "Sustainable Development". This scenario is an alternative to that used in the monograph and known as "Conventional Scenario". A detailed critical analysis of the scenarios developed by the international group of experts (Scenario Development Panel) during 1999-2000 which were submitted to the Second World Water Forum in the Hague shows that all these scenarios give quite an optimistic picture of a perspective water use development; the basic prerequisites of these scenarios, however, are not realistic at all and they do not take into account the available opportunities of many countries. Besides, the "Conventional Scenario" forecasting a development of water use on the model of the previous decades is the most realistic one, but it gives a critical water situation in many regions in the future. "Sustainable Development" scenario takes into account the main factors determining possibilities, volumes and structure of the present water use in certain regions and it is oriented to a wide use of modern technologies for freshwater use, in irrigation and industries in particular. In accordance with computations by the scenario of the "Sustainable Development", the world water use before 2025 would be practically stable; before 2025 it would equal 3900 km3/year which would be greater than that in 1995 by 2.7 % only; moreover, industrial water use would be lower by 10%; agricultural water use would be practically the same, meanwhile the municipal water use would be by about 25% greater due to the developing countries. According to the new scenario, more significant changes of water use may be expected on the continents. In Europe, North America and Australia a reduced water use would be from 24 to 5 % compared with that in 1995. On other continents it would be from 33% to 12 % higher. Still greater differentiation in the dynamics of water use is expected in natural-economic regions of the world. Nevertheless, it should be noted that a stabilization and even decrease of water use in the future can significantly decrease a load on water resources, but would not greatly affect the specific water availability in most regions in the world due to population growth. Only effective projects on improvement of technologies of freshwater use together with projects on increase of the available water resources may cardinally solve the problem of a perspective water supply in the world.

ADJUSTIBILITY AND FLEXIBILITY OF RESERVOIR SYSTEMS TO CHANGES IN DEMAND AND SUPPLY CONDITIONS

Carsten BRASS, Andreas H. SCHUMANN (Institute for Hydrology, Water Management and Environmental Engineering, Ruhr-University Bochum)

The future reliability of reservoir systems is subject to climate change, which induces variations in boundary conditions of the appropriate management policies. In order to retain the actual system performance mainly two options exists. First of all reservoir operation should be adapted to changes by optimization. If the results are not satisfying the second option would be structural changes of the reservoir system, e.g. by construction of new or extension of existing reservoirs. For both approaches reasonable forecasts of future requirements would be extremely helpful to initialize the complex planing and decision procedure for the necessary adoptions. As it becomes evident by the wide range of regional climate change assessments estimated by different GCMs (General Circulation Models), it seems to be impossible at the moment to make any quantitative prediction of future hydrological conditions. As a result it is infeasible to make assessments about the required changes of existing reservoir system in future. One option to cope with this problem consists in analyzing the range of thinkable climatic change scenarios in order to get an idea of the future behavior and necessary changes of reservoir systems with regard to its operation and their structure. In this paper a way to adapt reservoir systems to changes in demand and supply is presented. For this purpose a tool to optimize reservoir systems operation to changing demand and supply conditions by Flexible Stochastic Dynamic Programming (FSDP) was developed. It considers the inflow as first-order Markov process and generates management policies with a flexible time-step. The different objectives (release, drinking-water withdrawal, flow at a control-gauge downstream, energy production and storage-volume) can be varied interactively. They are combined in a weighted objective function. In order to estimate the combinations of weights which are suitable, a decomposition of the system into single reservoirs and a site-specific optimization with an automated variation of weights is proposed. An evaluation of the site-specific results is done by simulations with measured daily runoff-data. In this way the vulnerability of a reservoir system with respect to possible changes of the demand and/or supply conditions can be assessed. With the computed information weights of the different objectives for all reservoirs are chosen to optimize the future operation of the reservoir-system. System decomposition is used to cope with the ˝curse of dimensionality˝ to reduce the computational efforts. The applicability of the developed methodology is demonstrated by a case study.

WATER ALLOCATION FOR MULTIPLE USES BASED ON PROBABILISTIC RESERVOIR INFLOW FORECASTS

Ashish SHARMA[1], Upmanu LALL[2], Sankar ARUMUGAM[2] ([1]School of Civil and Environmental Engineering, The University of New South Wales, [2]International Research Institute for Climate

Prediction, Columbia University)

Allocating water to downstream users is a traditionally conservative exercise. How much water to allocate is decided based on stringent assumptions about the sequence of likely reservoir inflows (in many cases assumed to be the worst on record), and a requirement that the amount allocated for each use be reliable. In practice, the inflows that actually occur are often a predictable function of catchment storage and longer scale climatic fluctuations, and the water supplied for each use has a reliability that is influenced by the relative socio-economic considerations that may be applicable. This paper presents a framework for water allocation that is different from the traditional in the following respects: (a) it allows for the specification of the reliability associated with each water use, allowing for the formulation of a process where water can be auctioned between competing uses and users with a pre-specified reliability and value, and (b) it uses probabilistic forecasts of the likely reservoir inflows that take into account both local-scale factors such as prior inflow and rainfall, and larger scale climate related influences, which in this study are identified through a careful selection of predictors from climate indices and globally distributed, gridded sea surface temperature anomaly data. The approach is demonstrated through an application to the Oros reservoir in the state of Ceara, Brazil, with a simplified formulation assumes the uses to be confined to irrigation, and municipal and industrial water supply. The performance of the probabilistic forecasts is compared with that of the climatological or un-conditional forecasts within the proposed water allocation framework, the comparison being performed by forecasting each year on record in a cross-validatory manner. The results from this exercise point both to the usefulness of the relatively pragmatic water allocation framework proposed in this work, and to the use of climate based probabilistic forecasts that can lead to substantial savings of water in regions where the link to low-frequency climate variability is strong.

IMPROVED HEURISTIC RESERVOIR OPERATION USING CONTROL CURVES INCORPORATING THE VULNERABILITY NORM

Adebayo Johnson ADELOYE (Civil and Offshore Engineering, Heriot-Watt University)

Control or rule curves are an essential aspect of reservoir management in that by showing target storage levels in reservoirs in different periods, usually months, they are meant to guide reservoir operation. They however do not prescribe the amount of water to release from the reservoir; such an information can only be provided by an operating policy. However, the derivation of an operating policy often involves more complex analyses than that required for the derivation of control curves. Furthermore implementing an operating policy requires a user with specialist expertise not required for the implementation of control curves. For these reasons, most reservoir operators have tended to rely almost exclusively on control curves for reservoir operation. Traditionally, control curve targets are developed using non-sequential reservoir planning analysis. Efforts are then made to operate the reservoir in such a way that its level in any month does not fall below the target for that month. If the level falls below the target, such action must be taken to reverse the trend by reducing the amount of water put into supply. The problem is that a traditional control curve does not give any guidance on the level of cut back required to reverse the trend and there is therefore no guarantee that this objective will be achieved. Too little cut back will only make the recovery impossible or longer to achieve, while too much supply reduction will place unnecessary hardship on water users Therefore, one way to increase the effectiveness of control curves for reservoir operation while still benefiting from its relative ease of use is to introduce the vulnerability norm as one of its attributes. Vulnerability is a measure of water shortage and limiting the supply cut back during failures to the vulnerability should ensure that the reservoir level does not fall below the target. In the study reported here, control curves with the dual attributes of reliability and vulnerability were developed for seven separate reservoirs. The reservoir planning analysis used a sequential approach based on the modified sequent peak algorithm. Because the analysis was implemented within a Monte Carlo framework, uncertainty limits for the control curves were also developed. The derived control curves are then used to simulate the reservoirs, by which it was clearly demonstrated that by following the prescribed water shortage targets, future reservoir catastrophic failures are avoided. The results of the study are presented and ways by which the control curves can be used to improve the operation of reservoirs are discussed.

OPTIMAL SHORT TERM OPERATION OF MULTIPURPOSE RESERVOIRS SYSTEM UNDER LIMITED WATER SUPPLY

Giuseppe GIULIANO, Antonino CANCELLIERE, Giuseppe ROSSI (Department of Civil and Environmental Engineering, University of Catania (Italy))

A methodology is presented for deriving operating rules of a multipurpose reservoirs system through application of optimization and neural networks techniques. In order to find operating rules well suited to different degrees of drought severity, different scenarios of water resources availability, irrigation and municipal demands were hypothesized. A combination of the multiobjective optimization ε-constraints method and the weighting method was used to find nondominated solutions that represent the best trade-off between two competitive objectives, namely the sums of squared irrigation and municipal deficits. Then neural networks were built through adaptive techniques,calibrating the parameters in order to better model the data provided by the optimization model. In particular, irrigation releases were expressed as a function of the reservoirs storage volumes, irrigation demands and inflows. Effectiveness of the selected operating rules was assessed through simulationof the system operation on new data, on the basis of many operational indices. Results showed that operating rules obtained through neural networks can well model the output of the adopted multiobjective optimization model, and therefore can be effectively used for optimum short term operation.

SIMULATING THE DISCHARGE OF CHAO PHRAYA RIVER CONSIDERING RESERVOIR OPERATION

Naota HANASAKI, Taikan OKI, Shinjiro KANAE, Katumi MUSIAKE (Institute of Industrial Science, University of Tokyo)

In order to simulate global river discharge, global river routing network models (GRRNMs) have rapidly developed over the past decade. They have digital global river network and calculate river discharge by routing runoff. One practical problem of current GRRNM, is that they do not deal with reservoir operation. However, large number of rivers is regulated by reservoirs, and their impacts on river discharge are sometimes too large to neglect. In this paper, simple reservoir operation model for Total Runoff Integrating Pathways (TRIP), which is one of the GRRNMs, is introduced. The improvement in global river discharge simulation will provide us more reliable seasonal distribution of global water resources and its inter-annual fluctuation. At first, the model calculates release/storage of each reservoir based on their capacity and hydrological feature, in order to reduce mean inter-seasonal difference of

discharge (Basic operation, i.e. store in high inflow season and release in low). Then, additional release/storage is calculated according to the purpose of each reservoir and drought/flood event (Unique operation). For example, if a reservoir'Qsq main purpose is irrigation water supply, additional release/storage is supplied for the shortage of rainfall in the irrigated area in the lower reach. The model has simple structure and its global parameters such as distribution of irrigated area or climatic rainfall are derived from published global data sets, aims its global application. The model is applied to Chao Phraya River in Thailand as a case study. The basin is under tropic monsoon climate and has vast irrigated paddy field in its lower reach. The model dealt with two large reservoirs in the basin, namely ´Bhumibol´ and ´Sirikit.´ The resolution of TRIP was 1°×1° longitude-latitude and simulated period was two years from 1/Jan/1987 to 31/Dec/1988. The calculated release compared well with the observation, especially the release in dry season when supplying irrigation water for the second crop. Consequently the trend of discharge at the lower reach is dramatically improved compared with former version. It supports the usefulness of our model and possibility of global application. However due to the underestimated inflow to the reservoir, which is caused by runoff derived from LSMs, error occurred in simulation of storage. The performance of our reservoir operation model strongly depends on the inflow data, so the improvement of LSMs is a critical issue. For global application, development of additional model components is necessary to cope with climatic and regional variety. Also, collection of long-term, reliable reservoir operation data (at least daily inflow, release, storage) are indispensable, for modeling and validation.

EVALUATION OF ALTERNATE OBJECTIVE FUNCTIONS FOR OPTIMAL OPERATION OF AN IRRIGATION RESERVOIR UNDER MULTI-CROP ENVIRONMENT

Umamahesh Venkata NANDURI (Department of Civil Engineering, Regional Engineering College, Warangal)

In India, irrigation is one of the important purpose for which most reservoirs are operated. Many times these reservoirs operate under conditions of deficit water supply. Hence the development of appropriate mathematical models for optimal operation of irrigation reservoirs should receive greater attention. The proper formulation of the objective function of the optimization model to operate a reservoir is very important. The success or failure of the modeling effort depends largely on the formulation of an objective function, which represents with sufficient accuracy the goals of the operating policy.In the present study, three stochastic dynamic programming (SDP) models with different objective functions are used to develop operating policy for an irrigation reservoir, namely, Sri Rama Sagar Reservoir on River Godavari in the state of Andhra Pradesh in India. The reservoir is a major project meeting the irrigation requirements over a large command area. The three SDP models model the objectives of the reservoir with different levels of mathematical complexity. The performance of the reservoir under these three operating policies is compared through simulation. Three criteria, namely reliability, resilience and average annual deficit of water supply are used to evaluate the performance of the reservoir under the alternate operating policies developed.

A TREE MODEL FOR RAINFALL PREDICTION

A.W. JAYAWARDENA[1], Xu PENCHANG[2] ([1]Department of Civil Engineering, The University of Hong Kong, [2]Institute of Applied Mathematics, Chinese Academy of Sciences)

One of the unique characteristics of daily rainfall data in any region is that the time series contains a large number of zeros. This poses problems in modeling using either deterministic or stochastic approaches. In general, rainfall data has a deterministic behaviour in the large time scale and a stochastic behaviour in the small time scale. In this study, it is proposed to model daily rainfall by using tree models of average rainfall values and their transmitting probabilities. It is assumed that the average rainfall in a fixed long period of time in each year is similar, and in a short period within that long period, it is stochastic. The long term can be a season or a certain number of months. For simplicity in bifurcating at each successive level, a period of 64 days is considered as the long time scale (64 is a power of 2). If, for any given year, the 64 days average rainfall is considered as the root of a tree which has 2 branches which in turn has two branches until it comes to the daily rainfall. The next step is to determine the transmitting probability from the root to the branches in succession. The probability tree also will have a structure similar to that of the rainfall value tree. The probability tree can be obtained by defining the probabilities as functions of the values of rainfall at each level. With these two tree models, and knowing their root values, the rainfalls at all other levels can be estimated. This method is applied to simulate rainfalls at a number of stations in Hong Kong and in Thailand. The results are encouraging.

CHARACTERISTICS OF INTERCEPTION LOSS AND FORMULATION OF AN APPROPRIATE MODEL FOR THREE REGIONS WITH DIFFERENT CLIMATE AND FOREST CONDITION

Tae TOBA[1], Tekeshi OHTA[1], Nobuaki TANAKA[3] ([1]Graduate School of Bioagricultural Sciences, Nagoya University, [2]Frontier Observational Research System for Global Change, [3]Graduate School of Agriculture and Life Sciences, The University of Tokyo)

In the future, changes in the water cycle resulting from climate changes will seriously affect water resource management. Knowledge of the characteristics of interception loss on a regional scale is important forunderstanding changes in the water cycle and for water resource management. In forests, the percentage of gross precipitation lost to interception usuallyranges from 10 to 40%. When considering interception losses on a regionalscale, an understanding of forest structure and of climatic conditions, i.e. precipitation, is much more important than it is in analyses on a patch scale. Therefore, an interception loss model that is appropriate for various forest types is needed.We analyzed the characteristics of interception

loss at eight locations withdifferent climate and forest conditions, in boreal (east Siberia), temperate (Japan), and tropical (Thailand) forests. We used an interception loss model (Toba and Ohta, 2002) that was calibrated using data for six locations in two of these regions, and validated this model with the results for the remaining two points in two regions. Three study sites were located at 62°N, 129°E in boreal forest, three at 39°N, 140°E and one at 35°N, 137°E in temperate forest, and one at 18°N, 98°E in tropical forest; the forests had plant area indexes (PAI) ranging from 2.8 to 11.1. The PAI reflects forest structure. Throughfall, stemflow, gross precipitation, and meteorological elements (air temperature, relative humidity, wind speed, etc.) at each site were observed. Compared with gross precipitation measured at open sites, the percentage lost to interception ranged from 10 to 20% in the boreal forest, 10 to 15% in the temperate forest, and was about 10% in the tropical forest. We have not analyzed the characteristics of interception loss for the tropical forest site in detail yet, but these results will be described later in a full paper. At the other sites there were clear relationships between interception loss and precipitation intensity, saturation deficit, and rainfall duration. The canopy storage capacity increased with the PAI. Parameters in the model were decided using the relationships of throughfall, stemflow, and gross precipitation. We then evaluated the characteristics of interception loss using this model.

HS02/10A/C24-003OP Oral-Poster 1053

CHANGES IN THE HYDROLOGICAL CYCLE AND ITS EFFECTS ON THE ENVIRONMENT IN AN INLAND RIVER BASIN OF WETSREN CHINA

Jumpei KUBOTA[1], Tomohiro AKIYAMA[2], Yusuke YAMAZAKI[3] ([1]Research Institute for Humanity and Nature, [2]Graduate School of Environmental Studies, Nagoya University, [3]Graduate School of Agriculture, Kyoto University)

This paper focuses the effects of changes in the hydrological cycle during the past fifty years cased by the water resource development on the environment in the Heihe River basin, an inland river of the arid region in the western China. The Heihe River basin consists of three parts, namely the upper mountainous area which is the source of the Heihe River by rather big amount of precipitation and glaciers, the middle oasis area like Zangye and Jiuquan, and the lower terminal arid area like Ejina. Each area has independent hydrological condition and ecosystem. Surface runoff from the upper mountain area by rain and melt water of snow and glaciers is the only source of water available in the middle oases area and the lower arid area. The increase of water demand in the middle oases area mainly by irrigation for agricultural land has resulted in the decrease of surface water supply for the lower arid area. The degradation of vegetations and the difficulties of the usage of shallow groundwater in terms of not only quantity, but quality have become serious problems. Even in the middle oasis area, over 80% of the total discharge has been diverted from main river courses to many irrigation canals, resulting in not only the rise of groundwater level inside the cultivated oases, but also the increase of soil salinization area. At the same time, the decrease of discharges in the main river courses have formed deserted area. Developing a distributed hydrological model with the grid based information of land use and irrigation systems, the spatial distribution water budget in the Heihe River basin has been evaluated. The relationship between the water status and the degradation of vegetations and water quality were investigated. Based on this analysis, we found that the strategies of farm production in each area are closely related to hydrological status. Also, using several future scenarios including possible climate change and expansion of the economy of this area, the proper way to use the limited water resources minimize the degradation of the environment will be discussed.

HS02/10A/C24-004OP Oral-Poster 1057

SUB-SURFACE WATER CONTRIBUTION TO SURFACE WATER USING STOCHASTIC DIFFERENTIAL EQUATION

Gouldaria K. NOURBAEVA, So KAZAMA, Masaki SAWAMOTO (Department of Civil Engineering, Tohoku University)

The scheme is proposed to analyze the distribution of soil water balance characteristics in a river catchment. The water movement processes are considered using stochastic differential equation (SDE) to obtain the dynamics of interrelated catchment parameters including water table depth, soil saturation and equilibrium soil moisture content. The SDE includes total prediction error modeled as a wideband stochastic process with zero mean. The non-stationary solution of SDE is derived by the efficient fourth order Runge-Kutta approximation method. The Van Genuchten-type relationship is used to obtain the soil water content values from water table predictions. The Kalman filter was used to calibrate the stochastic model to measured data. The discrete-time recursive routine such as Kalman filter gives a maximum likelihood criterion in terms of the differences between measurements and predictions. Aquifer screen variation for single location was modeled from measured data. The spatial distribution of water table depth is evaluated from contributing area concept based on the relationship between topographic index and water table depth. According this theory, soil moisture depends on the location on the hillslope at the catchment scale and the water table depth is a function of flow accumulating area and location slope. Under topographic index conception from hydrologic and topographic characteristics of catchment, the distribution of water table depths, equilibrium soil moisture content and specific discharge in each time step were predicted. The model has adapted to a specific character of the Natori River basin in Japan as mountain catchments. The spatially distributed data considered in the modeling are designed as raster data to be compatible with GIS software. The contributing area and slope for each location are calculated using digital elevation model of the catchment. Predictions are obtained as time series of digital maps with 1km grid scale. In the case of the scant sources observed data, described technique gives preliminary representation of full space-time distribution of water budget charasteristisc in the catchment. Proposed scheme can be useful for assessment of water resources redistribution in the river basin at temporal and spatial scale.

HS02/10A/C24-005OP Oral-Poster 1101

EVOLUTION OF THE SOIL WATER STORAGE UNDER PRESENT AND CHANGED ATMOSPHERIC CONDITIONS

Urszula SOMOROWSKA (Faculty of Geography and Reg.Studies, Warsaw University, Krakowskie Przedm.30,00-927 Warsaw, Poland)

The wetness status of land surface is an important element of the soil-plant-atmosphere systems. Traditional approach assumes that main factors affecting spatial and temporal patterns of soil water content include precipitation, evapotranspiration, groundwater levels, topography, vegetation and soil types. The soil water storage balances the temporal surplus of water supply from precipitation against the atmospheric demands for evapotranspiration. In case of shallow groundwater levels the volume of the soil water storage is dependent on the groundwater level fluctuations. This study is a search for interactions between soil water storage and precipitation - main factor responsible for recharge of the soil water resources. The focus is on the dynamic soil water resources of the lowland basin situated in the central region of Poland, in the protected area of the Kampinos National Park. The analysis is

based on field measurements of soil moisture conducted over the period 1995-2002 in fourteen representative sites. The measurements were conducted using Time Domain Reflectometry meter tracking the characteristic stages of soil water storage of shallow soil layers. Specific question to be answered is what is the basin´s inertia that affects subsequent evolution of the soil moisture stages, and, in consequence, soil water storage. Enabling the answer to this question requires (i) understanding the soil moisture variability and interdependencies between soil moisture and key factors e.g. precipitation and evapotranspiration (ii) quantifying the effects of hazard atmospheric situations on the volume of soil water storage (iii) setting the scheme for predicting soil water storage under extreme atmospheric conditions. Range of natural variability of soil water storage was derived from the soil moisture profiles detected. Extreme and normal stages of the soil water resources were related to the antecedent precipitation. It was found that at least four months´ antecedent precipitation has an influence on temporal stages of the soil water storage, thus the system has its memory. Inertia of soil water resources has been additionally investigated indirectly by applying autocorrelation function to the monthly minimum baseflow. Evolution of the soil water storage have been analyzed for the observation period of eight years. Additionally, the changes in the volume of the soil water storage have been estimated depending on the depletion of groundwater level in selected dry, wet and normal years over the period 1955-2002. In this case water storage decrease function was applied which is a simple correlation model allowing estimation of water deficits as an effect of groundwater level drop. Depletion of soil water storage was set as dependent from the deficit of precipitation (precipitation minus evapotranspiration). The relation was parameterized according to the logarithmic equation established for wet, dry and average years. Assuming exaggerated atmospheric conditions, the depletion of soil water storage can be predicted.

CLIMATE, WATER AND ENERGY IN THE NORDIC COUNTRIES

Arni SNORRASON, Jona Finndis JONSDOTTIR (Hydrological Service, National Energy Authority)

In light of the recent IPCC Climate Change assessment and recent progress made in meteorological and hydrological modeling, the directors of the Nordic hydrological institutes (CHIN) initiated a research project **Climate, Water and Energy** (CWE) with funding from the Nordic Energy Research and the Nordic Council of Ministers focusing on climatic impact assessment in the energy sector. Climatic variability and change affect the hydrological systems, which in turn affect the energy sector, this will increase the risk associated with the development and use of water resources in the Nordic countries. Climate and hydrology are thoroughly intertwined through the hydrological cycle. In fact, one can claim that climatic change is nowhere more clearly manifested than in hydrological systems and processes. Changes in precipitation and temperature will have direct influences on runoff. Glaciers are especially vulnerable to climate change, for example increased temperature may result in increased runoff, at least temporarily. Climatic change may have a large influence on the temporal distribution of runoff within the year. The impacts on the hydropower industry are many and varied, many of which are directly linked to the hydrological changes. Climatic change will affect the hydropower sector in general. The changes will affect the total water available as well as both its spatial and temporal distribution. This will create both opportunities and benefits to the hydropower sector, but also problems and costs. In fact, it can be stated that the risk, in general, will increase due to increased hydrological uncertainty caused by climatic changes. New investment and design, as well as operational and management practices are needed to respond to these changes. The product of the project will be an in-depth analysis of the present status of research and know-how in the sphere of climatic and hydrological research. Furthermore it will be a synthesis and integration of present research with focus on the needs of the energy sector. It will also identify and prioritize key future research areas for the benefits of the energy sector. Finally it will provide comprehensive research proposals for top priority research areas. The Climate, Water and Energy project can create a platform for further scientific co-operation. Such co-operation could focus on issues concerning the interplay of climate and water in the Arctic region and could also be extended into a joint Nordic, European and North American research program focusing on the North Atlantic region and its role in the climate of the Northern Hemisphere, or the Globe as a whole. The role of e.g. the North Atlantic Oscillation (NAO) in climate variability, is thought to be of great significance for the meteorological and hydrological conditions in Europe as well as other regions.

RAINFALL VARIABILITY AND ITS IMPACTS ON WATER RESOURCES DEVELOPMENT IN PART OF OGUN-OSUN RIVER BASIN

Olusegun ADEAGA (Department of Geography, University of Lagos)

Highly variable rainfall over space and time constitutes major constraints to water resources development most especially in developing countries of the world. Also, major consequences of extreme hydrological events (flood and drought) and low mitigation techniques and inadequate technological know-how threaten water resources development in developing region. Evaluating the nature of hydrological processes that affect water resources variability most especially rainfall in parts of Ogun-Oshun River Basin will provide adequate knowledge towards providing information on the amount, reliability and timing of available renewable water resources within the region. Such information is necessary; if problematic issues on water resources availability and production are to be resolved in a sustainable way. A safe transition to sustainability is crucial to meeting the increasing water demand per capita in Ogun-Oshun basin. In this paper emphasis was based on rainfall variability characteristics in Ogun-Oshun basin and the telecommunication of the El-Nino events and sea surface temperatures (SST) on rainfall distribution within Ogun-Oshun basin. Also, time series and probability analysis of extreme rainfall events frequency distribution and probability of occurrence was also carried-out. All, the above analyzes was integrated into a Geographical Information System (GIS) framework for spatial analyses and scenario building. Finally, investigation was made on adequate measures to be taken towards extreme hydrological events prediction and planning.

HS02/10A/C24-008OP Oral-Poster 1113

HEAT FLUX OBSERVATION ACROSS THE AIR/WATER INTERFACE OF A SMALL RIVER

Mohammed Aslam M.A.[1], Akihiko KONDOH[2] ([1]Graduate School of Science and Technology, Chiba University, Chiba 263-8522, Japan, [2]Center for Environmental Remote Sensing (CEReS),Chiba University, Chiba 263-8522, Japan)

River water temperature information is very important in the studies of potential effects of climate change on freshwater system. The relationship between stream temperature and air temperature are always active. The linear regressions of river temperature versus air temperature are best fitted for this purpose. The applicability of linear regression has been verified in this study. The present study deals with water temperature and air temperature flux in a small river Kuriyamagawa, Chiba Prefecture, Japan, where long-term database is maintained by Chiba Prefecture Environment Department. Temperature data from 1976 to

1997 were employed for the analysis. The heat flux observation for water and air interface has been observed at three stations across the river covering both upstream and downstream at Arai-bashi (longitude 140.473E and latitude 35.696N), Kido-bashi (longitude 140.528E and latitude 35.622N) and Yohei-bashi (longitude140.464E and latitude 35.687N) respectively. The inter-annual trend of river water temperature follows the trend of air temperature in these locations. The maximum temperature has been recorded for the month of August and that of the minimum for the month of January. The heat exchange processes that contribute to surface water temperature have been analyzed and related to the air temperature on a monthly time scale. This regression analysis strongly supports the linear relationship between the air and water temperature flux, which are based on the best autocorrelation structure of river water time series. This results has shown that water temperature (Tw) and air temperature (Ta) can be related by a linear regression as, Tw = 0.7941 Ta + 2.2392 for this small river, where heat flux studies has been carried out. The river temperature and air temperature interface is very similar to the equilibrium temperature and air temperature relationship. Linear regression between river temperature and air temperatures are found to be accurate and are good for interpolation within the record length used in the analysis.

REPRESENTATION OF COMPLEX LOW-FREQUENCY FEATURES IN A DAILY RAINFALL MODEL

Timothy Ives HARROLD[1], Ashish SHARMA[2] ([1]CSIRO Atmospheric Resarch, [2]University of New South Wales)

Australian rainfall records contain complex low-frequency features that are associated with climate variability. Both the pattern of wet and dry days, and the average rainfall on a wet day, are linked to large-scale quasi-periodic variations such as the El Nino Southern Oscillation Index. These linkages are even more complex when wet days are treated in separate classes based on the number of adjacent wet days (i.e. solitary wet days; days at the start or end of a wet spell; and days in the middle of a wet spell). We present a stochastic model for generation of daily rainfall that considers these features in its formulation. We show that use of predictors that reflect the low-frequency variations can result in a more appropriate representation of rainfall variability at long time scales.

ASSESSMENT OF THE EFFECTS OF VEGETATION COVER CHANGES ON HYDROLOGIC REGIME

Mohammad Javad POURAGHNIAEI[1], M. MAHDAVI[2], B. SAGHAFIAN[3] ([1]Natural Resources Research Center of Semnan, [2]Professor of Tehran University,College of Natural Resources, [3]Associate Professor in Watershed management research of Tehran)

Hydrologic regime of watersheds has high importance and needs attention. Lack of management and planning in natural resources and land use, cause changes in hydrologic regime of watersheds and converting runoff to flood. To be aware of management feedbacks is necessary to have a successful management in a watershed. In this study, hydrographs of Neka Rud basin were compared for several land use conditions (1967, 1992 & 2000) according to 24 hours maximum precipitation of several return periods. At first, land cover maps of Neka Rud basin for different years (1967, 1992 & 2000) were provided. Old maps and aerial photographs of 1967, TM and ETM Landsat images of 1992 and 2000 were used to provide the land cover map of 1967, 1992 & 2000, respectively. Using area of each land cover (from land cover maps), area of each soil type in basin (from soil map of basin) and other necessary information for SCS method, curve number (CN) for each period was calculated (614.7, 65.5 & 67.1). For the next step, from rain gauge data and by use of hHyfa soft ware, 24 hours maximum precipitation for selected return periods was calculated. The hyetographs (spatial pattern) for each return period were drown from inter basin stations data, using surfer software. Then weighted average of this hyetographs identified the 24 hours maximum precipitation in basin area. Average of temporal pattern (using IDF curves) of Babolsar and Gorgan rain gauges -in side of basin- was used for temporal pattern of Neka Rud basin and hourly temporal pattern was extracted. These data were used in Hydrologic Modeling System (HMS) to predict the hydrographs for each land use condition (1967, 1992 &2000) and on the 24 hours Maximum precipitation of several return periods. This model needs to simulation, calibration and Validation steps for Neka Rud Basin situation before running for predict a hydrograph. The model was simulated by 3 real storm-runoff events that after optimization, each of them had special calibration coefficients (for initial absorption and lag time). An average of these calibration coefficients was used as the coefficient for Neka Rud basin. Validation was the last step before prediction. For this step a real storm run off event was used. The observed and predicted hydrograph had the same trends, this result was suitable and the calibration was valid. Finally, the calibrated model was used to predict the hydrographs of Neka Rud basin for various land cover conditions. After running of the model for each situation, the results showed an increasing trend for peak discharge and volume of runoff from 1967 to 2000.

MODELING THE INFLUENCE OF VARIATION IN ATMOSPHERIC PRECIPITATION ON THE HEAT AND WATER BALANCE COMPONENTS OF DRY AREAS

Alexey Vladimirovich BABKIN (Lab. of Hydroecological Research of Inland Water Bodies)

The aim of the work is the development of the mathematical model for research of the moisture and water-thermal regime dynamics within arid and semi-arid areas. The base of model is the differential equations of water and heat balance of soil. The income of energy (absorbed solar radiation), water outcome components (evaporation and run-off) and energy outcome components (turbulent heat-exchange of ground surface with atmosphere, evaporation and effective radiation) were related through heat and water storage of soil. The relations between income-outcome characteristics and storage components permitted the soil water and heat balance equations to combine into the system. Its solutions were found for leap-pattern and linear changes of precipitation and for their variation simulated by periodic function. The increase of precipitation within arid and semi-arid areas causes the increase of soil water storage, evaporation and run-off and reduction of the heat storage and energy outcome for turbulent heat-exchange and effective radiation. The dynamics of characteristics of semi-arid area of Caspian Lowland and Western Kazakhstan was calculated for 50 mm/year leap-pattern increase of precipitation and for linear precipitation increase with the velocity of 5 mm/year2. For leap-pattern change of precipitation the climatic and hydrologic characteristics of the territory reach the values of new equilibrium state for the time less than the year. Under linear precipitation increase the changes of area characteristics become linear for the time interval less than half of year. The oscillation precipitation causes the variation of area characteristics. The extremes of climatic and hydrology characteristics of area have a time lag to the respective precipitation extreme. For the same variation period the time delay of area characteristics is different. After the precipitation extreme the evaporation reach its extreme value the first. The extremes of absorbed solar radiation, water storage of soil and run-off appear some time later. The heat

---

storage extreme of opposite phase is the last.

MODELING WATER QUALITY BY USING NEURAL NETWORKS

Jian-Ping SUEN, Wayland J. EHEART (Department of Civil and Environmental Engineering, University of Illinois at Urbana-Champaign)

In this study, artificial neural networks (ANNs), are applied to estimating the nitrate concentration in a typical Midwestern river, i.e., the Sangamon River in Illinois. In Illinois, and throughout the Midwestern US, nitrate has recently become an increasingly important problem in drinking water quality. This is due to a somewhat recent change in the EPA nitrate standard and to the increasingly widespread use of chemical fertilizers in agriculture. Two ANNs, Back Propagation Neural Networks (BPNN) and Radial Basis Function Neural Networks (RBFNN), were compared with regard to their effectiveness in water quality modeling. BPNN uses a gradient descent method, modifying the weight by simulation errors to construct the neural network. RBFNN uses a fuzzy min-max network to do the first clustering part and multivariate regression method to construct the neural network. RBFNN is much faster than traditional BPNN and the results of RBFNN also appear to be more robust. The study compared these two types of ANNs to traditional regression and traditional mechanistic water quality modeling. Comparisons were based on overall accuracy and on the frequency of false-negative prediction, i.e., the frequency with which the model would predict the nitrate concentration to be below the standard when it actually exceeded it. The study showed that the RBFNN achieved the best results of all models in terms of overall accuracy, and both BPNN and RBFNN had the same false-negative frequency which has better than traditional models.

TIME SCALE ANALYSIS FOR INVESTIGATING STATIONARITY OF HYDROLOGIC TIME SERIES

A. Ramachandra RAO[1] ([1]School of Civil Engineering, Purdue University, [2]Irrigation and Hydraulic Department, Faculty of Engineering, Cairo University)

To overcome the difficulties encountered in conventional spectral anaylsis, a different approach known as Wavelet analysis has been introduced during the past 10 years (Daubechies, 1992; Combes et al., 1990; Mallat, 1996; Meyer, 1993; Strang and Nguyen, 1996; Chui, 1992). In Wavelet analysis, a different type of basis functions, called Wavelets, are used. Wavelets, as opposed to sine and cosine functions, have a limited extent in time (a limited support), and are therefore localized in time as well as in frequency. In the theory of Wavelet transforms, the notion of ´frequency´ is changed to an equivalent one of ´scale´, where large scales correspond to low frequencies and small scales correspond to high frequencies. Wavelet analysis provides a technique for analyzing the structure of a time series by using variable size windows. By using the Wavelet transform the signal is decomposed into components of different scales. This offers a method for a local examination of the signal, a multi-scale outlook, and a time-scale analysis (Misiti et al., 1996). Wavelet analysis can be used as a tool for performing a wide range of tasks which include: detecting discontinuities in signals, detecting long-term evolution (trends), detecting self similarity (fractal signals), identifying pure frequencies (time-frequency analysis), suppression, and compression of signals. Wavelet analysis is used in this paper to investigate the stationarity of hydrologic and climatic time series as well as tree-ring series. Annual rainfall, runoff and temperature series from the Midwestern United States are used in the study. The results indicate the nonstationarities in these time series, thereby demonstrating the use of wavelets in the study of climatic variation. The time-scale structures in these time series are studied and the relationships between them are investigated. Also, Wavelet analysis is used for assessing similarities between different time series at different scales in the region under study. References Chui, C.K. 1992 An Introduction to Wavelets. THE RELATION BETWEEN δ18O IN MONSOONAL PRECIPITATION AND AIR-SEA ACTIVITY, ASTRONOMICAL AND METEOROLOGICAL FACTORS

Hongxi PANG, Yuanqing HE (Lab ice core, Cold and Arid Regions environmental and Engineering Research Institute, Chinses Academy Sciences)

The variations of isotopic content are different, with different locations and climatic types. The isotopic contents in precipitation vary complicatedly over monsoon regions in mid-latitude zones. The isotopic data in precipitation at New Delhi (the IAEA/WMO station; 28.58ºN,77.2ºE), located in southwest monsoon region, are analyzed, suggested that the δ18O values vary in 11 years cycle, which is closely agreed with that of sunspot; the strong correlation between δ18O and T/P ,a parameter by coupled temperature and rainfall; the remote positive correlation between δ18O and ENSO event induced by the interactions of coupled air-sea systems in tropical Indian Ocean and Pacific Ocean; and rainy drops evaporated is the key reason to lead the positive correlation between δ18O and zonal wind velocity at the height of 500mb while the amount and temperature effect strengthen this correlation.

SCALES OF HYDROLOGICAL CHANGES IN VOLGA RIVER BASIN POSSIBLE AT CLIMATE CHANGES

Alexander GEORGIADI (Department of Hydrology, Institute of Geography, RAS)

Three main approaches for model using as tool for assessments of possible hydrological regime changes which differ from each other by type of model are developed. One of them is based on physically based water cycle models (including SVAT models) that are used for small site or rather small watershed (Georgiadi, Nazarov, 1997; Kashutina, 1999 and others). Simplified monthly water budget models that could be used for wide diapason of spatial scale (Georgiadi, Milyukova, 2001). Mean annual river runoff could be estimated on the basis of rather simple relationships between water budget components and climatic elements (Belyaev, Georgiadi, 1989, 1992; Georgiadi, 1991, 1993; Velichko et al., 1992; Georgiadi, Jai-Ho Oh, Yong Hee Lee, 2000). The paper presents the assessments of possible changes of spring flood and annual river runoff changes as well as changes of intranual distribution of river runoff in Volga river basin (to Volgograd) at the Holocene Optimum (6 thou. years before present) as well as at a doubling of atmospheric CO_2. The

---

data of experiments on a global climate model of Moscow State University (Kislov, 1992) and Geophysical Fluid Dynamics Laboratory (GFDL), Prenceton University, USA were used as the scenario of climate change. The hydrological changes are determined on the basis of original model of monthly water balance. In the present work the model of formation of a monthly water balance for plain watersheds, allowing to estimate influence such important hydrological factors as potential evaporation, snow cover accumulation and snow melting, infiltration of water into the ground and its deep infiltration, soil moisture reserve change. The model allows to compute dynamics of runoff losses. This model could be used for calculate of rain and snow melting flow. The conditions of river runoff formation at various sites of watershed are non-uniform, at the same time there is a limited enough information on the soil hydrophysical characteristics, and as the rather rough estimations of some other characteristics of watersheds. Therefore for identification of some parameters of model the method of optimization was used. The calculations of a monthly river runoff for main part of Volga watershed for grid cells 1°x1° were made. The following monthly average long-term data were used: precipitation, air temperature, soil moisture reserve at field capacity, river runoff. All calculations were made for monthly time steps, but were used approach based on using so called quasi-daily calculations.

HS02/10A/C24-016OP Oral-Poster 1145

THE DECREASE OF THE PRECIPITATION IN PERIODS OF THE YEAR AS A SIGN OF CLIMATIC CHANGE: CASES STUDIED IN PORTUGAL

Maria Manuela PORTELA, Antonio de Carvalho QUINTELA (Instituto Superior Tecnico (IST))

A more irregular distribution of the precipitation within the year and a significant reduction of its amounts during some periods of the year are generally pointed out as consequences of the climatic change that seems to occur in Portugal. To be considered a sign of climatic change, the previous reduction must correspond to an increasing tendency persisting along the years. In order to detect variations having a persistent nature in temporal series of precipitation in Portugal, two procedures were applied: the classic method of moving averages and a procedure, expressly developed within the scope of the study that originated this article, based on a statistical comparison of the precipitation averages during certain intervals of time in which the recording periods were divided. The applications carried out for precipitation series in eleven gauging stations in Portugal denote that the amount of rain during the 2nd quarter of the hydrologic year (from January to March), and specially in March, is clearly decreasing.

HS02/10A/C24-017OP Oral-Poster 1149

CLIMATE CHANGE, GLACIER MASS BALANCE AND WATER RESOURCES

David N. COLLINS, Oliver G. MACDONALD (School of Environment & Life Sciences, University of Salford)

Disproportionately large contributions of runoff arise from the portions of catchments overlying the high mountain areas of the world, as a result of the orographic increase of precipitation with elevation. At present, high specific discharges from glacierised high mountains are also generally enhanced by destocking of ice from the many thousands of often small glaciers which characterise ranges such as the western cordillera of the Americas, the Alps, and the Himalaya. River flows have often doubled, between the cool 1970s and warm 1990s, reflecting in the Alps, for example, summer air temperature increases of about 2°C over the same period. However, enhanced river flows can not go on for ever. As warming continues, glacier mass loss and diminishing glacierised partial areas of catchments will ultimately result in reduction of annual total discharge with greater variability from year to year. Glaciers will become reduced in size in most areas over a timescale of 20 – 50 years. Warmer air temperatures will result in the freezing level rising in the atmosphere so that where snow formerly fell precipitation will occur as rain. Winter snow pack will probably decline and snow cover duration shorten. Heavy rainfall whilst the transient snowline stood at high elevation resulted in severe summer flood events in the Alps and the Karakoram in the warm 1990s. Daily integration of air temperature and precipitation from results of the HadCM3Gga1 experiment for 2.5 latitude x 3.75 longitude degree grid square resolution are coupled with standardised glacierised basins, downscaled through derivation of statistical relationships between regional climate (NCEP/NCAR reanalysis project), and actual glaciologically-relevant meteorological observations obtained at mountain stations. In the short term, warming increases flow, but coupled with deglaciation, greatly reduced flows will have serious consequences for water resources, particularly where mountain runoff drains to neighbouring arid lowlands.

HS02/10A/C24-018OP Oral-Poster 1153

THE HIGHEST ALTITUTE ICE CORES IN THE HIMALAYAS RECORD ANTHROPOGENIC POLLUTION

Tandong YAO[1], Keqin DUAN[2], Shucheng XIE[2], Wenmian HUO[2], Lide TIAN[2] ([1]Prof., [2]Dr.)

High resolution, well-dated ice core records, especially low-latitude ice cores near the populated regions provide a unique tool to study and to evaluate the impact of anthropogenic activities on environment and climate. Recently ice cores were recovered at an altitude of 7200m on the Dasuopu Glacier located in the Xixiabangma Mountain. The high elevation of the coring site provides very good background to detect any anthropogenic pollution. Organic and inorganic methods are applied to the Dasuopu ice core analyses. The analyses detected petroleum residues from the ice core. Our study has concluded that the material is from the oil combustion in Kuwait and vehicle pollution in India. The measured lead concentration ranges from $16\times10\text{-}12g/g$ to $161.7\times10\text{-}12g/g$. Lead concentration increases significantly since the 1940s. A very dramatic rise happened in the 1980s in which the mean lead concentration reached to $161.7\times10\text{-}12g/g$. The organic and inorganic analyses indicated that the anthropogenic pollution has already impacted the environment at 7200m a.s.l. in the Himalayas.

HS02/10A/C24-019OP Oral-Poster 1157

ATMOSPHERIC METHANE OVER THE PAST 1000 YEARS FROM A SUB-TROPICAL ICE CORE

Baiqing XU[1], Tandong YAO[2], Jerome CHAPPELLAZ[2], Lonie THOMPSON[2], Ninglian WANG[2], Lide TIAN[1] ([1]Dr., [2]Prf.)

A high-resolution methane record from an ice core recovered above 7200m of altitude on the Dasuopu Glacier in the Himalayas, reveals similar trend of methane concentration fluctuations with the polar region records. The highdegree of detail of the Dasuopu record over the last century allows revealing a significant period between the two World Wars when the anthropogenic methane increase was put to a halt. This sub-tropical methanerecord also allows quantifying for the first time the difference of methanemixing ratio between polar and sub-tropical latitudes during pre-industrialtime. The average difference is 120 ppbv with Greenland and 160 ppbv with Antarctica. The record suggests that the tropical latitudes

might represent large percent of the global methane sources in pre-industrial time. In addition, the temporal fluctuation of the pre-industrial methane records suggests that Monsoon evolution incorporated with high methane input in the south Asia might be responsible for the relatively high methaneconcentration observed in the Dasuopu ice core around 1700 AD.

ICE TEMPERATURE VARIATION IN PUROUGANRI ICE FIELD ON THE TIBETANPLATEAU

Jianchen PU[1], Tandong YAO[1], Ninglian WANG[2], Keqin DUAN[2], Lide TIAN[2] ([1]Prof., [2]Dr.)

Puruogangri ice field is located in the middle of the Tibetan Plateau, with a total area of 422.58km2. Four ice cores with a depth of 154m, 118m, 80m and 20m respectively. The ice temperature was measured in the 4 holes using resistance thermometer. The ice temperature shows same trend in the 4 holes. The ice temperature in the above 2m is intensively influenced by cold wave from the ice surface. Under that the ice temperature curve shows a warm-season type. The lowest ice temperature is -9.9° measured at 12m depth. The ice temperature increase downwards in a linear manner under 12m, but the increasing ratio is lower than the decreasing ratio in the upper 12m. During the observation, the ice temperature decreased obviously in the upper 4m of the ice hole, and the decrease is vanished downwards. In the 80m ice hole, the ice temperature decreased 0.62° from 18:50 of October 18 to 14:40 of October 21, which a daily average of 0.2°. The ice temperature decreased 1.15° in the same period, with a daily average of 0.3°. There was no obvious variation in 12m depth.

HS02/10A/C24-021OP Oral-Poster 1205

THE INFLUENCE OF THE SNOW COVER AND CLIMATE INTERSECTION TO EXTRMILY HYDROLOGICAL SITUATIONS IN THE SNBMPUNTANE ZONE (NORTH SLOPE OS CAUCASUS AS AXAMPLE)

Lev M. KITAEV (Department of climatology, Institute of Geography RAS)

The data bases of the snow thickness for the period 1966-1990 are compiled. In these bases 41 stations over the Great Caucasus ranges and 636 stations over the East European plain are included. The average snow thickness for the winter period (snowiness) is calculated. Their interannual changes in different regions in relation to atmosphere circulation are investigation. The coefficient of variation for the averaged values for all the plain and for all mountain stations is of the order 30%. For the single Caucasian stations with the high snowiness the coefficient of variation is about 30-45%, the maximum deviation is about 90%. For the single stations with the low snowiness the coefficient of variation is about 90-100% with 3-5 times maximum deviation. Over the East European plain with North Caucasian plain the snowiness was low over the period 1966-1977 and high over the period of 1978-1990. The zonal circulation prevailed in the first and the meridional one in the second period. The snowiness trend in 1966-1990 was positive. Cases of the high and low snowiness alternated incoherently over Grate Caucasus. The significant trend is absent. That is the result of different circulation factors of snow accumulation in dependence on the topography. In the high snowiness years over the Great Caucasus the frequency of the southern lows or the blocking high over the East European plain is above the average. During the blocking highs the western lows are concentrated the high southern periphery. In the half of years the anomalies signs for Caucasus and the plains are opposite. This has to lead to the mutual compensation of melted run-off anomalies related to mountain and plash parts of the North Caucasian river basins. Combinations of extremely interannual maximal and minimal annual snow depth of Caucasus and its north submontane zone were generated. The potential contribution of a snow cover of extreme years to a river drain is revealed.

HS02/10A/C24-022OP Oral-Poster 1209

RISK ASSESSMENT OF FLOOD CONTROL SYSTEM OF THE YANGTZE CENTERED ON THE THREE GORGES PROJECT

Shenglian GUO, Xiangrong TIAN, Caijun WANG, Honggang ZHANG, Pan LIU (Department.of Hydrology and Water Resources, Wuhan University)

The Three Gorges project (TGP) is the largest hydropower project in the world. TGP possesses huge comprehensive benefits, including flood control, power generation, navigation improvement, etc. Flood control is the key and also the essential one with the largest ecological and environmental benefits. TGP's construction commenced in 1994 and the first turbine will generate hydropower in 2003 May, and the whole project will be completed in 2008. Based on the characteristics of flood control system of the Yangtze River centered on Three Gorges Reservoir (TGR), one and two dimensional hydraulic flood routing models and multiple-input single output linear system models were proposed and developed by using numerical methods and modern system engineering principles. Four inter-basins, Shashi, Luoshan, Hankou and Dongting Lake, are selected for flood simulation case study. The models were applied to these inter-basins and the simulated flood hydrographs were compared with those depicted from observed data. The river network in the lake region and the river-lake relationship are considerable complicated and investigated in detail. The results were satisfactory with high model efficiencies and low relative errors. The model will provide technical support and service for flood forecasting and flood dispatch decision as well as risk analysis in this region. The results show that under the condition of the 1998 large flood, if TGR conducting the compensation operation for the Jingjiang area, the highest water level in the Shashi, Luoshan and Hankou hydrological stations would decrease 0.86m, 0.78m and 0.44m respectively. The risk herein means that under different frequency of designed flood of TGR, how much is the risk corresponding to the flood control system of the Yangtze basin after the upstream flood is regulated by TGR. The 1954 large flood (with flood diversion) and the 1998 large flood (without flood diversion) are chosen as prototype for this study. The risk of flood control system in the Yangtze basin is analyzed based on the TGR operation regulations and flood detention area management rules. It is shown that with 22.15 billion m^3 of TGR regulating capacity and incorporating with embankment, flood diversion and other non-engineering measures, the bank failure along Jingjiang river reach due to heavy flood, which usually cause huge mortality and million's homeless, can be effectively avoided. It can also protect millions people in downstream plain from flood menace and the consequent ecological and environmental destruction. The irreplaceable function of TGR for flood control will greatly ensure the harmonized development of social economy in the middle and lower reaches of the Yangtze.

HS02/10A/C24-023OP Oral-Poster 1213

CROSS-CORRELATION ANALYSIS BY KENDALL'S τ BETWEEN CATEGORIZED SOI AND THE NONEXCEEDANCE PROBABILITY OF PRECIPITATION IN KOREA

Young-Hoon JIN, Akira KAWAMURA, Kenji JINNO (Institute of environmental systems, Kyushu University)

H

El Niño/Southern Oscillation (ENSO) has influenced on the hydrological variables on global scale, but the influence of ENSO is not so clear in middle to high latitude including Korea and Japan. Especially, the quantitative influence of ENSO is difficult to be revealed in this region. There are several researches to reveal the correlation between Southern Oscillation Index (SOI) and the hydrological variables in Korea. Moon (2001) applied Multi-channel Singular Spectral Analysis (M-SSA) to the precipitation in Korea for identifying the coherent space-time patterns of low frequency harmonic element between SOI and the precipitation. Shin (2002) revealed the significant influence of El Niño/ La Niña on the flood and drought in Korea, using the statistical robust cross-correlation analysis. Kawamura et al. (2000) succeeded to detect the direct and significant correlation between SOI and precipitation/temperature in Fukuoka, Japan by categorizing SOI into five groups according to their magnitudes. Therefore we used the categorized SOI for revealing the relationship with the monthly precipitation at Pusan, Mokpo, and Inchon in Korea. In the kind of study, the appropriate transformation of the hydrological variables is often critical to obtain better results. It is difficult to normalize the precipitation data in the present study area because there are some months with no precipitation (less than 0.1 mm), whereas the precipitation data in Fukuoka were easy to be normalized by cubic root transformation. So in the present study we uniquely applied the nonexceedance probability transformation instead of the usual ones such as logarithmic and power transformations. We also applied Kendall's correlation coefficient (τ) when carrying out the cross-correlation analysis as well as the usual Pearson's correlation coefficient (r). The Kendall's τ is a rank-based procedure and is therefore resistant to the effect of extreme values and to deviations from a linear relationship. Most of all, this correlation coefficient can be applied to the data whose distribution is non-normal and unknown. These properties of Kendall's τ are well suited for the data of the present study, because the used data cannot be easily transformed normally, as mentioned earlier. The results from these approaches which used the nonexceedance probability and the Kendall's τ show that there are several significant correlations between the categorized SOI and precipitation in Korea. Especially, the correlation coefficients, which are significant at 1 % level in both Kendall's τ and Pearson's r, were detected only at Pusan station under the "Strong La Niña" category with lag time four months. The correlation coefficients in both Mokpo and Inchon stations were obtained only at the 5 % significance level for various lag times. From these results, we can infer that the influence of SOI on the precipitation in Korea is stronger at Pusan than at both Mokpo and Inchon stations, and that the stronger the La Niña event, the less the precipitation four months later in Pusan.

RESERVOIRS AND GLOBAL CHANGE - AN EVALUATION APPROACH

Elke PETERSSON[1], Manfred W. OSTROWSKI[2] ([1]Centre for Interdisciplinary Studies of Technology, Darmstadt University of Technology, [2]Institute for Hydraulics and Water Resources engineering, Darmstadt University of Technology)

The availability and quality of water have been crucial for the development of all human societies. On the other hand water bodies are integral parts of the natural environment. To satisfy societal water demands e.g. for domestic, industrial and agricultural uses, for electricity generation and to protect human settlements from extreme floods, systems for water storage and distribution have been developed over the centuries to balance the uneven distribution of water in space and time. Situated in the stream bed of a river, dams and reservoirs interrupt the natural hydrological cycle. Their dominant position in the hydrologic cycle makes them very sensitive to all kinds of changes in the catchment, among others global impacts on land use, climate, settlement structures or living standards. Vice versa dams strongly affect the spatially distributed, complex system of ecology, economy and society in the catchment both up- and downstream of the reservoir. The occurrence of negative impacts due to large dams led to serious conflicts about future dams. Nevertheless, water shortages due to climatic conditions and their changes, that are faced by enormous water and energy demands due to rising living standards of a growing world population, seem to require further dam construction, even if demand management is optimised. According to the American Society of Civil Engineers´ sustainability criteria for water resource systems and the recent WCD report, the planning of a dam has to span its whole life cycle from options assessment to reassessment of an implemented project to decommissioning. The planning procedures of the future have to break up the rigidity of present day technology-focused planning assumptions, that are mainly based on information regarding actual and past conditions. In the long run this will open a greater scope, supporting the integration of supply security, risk issues, transience of the natural system and stakeholder acceptance. To reach a sustainable development in line with the WCD report the corresponding information and knowledge has to be carefully structured and evaluated. The highly complex and dynamical system of interrelated physical and non-physical processes that involves many different groups of stakeholders constitutes the need for a model-oriented decision support system. The major challenge is the development of a generic evaluation approach. In the given context the presentation will define the goals, the corresponding requirements as well as the difficulties of the evaluation approach. An integrated analysis and structure of the complex interrelations between dams, ecology, economy and society will be presented as the basis of the evaluation module. Furthermore potential users, their needs as well as the limits of computer-based evaluation procedures in the very specific context of dam construction will be identified. Special focus will be on the constraints arising from the need to jointly evaluate qualitative and quantitative aspects. In this regard the methodological potential of multi-criteria analysis will be investigated.

HS02/10P/C24-002	1415

WATER MANAGEMENT IN INDIA'S NATIONAL WATER POLICY

Sitharama Murty KOTTAPALLI (Coordinator of Geoarchives, International Commission on the History of Geological Sciences (INHIGEO))

The predominant source of water in India is the rainfall. The Himalayan rivers have an additional source in the glaciers which sustain a perennial supply. The peculiar climatic diversity the country has is also responsible for the variation in the water availability. The average annual precipitation by way of rain and snow over India´s landmass is 4000 km3, but the annual water resources of the country have been estimated by the National Commission as 1953 km3, including groundwater component of 432 km3. But the usable water resources as estimated by the Commission are 690 km3 of surface water and 396 km3 of groundwater, making up a total of 1086 km3. At present the resource used is about 600 km3. The growth in population, urbanization and demands from various sectors would find this insufficient. In face, by the year 2050 this would be found inadequate as the total requirement of water would be between 973 to 1180 km3 depending upon the projections. The National Water Policy, adopted in 1987 recommended that economic development and activities including agricultural, industrial and urban development should be planned with due regard to the constraints imposed by the configuration of water availability. It also stressed efficiency in the use of water and conservation consciousness in the minds of the people, through education, regulation, incentives and disincentives. Priority was accorded to drinking water. The inadequacies of the 1987 National Water Policy slowly began to be felt as a result of which the Central government recently announced a revised National Water Policy. Some major changes are : recognition of water as a part of a larger ecological system; rainwater harvesting is to be of much importance; watershed management through extensive soil conservation, catchment area treatment, preservation of forests and increasing the forest cover; drainage system recognized as an integral part of project planning; involvement and participation of beneficiaries and other stakeholders in the project planning stage itself and onwards; the need to get optimal productivity per unit of water; reclamation of water - logged / saline affected lands; monitoring and evaluating the performance and socio - economic impact of the projects undertaken. The National Perspective for Water Resources Development envisages a long - term plan of interlinking of rivers of the north to those in the south, that hopes to solve the problems of floods and drought etc. As per the constitution of India, Water is a State subject. The Supreme Court declared Water as a Fundamental Right. Any policy of management of water resources has to keep in mind these two basic points.

HS02/10P/C24-003	1430

TOWARDS A NEW PARADIGMA FOR INTEGRATED WATER RESOURCES MANGEMENT AND DEVELOPMENT IN INDONESIA

Joesron LOEBIS (Research Coordinator on Water Resources)

By 1999 Indonesia is entering a whole new era by issuing and implementing the Law 22 on Regional Government. The spirit of the new law is to decentralizing the authority and responsibility from central to the regional government in aim to achieve more equals distributed welfare of the nation. Regional government are no more heavily dependent on central government policy. Instead now they have in their hand huge authority and responsibility to initiate the management of all self-nation resources. This covers all sectors, and water resources sector has no exception. Focusing on water resources sector, the effort taken in this time will concentrated on its management and development aspects regarding the strategic issue mention above. In order to achieve the objectives of efficiency and effectiveness of water supply to all stakeholders, it is a great urgency to implement the policy on ´one river basin, one plan and one integrated water resources management and development´ This policies focusing on establishing proper institutional framework, exploring self-financial system management, legal aspect and water right in development and management. Here, establishing institutional framework is the main issue and priority, and indeed a very complex issue since intersecting domains of economic, society, law culture, science and technology. Thus, any consideration within this framework should involve an interdisciplinary analysis of all the above factors. Furthermore, it will cover several important activities that is modification of existing institutional and legal aspect on water resources related to present law and regulation, establishing networking on hydrological data collection, provided decision support system, conjunctive use on surface and groundwater at the local levels, water quality control and role shearing between central and regional government.

HS02/10P/C24-004	1445

SOIL AND WATER CONSERVATION STRATEGIES IN THE LAKE OF RAWA DANO, WEST JAVA, INDONESIA

Seno ADI (BPP Teknologi)

The Rawa Dano lake lies within the caldera of volcano in the west Java. Locally, Rawa Dano means swampy lake as indicated that the lake mostly covered by the swamp forest and water plantation in the elevation of 90's m above sea level. The lake ecosystem has a main role as a water supply for the Krakatao Industrial Estate as well as for the city of Cilegon, West Java. So the soil degradation in around this lake catchment as identified the sediment carried over 71 million ton/year or 3.32 ton/ha/year and water plant blooming is threatening of water resources availability. Therefore the soil and water conservation strategies are needed urgently to mitigate the erosion and nutrient loss to the lake. The civil engineering approach should be constructed by conducting the control dam, check dam, and gully plug/drop especially in the land slope of $> 30\%$ which is indicated by high erosion hazard. The vegetative approach then has to be implemented by conducting the minimum tillage farming, agroforestry, or farming forest. The establishment of the lake authority seems to be important to restore the hydrological function by controlling the forest encroachment, soil & water conservatin practice, and community development. Thus, the lake authority get the retribution from the water beneficiaries then the budget has to be reinvested for soil and water conservation practice.

ASSESSMENT OF IMPACT OF URBANISATION ON STORMWATER RUNOFF

Rathnam Venkata ERVA, Jayakumar V. K. (Lecturer)

Increasing problems in urban stormwater management consequent to urbanization has been realized and appreciated in many hydrologic studies. Stormwater drainage and management systems are designed and constructed to cope up with the increase in runoff due to increased imperviousness of the land due to developmental activities. For the design of an adequate drainage system, it is essential to understand the changes in stormwater runoff quantity and quality with land use changes. Urbanisation usually results in increase in

volume and velocity of runoff, produces larger peak, decrease in the time to peak, downstream flooding and increase in pollutant loadings. The principal effects of land use change have been discussed by Geiger et al (1987),ASCE (1996) and Dunne and Leopold (1978), Overton and Meadows (1976), Urbanos and Stahre (1993) and many others. Runoff estimation techniques include: hydrograph methods and peak discharge methods. Many applications allow use of the peak flow analysis and the procedures are much less time consuming than the complete hydrograph method. The objective of the present study is to investigate the impact of land use changes due to urbanisation onstormwater runoff in part of Hyderabad city, in southern part of India. Duringthe last 20 years, urbanisation has taken place at an alarmingly rapid rate in the Hyderabad city. Land use change maps and rainfall data for the period1980-2000 are available. Using the available data, increase in built-up areaand impervious surface with the progression of urbanisation are estimated. Design storms of different return periods 2, 5, 10, 25, 50 and 100- years are developed. SCS (NRCS) curve numbers and runoff coefficients are estimated.The generated runoff from different design storm is computed using a welldocumented package, SMADA, as well as the rational method, as to study how runoff volume is increasing with increase in impervious area. It is observed from the studies that the rational method gave higher peaks for alldesign storms, while the SMADA, which uses SCS hydrograph method resulted in increased runoff duration. An assessment is also made of possible expansion of built-up area with increased urbanisation in future and consequent storm runoff volume is investigated.

USE OF PHYSICALLY BASED MODEL FOR FLOOD ESTIMATION IN SMALL CATCHMENTS IN A DATA SCARCE ENVIRONMENT

Jayakumar KANDATHIL VALAPPIL[1], Ramaseshan S.[2] ([1]Regional Engineering College, [2]Indian Institute of Technology)

Estimates of flood are required for the design and economic appraisal of a variety of engineering works. When adequate and appropriate data area available for the basin, conventional methods like frequency analysis or use of unit hydrographs and other rainfall-runoff procedures may be applied to model the basin system. When this is combined with the design storm, the design flood may be derived. Data available for small catchments are generally inadequate for these approaches. Empirical approaches may be used to model such small catchments.Since generally adequate data are available for estimating design storms, it seems worthwhile to derive relationships between storm rainfall and runoff. The parameters of the model may then be related to the characteristics of the storm and physiographic features of the watershed to yield regional relationship between storms and floods. But a more realistic and alternate approach is to model the catchment runoff process according to physical principles. Information regarding physiography, soils, vegetation and drainage pattern of the catchment is used in the physically based models. The catchment is decomposed into a network of channels and overland flow segments. Using the physical characteristics of each component and appropriate hydraulic equations, the hydrologic processes are simulated using the distributed parameter model. Necessary values of the coefficients and constants are specified from physical characteristics of the watershed or are obtained from calibration of the model with observed data. The study reported is essentially a regional case study of flood estimation in small catchments in a part of North Brahmaputra basin, in the north-eastern part of India. The scope of the study is to apply, in a data scarce environment, a physically based model, DRRRM and to study the regional variation, if any, of the parameter of the model and also to judge the validity for flood estimation. Data regarding catchment plan, cross section at the bridge sites and hourly rainfall and stage data for about 10 catchments in the region were available for the study for a very limited period of 3 to 4 years. The catchment area ranged from 7 km2 to 215 km2. After preliminary analysis of the data for errors, only seven basins were found to be suitable for analysis. The results of the study indicated that a constant parameter physically based model for small catchments in the region is realistic. The design flood estimated using this model compared favourably with other approaches reported in the literature. The study shows that because of the easy availability of, and competence with computers and software in field organizations, it seems preferable to adopt a distributed parameter model with relevant field data rather than using empirical statistical relationships of questionable reliability.

PHYSICALLY-BASED MODELS FOR FLOODS MODELLING IN THE MEDITERRANEAN AREA

Philippe GOURBESVILLE[1], Vncent GUNOT[2] ([1]University of Nice- Sophia Antipolis, [2]International Institute for Infrastructural Hydraulics and Environmental Engineering - IHE)

Extreme hydrological events are characterised by the scarcity of data (in terms of spatial and temporal frequency). This problem becomes more acute when it comes to modelling the response of large catchments with small concentration times due to particular morphology or rainfall intensities. The classical approach to modelling, (that consists of trying of tuning the model parameters so as to bring the calculations as close as possible to the measurements) becomes highly questionable because it may turn out to be extremely harmful to the predictive power of the model. The present paper addresses uncertainty in modelling the flash flood of 05.11.1994 on the Var watershed (France, 2820 km2). This watershed, located in the French riviera, is characterised by steep slopes, narrow valleys and large topography curvatures, making the flow pattern extremely complex. Seven models of the catchment were built using the Mike She hydrological modelling system. These models have different structures, geometries, or parameter values. The analysis of the model results on the flash flood of 05.11.1994 leads to the following conclusion: - the physically based approach is efficient and the flood characteristics are well reproduced; - the main sources for uncertainty in model results are, by decreasing order of importance: (i) the model structure, i.e. the assumptions concerning the dominant phenomena and how they are modelled, (ii) the model geometry and (iii) the value of the model parameters. This shows that, for this particular case at least, it is much more important to have a good knowledge of the phenomena occurring on the catchment, as well as of the particular geometrical feature, than to try to calibrate the parameters of the model. On the contrary, blind calibration of the model may jeopardise its predictive capabilities.

FLOOD FORECASTING & MANAGEMENT IN PAKISTAN

Shaukat A. AWAN (Pakistan Meteorological Department)

Floods in Pakistan are mainly caused by the heavy monsoon rains during the summer monsoon period from July to September. Meteorologically there are two situations which cause flood producing rains in the upper catchments of the rivers. The two meteorological situations in relations to different conditions of intensity and movement of low/depression may produce three categories of floods as described below. i) Meteorological Situation For Category-I Floods A situation when the seasonal low is a semi permanent weather system situated over south eastern Balochistan, south western Punjab, adjoining parts of Sindh get intensified (due to westerly wave) and causes the moisture from Arabian Sea to be brought

up to upper catchments of Chenab and Jhelum rivers resulting in heavy downpour along windward slopes of mountain ranges due to orographic lifting of moist air mass. ii) Meteorological Situation for Category-II & Category-III Floods Second flood generating meteorological situation is linked with monsoon low/depression. Such monsoon systems originate in Bay of Bengal region and then move across India in general west/north westerly direction arrive over Rajasthan or any of adjoining states of India. After this monsoon depression may take any one of following three courses. a) Continue moving straight west causing heavy wide-spread rains over Sindh/Balochistan. However, no river flooding shall occur in this case. b) Recurve in the north east direction towards upper catchments of Sutlej, Ravi and Chenab rivers causing extremely heavy rainfall and consequently floods first across border in India and then (within hours) at Rim Stations in Pakistan. This is Category-II flood situation. c) Continue moving in northerly direction (under the effect of a strong westerly over plains of Lahore/Gujranwala Divisions to finally end up over Rawalpindi/Hazara Divisions. Upper catchments of Chenab, Jhelum and Indus rivers come under its influence. Flood management process in Pakistan is multi-functional involving a number of different organizations. First step in the process is issuance of flood forecast/warning. This function has been assigned to Pakistan Meteorological Department(PMD) since basic cause of the floods in Pakistan is the rainfall which can be best predicted and monitored by PMD utilizing satellite cloud pictures and quantitative precipitation measurement radar data, in addition to the conventional weather forecasting facilities. For quantitative flood forecasting, hydrological data is obtained through Provincial Irrigation Department and WAPDA. WAPDA´s telemetric system is an important source of hydrological data for flood forecasting purposes. A most modern ´S-Band´ Doppler weather radar has recently been provided to PMD, while a new hydrometric data measurement and transmission system is being established by WAPDA. Furthermore, improved rainfall/runoff and flood routing models have been developed to provide more reliable and explicit flood information to flood prone population.

HS02/10P/C24-005OP   Oral-Poster   **1531**

DETECTION ON RAINFALL VARIETY IN WESTERN TAIWAN

Pao Shan YU, Chia Wen SUNG, Tao Chang YANG (Department of Hydraulics & Ocean Engineering ,National Cheng Kung University)

Global climate change and its influence on water resource are the worldwide issues. This paper aims to investigate the variety of historical rainfall on Taiwan. This study on local climate change may provide the reference for climate change study on Asia region. As the area of Taiwan is too small, the GCM is not suitable for our investigation on climate change. Therefore, the statistical method of Mann-Whitney-Pettitt test was applied to detect the change points of annual rainfall depth in the historical records. Rainfall records from four meteorological stations of the Central Weather Bureau distributed over western Taiwan, including Taipei, Taichung, Tainan and Hengchunstations, were adopted as our data set which almost have one hundred years records.It is found that the change points at these four stations vary from 1956 to 1968. As the rain fall during May and June is important for the reservoir operation in Taiwan and the annual maximum daily rainfall has extreme influenceson the rainfall design. Hence, the difference between rainfall characteristics, including the rainfall during May and June and annual maximum daily rainfall, before and after the change point for each station was investigated This work found that the rainfall during May and June, and annual maximum daily rainfall in Northern Taiwan have increase trend However, the rainfall characteristics in the Middle and Southern Taiwan have decrease trend For example, the 100-year return period maximum daily rainfall estimated by using Log-Person type III in Northern Taiwan increases around 17%. There are decrease round 20% in the Middleand Southern Taiwan.

HS02/10P/C24-006OP   Oral-Poster   **1535**

THE INTEGRATED RISK ANALYSIS OF OVER-STANDARD FLOOD FOR FLOOD CONTROL SYSTEM

Xiang ZHANG[1], Xinyu WANG[2], Guowei LAI[3] ([1]Dept. of Hydrology and Water Resources, Wuhan University, [2]Institute of Planning and Design, Changjiang Water Resources Comission, [3]Dept. of Hydropower, Wuhan University)

The flood control system mainly consists of reservoir, levee and flood spreading area with a certain flood control standard. The natural flood is a stochastic event. No matter how high the flood control standard is, the probability that the flood exceeds the standard still exists. So the risk analysis for the over-standard flood is very important for the flood control planning and the construction of flood control system.The traditional flood risk analysis may mainly concern with the hydrological and/or hydraulic uncertainty. The engineering uncertainty, such as the reliability of dam and levee, is seldom considered combined with them. In fact, facing the over-standard flood, the reliability of dam and levee strongly influence the ability of flood control system resisting flood. So the integrated risk analysis, considering the hydrological and engineering risk, may provide more thoroughly the information about the ability of flood control system. For the hydrological risk analysis of over-standard flood, we apply the compound Poisson model. It is a kind of risk value model based on stochastic point process theory and is superior with the typical characteristic discussing the frequency problem in time domain. Its discharge threshold for the selection of sample can be very low, and the discharge or the flood peak exceeding the threshold may be selected as the samples. It has been used to study the annual over-standard flood risk of flood control system. The engineering risk is caused by the uncertainty factors that influence the safety of engineering structure, including the load and the mechanics characteristics of material. In this paper, we apply the reliability theory to evaluate the engineering structure safety. The methods for the engineering safety of gravity dam and earth bank are discussed respectively. In order to calculate the integrated risk rate, the hydrological and engineering risk are considered as compatible events. The Selective Probability is used to calculate the integrated risk rate of compatible events. The case study about the flood control system in the Lishui catchment is done. The objective of flood protection is to control that the designing flood of 50 year recurrence through the operation of flood control system is lower than the safety discharge of downstream channel at Sanjiangkou station, 12000m3/s. So we discuss the three different operating schemes by the hydrological risk analysis, and calculate the engineering safety of the three dams and levee in Lishui catchment. Through the integrated risk analysis, the optimal operating scheme and the weak link in the flood control system are suggested. The result illustrates that these methods are practical in integrated risk analysis of flood control system and the results of integrated risk analysis are useful in decision making for flood control planning.

HS02/10P/C24-007OP   Oral-Poster   **1539**

LONG-TERM CHANGE IN DAILY RAINFALL CHARACTERISTICS AT OKAYAMA

Hidetaka CHIKAMORI, Akihiro NAGAI (Faculty of Environmental Science and Technology, Okayama University)

Rainfall characteristics is said to change in recent decades. It is said that rainfall has concentrated in the shorter duration than before so that occurrence of extreme hydrological events like floods and droughts have become more frequent and the disasters related to

these events become more severe than before. The changes are attributed to global climate change like global warming and/or local environmental change like heat island effect.The purpose of this paper is to statistically clarify the long-term change in rainfall characteristics, that is, frequency distribution of rainfall depth, rainfall and no-rainfall duration and so on. A statistical analysis was performed for 100-year (1898-1997) daily rainfall record at Okayama Meteorological Observatory, Japan. In this analysis, we defined a storm as a succession of rainy days, and examined statistical characteristics of total rainfall and duration of a storm, storm inter-arrival time and interval between storms. The record was divided into two 50-year periods or three 33-year periods. In the two periods case, the period of 1898-1947 and that of 1948-1997 were named as I_{50} and II_{50} periods, respectively. In the three periods case, the period of 1899-1931, that of 1932-1964 and that of 1965-1997 were named as I_{33}, II_{33} and III_{33} periods, respectively, where the record of 1897 was excluded for the analysis.First, we examined frequency distribution of annual maximum of a storm rainfall in each record period, and found that the storm rainfall with the equally probability is becoming larger year by year. Gumbel distribution was applied to each data of the record period, and the result shows, for example, that 100-year storm rainfall increases by 17 % in the period II_{33} and by 67 % in the period III_{33} comparing with that in the period I_{33}. Second, we examined frequency distribution of storm duration and found that the storm duration tends to decrease from year to year. Thus the more rainfall happens in the shorter duration so that average rainfall intensity in a storm tends to increase. Finally, we examined frequency distribution of interval between storms, and found that the interval tends to increase year by year. Gumbel distribution was applied to each data of the record period, and the result shows, for example, that 100-year interval between storms in the period III_{33} becomes five times larger than that in the period I_{33}. The results show the apparent change in frequency distribution of rainfall characteristics in recent decades. The change tends to shorten return period of the hydrologic design value such as design discharge or design rainfall of the water use or control plans designed before so that the risks of floods or those of droughts are both increasing. The fact suggest us necessity to reconsider magnitude of design floods and droughts for water resources planning and management.

HIDROLOGICAL REGIONALIZATION USING THE TCEV METHOD WITH THE SUPPORT OF A GEOGRAPHICAL INFORMATION SYSTEM

Cristiane M. FINZI, Iara Righi AMRAL, Bruno Rabelo VERSIANI (Centro de Pesquisas Hidraulicas e Recursos H?Aricos - EHR - Escola de Engenharia - UFMG)

The analysis of a statistical model allows a better evaluation of the spatial variability of the hidro-climatological phenomena . The application of that model is called ˝ regionalization ˝. The paper focus the Two Component ExtremeValue, TCEV Model, (Rossi et al., 1984), which tries to describe the extreme values of a statistical series, as maximum precipitation an maximum flood data.The regionalization method based on this model allows to identify hidrological homogeneous regions in a watershed, in terms of maximum values of precipitation and flood.The determination of those regions allows to evaluate realistic estimates for the involved variables, concerning studies and projects of water resources management, in the state of Minas Gerais, Brazil, mainly in a watershed where there is a lack of data.Previous studies applied the method in the southern portion of the Sao Francisco watershed. In this paper one compares the results when more data are included extending the study region. The statistical characteristics of maximum precipitation and flood determine the homogeneous regions.. The methodology is developed in three stages: the first seeks the determination of the homogeneous regions according to the similarity of the coefficient of skewness and the second stage is the determination of sub regions where the coefficient of variation remains practically contant. The third stage is the determination of the index flood, based on the physical and climatic characteristics of the region. The results of the application of the methodology are the quantile estimates of the maximum values of precipitation and flood, specially in some regions with lack of data.In this application, one determine three homogeneous concerning maximum flood and five regions concerning maximum precipitation. In some of those areas the statistical regional curve is similar to the Gumbel model. In this case the TCEV method could not be applied. This means that the samples used in the calibration of the regional statistical model don´t identify outliers values.

WATER RESOURCES SUSTAINABILITY IN THE CONTEXT OF CLIMATE VARIABILITY AND INCREASING EXTREME EVENTS IN THE HIMALAYAN-INDO-GANGETIC PLAINS

R. B. SINGH (Department of Geography, University of Delhi)

The Himalayan environment is subject to significant and uncertain changes. Variation in climatic conditions could result in large-scale changes in the Indo-Gangetic ecosystem. The Himalaya which is fragile and globally important ecosystem, is also known as the water towers of the earth surface and rich repositories of biological diversity. Variability in climatic conditions influence water resource sustainability of the plains. In the present paper an attempt has been made to analyse the impact of climatic variability and other mountain extremes particularly floods on the Indo-Gangetic plains. Paucity of observational data and analysis makes the study on mountain areas rather difficult. The issues of Himalayan - Indo-Gangetic plains interactions including the nature and quantities of materials transported from highland to valleys along with the dynamics of land use induced sediment erosion processes and floods attract particular attention at different temporal and spatial scales. The Indo-Gangetic plains include region of national significance in terms of dense and increasing human population. There exists very large and variable discharges of fresh water, suspended sediments and dissolved matter. The present pattern of flooding suggests that high productivity is no longer being sustained. Shrinking natural resource base (per capita availability of land/water devoted to agriculture) and declining quality of resources are increasing the risk to our ability to meet the basic needs of the growing population of the region. In addition a range of socio- economic factors emerging out of flood problems impact land use and the food security. Investments in irrigation development are unattractive and have declined. Competing uses for water would force shifts in crops/cropping pattern. Soil-characteristics as well as cropping system in the Indo-Gangetic plain region is largely uniform. There are, however, a number of variations within the region. There are 6 agro-ecological regions and 12 sub-regions. Irrigation facilities are available to the maximum extent in the north- west and minimum in the east. The size and distribution of the land holding varies from 3.6 hectares in the north-west to approx. 1 hectare in the Bengal Region. There are vast differences in actual and potential yields, earning from about 6-tons/hectare in the north-eastern region to as low as 2 tons/hectare in the east having frequent flood prone areas. Major sustainability issues require focus on the ecosystem functioning, agro-biodiversity (including soil biota), loss in soil fertility, hazards, declining water table and rising water table / water logging etc. Managing floods in one region often co-exists with managing droughts in another region. The need for a comprehensive watershed based planning integrating land and water resources is urgently felt so as to monitor and manage the water resources of this region optimally. The strategy reflects a major conceptual shift towards risk reduction i.e. culture of prevention.

APPROACH FOR ASSESSMENT OF RISK AND CHANGES IN EXTREME HYDROLOGICAL CHARACTERISTICS

Helen (Elena) Vladislavovna LOBANOVA (IAHS member, Senior Scientist)

One of the main practical application of hydrology is connected with a frequency analysis of extreme hydrological events such as floods and droughts. New Federal normative documents in Russia (Construction Norms and Rules, Code of Rules) take into account two kind of safety and risk assessment: -for existing water projects under some period of operation, -for future water projects. The first direction condition by the following reasons: short-term records in the past, new effective methods of computations which have been developed in last time, modern changes (climate change, man´s impacts). These peculiarities lead to a necessity of possible re-computation of design hydrological characteristics for the existing hydraulic constructions and other water projects to increase their safety. The algorithm of assessment and re-computation includes the following main steps: -extraction of the components in time series which connect with ˝natural˝ conditions and with ˝pure˝ impact of existing constructions on the runoff; -assessment of stability of working existing hydraulic constructions and other water projects (analysis of man´s activity component); -assessment of climate change in time series in ˝natural˝ conditions (extraction and analysis of modern long-term climate change component); -determination of design extreme values taking into account the last observation, new methods and changing conditions; -comparison of the determined design values with the same one, which have been obtained before the construction of this hydraulic structure and making the decision about the re-computation. Such scheme characterizes a monitoring of design hydrological characteristics for changing conditions. New methods have been developed for a realization of this algorithm and they are: -methods for extraction of runoff components connected with operation by existing hydraulic and other kind of constructions and under different availability of the information; -methods for extraction of climate variability and long-term climate change components; -methods for assessment of statistical efficiency and contributions of climate change and water management; -assessment of empirical probability of non-regular extreme events such as floods and droughts taking into account historical information; -decision the problems of non-homogeneity of the extreme data by statistical criteria for testing of outlying data and application of the composition of distribution functions for non-homogeneous records; -methods for assessment of random errors of design hydrological events taking into account short-term period of the regular observations, palaeo-restorations and long-term period of future operation in changing conditions. Application of developed approach and methods have been given for some different examples: -re-computation of maximum design discharges for the cascade of the Dnieper hydropower stations; -re-computation of design maximum water level for the Lena River - Lensk city; -assessment of long-term operation of main hydropower stations in Russia for different hydrological characteristics (water resources, extremes, etc); -using of palaeo-restoration of annual runoff in more than 4000 years for assessment of climate changes and random errors of design values; -assessment of changes in low flow for different regions of Russia under climate change.

ASSESSMENT OF THE RISKS OF EXTREME RAINS OCCURENCE DEPENDING ON THEIR GENESIS

Ionel HAIDU (Dept.of Geography, Univ.of Cluj-Napoca)

Usually, in a study that has in view the rain falls that produce high floods, a single raw of maximum yearly values are to be analyzed, indifferently of the type from which those rains derive. It is to be appreciated that the rains with a maximum intensity are "covering", and there is no need to apply at diverse informative sources. This is a quantitative concept which refers only to the magnitude of the extremes (torrential rains, high floods) which would have unexpected hydrotechnical and social consequences. On the other hand, a qualitative approach, respectively the analysis of the extremes on genetic categories may reduce the uncertainties. It is possible that the set of the extremes (for instance, in the case of the rains with a yearly maximum intensity, but also in other cases) will lack the same statistical population as a source. Another example is given by the possible appearance in the observations raw of a value with an extraordinary magnitude, which is aberrant from a statistical point of view, and which must be removed by the analyst from the analyzed sample, in order to obtain ˝fair˝ adjustments. Thus, the historic maximum intensity of 8.5 mm/min registered at Borod station (west of Romania) that far exceeds the value of 2.77 mm/min, representing the average of those 28 years of observations, can not be explained by the statistics of extreme values. That's why it is useful to set up series of values on genetic categories, suspecting the possibility to find out many source-populations of the extremes. Besides the series of yearly maximum intensities, set up indifferent of the generating rain type (28 values), the succession of yearly maximum intensities produced by rains of thermic convection and the series of yearly maximum intensities produced by frontal rains, have been built. Were considered too, series having source couple of months: May-June typical of the most intense period of cyclonic activity and July-August specific for the most active period of thermic convection. For the length of the whole rainy season (April – September), in which the rains of thermic convection and the frontal rains can coexist, the monthly series of maximum intensities was also taken into consideration. While the frequency model of the series of yearly maximum values is, clearly, that of an exponential type, the genetic series are different. The maximum intensities generated by convective rains can be also adjusted through a lognormal model of 2 parameters though from the point of view of graphic correspondence, the best law is that of GEV type, on the theoretical curve being situated even the historical maximum of 8.5 mm/min. In the case of frontal rains, the candidate laws are Gumbel, Lognormal and exponential, and from those with 3 parameters, the GEV. The most adequate laws for the case of bimonthly and monthly series are also described. The paper approaches in its final part the possible genetic explanations of the extreme events, which can have different consequences as regards the high floods appearance.

HS02b-Posters — Thursday, July 10

WATER RESOURCES SYSTEMS: GLOBAL CHANGE, RISK ASSESSMENT AND WATER MANAGEMENT (ICWRS, ICASVR, ICSW, ICWQ)
Location: Site D

The scheme is proposed to analyze the distribution of soil water balance characteristics in a river catchment. The water movement processes are considered using stochastic differential equation (SDE) to obtain the dynamics of interrelated catchment parameters including water table depth, soil saturation and equilibrium soil moisture content. The SDE includes total prediction error modeled as a wideband stochastic process with zero mean. The non-stationary solution of SDE is derived by the efficient fourth order Runge-Kutta approximation method. The Van Genuchten-type relationship is used to obtain the soil water content values from water table predictions. The Kalman filter was used to calibrate the stochastic model to measured data. The discrete-time recursive routine such as Kalman filter gives a maximum likelihood criterion in terms of the differences between measurements and predictions. Aquifer screen variation for single location was modeled from measured data. The spatial distribution of water table depth is evaluated from contributing area concept based on the relationship between topographic index and water table depth. According this theory, soil moisture depends on the location on the hillslope at the catchment scale and the water table depth is a function of flow accumulating area and location slope. Under topographic index conception from hydrologic and topographic characteristics of catchment, the distribution of water table depths, equilibrium soil moisture content and specific discharge in each time step were predicted. The model has adapted to a specific character of the Natori River basin in Japan as mountain catchments. The spatially distributed data considered in the modeling are designed as raster data to be compatible with GIS software. The contributing area and slope for each location are calculated using digital elevation model of the catchment. Predictions are obtained as time series of digital maps with 1km grid scale. In the case of the scant sources observed data, described technique gives preliminary representation of full space-time distribution of water budget charasteristisc in the catchment. Proposed scheme can be useful for assessment of water resources redistribution in the river basin at temporal and spatial scale.

A TREE MODEL FOR RAINFALL PREDICTION

A.W. JAYAWARDENA[1], Xu PENCHANG[2] ([1]Department of Civil Engineering, The University of Hong Kong, [2]Institute of Applied Mathematics, Chinese Academy of Sciences)

One of the unique characteristics of daily rainfall data in any region is that the time series contains a large number of zeros. This poses problems in modeling using either deterministic or stochastic approaches. In general, rainfall data has a deterministic behaviour in the large time scale and a stochastic behaviour in the small time scale. In this study, it is proposed to model daily rainfall by using tree models of average rainfall values and their transmitting probabilities. It is assumed that the average rainfall in a fixed long period of time in each year is similar, and in a short period within that long period, it is stochastic. The long term can be a season or a certain number of months. For simplicity in bifurcating at each successive level, a period of 64 days is considered as the long time scale (64 is a power of 2). If, for any given year, the 64 days average rainfall is considered as the root of a tree which has 2 branches which in turn has two branches until it comes to the daily rainfall. The next step is to determine the transmitting probability from the root to the branches in succession. The probability tree also will have a structure similar to that of the rainfall value tree. The probability tree can be obtained by defining the probabilities as functions of the values of rainfall at each level. With these two tree models, and knowing their root values, the rainfalls at all other levels can be estimated. This method is applied to simulate rainfalls at a number of stations in Hong Kong and in Thailand. The results are encouraging.

CHARACTERISTICS OF INTERCEPTION LOSS AND FORMULATION OF AN APPROPRIATE MODEL FOR THREE REGIONS WITH DIFFERENT CLIMATE AND FOREST CONDITION

Tae TOBA[1], Tekeshi OHTA[1], Nobuaki TANAKA[3] ([1]Graduate School of Bioagricultural Sciences, Nagoya University, [2]Frontier Observational Research System for Global Change, [3]Graduate School of Agriculture and Life Sciences, The University of Tokyo)

In the future, changes in the water cycle resulting from climate changes will seriously affect water resource management. Knowledge of the characteristics of interception loss on a regional scale is important forunderstanding changes in the water cycle and for water resource management. In forests, the percentage of gross precipitation lost to interception usually ranges from 10 to 40%. When considering interception losses on a regionalscale, an understanding of forest structure and of climatic conditions, i.e. precipitation, is much more important than it is in analyses on a patch scale. Therefore, an interception loss model that is appropriate for various forest types is needed.We analyzed the characteristics of interception loss at eight locations with different climate and forest conditions, in boreal (east Siberia), temperate (Japan), and tropical (Thailand) forests. We used an interception loss model (Toba and Ohta, 2002) that was calibrated using data for six locations in two of these regions, and validated this model with the results for the remaining two points in two regions. Three study sites were located at 62°N, 129°E in boreal forest, three at 39°N, 140°E and one at 35°N, 137°E in temperate forest, and one at 18°N, 98°E in tropical forest; the forests had plant area indexes (PAI) ranging from 2.8 to 11.1. The PAI reflects forest structure. Throughfall, stemflow, gross precipitation, and meteorological elements (air temperature, relative humidity, wind speed, etc.) at each site were observed. Compared with gross precipitation measured at open sites, the percentage lost to interception ranged from 10 to 20% in the boreal forest, 10 to 15% in the temperate forest, and was about 10% in the tropical forest. We have not analyzed the characteristics of interception loss for the tropical forest site in detail yet, but these results will be described later in a full paper. At the other sites there were clear relationships between interception loss and precipitation intensity, saturation deficit, and rainfall duration. The canopy storage capacity increased with the PAI. Parameters in the model were decided using the relationships of throughfall, stemflow, and gross precipitation. We then evaluated the characteristics of interception loss using this model.

CHANGES IN THE HYDROLOGICAL CYCLE AND ITS EFFECTS ON THE ENVIRONMENT IN AN INLAND RIVER BASIN OF WETSREN CHINA

Jumpei KUBOTA[1], Tomohiro AKIYAMA[2], Yusuke YAMAZAKI[3] ([1]Research Institute for Humanity and Nature, [2]Graduate School of Environmental Studies, Nagoya University, [3]Graduate School of Agriculture, Kyoto University)

This paper focuses the effects of changes in the hydrological cycle during the past fifty years cased by the water resource development on the environment in the Heihe River basin, an inland river of the arid region in the western China. The Heihe River basin consists of three parts, namely the upper mountainous area which is the source of the Heihe River by rather big amount of precipitation and glaciers, the middle oasis area like Zangye and Jiuquan, and the lower terminal arid area like Ejina. Each area has independent hydrological condition and ecosystem. Surface runoff from the upper mountain area by rain and melt water of snow and glaciers is the only source of water available in the middle oases area and the lower arid area. The increase of water demand in the middle oases area mainly by irrigation for agricultural land has resulted in the decrease of surface water supply for the lower arid area. The degradation of vegetations and the difficulties of the usage of shallow groundwater in terms of not only quantity, but quality have become serious problems. Even in the middle oasis area, over 80% of the total discharge has been diverted from main river courses to many irrigation canals, resulting in not only the rise of groundwater level inside the cultivated oases, but also the increase of soil salinization area. At the same time, the decrease of discharges in the main river courses have formed deserted area. Developing a distributed hydrological model with the grid based information of land use and irrigation systems, the spatial distribution water budget in the Heihe River basin has been evaluated. The relationship between the water status and the degradation of vegetations and water quality were investigated. Based on this analysis, we found that the strategies of farm production in each area are closely related to hydrological status. Also, using several future scenarios including possible climate change and expansion of the economy of this area, the proper way to use the limited water resources minimize the degradation of the environment will be discussed.

EVOLUTION OF THE SOIL WATER STORAGE UNDER PRESENT AND CHANGED ATMOSPHERIC CONDITIONS

Urszula SOMOROWSKA (Faculty of Geography and Reg.Studies, Warsaw University, Krakowskie Przedm.30,00-927 Warsaw, Poland)

The wetness status of land surface is an important element of the soil-plant-atmosphere systems. Traditional approach assumes that main factors affecting spatial and temporal patterns of soil water content include precipitation, evapotranspiration, groundwater levels, topography, vegetation and soil types. The soil water storage balances the temporal surplus of water supply from precipitation against the atmospheric demands for evapotranspiration. In case of shallow groundwater levels the volume of the soil water storage is dependent on the groundwater level fluctuations. This study is a search for interactions between soil water storage and precipitation - main factor responsible for recharge of the soil water resources. The focus is on the dynamic soil water resources of the lowland basin situated in the central region of Poland, in the protected area of the Kampinos National Park. The analysis is based on field measurements of soil moisture conducted over the period 1995-2002 in fourteen representative sites. The measurements were conducted using Time Domain Reflectometry meter tracking the characteristic stages of soil water storage of shallow soil layers. Specific question to be answered is what is the basin´s inertia that affects subsequent evolution of the soil moisture stages, and, in consequence, soil water storage. Enabling the answer to this question requires (i) understanding the soil moisture variability and interdependencies between soil moisture and key factors e.g. precipitation and evapotranspiration (ii) quantifying the effects of hazard atmospheric situations on the volume of soil water storage (iii) setting the scheme for predicting soil water storage under extreme atmospheric conditions. Range of natural variability of soil water storage was derived from the soil moisture profiles detected. Extreme and normal stages of the soil water resources were related to the antecedent precipitation. It was found that at least four months´ antecedent precipitation has an influence on temporal stages of the soil water storage, thus the system has its memory. Inertia of soil water resources has been additionally investigated indirectly by applying autocorrelation function to the monthly minimum baseflow. Evolution of the soil water storage have been analyzed for the observation period of eight years. Additionally, the changes in the volume of the soil water storage have been estimated depending on the depletion of groundwater level in selected dry, wet and normal years over the period 1955-2002. In this case water storage decrease function was applied which is a simple correlation model allowing estimation of water deficits as an effect of groundwater level drop. Depletion of soil water storage was set as dependent from the deficit of precipitation (precipitation minus evapotranspiration). The relation was parameterized according to the logarithmic equation established for wet, dry and average years. Assuming exaggerated atmospheric conditions, the depletion of soil water storage can be predicted.

CLIMATE, WATER AND ENERGY IN THE NORDIC COUNTRIES

Arni SNORRASON, Jona Finndis JONSDOTTIR (Hydrological Service, National Energy Authority)

In light of the recent IPCC Climate Change assessment and recent progress made in meteorological and hydrological modeling, the directors of the Nordic hydrological institutes (CHIN) initiated a research project **Climate, Water and Energy** (CWE) with funding from the Nordic Energy Research and the Nordic Council of Ministers focusing on climatic impact assessment in the energy sector. Climatic variability and change affect the hydrological systems, which in turn affect the energy sector, this will increase the risk associated with the development and use of water resources in the Nordic countries. Climate and hydrology are thoroughly intertwined through the hydrological cycle. In fact, one can claim that climatic change is nowhere more clearly manifested than in hydrological systems and processes. Changes in precipitation and temperature will have direct influences on runoff. Glaciers are especially vulnerable to climate change, for example increased temperature may result in increased runoff, at least temporarily. Climatic change may have a large influence on the temporal distribution of runoff within the year. The impacts on the hydropower industry are many and varied, many of which are directly linked to the hydrological changes. Climatic change will affect the hydropower sector in general. The changes will affect the total water available as well as both its spatial and temporal distribution. This will create both opportunities and benefits to the hydropower sector, but also problems and costs. In fact, it can be stated that the risk, in general, will increase due to increased hydrological uncertainty caused by climatic changes. New investment and design, as well as operational and management practices are needed to respond to these changes. The product of the project will be an in-depth analysis of the present status of research and know-how in the sphere of climatic and hydrological research. Furthermore it will be a synthesis and integration of present research with focus on the needs of the energy sector. It will also identify and prioritize key future research areas for the benefits of the energy sector. Finally it will provide comprehensive research proposals for top priority research areas. The Climate, Water and Energy project can create a platform for further scientific co-operation. Such co-operation could focus on issues concerning the interplay of climate and water in the Arctic region and could also be extended into a joint Nordic, European and North American research program focusing on the North Atlantic region and its role in the climate of the Northern Hemisphere, or the Globe as a whole. The role of e.g. the North Atlantic Oscillation (NAO) in climate

variability, is thought to be of great significance for the meteorological and hydrological conditions in Europe as well as other regions.

RAINFALL VARIABILITY AND ITS IMPACTS ON WATER RESOURCES DEVELOPMENT IN PART OF OGUN-OSUN RIVER BASIN

Olusegun ADEAGA (Department of Geography, University of Lagos)

Highly variable rainfall over space and time constitutes major constraints to water resources development most especially in developing countries of the world. Also, major consequences of extreme hydrological events (flood and drought) and low mitigation techniques and inadequate technological know-how threaten water resources development in developing region. Evaluating the nature of hydrological processes that affect water resources variability most especially rainfall in parts of Ogun-Oshun River Basin will provide adequate knowledge towards providing information on the amount, reliability and timing of available renewable water resources within the region. Such information is necessary; if problematic issues on water resources availability and production are to be resolved in a sustainable way. A safe transition to sustainability is crucial to meeting the increasing water demand per capita in Ogun-Oshun basin. In this paper emphasis was based on rainfall variability characteristics in Ogun-Oshun basin and the telecommunication of the El-Nino events and sea surface temperatures (SST) on rainfall distribution within Ogun-Oshun basin. Also, time series and probability analysis of extreme rainfall events frequency distribution and probability of occurrence was also carried-out. All, the above analyzes was integrated into a Geographical Information System (GIS) framework for spatial analyses and scenario building. Finally, investigation was made on adequate measures to be taken towards extreme hydrological events prediction and planning.

HS02b/10P/D-008 Poster 1630-128

HEAT FLUX OBSERVATION ACROSS THE AIR/WATER INTERFACE OF A SMALL RIVER

Mohammed Aslam M.A.[1], Akihiko KONDOH[2] ([1]Graduate School of Science and Technology, Chiba University, Chiba 263-8522, Japan, [2]Center for Environmental Remote Sensing (CEReS),Chiba University, Chiba 263-8522, Japan)

River water temperature information is very important in the studies of potential effects of climate change on freshwater system. The relationship between stream temperature and air temperature are always active. The linear regressions of river temperature versus air temperature are best fitted for this purpose. The applicability of linear regression has been verified in this study. The present study deals with water temperature and air temperature flux in a small river Kuriyamagawa, Chiba Prefecture, Japan, where long-term database is maintained by Chiba Prefecture Environment Department. Temperature data from 1976 to 1997 were employed for the analysis. The heat flux observation for water and air interface has been observed at three stations across the river covering both upstream and downstream at Arai-bashi (longitude 140.473E and latitude 35.696N), Kido-bashi (longitude 140.528E and latitude 35.622N) and Yohei-bashi (longitude140.464E and latitude 35.687N) respectively. The inter-annual trend of river water temperature follows the trend of air temperature in these locations. The maximum temperature has been recorded for the month of August and that of the minimum for the month of January. The heat exchange processes that contribute to surface water temperature have been analyzed and related to the air temperature on a monthly time scale. This regression analysis strongly supports the linear relationship between the air and water temperature flux, which are based on the best autocorrelation structure of river water time series. This results has shown that water temperature (Tw) and air temperature (Ta) can be related by a linear regression as, Tw = 0.7941 Ta + 2.2392 for this small river, where heat flux studies has been carried out. The river temperature and air temperature interface is very similar to the equilibrium temperature and air temperature relationship. Linear regression between river temperature and air temperatures are found to be accurate and are good for interpolation within the record length used in the analysis.

REPRESENTATION OF COMPLEX LOW-FREQUENCY FEATURES IN A DAILY RAINFALL MODEL

Timothy Ives HARROLD[1], Ashish SHARMA[2] ([1]CSIRO Atmospheric Resarch, [2]University of New South Wales)

Australian rainfall records contain complex low-frequency features that are associated with climate variability. Both the pattern of wet and dry days, and the average rainfall on a wet day, are linked to large-scale quasi-periodic variations such as the El Nino Southern Oscillation Index. These linkages are even more complex when wet days are treated in separate classes based on the number of adjacent wet days (i.e. solitary wet days; days at the start or end of a wet spell; and days in the middle of a wet spell). We present a stochastic model for generation of daily rainfall that considers these features in its formulation. We show that use of predictors that reflect the low-frequency variations can result in a more appropriate representation of rainfall variability at long time scales.

HS02b/10P/D-010 Poster 1630-130

ASSESSMENT OF THE EFFECTS OF VEGETATION COVER CHANGES ON HYDROLOGIC REGIME

Mohammad Javad POURAGHNIAEI[1], M. MAHDAVI[2], B. SAGHAFIAN[3] ([1]Natural Resources Research Center of Semnan, [2]Professor of Tehran University,College of Natural Resources, [3]Associate Professor in Watershed management research of Tehran)

Hydrologic regime of watersheds has high importance and needs attention. Lack of management and planning in natural resources and land use, cause changes in hydrologic regime of watersheds and converting runoff to flood. To be aware of management feedbacks is necessary to have a successful management in a watershed. In this study, hydrographs of Neka Rud basin were compared for several land use conditions (1967, 1992 & 2000) according to 24 hours maximum precipitation of several return periods. At first, land cover maps of Neka Rud basin for different years (1967, 1992 & 2000) were provided. Old maps and aerial photographs of 1967, TM and ETM Landsat images of 1992 and 2000 were used to provide the land cover map of 1967, 1992 & 2000, respectively. Using area of each land cover (from land cover maps), area of each soil type of basin (from soil map of basin) and other necessary information for SCS method, curve number (CN) for each period was calculated (614.7, 65.5 & 67.1). For the next step, from rain gauge data and by use of hHyfa soft ware, 24 hours maximum precipitation for selected return periods was calculated. The hyetographs (spatial pattern) for each return period were drown from inter basin stations data, using surfer software. Then weighted average of this hyetographs identified the 24 hours maximum precipitation in basin area. Average of temporal pattern (using IDF curves)

of Babolsar and Gorgan rain gauges -in side of basin- was used for temporal pattern of Neka Rud basin and hourly temporal pattern was extracted. These data were used in Hydrologic Modeling System (HMS) to predict the hydrographs for each land use condition (1967, 1992 &2000) and on the 24 hours Maximum precipitation of several return periods. This model needs to simulation, calibration and Validation steps for Neka Rud Basin situation before running for predict a hydrograph. The model was simulated by 3 real storm-runoff events that after optimization, each of them had special calibration coefficients (for initial absorption and lag time). An average of these calibration coefficients was used as the coefficient for Neka Rud basin. Validation was the last step before prediction. For this step a real storm run off event was used. The observed and predicted hydrograph had the same trends, this result was suitable and the calibration was valid. Finally, the calibrated model was used to predict the hydrographs of Neka Rud basin for various land cover conditions. After running of the model for each situation, the results showed an increasing trend for peak discharge and volume of runoff from 1967 to 2000.

HS02b/10P/D-011 Poster 1630-131

MODELING THE INFLUENCE OF VARIATION IN ATMOSPHERIC PRECIPITATION ON THE HEAT AND WATER BALANCE COMPONENTS OF DRY AREAS

Alexey Vladimirovich BABKIN (Lab. of Hydroecological Research of Inland Water Bodies)

{BR}The aim of the work is the development of the mathematical model for research of the moisture and water-thermal regime dynamics within arid and semi-arid areas. The base of model is the differential equations of water and heat balance of soil. The income of energy (absorbed solar radiation), water outcome components (evaporation and run-off) and energy outcome components (turbulent heat-exchange of ground surface with atmosphere, evaporation and effective radiation) were related through heat and water storage of soil. {BR}The relations between income-outcome characteristics and storage components permitted the soil water and heat balance equations to combine into the system. Its solutions were found for leap-pattern and linear changes of precipitation and for their variation simulated by periodic function. The increase of precipitation within arid and semi-arid areas causes the increase of soil water storage, evaporation and run-off and reduction of the heat storage and energy outcome for turbulent heat-exchange and effective radiation.{BR}The dynamics of characteristics of semi-arid area of Caspian Lowland and Western Kazakhstan was calculated for 50 mm/year leap-pattern increase of precipitation and for linear precipitation increase with the velocity of 5 mm/year2. For leap-pattern change of precipitation the climatic and hydrologic characteristics of the territory reach the values of new equilibrium state for the time less than the year. Under linear precipitation increase the changes of area characteristics become linear for the time interval less than half of year. {BR}The oscillation of precipitation causes the variation of area characteristics. The extremes of climatic and hydrology characteristics of area have a time lag to the respective precipitation extreme. For the same variation period the time delay of area characteristics is different. After the precipitation extreme the evaporation reach its extreme value the first. The extremes of absorbed solar radiation, water storage of soil and run-off appear some time later. The heat storage extreme of opposite phase is the last.

HS02b/10P/D-012 Poster 1630-132

MODELING WATER QUALITY BY USING NEURAL NETWORKS

Jian-Ping SUEN, Wayland J. EHEART (Department of Civil and Environmental Engineering, University of Illinois at Urbana-Champaign)

In this study, artificial neural networks (ANNs), are applied to estimating the nitrate concentration in a typical Midwestern river, i.e., the Sangamon River in Illinois. In Illinois, and throughout the Midwestern US, nitrate has recently become an increasingly important problem in drinking water quality. This is due to a somewhat recent change in the EPA nitrate standard and to the increasingly widespread use of chemical fertilizers in agriculture. Two ANNs, Back Propagation Neural Networks (BPNN) and Radial Basis Function Neural Networks (RBFNN), were compared with regard to their effectiveness in water quality modeling. BPNN uses a gradient descent method, modifying the weight by simulation errors to construct the neural network. RBFNN uses a fuzzy min-max network to do the first clustering part and multivariate regression method to construct the neural network. RBFNN is much faster than traditional BPNN and the results of RBFNN also appear to be more robust. The study compared these two types of ANNs to traditional regression and traditional mechanistic water quality modeling. Comparisons were based on overall accuracy and on the frequency of false-negative prediction, i.e., the frequency with which the model would predict the nitrate concentration to be below the standard when it actually exceeded it. The study showed that the RBFNN achieved the best results of all models in terms of overall accuracy, and both BPNN and RBFNN had the same false-negative frequency which has better than traditional models.

TIME SCALE ANALYSIS FOR INVESTIGATING STATIONARITY OF HYDROLOGIC TIME SERIES

A. Ramachandra RAO[1] ([1]School of Civil Engineering, Purdue University, [2]Irrigation and Hydraulic Department, Faculty of Engineering, Cairo University)

To overcome the difficulties encountered in conventional spectral anaylsis, a different approach known as Wavelet analysis has been introduced during the past 10 years (Daubechies, 1992; Combes et al., 1990; Mallat, 1996; Meyer, 1993; Strang and Nguyen, 1996; Chui, 1992). In Wavelet analysis, a different type of basis functions, called Wavelets, are used. Wavelets, as opposed to sine and cosine functions, have a limited extent in time (a limited support), and are therefore localized in time as well as in frequency. In the theory of Wavelet transforms, the notion of ´frequency´ is changed to an equivalent one of ´scale´, where large scales correspond to low frequencies and small scales correspond to high frequencies. Wavelet analysis provides a technique for analyzing the structure of a time series by using variable size windows. In effect, by using the Wavelet transform the signal is decomposed into components of different scales. This offers a method for a local examination of the signal, a multi-scale outlook, and a time-scale analysis (Misiti et al., 1996). Wavelet analysis can be used as a tool for performing a wide range of tasks which include: detecting discontinuities in signals, detecting long-term evolution (trends), detecting self similarity (fractal signals), identifying pure frequencies (time-frequency analysis), suppression, and compression of signals. Wavelet analysis is used in this paper to investigate the stationarity of hydrologic and climatic time series as well as tree-ring series. Annual rainfall, runoff and temperature series from the Midwestern United States are used in the study. The results indicate the nonstationarities in these time series, thereby demonstrating the use of wavelets in the study of climatic variation. The time-scale structures in these time series are studied and the relationships between them are investigated. Also, Wavelet analysis is used for assessing similarities between different time series at different scales in the region under study. References Chui, C.K. 1992 An Introduction to Wavelets. THE RELATION BETWEEN δ18O IN MONSOONAL PRECIPITATION AND AIR-SEA ACTIVITY, ASTRONOMICAL AND METEOROLOGICAL FACTORS

Hongxi PANG, Yuanqing HE (Lab ice core, Cold and Arid Regions environmental and Engineering Research Institute, Chinses Academy Sciences)

The variations of isotopic content are different, with different locations and climatic types. The isotopic contents in precipitation vary complicatedly over monsoon regions in mid-latitude zones. The isotopic data in precipitation at New Delhi (the IAEA/WMO station; 28.58ºN,77.2ºE), located in southwest monsoon region, are analyzed, suggested that the δ18O values vary in 11 years cycle, which is closely agreed with that of sunspot; the strong correlation between δ18O and T/P ,a parameter by coupled temperature and rainfall; the remote positive correlation between δ18O and ENSO event induced by the interactions of coupled air-sea systems in tropical Indian Ocean and Pacific Ocean; and rainy drops evaporated is the key reason to lead the positive correlation between δ18O and zonal wind velocity at the height of 500mb while the amount and temperature effect strengthen this correlation.

SCALES OF HYDROLOGICAL CHANGES IN VOLGA RIVER BASIN POSSIBLE AT CLIMATE CHANGES

Alexander GEORGIADI (Department of Hydrology, Institute of Geography, RAS)

Three main approaches for model using as tool for assessments of possible hydrological regime changes which differ from each other by type of model are developed. One of them is based on physically based water cycle models (including SVAT models) that are used for small site or rather small watershed (Georgiadi, Nazarov, 1997; Kashutina, 1999 and others). Simplified monthly water budget models that could be used for wide diapason of spatial scale (Georgiadi, Milyukova, 2001). Mean annual river runoff could be estimated on the basis of rather simple relationships between water budget components and climatic elements (Belyaev, Georgiadi, 1989, 1992; Georgiadi, 1991, 1993; Velichko et al., 1992; Georgiadi, Jai-Ho Oh, Yong Hee Lee, 2000). The paper presents the assessments of possible changes of spring flood and annual river runoff changes as well as changes of intraanual distribution of river runoff in Volga river basin (to Volgograd) at the Holocene Optimum (6 thou. years before present) as well as at a doubling of atmospheric CO₂. The data of experiments on a global climate model of Moscow State University (Kislov, 1992) and Geophysical Fluid Dynamics Laboratory (GFDL), Prenceton University, USA were used as the scenario of climate change. The hydrological changes are determined on the basis of original model of monthly water balance. In the present work the model of formation of a monthly water balance for plain watersheds, allowing to estimate influence such important hydrological factors as potential evaporation, snow cover accumulation and snow melting, infiltration of water into the ground and its deep infiltration, soil moisture reserve change. The model allows to compute dynamics of runoff losses. This model could be used for calculate of rain and snow melting flow. The conditions of river runoff formation at various sites of watershed are non-uniform, at the same time there is a limited enough information on the snow hydrophysical characteristics, and as the rather rough estimations of some other characteristics of watersheds. Therefore for identification of some parameters of model the method of optimization was used. The calculations of a monthly river runoff for main part of Volga watershed for grid cells 1ºx1º were made. The following monthly average long-term data were used: precipitation, air temperature, soil moisture reserve at field capacity, river runoff. All calculations were made for monthly time steps, but were used approach based on using so called quasi-daily calculations.

THE DECREASE OF THE PRECIPITATION IN PERIODS OF THE YEAR AS A SIGN OF CLIMATIC CHANGE: CASES STUDIED IN PORTUGAL

Maria Manuela PORTELA, Antonio de Carvalho QUINTELA (Instituto Superior Tecnico (IST))

A more irregular distribution of the precipitation within the year and a significant reduction of its amounts during some periods of the year are generally pointed out as consequences of the climatic change that seems to occur in Portugal. To be considered a sign of climatic change, the previous reduction must correspond to an increasing tendency persisting along the years. In order to detect variations having a persistent nature in temporal series of precipitation in Portugal, two procedures were applied: the classic method of moving averages and a procedure, expressly developed within the scope of the study that originated this article, based on a statistical comparison of the precipitation averages during certain intervals of time in which the recording periods were divided. The applications carried out for precipitation series in eleven gauging stations in Portugal denote that the amount of rain during the 2nd quarter of the hydrologic year (from January to March), and specially in March, is clearly decreasing.

CLIMATE CHANGE, GLACIER MASS BALANCE AND WATER RESOURCES

David N. COLLINS, Oliver G. MACDONALD (School of Environment & Life Sciences, University of Salford)

Disproportionately large contributions of runoff arise from the portions of catchments overlying the high mountain areas of the world, as a result of the orographic increase of precipitation with elevation. At present, high specific discharges from glacierised high mountains are also generally enhanced by destocking of ice from the many thousands of often small glaciers which characterise ranges such as the western cordillera of the Americas, the Alps, and the Himalaya. River flows have often doubled, between the cool 1970s and warm 1990s, reflecting in the Alps, for example, summer air temperature increases of about 2°C over the same period. However, enhanced river flows can not go on for ever. As warming continues, glacier mass loss and diminishing glacierised partial areas of catchments will ultimately result in reduction of annual total discharge with greater variability from year to year. Glaciers will become reduced in size in most areas over a timescale of 20 – 50 years. Warmer air temperatures will result in the freezing level rising in the atmosphere so that where snow formerly fell precipitation will occur as rain. Winter snow pack will probably decline and snow cover duration shorten. Heavy rainfall whilst the transient snowline stood at high elevation resulted in severe summer flood events in the Alps and the Karakoram in the warm 1990s. Daily integration of air temperature and precipitation

from results of the HadCM3Gga1 experiment for 2.5 latitude x 3.75 longitude degree grid square resolution are coupled with standardised glacierised basins, downscaled through derivation of statistical relationships between regional climate (NCEP/NCAR reanalysis project), and actual glaciologically-relevant meteorological observations obtained at mountain stations. In the short term, warming increases flow, but coupled with deglaciation, greatly reduced flows will have serious consequences for water resources, particularly where mountain runoff drains to neighbouring arid lowlands.

THE HIGHEST ALTITUTE ICE CORES IN THE HIMALAYAS RECORD ANTHROPOGENIC POLLUTION

Tandong YAO[1], Keqin DUAN[2], Shucheng XIE[2], Wenmian HUO[2], Lide TIAN[2] ([1]Prof., [2]Dr.)

High resolution, well-dated ice core records, especially low-latitude ice cores near the populated regions provide a unique tool to study and to evaluate the impact of anthropogenic activities on environment and climate. Recently ice cores were recovered at an altitude of 7200m on the Dasuopu Glacier located in the Xixiabangma Mountain. The high elevation of the coring site provides very good background to detect any anthropogenic pollution. Organic and inorganic methods are applied to the Dasuopu ice core analyses. The analyses detected petroleum residues from the ice core. Our study has concluded that the material is from the oil combustion in Kuwait and vehicle pollution in India. The measured lead concentration ranges from 16×10-12g/g to 161.7×10-12g/g. Lead concentration increases significantly since the 1940s. A very dramatic rise happened in the 1980s in which the mean lead concentration reached to 161.7×10-12g/g. The organic and inorganic analyses indicated that the anthropogenic pollution has already impacted the environment at 7200m a.s.l. in the Himalayas.

ATMOSPHERIC METHANE OVER THE PAST 1000 YEARS FROM A SUB-TROPICAL ICE CORE

Baiqing XU[1], Tandong YAO[2], Jerome CHAPPELLAZ[2], Lonie THOMPSON[2], Ninglian WANG[2], Lide TIAN[1] ([1]Dr., [2]Prf.)

A high-resolution methane record from an ice core recovered above 7200m of altitude on the Dasuopu Glacier in the Himalayas, reveals similar trend of methane concentration fluctuations with the polar region records. The highdegree of detail of the Dasuopu record over the last century allows revealing a significant period between the two World Wars when the anthropogenic methane increase was put to a halt. This sub-tropical methanerecord also allows quantifying for the first time the difference of methanemixing ratio between polar and sub-tropical latitudes during pre-industrialtime. The average difference is 120 ppbv with Greenland and 160 ppbv with Antarctica. The record suggests that the tropical latitudes might represent large percent of the global methane sources in pre-industrial time. In addition, the temporal fluctuation of the pre-industrial methane records suggests that Monsoon evolution incorporated with high methane input in the south Asia might be responsible for the relatively high methaneconcentration observed in the Dasuopu ice core around 1700 AD.

ICE TEMPERATURE VARIATION IN PUROUGANRI ICE FIELD ON THE TIBETANPLATEAU

Jianchen PU[1], Tandong YAO[1], Ninglian WANG[2], Keqin DUAN[2], Lide TIAN[2] ([1]Prof., [2]Dr.)

Puruogangri ice field is located in the middle of the Tibetan Plateau, with a total area of 422.58km2. Four ice cores with a depth of 154m, 118m, 80m and 20m respectively. The ice temperature was measured in the 4 holes using resistance thermometer. The ice temperature shows same trend in the 4 holes. The ice temperature in the above 2m is intensively influenced by cold wave from the ice surface. Under that the ice temperature curve shows a warm-season type. The lowest ice temperature is -9.9° measured at 12m depth. The ice temperature increase downwards in a linear manner under 12m, but the increasing ratio is lower than the decreasing ratio in the upper 12m. During the observation, the ice temperature decreased obviously in the upper 4m of the ice hole, and the decrease is vanished downwards. In the 80m ice hole, the ice temperature decreased 0.62° from 18:50 of October 18 to 14:40 of October 21, which a daily average of 0.2°. The ice temperature decreased 1.15° in the same period, with a daily average of 0.3°. There was no obvious variation in 12m depth.

THE INFLUENCE OF THE SNOW COVER AND CLIMATE INTERSECTION TO EXTRMILY HYDROLOGICAL SITUATIONS IN THE SNBMPUNTANE ZONE (NORTH SLOPE OS CAUCASUS AS AXAMPLE)

Lev M. KITAEV (Department of climatology, Institute of Geography RAS)

The data bases of the snow thickness for the period 1966-1990 are compiled. In these bases 41 stations over the Great Caucasus ranges and 636 stations over the East European plain are included. The average snow thickness for the winter period (snowiness) is calculated. Their interannual changes in different regions in relation to atmosphere circulation are investigation. The coefficient of variation for the averaged values for all the plain and for all mountain stations is of the order 30%. For the single Caucasian stations with the high snowiness the coefficient of variation is about 30-45%, the maximum deviation is about 90%. For the single stations with the low snowiness the coefficient of variation is about 90-100% with 3-5 times maximum deviation. Over the East European plain with North Caucasian plain the snowiness was low over the period 1966-1977 and high over the period 1978-1990. The zonal circulation prevailed in the first and the meridional one in the second period. The snowiness trend in 1966-1990 was positive. Cases of the high and low snowiness alternated incoherently over Grate Caucasus. The significant trend is absent. That is the result of different circulation factors of snow accumulation in dependence on the topography. In the high snowiness years over the Great Caucasus the frequency of the southern lows or the blocking high over the East European plain is above the average. During the blocking highs the western lows are concentrated the high southern periphery. In the half of years the anomalies signs for Caucasus and the plains are opposite. This has to lead to the mutual compensation of melted run-off anomalies related to mountain and plash parts of the North Caucasian river basins. Combinations of extremely interannual maximal and minimal annual snow depth of Caucasus and its north submontane zone were generated. The potential contribution of a snow cover of extreme years to a river drain is revealed.

RISK ASSESSMENT OF FLOOD CONTROL SYSTEM OF THE YANGTZE CENTERED ON THE THREE GORGES PROJECT

Shenglian GUO, Xiangrong TIAN, Caijun WANG, Honggang ZHANG, Pan LIU (Department.of Hydrology and Water Resources, Wuhan University)

The Three Gorges project (TGP) is the largest hydropower project in the world. TGP possesses huge comprehensive benefits, including flood control, power generation, navigation improvement, etc. Flood control is the key and also the essential one with the largest ecological and environmental benefits. TGP's construction commenced in 1994 and the first turbine will generate hydropower in 2003 May, and the whole project will be completed in 2008. Based on the characteristics of flood control system of the Yangtze River centered on Three Gorges Reservoir (TGR), one and two dimensional hydraulic flood routing models and multiple-input single output linear system models were proposed and developed by using numerical methods and modern system engineering principles. Four inter-basins, Shashi, Luoshan, Hankou and Dongting Lake, are selected for flood simulation case study. The models were applied to these inter-basins and the simulated flood hydrographs were compared with those depicted from observed data. The river network in the lake region and the river-lake relationship are considerable complicated and investigated in detail. The results were satisfactory with high model efficiencies and low relative errors. The model will provide technical support and service for flood forecasting and flood dispatch decision as well as risk analysis in this region. The results show that under the condition of the 1998 large flood, if TGR conducting the compensation operation for the Jingjiang area, the highest water level in the Shashi, Luoshan and Hankou hydrological stations would decrease 0.86m, 0.78m and 0.44m respectively. The risk herein means that under different frequency of designed flood of TGR, how much is the risk corresponding to the flood control system of the Yangtze basin after the upstream flood is regulated by TGR. The 1954 large flood (with flood diversion) and the 1998 large flood (without flood diversion) are chosen as prototype for this study. The risk of flood control system in the Yangtze basin is analyzed based on the TGR operation regulations and flood detention area management rules. It is shown that with 22.15 billion m³ of TGR regulating capacity and incorporating with embankment, flood diversion and other non-engineering measures, the bank failure along Jingjiang river reach due to heavy flood, which usually cause huge mortality and million's homeless, can be effectively avoided. It can also protect millions people in downstream plain from flood menace and the consequent ecological and environmental destruction. The irreplaceable function of TGR for flood control will greatly ensure the harmonized development of social economy in the middle and lower reaches of the Yangtze.

CROSS-CORRELATION ANALYSIS BY KENDALL'S τ BETWEEN CATEGORIZED SOI AND THE NONEXCEEDANCE PROBABILITY OF PRECIPITATION IN KOREA

Young-Hoon JIN, Akira KAWAMURA, Kenji JINNO (Institute of environmental systems, Kyushu University)

El Niño/Southern Oscillation (ENSO) has influenced on the hydrological variables on global scale, but the influence of ENSO is not so clear in middle to high latitude including Korea and Japan. Especially, the quantitative influence of ENSO is difficult to be revealed in this region. There are several researches to reveal the correlation between Southern Oscillation Index (SOI) and the hydrological variables in Korea. Moon (2001) applied Multi-channel Singular Spectral Analysis (M-SSA) to the precipitation in Korea for identifying the coherent space-time patterns of low frequency harmonic element between SOI and the precipitation. Shin (2002) revealed the significant influence of El Niño/ La Niña on the flood and drought in Korea, using the statistical robust cross-correlation analysis. Kawamura et al. (2000) succeeded to detect the direct and significant correlation between SOI and precipitation/temperature in Fukuoka, Japan by categorizing SOI into five groups according to their magnitudes. Therefore we used the categorized SOI for revealing the relationship with the monthly precipitation at Pusan, Mokpo, and Inchon in Korea. In the kind of study, the appropriate transformation of the hydrological variables is often critical to obtain better results. It is difficult to normalize the precipitation data in the present study area because there are some months with no precipitation (less than 0.1 mm), whereas the precipitation data in Fukuoka were easy to be normalized by cubic root transformation. So in the present study we uniquely applied the nonexceedance probability transformation instead of the usual ones such as logarithmic and power transformations. We also applied Kendall's correlation coefficient (τ) when carrying out the cross-correlation analysis as well as the usual Pearson's correlation coefficient (r). The Kendall's τ is a rank-based procedure and is therefore resistant to the effect of extreme values and to deviations from a linear relationship. Most of all, this correlation coefficient can be applied to the data whose distribution is non-normal and unknown. These properties of Kendall's τ are well suited for the data of the present study, because the used data cannot be easily transformed naturally, as mentioned earlier. The results from these approaches which used the nonexceedance probability and the Kendall's τ show that there are several significant correlations between the categorized SOI and precipitation in Korea. Especially, the correlation coefficients, which are significant at 1 % level in both Kendall's τ and Pearson's r, were detected only at Pusan station under the "Strong La Niña" category with lag time four months. The correlation coefficients in both Mokpo and Inchon stations were obtained only at the 5 % significance level for various lag times. From these results, we can infer that the influence of SOI on the precipitation in Korea is stronger at Pusan than at both Mokpo and Inchon stations, and that the stronger the La Niña event, the less the precipitation four months later in Pusan.

ASSESSMENT OF IMPACT OF URBANISATION ON STORMWATER RUNOFF

Rathnam Venkata ERVA, JAYAKUMAR V. K. (Lecturer)

Increasing problems in urban stormwater management consequent to urbanization has been realized and appreciated in many hydrologic studies. Stormwater drainage and management systems are designed and constructed to cope up withthe increase in runoff due to increased imperviousness of the land due to developmental activities. For the design of an adequate drainage system, it is essential to understand the changes in stormwater runoff quantity and quality with land use changes. Urbanisation usually results in increase in volume and velocity of runoff, produces larger peak, decrease in the time to peak, downstream flooding and increase in pollutant loadings. The principal effects of land use change have been discussed by Geiger et al (1987),ASCE (1996) and Dunne and Leopold (1978), Overton and Meadows (1976), Urbanos and Stahre (1993) and many others. Runoff estimation techniques include: hydrograph methods and peak discharge methods. Many applications allow use of the peak flow analysis and the procedures are much less time consuming than the complete hydrograph method. The objective of the present study is to investigate the impact of land use changes due to urbanisation onstormwater runoff in part of Hyderabad city, in southern part of India. Duringthe last 20 years, urbanisation has taken place at an alarmingly rapid rate in the Hyderabad city. Land use change maps and rainfall data for the period1980-2000 are available. Using the available data, increase in built-up

areaand impervious surface with the progression of urbanisation are estimated. Design storms of different return periods 2, 5, 10, 25, 50 and 100- years are developed. SCS (NRCS) curve numbers and runoff coefficients are estimated.The generated runoff from different design storm is computed using a welldocumented package, SMADA, as well as the rational method, as to study how runoff volume is increasing with increase in impervious area. It is observed from the studies that the rational method gave higher peaks for alldesign storms, while the SMADA, which uses SCS hydrograph method resulted in increased runoff duration. An assessment is also made of possible expansion of built-up area with increased urbanisation in future and consequent storm runoff volume is investigated.

USE OF PHYSICALLY BASED MODEL FOR FLOOD ESTIMATION IN SMALL CATCHMENTS IN A DATA SCARCE ENVIRONMENT

Jayakumar KANDATHIL VALAPPIL[1], Ramaseshan S.[2] ([1]Regional Engineering College, [2]Indian Institute of Technology)

Estimates of flood are required for the design and economic appraisal of a variety of engineering works. When adequate and appropriate data area available for the basin, conventional methods like frequency analysis or use of unit hydrographs and other rainfall-runoff procedures may be applied to model the basin system. When this is combined with the design storm, the design flood may be derived. Data available for small catchments are generally inadequate for these approaches. Empirical approaches may be used to model such small catchments.Since generally adequate data are available for estimating design storms, it seems worthwhile to derive relationships between storm rainfall and runoff. The parameters of the model may then be related to the characteristics of the storm and physiographic features of the watershed to yield regional relationship between storms and floods. But a more realistic and alternate approach is to model the catchment runoff process according to physical principles. Information regarding physiography, soils, vegetation and drainage pattern of the catchment is used in the physically based models. The catchment is decomposed into a network of channels and overland flow segments. Using the physical characteristics of each component and appropriate hydraulic equations, the hydrologic processes are simulated using the distributed parameter model. Necessary values of the coefficients and constants are specified from physical characteristics of the watershed or are obtained from calibration of the model with observed data. The study reported is essentially a regional case study of flood estimation in small catchments in a part of North Brahmaputra basin, in the north-eastern part of India. The scope of the study is to apply, in a data scarce environment, a physically based model, DRRRM and to study the regional variation, if any, of the parameter of the model and also to judge the validity for flood estimation. Data regarding catchment plan, cross section at the bridge sites and hourly rainfall and stage data for about 10 catchments in the region were available for the study for a very limited period of 3 to 4 years. The catchment area ranged from 7 km2 to 215 km2. After preliminary analysis of the data for errors, only seven basins were found to be suitable for analysis. The results of the study indicated that a constant parameter physically based model for small catchments in the region is realistic. The design flood estimated using this model compared favourably with other approaches reported in the literature. The study shows that because of the easy availability of, and competence with computers and software in field organizations, it seems preferable to adopt a distributed parameter model with relevant field data rather than using empirical statistical relationships of questionable reliability.

PHYSICALLY-BASED MODELS FOR FLOODS MODELLING IN THE MEDITERRANEAN AREA

Philippe GOURBESVILLE[1], Vncent GUNOT[2] ([1]University of Nice- Sophia Antipolis, [2]International Institute for Infrastructural Hydraulics and Environmental Engineering - IHE)

Extreme hydrological events are characterised by the scarcity of data (in terms of spatial and temporal frequency). This problem becomes more acute when it comes to modelling the response of large catchments with small concentration times due to particular morphology or .rainfall intensities. The classical approach to modelling, (that consists of trying of tuning the model parameters so as to bring the calculations as close as possible to the measurements) becomes highly questionable because it may turn out to be extremely harmful to the predictive power of the model. The present paper addresses uncertainty in modelling the flash flood of 05.11.1994 on the Var watershed (France, 2820 km2). This watershed, located in the French riviera, is characterised by steep slopes, narrow valleys and large topography curvatures, making the flow pattern extremely complex. Seven models of the catchment were built using the Mike She hydrological modelling system. These models have different structures, geometries, or parameter values. The analysis of the model results on the flash flood of 05.11.1994 leads to the following conclusion: - the physically based approach is efficient and the flood characteristics are well reproduced; - the main sources for uncertainty in model results are, by decreasing order of importance: (i) the model structure, i.e. the assumptions concerning the dominant phenomena and how they are modelled, (ii) the model geometry and (iii) the value of the model parameters. This shows that, for this particular case at least, it is much more important to have a good knowledge of the phenomena occurring on the catchment, as well as of the particular geometrical feature, than to try to calibrate the parameters of the model. On the contrary, blind calibration of the model may jeopardise its predictive capabilities.

HS02b/10P/D-027   Poster   1630-147

FLOOD FORECASTING & MANAGEMENT IN PAKISTAN

Shaukat A. AWAN (Pakistan Meteorological Department)

Floods in Pakistan are mainly caused by the heavy monsoon rains during the summer monsoon period from July to September. Meteorologically there are two situations which cause flood producing rains in the upper catchments of the rivers. The two meteorological situations in relations to different conditions of intensity and movement of low/depression may produce three categories of floods as described below. i) Meteorological Situation For Category-I Floods A situation when the seasonal low is a semi permanent weather system situated over south eastern Balochistan, south western Punjab, adjoining parts of Sindh get intensified (due to westerly wave) and causes the moisture from Arabian Sea to be brought up to upper catchments of Chenab and Jhelum rivers resulting in heavy downpour along windward slopes of mountain ranges due to orographic lifting of moist air mass. ii) Meteorological Situation for Category-II & Category-III Floods Second flood generating meteorological situation is linked with monsoon low/depression. Such monsoon systems originate in Bay of Bengal region and then move across India in general west/north westerly direction arrive over Rajasthan or any of adjoining states of India. After this monsoon depression may take any one of following three courses. a) Continue moving straight west causing heavy wide-spread rains over Sindh/Balochistan. However, no river flooding shall occur in this case. b) Recurve in the north east direction towards upper catchments of Sutlej, Ravi and Chenab rivers causing extremely heavy rainfall and consequently floods first across border in India and then (within hours) at Rim Stations in Pakistan. This is Category-II

flood situation. c) Continue moving in northerly direction (under the effect of a strong westerly over plains of Lahore/Gujranwala Divisions to finally end up over Rawalpindi/Hazara Divisions. Upper catchments of Chenab, Jhelum and Indus rivers come under its influence. Flood management process in Pakistan is multi-functional involving a number of different organizations. First step in the process is issuance of flood forecast/warning. This function has been assigned to Pakistan Meteorological Department (PMD) since basic cause of the floods in Pakistan is the rainfall which can be best predicted and monitored by PMD utilizing satellite cloud pictures and quantitative precipitation measurement radar data, in addition to the conventional weather forecasting facilities. For quantitative flood forecasting, hydrological data is obtained through Provincial Irrigation Department and WAPDA. WAPDA´s telemetric system is an important source of hydrological data for flood forecasting purposes. A most modern ´S-Band´ Doppler weather radar has recently been provided to PMD, while a new hydrometric data measurement and transmission system is being established by WAPDA. Furthermore, improved rainfall/runoff and flood routing models have been developed to provide more reliable and explicit flood information to flood prone population.

DETECTION ON RAINFALL VARIETY IN WESTERN TAIWAN

Pao Shan YU, Chia Wen SUNG, Tao Chang YANG (Department of Hydraulics & Ocean Engineering ,National Cheng Kung University)

Global climate change and its influence on water resource are the worldwide issues. This paper aims to investigate the variety of historical rainfall on Taiwan. This study on local climate change may provide the reference for climate change study on Asia region. As the area of Taiwan is too small, the GCM is not suitable for our investigation on climate change. Therefore, the statistical method of Mann-Whitney-Pettitt test was applied to detect the change points of annual rainfall depth in the historical records. Rainfall records from four meteorological stations of the Central Weather Bureau distributed over western Taiwan, including Taipei, Taichung, Tainan and Hengchunstations, were adopted as our data set which almost have one hundred years records.It is found that the change points at these four stations vary from 1956to 1968. As the rainfall during May and June is important for the reservoir operation in Taiwan and the annual maximum daily rainfall has extreme influenceson the rainfall design. Hence, the difference between rainfall characteristics, including the rainfall during May and June and annual maximum daily rainfall, before and after the change point for each station was investigated This work found that the rainfall during May and June, and annual maximum daily rainfall in Northern Taiwan have increase trend However, the rainfall characteristics in the Middle and Southern Taiwan have decrease trend For example, the 100-year return period maximum daily rainfall estimated by using Log-Person type III in Northern Taiwan increases around 17%. There are decrease round 20% in the Middleand Southern Taiwan.

HS02b/10P/D-029 Poster **1630-149**

THE INTEGRATED RISK ANALYSIS OF OVER-STANDARD FLOOD FOR FLOOD CONTROL SYSTEM

Xiang ZHANG[1], Xinyu WANG[2], Guowei LAI[3] ([1]Dept. of Hydrology and Water Resources, Wuhan University, [2]Institute of Planning and Design, Changjiang Water Resources Comission, [3]Dept. of Hydropower, Wuhan University)

The flood control system mainly consists of reservoir, levee and flood spreading area with a certain flood control standard. The natural flood is a stochastic event. No matter how high the flood control standard is, the probability that the flood exceeds the standard still exists. So the risk analysis for the over-standard flood is very important for the flood control planning and the construction of flood control system.The traditional flood risk analysis may mainly concern with the hydrological and/or hydraulic uncertainty. The engineering uncertainty, such as the reliability of dam and levee, is seldom considered combined with them. In fact, facing the over-standard flood, the reliability of dam and levee strongly influence the ability of flood control system resisting flood. So the integrated risk analysis, considering the hydrological and engineering risk, may provide more thoroughly the information about the ability of flood control system. For the hydrological risk analysis of over-standard flood, we apply the compound Poisson model. It is a kind of risk value model based on stochastic point process theory and is superior with the typical characteristic discussing the frequency problem in time domain. Its discharge threshold for the selection of sample can be very low, and the discharge or the flood peak exceeding the threshold may be selected as the samples. It has been used to study the annual over-standard flood risk of flood control system. The engineering risk is caused by the uncertainty factors that influence the safety of engineering structure, including the load and the mechanics characteristics of material. In this paper, we apply the reliability theory to evaluate the engineering structure safety. The methods for the engineering safety of gravity dam and earth bank are discussed respectively. In order to calculate the integrated risk rate, the hydrological and engineering risk are considered as compatible events. The Selective Probability is used to calculate the integrated risk rate of compatible events. The case study about the flood control system in the Lishui catchment is done. The objective of flood protection is to control that the designing flood of 50 year recurrence through the operation of flood control system is lower than the safety discharge of downstream channel at Sanjiangkou station, 12000m3/s. So we discuss the three different operating schemes by the hydrological risk analysis, and calculate the engineering safety of the three dams and levee in Lishui catchment. Through the integrated risk analysis, the optimal operating scheme and the weak link in the flood control system are suggested. The result illustrates that these methods are practical in integrated risk analysis of flood control system and the results of integrated risk analysis are useful in decision making for flood control planning.

LONG-TERM CHANGE IN DAILY RAINFALL CHARACTERISTICS AT OKAYAMA

Hidetaka CHIKAMORI, Akihiro NAGAI (Faculty of Environmental Science and Technology, Okayama University)

Rainfall characteristics is said to change in recent decades. It is said that rainfall has concentrated in the shorter duration than before so that occurrence of extreme hydrological events like floods and droughts have become more frequent and the disasters related to these events become more severe than before. The changes are attributed to global climate change like global warming and/or local environmental change like heat island effect.The purpose of this paper is to statistically clarify the long-term change in rainfall characteristics, that is, frequency distribution of rainfall depth, rainfall and no-rainfall duration and so on. A statistical analysis was performed for 100-year (1898-1997) daily rainfall record at Okayama Meteorological Observatory, Japan. In this analysis, we defined a storm as a succession of rainy days, and examined statistical characteristics of total rainfall and duration of a storm, storm inter-arrival time and interval between storms. The record was divided into two 50-year periods or three 33-year periods. In the two periods case, the period of 1898-1947 and that of 1948-1997 were named as I_{50} and II_{50} periods, respectively. In the three periods case, the period of 1899-1931, that of 1932-1964 and that of 1965-1997 were named as I_{33}, II_{33} and III_{33}

periods, respectively, where the record of 1897 was excluded for the analysis.First, we examined frequency distribution of annual maximum of a storm rainfall in each record period, and found that the storm rainfall with the equally probability is becoming larger year by year. Gumbel distribution was applied to each data of the record period, and the result shows, for example, that 100-year storm rainfall increases by 17 % in the period II_{33} and by 67 % in the period III_{33} comparing with that in the period I_{33}. Second, we examined frequency distribution of storm duration and found that the storm duration tends to decrease from year to year. Thus the more rainfall happens in the shorter duration so that average rainfall intensity in a storm tends to increase. Finally, we examined frequency distribution of interval between storms, and found that the interval tends to increase year by year. Gumbel distribution was applied to each data of the record period, and the result shows, for example, that 100-year interval between storms in the period III_{33} becomes five times larger than that in the period I_{33}. The results show the apparent change in frequency distribution of rainfall characteristics in recent decades. The change tends to shorten return period of the hydrologic design value such as design discharge or design rainfall of the water use or control plans designed before so that the risks of floods or those of droughts are both increasing. The fact suggest us necessity to reconsider magnitude of design floods and droughts for water resources planning and management.

HIDROLOGICAL REGIONALIZATION USING THE TCEV METHOD WITH THE SUPPORT OF A GEOGRAPHICAL INFORMATION SYSTEM

Cristiane M. FINZI, Iara Righi AMRAL, Bruno Rabelo VERSIANI (Centro de Pesquisas Hidraulicas e Recursos HúAricos - EHR - Escola de Engenharia - UFMG)

The analysis of a statistical model allows a better evaluation of the spatial variability of the hidro-climatological phenomena . The application of that model is called ˝ regionalization ˝. The paper focus the Two Component ExtremeValue, TCEV Model, (Rossi et al., 1984), which tries to describe the extreme values of a statistical series, as maximum precipitation an maximum flood data.The regionalization method based on this model allows to identify hidrological homogeneous regions in a watershed, in terms of maximum values of precipitation and flood.The determination of those regions allows to evaluate realistic estimates for the involved variables, concerning studies and projects of water resources management, in the state of Minas Gerais, Brazil, mainly in a watershed where there is a lack of data.Previous studies applied the method in the southern portion of the Sao Francisco watershed. In this paper one compares the results when more data are included extending the study region. The statistical characteristics of maximum precipitation and flood determine the homogeneous regions.. The methodology is developed in three stages: the first seeks the determination of the homogeneous regions according to the similarity of the coefficient of skewness and the second stage is the determination of sub regions where the coefficient of variation remains practically contant. The third stage is the determination of the index flood, based on the physical and climatic characteristics of the region. The results of the application of the methodology are the quantile estimates of the maximum values of precipitation and flood, specialy in some regions with lack of data.In this application, one determine three homogeneous concerning maximum flood and five regions concerning maximum precipitation. In some of those areas the statistical regional curve is similar to the Gumbel model. In this case the TCEV method could not be applied. This means that the samples used in the calibration of the regional statistical model don´t identify outliers values.

WATER RESOURCES SUSTAINABILITY IN THE CONTEXT OF CLIMATE VARIABILITY AND INCREASING EXTREME EVENTS IN THE HIMALAYAN-INDO-GANGETIC PLAINS

R. B. SINGH (Department of Geography, University of Delhi)

The Himalayan environment is subject to significant and uncertain changes. Variation in climatic conditions could result in large-scale changes in the Indo-Gangetic ecosystem. The Himalaya which is fragile and globally important ecosystem, is also known as the water towers of the earth surface and rich repositories of biological diversity. Variability in climatic conditions influence water resource sustainability of the plains. In the present paper an attempt has been made to analyse the impact of climatic variability and other mountain extremes particularly floods on the Indo-Gangetic plains. Paucity of observational data and analysis makes the study on mountain areas rather difficult. The issues of Himalayan - Indo-Gangetic plains interactions including the nature and quantities of materials transported from highland to valleys along with the dynamics of land use induced sediment erosion processes and floods attract particular attention at different temporal and spatial scales. The Indo-Gangetic plains include region of national significance in terms of dense and increasing human population. There exists very large and variable discharges of fresh water, suspended sediments and dissolved matter. The present pattern of flooding suggests that high productivity is no longer being sustained. Shrinking natural resource base (per capita availability of land/water devoted to agriculture) and declining quality of resources are increasing the risk to our ability to meet the basic needs of the growing population of the region. In addition a range of socio- economic factors emerging out of flood problems impact land use and the food security. Investments in irrigation development are unattractive and have declined. Competing uses for water would force shifts in crops/cropping pattern. Soil-characteristics as well as cropping system in the Indo-Gangetic plain region is largely uniform. There are, however, a number of variations within the region. There are 6 agro-ecological regions and 12 sub-regions. Irrigation facilities are available to the maximum extent in the north- west and minimum in the east. The size and distribution of the land holding varies from 3.6 hectares in the north-west to approx. 1 hectare in the Bengal Region. There are vast differences in actual and potential yields, earning from about 6-tons/hectare in the north-eastern region to as low as 2 tons/hectare in the east having frequent flood prone areas. Major sustainability issues require focus on the ecosystem functioning, agro-biodiversity (including soil biota), loss in soil fertility,   hazards, declining water table and rising water table / water logging etc. Managing floods in one region often co-exists with managing droughts in another region. The need for a comprehensive watershed based planning integrating land and water resources is urgently felt so as to monitor and manage the water resources of this region optimally. The strategy reflects a major conceptual shift towards risk reduction i.e. culture of prevention.

HS02b/10P/D-033 Poster **1630-153**

APPROACH FOR ASSESSMENT OF RISK AND CHANGES IN EXTREME HYDROLOGICAL CHARACTERISTICS

Helen (Elena) Vladislavovna LOBANOVA (IAHS member, Senior Scientist)

One of the main practical application of hydrology is connected with a frequency analysis of extreme hydrological events such as floods and droughts. New Federal normative documents in Russia (Construction Norms and Rules, Code of Rules) take into account two kind of safety and risk assessment: -for existing water projects under some period of operation, -for future water projects: The first direction condition by the following reasons: short-term records in the past, new effective methods of computations which have been

H

developed in last time, modern changes (climate change, man´s impacts). These peculiarities lead to a necessity of possible re-computation of design hydrological characteristics for the existing hydraulic constructions and other water projects to increase their safety. The algorithm of assessment and re-computation includes the following main steps: -extraction of the components in time series which connect with ˝natural˝ conditions and with ˝pure˝ impact of existing constructions on the runoff; -assessment of stability of working existing hydraulic constructions and other water projects (analysis of man´s activity component); -assessment of climate change in time series in ˝natural˝ conditions (extraction and analysis of modern long-term climate change component); -determination of design extreme values taking into account the last observation, new methods and changing conditions; -comparison of the determined design values with the same one, which have been obtained before the construction of this hydraulic structure and making the decision about the re-computation. Such scheme characterizes a monitoring of design hydrological characteristics for changing conditions. New methods have been developed for a realization of this algorithm and they are: -methods for extraction of runoff components connected with operation by existing hydraulic constructions and other kind of constructions and under different availability of the information; -methods for extraction of climate variability and long-term climate change components; -methods for assessment of statistical efficiency and contributions of climate change and water management; -assessment of empirical probability of non-regular extreme events such as floods and droughts taking into account historical information; -decision the problems of non-homogeneity of the extreme data by statistical criteria for testing of outlying data and application of the composition of distribution functions for non-homogeneous records; -methods for assessment of random errors of design hydrological events taking into account short-term period of the regular observations, palaeo-restorations and long-term period of future operation in changing conditions. Application of developed approach and methods have been given for some different examples: -re-computation of maximum design discharges for the cascade of the Dnieper hydropower stations; -re-computation of design maximum water level for the Lena River - Lensk city; -assessment of long-term operation of main hydropower stations in Russia for different hydrological characteristics (water resources, extremes, etc); -using of palaeo-restoration of annual runoff in more than 4000 years for assessment of climate changes and random errors of design values; -assessment of changes in low flow for different regions of Russia under climate change.

HS02b/10P/D-034 Poster **1630-154**

ASSESSMENT OF THE RISKS OF EXTREME RAINS OCCURENCE DEPENDING ON THEIR GENESIS

Ionel HAIDU (Dept.of Geography, Univ.of Cluj-Napoca)

Usually, in a study that has in view the rain falls that produce high floods, a single raw of maximum yearly values are to be analyzed, indifferently of the type from which those rains derive. It is to be appreciated that the rains with a maximum intensity are "covering", and there is no need to apply at diverse informative sources. This is a quantitative concept which refers only to the magnitude of the extremes (torrential rains, high floods) which would have unexpected hydrotechnical and social consequences. On the other hand, a qualitative approach, respectively the analysis of the extremes on genetic categories may reduce the uncertainties. It is possible that the set of the extremes (for instance, in the case of the rains with a yearly maximum intensity, but also in other cases) will lack the same statistical population as a source. Another example is given by the possible appearance in the observations raw of a value with an extraordinary magnitude, which is aberrant from a statistical point of view, and which must be removed by the analyst from the analyzed sample, in order to obtain ˝fair˝ adjustments. Thus, the historic maximum intensity of 8.5 mm/min registered at Borod station (west of Romania) that far exceeds the value of 2.77 mm/min, representing the average of those 28 years of observations, can not be explained by the statistics of extreme values. That's why it is useful to set up series of values on genetic categories, suspecting the possibility to find out many source-populations of the extremes. Besides the series of yearly maximum intensities, set up indifferent of the generating rain type (28 values), the succession of yearly maximum intensities produced by rains of thermic convection and the series of yearly maximum intensities produced by frontal rains, have been built. Were considered too, series having source couple of months: May-June typical of the most intense period of cyclonic activity and July-August specific for the most active period of thermic convection. For the length of the whole rainy season (April – September), in which the rains of thermic convection and the frontal rains can coexist, the monthly series of maximum intensities was also taken into consideration. While the frequency model of the series of yearly maximum values is, clearly, that of an exponential type, the genetic series are different. The maximum intensities generated by convective rains can be also adjusted through a lognormal model of 2 parameters though from the point of view of graphic correspondence, the best law is that of GEV type, on the theoretical curve being situated even the historical maximum of 8.5 mm/min. In the case of frontal rains, the candidate laws are Gumbel, Lognormal and exponential, and from those with 3 parameters, the GEV. The most adequate laws for the case of bimonthly and monthly series are also described. The paper approaches in its final part the possible genetic explanations of the extreme events, which can have different consequences as regards the high floods appearance.

ENVIRONMENTAL FLOW REQUIREMENTS IN WATER RESOURCE PLANNING AND OPERATION

Denis HUGHES (Institute for Water Research, Rhodes University)

Many rivers throughout the world are impacted by either upstream reservoirs, run-of-river abstractions or stream flow reduction activities, such as commercial afforestation. Against this background, the new South African Water Act of 1998 introduced the need to reserve a certain proportion of the natural flow regime of rivers to ensure in the long-term that all water resource developments are environmentally sustainable. A relatively simple model is described that has the following characteristics and benefits with respect to the determination of instream flow requirements.- The model is consistent with the current main South African approach to setting environmental flows (Building Block Methodology). - The

model is designed for use in gauged or ungauged basins.- The model can be used to support site specific determinations carried out by a group of freshwater ecology specialists, but can also be used to generate low confidence desktop estimates based on a set of regional parameters.- One of the outputs of the model is a time series of environmental flow requirements with the same length as the input natural time series of monthly flow volumes that is used to determine the patterns of variability in the requirements.-The model generates outputs that are consistent with the standard water resource system yield analysis models used in South Africa. It is therefore relatively straightforward to assess the degree to which the required environmental flows have an impact on system yields. It is also possible to assess the impact of system operating rules on river flows and whether environmental flow requirements will still be achieved.-The output from model can be used to assess the extent to which existing, or future, water use licences are likely to impact on environmental sustainability. A further simple procedure has been developed to be able to analyse such impacts in relatively small river basins which do not have major dam storage and where the application of a complex system yield model would be inappropriate.-The model is also designed to provide outputs that can be used in the operation of water resource schemes, although there are still a number of issues that have to be addressed before this can be considered a practical proposition.The paper will briefly describe the basis of the model, the origin of the regional parameters, explain its use under different situations and how it is associated with other standard methods of water resource management analysis in South Africa. The role that the model is currently playing in enabling the implementation of the environmental components of the new Water Act will also be discussed. The paper will also discuss possibleways in which new information on streamflow-biota relationships can be used to improve the confidence in the model results.

INTEGRATED WATER RESOURCES MANAGEMENT UNDER COMPLEX HYDRO-POLITICAL CONDITIONS- THE PALESTINIAN CASE STUDY

Ayman Ismail RABI, Natasha Goerge CARMI, Abdellatif KHALED (Palestinian Hydrology Group)

Integrated water resources management in the Jordan River Basin is hindered by the complex hydro-political situation, which is characterized by natural water scarcity, shared nature of water resources, conflicting demands, and intensive development and use of resources. In addition, the lack of final water agreements defining the exact shares, roles and responsibilities of each riparian, especially the Palestinians, coupled with the lack of water laws, regulations and plans make it difficult to manage these resources efficiently, especially under the given uncertainties. The foremost significant uncertainty is the one related to climate change in general and to drought in particular. Changes in climate over the years have assisted in aggravating problems in water quantity and quality. Given that the region is characterized by a high variability in rainfall depth over time and space, the occurrence of a drought event is a random variable. The analysis of drought years over the past 50 years shows non-uniform return periods. In 1998/99, the rainfall record in the winter was the minimum in the past 100 yearlong history of rainfall records. This drought has led to a rise in the salinity & chloride concentration. In addition, there has been a decline in groundwater levels, a reduction in groundwater storage, an increase in the volume of water pumped, and a drop in the discharge of springs. Accordingly, water shortage has become very acute and available supply falls short in meeting demand. Under the foreseeable future scenarios of population growth and development needs, this water shortage is expected to intensify. The average population growth rate is estimated at 4% which, means that the population is expected to double in the coming two decades. In addition, nearly 50% of the population is young; i.e., new housing units and other infrastructure development will be needed to accommodate the growing needs. This paper will define, based on a case study, the various drought phenomena that play a major role in planning for the management of droughts and/or other uncertainties in a semi-arid environment. Furthermore, it will address the most crucial yet delegate water supply and demand issues under various development scenarios. In addition, the paper will highlight the role of ecosystem services in adopting the concept of resource sustainability while trying to meet the water use requirements of the various adverse uses. Finally, the paper will look into the foreseeable urban development and its likely impact on resource availability, both in terms of water quantity and quality.

RESTORATION OF URBAN WATER CYCLE WITH URBAN RENEWAL

Srikantha HERATH[1], Katumi MUSIAKE[2], Sadayuki HIRONAKA[2] ([1]Institute of Industrial Science, University of Tokyo, [2]Institute of Industrial Science, The University of Tokyo)

Urban water cycle consists of natural water cycle components such as rainfall runoff processes, evapotranspiration, infiltration and subsurface processes as well as discharge components arising from human water use such as water supply and irrigation. In addition to complex interactions among these components, the urban water cycle is deeply influenced by the human intervention, especially the alteration of infiltration, evaporation and runoff processes associated with urbanization. The authors have clarified these complex interactions and quantified the urban water cycle through distributed hydrological modeling in a well-equipped urban catchment located in the suburbs of Tokyo, Japan, which has high-resolution spatial and temporal data accumulated for more than a decade. One of the major adverse effects of urbanization has been the increase of impervious areas that has resulted in an increase of flood runoff, both in volume and peak discharge, and the associated reduction of ground water recharge that leads to reduced river low flows deteriorating amenity functions and water quality. In order to restore the urban water cycle, artificial infiltration through infiltration facilities has been proposed, where infiltration trenches and collection boxes installed at residential areas collect rainwater and let it infiltrate recharging the ground water. During the past few years, a water cycle management committee has been set up in the study catchment with the participation of various stakeholders to improve the urban water cycle. One of the measures adopted has been to install infiltration systems systematically in all residential housing complexes within the catchment. A study has been carried out where a distributed hydrological model has been set up for the catchment at 50m spatial resolution coupled to a grid level infiltration facility modeling system. Long-term scenario analysis has been carried out for installation of infiltration systems covering 1%, 2% and 4% of dense urban areas, simulating hydrological processes at 1-hour time step resolution for a number of years. The results show that total runoff volume reductions of 63%, 54% and 47% can be achieved for a 5 yr return period rainfall, while improvements of .5 mm per day of low flow quantities can be expected from the infiltration system implementation. Next, installation of infiltration systems with urban renewal is considered. The Urban Development Corporation of Japan manages most residential housing schemes in the catchment where houses are replaced every 30 years whereas other residential and infrastructure too have a similar renewal practice. With the detailed information of the expected urban land cover changes and the urban renewal plans, it was possible to map the urban renewal and infiltration facilities installation options that gives a clear picture of the state of urban water environment and its restoration potential.

HS02/11A/C24-004   0915

METHOD OF SATELLITE MONITORING OF RESERVOIR STORAGES FOR EFFICIENT REGIONAL WATER MANAGEMENT

Jun MAGOME[1], Hiroshi ISHIDAIRA[2], Kuniyoshi TAKEUCHI[2] ([1]Graduate Student, Yamanashi University, [2]Graduate School of Engineering, Yamanashi University)

More than 41,413 dams over the height of 15m are now in operation in the world serving for various important purposes in their region. Their efficient use, especially a group of reservoirs integrated in a region, is the most important subject in integrated water resources management. It necessitates the regional monitoring of water storage in reservoirs, especially its seasonal variation for strategic risk management. Since the ground observations of reservoir storages are often not available to the users due to lack of proper information transmission network as well as, in some cases, administrative barriers, it is desirable to develop technology to monitor water storage by the use of satellite remote sensing technique. In this study, we propose a new method of estimating water storage in reservoirs based on satellite observations and digitized topographical data. In the method proposed, the area of water surface (A) measured from satellite images is transformed into the volume of water storage (V) by using the relationship between the area of water surface (A) and the volume of water storage (V) (called as ˝A-V relation˝) derived from Digital Elevation Model (DEM). Other method which combines the area of water surface (A) measured from satellite images and water level derived from satellite radar altimeter is also shown. In order to identify the area of water surface of reservoirs (A), the satellites and sensors used are : JERS-1/SAR, SPOT/HRV, ADEOS/AVNIR. The radar altimeter system mounted on TOPEX/POSEIDON was used for deriving water revel.These methods are applied to the Yagisawa-reservoir in Japan and Volta Lake of Akosombo dam in Ghana to verify the possibility of estimating the water storage in reservoirs The derived average accuracy based on satellite images and DEM for Yagisawa-reservoir was , in terms of percentage error, 8.3% (SPOT/HRV and ADEOS/AVNIR : semi-automated), 8.2%(JERS-1/SAR : image reading) and 19.7 % (JERS-1/SAR : semi-automated) as against observations at dam site. As for Volta Lake, since observations at dam site was not obtained, annual variation of water storage in reservoirs calculated from long term discharge data was used for verification. As a result, accuracy of both methods was relatively good. Consequently, the high potential of estimating reservoir storage from satellite and its use for regional water management were demonstrated.

HS02/11A/C24-005   0930

INTERMITTENT UTILIZATION OF WATER RESOURCES IN AN OASIS REGION FOR THE LAST 2000 YEARS

Masayoshi NAKAWO (Research Institute for Humanity and Nature)

A decrease in water resources has become a serious problem lately in the Heihe River basin, an oasis region, in western China. In the downstream region, in particular, groundwater level has decreased and the local ecosystem has become poorer and poorer. Lakes formed at the termini of the river have dried up and disappeared already. The local people, who are mainly living on nomadic activities, are facing to a water scarcity even for their drinking water, and to difficulties in keeping their animals. It was pointed out that the decrease of water resources is caused by an overuse of the river water upstream where agricultural development has become intense with irrigation systems in these days. Looking back the history of the region, however, we can find similar situations in the last 2000 years. In the Han Dynasty, many solders were sent by the government as colonial troops to this basin, and a vast area was cultivated through an introduction of irrigation systems, in order to fight against the Hunnu, a powerful nomadic people at that time. This seems to have taken place in the Tang Dynasty as well, but with smaller scale, which could have been stressed by the Toqquz Oghuz Empire. The empire, however, has collapsed suddenly, and many historians blamed a climate change for the collapse. In the era of the Xixia and Yuan Dynasties, nomadic troops have occupied the region, and an 'interdependent society appears to have been established, when the famous Heicheng City was in prosperity. The population in the region has drastically decreased during the Ming Dynasty, but again increased dramatically during the Qing Dynasty indicating that water utilization for agriculture must have increased extremely in this era. The water demand in the region has been evolved intermittently as mentioned above, in accordance with the evolution of the society such as changes of ruling government. During the last 2000 years, however, climate has also changed significantly, which would have affected the society of the region. The sudden collapse of the Toqquz Oghuz Empire can be one of the examples. For considering the environmental problems taking place now, it is necessary to examine both the natural changes and the changes in the society, and their interaction. We would be able to obtain a clue for solving the recent problems by examining what happened in the history.

HS02/11A/C24-006   0945

EFFECTS OF CLIMATE CHANGE ON IRRIGATION ACTIVITIES: A CASE STUDY OF BENIN-OWENA RIVER BASIN IRRIGATION PROJECTS

Catherine Imhangulaya IKHILE[1], George Ubuihoro IKHILE[2] ([1]Department of Geography and Regional Planning, [2]Scripture Union (Nigeria))

This study examines the effects of climate change on irrigation activities in Edo State under the Benin-Owena River Basin Irrigation project in SW Nigeria. Data was collected for Benin City on rainfall and temperature from 1960-2000 and on irrigation activities from 1990-2000. Results show that the annual rainfall pattern for Benin City showed a wide variation between 1960-1980. For example, in 1965, an annual total rainfall figure of 3000mm was recorded as against a figure of 1702.9mm in 1972, the highest monthly reading being in July 1965 (about 1000mm). The variation in rainfall between 1980-2000 is fairly less varied but generally much lower. The lowest annual total rainfall figure of 1227.6mm was recorded in 1986 as against the highest figure re corded in these decades which was 2773.8mm in 1992. The period, 1982-1986, showed the greatest downward trend in annual rainfall totals. There was a significant relationship between mean annual rainfall and temperature in this period at 0.01. The temperature conditions for the period is as shown below Decade Mean Max range (°C) Mean mini range (°C) Mean Annual range (°C) Decadal range (°C) The annual mean rose steadily from 1960 to 2000. During the 1960-1970 decade, it was 25.8°C to 27.0°C (decadal range: 1.2°C). During the 1971-1980 decade, it was 26.3°C to 27.5°C (decadal range: 1.2°C). During the 1981-1990 decade, it was 27.1°C to 27.6°C (decadal range: 0.5°C). In this decade, the climate of Nigeria was described as playing a climatic drama (Ojo, 1987). There were lots of fluctuations and the weather became more unpredictable. The farmers were a lot more confused and uncertain about their crops performance. The last decade, 1991-2000, has been the warmest with annual mean temperature ranging from 27.2°C to 28.2°C (decadal range: 1.0°C). The temperature appears to be on the increase in Edo State coupled with fluctuating rainfall. This is an indication of global warming and climate change. There is a significant relationship between mean annual rainfall and temperature in the study period at 0.01. This shows a gradual warming up of the environment from 1960-2000. The mean annual temperature rose steadily. This is an indication of global warming. These observed patterns of variation in rainfall and temperature

coupled with increasing population and other factors caused the farmers and policy makers in Nigeria to embark on massive irrigation programmes in Nigeria.From the analysis of irrigation projects in Edo State, it is observed that at the onset of the irrigation schemes in the 1990s, only a few projects were in operation. The total available irrigable land area was about 500 hectares and they were mostly small scale. By the year 2000, more irrigation projects had been embarked upon and the total land area involved was about 6295 hectares. Most of the former schemes have been upgraded to medium and large-scale schemes.

HS02/11A/C24-007   1000

IMPACT OF GURARA RIVER (NIGERIA) INTERBASIN WATER TRANSFER SCHEME ON RIVER KADUNA AT SHIRORO DAM

Onemayin David JIMOH, O. S. AYODEJI (Civil Engineering Department, Federal University of Technology)

River Kaduna is impounded at Shiroro for the purpose of generating electricity only. There is a persistent low reservoir level between November and June due to seasonal flow in the river. One of the aims of the Gurara River interbasin water transfer scheme is to transfer 1500 Mcu.m (which is about 10% of the mean annual inflow to Shroro reservoir) of water from Gurara River between December and May to Shiroro reservoir. The interbasin water transfer is meant to stabilize the reservoir level at Shiroro dam. This paper examines the effect of the water transfer on the storage level at Shiroro. Fourteen years of daily inflow record was used to study the real-time operation of the reservoir. It was observed that the reservoir attained its maximum operating level in July and maintained it till September or October due to the transfer. Whereas, maximum operating level would have been attained in August without the transfer into the reservoir. Although the interbasin water transfer into Shiroro reservoir will enhance power generation, but there will be an increase in the frequency and severity of annual flooding of the downstream sector of the dam. Appropriate flood damage mitigation measures are recommended for Kaduna River basin, so as to optimize the benefit of the interbasin water transfer scheme.

MAXIMUM OVERLAND FLOW IN RIVER BASIN AND LANDUSE

Elena ASABINA (Russian Research Institute for Intergrated Water Management and Protection)

Present paper is the case of study of the basin where water resources for large city water supply are being formed. High economical activity in the basin transforms environment. Change of landuse structure such as transformation of forests into farmlands, meadows into pasture lands, bogs into meadows, etc. leads to changing of overland flow which presents the main component of river runoff. Solved problem is to assess how the values of overland flow depend on character of landscape. To prevent negative consequences of these processes for runoff regime it needed to reveal the areas in the basin where main quantities of overland flow are to be generated and to protect them against possible landuse. Values of precipitation were almost equaled in different areas of studied basin. However, significant differentiation of overland flow in the space of the basin was found that is explained by differences of overland flow genesis such as characteristics of land surface. Character of landscape and soil type cause different conditions in the basin. Each of landscapes in combination with topography and soil can be considered as certain runoff-producing unit, which characteristic is uniform conditions of overland flow genesis. Hence, the river basin as a whole and its different areas were represented by combination of various runoff-producing units and overland flow was evaluated in different areas of the basin. Also, overland flow was assessed for different phases of hydrological regime such as winter low water, spring flood, and summer low water with rain floods. It was found that main amount of overland flow is being formed during spring flood and in upstream but not in downstream part of the basin as it was thought earlier. Obtained conclusion will allow providing optimal landuse practice in future.

ARTIFICIAL NEURAL NETWORK MODELING OF THE RAINFALL-RUNOFF EXTREME EVENTS

Dionysia PANAGOULIA, Nikos MARATOS (Department of Water Resources, Hydraulics and Maritime Engineering, National Technical Univercity of Athens)

An artificial neural network (ANN) is a reliable mathematical mechanism in modeling the complex nonlinear relationships between input and output timeseries. ANN models have been proven effective and efficient to model the rainfall-runoff relationship in situations where explicit features of the internal hydrological subprocesses are difficult to be described using physically based equations. A new algorithm using a combination of linear least squares and multistart simplex optimization is developed to show the mechanism and parameters of three-layer feed forward ANN models and the potential of such models for simulating and forecasting the high-and low-flow events over a mountainous catchment. The output "rain plus melt" from the snow accumulation and ablation model of the US National Weather Service (US NWS) applied on a medium-sized mountainous catchment. The Mesochora catchment in Central Greece was used as input to ANN model. The conceptual soil moisture accounting model (SMA) of the US NWS applied, as well, over the same catchment, for comparison of extreme values. The RMSE (root mean square error) and %VE (percent volume error) statistics, for each model, computed separately for flows above and below the 15-year meandaily flow and presented as a function of the total annual flow for eachdata year. Note that the five calibration years were the driest of the 15 data years. Clearly, RMSEA (root mean square error above-mean daily flow) performance of the SMA model is worse than that of ANN on all years. The results of the RMSEB statistic (root mean square error below-mean daily flow) indicate that ANN model performs best for all of the years. The %VEA (percent volume error for above-mean daily flow) statistic indicates thatthe ANN model consistently has the smallest bias, while the SMA performance is poor. The %VEB (percent volume error for below-mean daily flow) statistic shows the poor performance of SMA model. We should not point out that the poorperformance of the SMA model does not

reflect so much on the ability of the model as it does on the calibration procedure used. In addition, an 'expert' would not allow the model error bias at various flow levels to deteriorate so much while minimizing the error variance. Although the ANN model developed here, by no means, could substitute a physically based conceptual model, the results indicate that the ANN model may provide best performance when only dry years of data are used for calibration.

DETERMINATION OF INSTANTENEOUS UNIT HYDROGRAPH WITH CLARK'S TECHNIQUE IN GIS

Musa YILMAZ, Nurunnisa USUL (Water Resources Lab. Department of Civil Eng. Middle East Technical University)

Determination of unit hydrographs for the basins is very important for the design of hydraulic structures. When there are observed rainfall-runoff data for the storms they are obtained by using these data, but when there are no observed data they are obtained by using synthetic unit hydrograph methods. In this study one such method is used together with Geographical Information Systems techniques. Application of Clark's synthetic unit hydrograph technique with GIS technology requires the estimation of three parameters of the original methodology. Time of concentration, Tc, is derived from SCS lag equation, reservoir storage coefficient, R, from an observed storm hydrograph and the time-area histogram is determined from the Digital Elevation Model of the basin. The translation hydrograph is then derived from time-area graph by applying a unit excess rainfall over the basin. After performing a linear reservoir routing, the translation hydrograph is routed to the basin outlet and the Instantaneous Unit Hydrograph of the basin is obtained. It can be used to obtain any duration unit hydrograph and then storm hydrographs for this basin. Such a study is performed for two different size basins in Turkey and the results are compared with the observed unit hydrographs of the basins and a discussion is given.

ARIDIFICATION AND THE INCREASE OF FLOOD EVENTS IN CENTRAL EUROPE

János RAKONCZAI, Katalin BÓDIS, Ferenc KOVÁCS (Department of Physical Geography, University of Szeged)

Hydrological events in Central Europe (including the more thoroughly analyzed Hungary) began to show a strange kind of controversy in the past decades. It is clearly visible through statistics that precipitation has decreased significantly (with about 10 %), at the same time however, the number of flood events shows a remarkable increase. In the year 2000 the situation was really peculiar, because in the beginning of a persistent drought significant flood prevention efforts had to be made along the Tisza river i. e. drought and flood at the same time! We demonstrate the characteristics and consequences of the aridification process from several aspects. Beginning as early as 1910 precipitation in Hungary is dropping constantly. Statistical analyses show that the reduction did not bring about the decrease of variability; fluctuation was merely transferred into a lower range of values, clearly showing the decrease in the average amount of precipitation. The persevering drop of precipitation has produced a significant decline in the amount of groundwater. This process became obvious since the early 0-s. We have determined through detailed GIS analysis the spatial and temporal changes in the level of groundwater and the total deficiency in subsurface waters. One of the most important consequences of the analysis is that in some areas even the significantly rainy years could not stop the decrease of groundwater meaning that the drop of precipitation clearly appears in subsurface waters. (It is important to bear in mind that the decrease of subsurface waters in closely connected to relief: in plain areas that are higher than their surroundings the decrease is more significant.) To determine the reaction of foliage to aridification we executed spatial analysis based on Remote Sensing methods.Throughout the world, floods became more frequent in the past decades. This is caused by both natural processes as well as the changes in social and economical structures. Extensive growth of agriculture became possible by creating arable lands through massive river regulation works. However population growth can also cause people to move into areas that are endangered by floods. Floods are thus just the products of natural processes in such areas. The truth is however, that due to human interventions, areas of potential flood-risk has expanded as well. The higher water levels in regulated rivers or the huge amount of water stored in large reservoirs both lead to flood risks to get higher than they would naturally be. In addition to the above, meteorological extremities also augment the possibilities for floods. The flood disasters of recent years all over the world and in Central Europe clearly demonstrate this as well. In this lecture we will, through demonstrating several floods, evaluate their natural and social background. It can be said that now floods can appear in any part of the year due to climatic changes, nature can produce quite peculiar extremities (extraordinary amounts of precipitation; record breaking flood levels along the Tisza river in four consecutive years), as well as the way human actions affect natural processes.

DEVELOPMENT OF NEW TECHNOLOGIES OF FLOOD SIMULATION AND FORECASTING IN REAL-TIME

Sandra Gabriela GARCIA (Technical University of Cartagena. Department of Thermic Engineering and Fluids)

The flash floods constitute one of the main problems of the Mediterranean semiarid zones of Spain. The convective storms of high intensity, typical of these zones, produce hydrological events that can turn out to be catastrophic. Due to the scanty existing time between the runoff hydrograph peak and the associated rainfall, the warning of flooding must be based on meteorological and hydrological forecasting. The coordination among the responsible authorities in the operational flood management, needs real-time operative decision support system. The use of Geographical Information Systems (GIS) in the development of these support tools, it constitutes a foreseeable direction. The GIS allow an efficient integration of information with a high spatiotemporal resolution, and spatially distributed hydrologic models oriented to runoff simulation and prediction in real time. The development of new methodologies and tools that allows the operative integration of radar rainfall fields and short term quantitative rainfall forecasting as input to distributed spatially rainfall-runoff models, are proposed. Finally, it is to be underlined that this work incorporates the use of new technologies (GIS, remote sensing, Digital Elevation Models) and the most recent developments in aspects of estimation and treatment of the spatial distribution of soil moisture and the flow in the unsaturated zone. The main objective is to improve the forecasts of flash floods applying a decision support tool in real-time named *Shyska*, developed with GIS-embedded functions.

SPATIAL-TEMPORAL APPROPRIATENESSES OF EXTREME PROCESSES FORMATION IN RIVERS SYSTEMS OF REGIONS WITH SHARP CONTINENTAL CLIMATE

Leonid M. KORYTNYI, N. V. KICHIGINA (Institute of Geography Siberian Branch Russian Academy of Sciences)

Spatial-temporal appropriatenesses of floods and shallows formation in main basins of East Siberia- the Enisey, Angara, Lena rivers, Lake Baikal are researched.Genetic and statistical regional analysis considers the specific of physiography conditions and also the peculiarities of sharp continental climate that has a tendency to change for the last ten years. Long-term series of flow on 120 hydrological gauge lines are the basis. Floods and shallows characteristics are determined: causes of extreme situations, their recurrence, geophysical and hydroengineering factors. Zoning of East Siberia on floods risk is implemented and statistic analysis of flow´ extremes and curves of maximum flow distribution as well. Researches are directed to decrease extreme situations in water resources´ systems. Effectiveness of different gear of risk management, the system of ecological insurance in particular is considered. For a number of regions the risk areas in the valleys of main extreme flood rivers is marked out and regulations of economic activity in these valleys are worked out. In the base of regulations there is the combination of four types of arrangements: geoecological, economical, engineering, and legal.

DEVELOPMENT OF WATERSHED RAINFALL-RUNOFF MODEL BASED ON THE PARTIAL CONTRIBUTING AREA CONCEPT

Chin-Hsin CHANG[1] ([1]Department of River and Harbor Engineering, National Taiwan Ocean University, [2]Department of River and Harbor Engineering, National Taiwan Ocean University)

The objective of this study is to develop a rainfall-runoff model based on the partial contributing area (Betson, 1964; PCA) concept. The influence factors of the PCA phenomena were investigated. The size of the PCA during storm is derived from TOPMODEL theory and estimated by using a digital elevation model (DEM). The PCA concept was then combined with a kinematic-wave based geomorphic instantaneous unit hydrograph model (Lee and Yen, 1997; KW-GIUH) for rainfall-runoff simulation. In the KW-GIUH runoff simulation considering PCA concept, the surface runoff mechanism was simulated by Manning's formula, and the subsurface runoff was approximated by Darcy's law.The Hen-Chi watershed in northern Taiwan was used to demonstrate the capability of the proposed model. The PCA size and geomorphic factors of the study watershed were obtained using a DEM, and SPOT satellite images were adopted for land cover analysis to obtain the roughness coefficient. The results showed that significant improvements were found in the simulation of rising and recession hydrographs.

REAL TIME FLOOD FORECASTING: A CASE STUDY OF THE JHELUM RIVER, PAKISTAN

Sajjad AHMAD (Department of Urban and Regional Planning, University of California, Irvine)

A modeling system is developed for real-time flood and reservoir inflow forecasting. It comprises a lumped conceptual rainfall runoff model, a hydrodynamic model for river routing, and an up dating procedure for real time operation of reservoirs. The model is implemented for the Jhelum River Basin in Pakistan, with watershed area of 14860 km2 and the Mangla Reservoir situated at the down stream end. The model is calibrated and verified at five gauging stations using daily rainfall data from twelve rain gauges and daily discharge data from three stream gauging stations for the period 1985 to 1991. Statistical parameters are used to evaluate the performance of the model. Real time forecasts of historic floods of 1976 and 1992 are performed with 24 hour and 6 hour lead times respectively. Sensitivity analysis on quantitative precipitation forecast (QPF) is made. The model performance for short term forecasts that is, 6 to 24 hours indicate robust system behavior in real time inflow prediction. Results indicate that if the accuracy of precipitation forecast is greater than 60 %, the error in the forecasted stream flow is less than 25 % for huge flood events. Sensitivity analyses show that large historic floods are highly sensitive to QPF.

REVISITING 1992 FLOODS IN PAKISTAN: OPERATION OF MANGLA RESERVOIR

Sajjad AHMAD (Department of Urban and Regional Planning, University of California, Irvine)

Occurrence of floods is a natural phenomenon all over the world. With the increase in population and human activity in the floodplains, flood damages represent escalating hazard in many countries, despite increasing investments in flood control measures. Reservoirs are important structural measures to reduce damages caused by floods. Reservoir operation during large flood events is crucial in utilizing reservoirs as flood damage reduction options. In 1992 a catastrophic flood passed through the Mangla Reservoir on the Jhelum River in Pakistan. Operation of reservoir resulted in severe flooding of down stream areas causing damages to lives and property. A reservoir operation model is developed for the Mangla Reservoir. Model is calibrated for the flood event of 1976. The simulation model is used to investigate the water levels in the Mangla reservoir that would have resulted in 1992 with releases of 5700 m3/s (safe passage down stream) and 8500 m3/s (high flooding conditions down stream). Simulations revealed that it was possible to accommodate a considerable volume of the 1992 flood in the reservoir. However, to operate the reservoir in this way, difficult decisions have to be made during the flood. This can only be done with a full overview of the flood situation and in close cooperation with the concerned agencies. It also requires that the procedures for the reservoir operation for such a situation be already developed.

HS02/11A/C24-010OP Oral-Poster **1121**

STOCHASTIC MODEL OF THE RUNOFF FLUCTUATIONSOF THE RIVERS WITH A FLOOD FLOW REGIME

Andrei V. KHRISTOFOROV[1], Taras V. SAMBORSKY[2] ([1]Department of Hydrology, University of Moscow, [2]Department of Oceanology, University of Moscow)

The stochastic model of fluctuations of a runoff during a flood period is offered. It includes a stochastic model of the hydrograph of a flood season and stochastic model of the annual fluctuations of its characteristics. The stochastic model of the hydrograph is based on the approximation of the individual hydrographs of separate flood peaks and base flow and their superposition into the unit hydrograph of the whole flood period. The parametres of the approximation - base flow, number of flood peaks, dates of their passage, their maximums,

durations of the growth and intensity of recession. All these characteristics are considered to be the random variables. The sequence of flood peaks during a flood period is described by a model of Poisson process. The model of annual fluctuations includes the description of probability distribution of hydrograph elements, correlation between them, autocorrelation of their annual fluctuations, their probable climatic and man-made regular changes. The number of flood peaks is the major characteristic of flood season. It can be considered as an index of flood forming situations of the year. The realization of model includes the Monte-Carlo method and theoretical formulas suggested for transition from model elements to any river flow characteristics of flood season. In a case of some regular changes caused by climate or economic activity the principles of correction of the parameters of probability distribution of model elements are suggested. The adequacy of the model was succesfully tested on a base of hydrolodic data for 68 rivers of the world. These are the rivers of the Amur basin and Northern Caucasus in Russia, North Korea, Ukrainian Carpathians, Georgia, USA, Algeria and Surinam. The statistical stability of the model is rather high. The basic parameters of the model can be estimated with the errors no more than 5-10% already in a case of 10-15 years of hydrologic observations. The model is intended for the hydrologic computations of any characteristics of the river flow of flood season for a weakly studied rivers in a case when a lack of hydrometeorologic observations don't allows to use the models of river flow formation. The model permits to increase the accuracy of hydrological computations by a factor of 1,5 - 2 and more in comparison with normative methods used now. The application of the model is not limited by the traditional problems of hydrologic computations. This is confirmed by an example of model application for the analysis of the systematic increase of the annual river flow which was discovered for the rivers of Mid-Atlantic of USA from the beginning of 70-ties.

IMPACT OF POPULATION GROWTH AND THE CLIMATE CHANGE ON THE QUANTITY OF WATER RESOURCES IN NORTH EASTERN REGION OF INDIA

Uttam C. SHARMA (Indian Council of Agricultural Research)

The north-eastern region of India, comprising seven states, has a geographical area of 255,090 sq km. The region is extremely rich in water resources but continuous increase in human interference and mismanagement has rendered these resources in fragile state. The region receives about 510 cubic km of water as annual rainfall. It has two major river basins viz. Brahamputra and Barak, which drain 194413 and 78150 sq km area with an annual runoff of 537.0 and 59.8 cubic km, respectively. The region has a total surface and ground water potential of 1064.8 and 16.6 cubic km. The scenario appears to be quite encouraging but indiscriminate use of water resources has caused land and environmental degradation in the region. Against an irrigation potential of 3.68 million ha, only 10.6% has been exploited. The population in the region has increased from 10.5 million in 1951 to 40.3 million in 2001, that is, it has grown 4 folds in 50 years, thereby exerting tremendous pressure on land and water resources. More than 82% of the population is rural based, whose main occupation is agriculture. Prevalence of shifting cultivation has resulted in deforestation and annual soil loss of 88.3 million tonnes through run-off from hill slopes, causing silting of river beds and frequent occurrence of floods. Due to population pressure, more and more forest area is being brought under plough, putting whole ecology in peril. The declining trend in rainfall and frequent temperature fluctuations are a signal for climate change. The demand for water for domestic use has suddenly increased due to fast population growth and change in life lifestyle of the people. At present, about 2.9 and 20.0 cubic km of water is required for domestic and irrigation and 1.5 cubic km each for energy, industry and other miscellaneous uses. In towns, generally the raw rainwater is supplied for domestic use while the people in rural areas have to depend on stream or pond water collected during monsoon. Seasonal rainfall flushes the catchments earlier charged with polluted environment. This polluted water results in frequent occurrence of diseases like cholera, jaundice, diarrhea and typhoid. Water demand is high and the supply does not commensurate with it. Due to mismanagement of rainwater, about 3586 thousand ha of land has become prone to floods. Further, the quality of water has also deteriorated due to its being polluted with nitrates, chlorides and sulphates with increased use of fertilizers and pesticides in an effort to increase crop productivity in the region. If the rate of population increase remains unabated, the water resources are likely to dwindle further as also deterioration in the quality of water. A multidisciplinary study, based on watershed approach, is in progress since 1983, to evolve new farming system to replace shifting cultivation, judicious management of rain-water and monitoring of soil, nutrients and water yield through surface and base flows. Lot of useful data has been generated which will help in planning, developing and improving the water resources in the region.

HS02/11A/C24-012OP   Oral-Poster   1129

MANAGEMENT OF WATER RESOURCES IN KANDI (DROUGHT PRONE) ZONE OF JAMMU PROVINCE FOR HIGHER CROP PRODUCTIVITY

Vikas SHARMA (S.K. UNIVERSITY OF AGRICULTURAL SCIENCES AND TECHNOLOGY-JAMMU)

The *kandi* zone of Jammu province of Jammu and Kashmir state of India is characterized by low rainfall ($<$650 mm), deep water table, undulating topography, poor soil fertility with land surface full of sand stones, soil moisture stress, frequent droughts and acute scarcity of water for domestic use and crop production. The *kandi* zone has two major river basins *viz.* Chenab and Tawi, which pass through deep gorges and undulating terrain, draining entire Jammu region. About 3.5 to 5.0 km³ of water is received as annual rainfall, mostly during July and August. Rest of the period during the year remains dry except few showers during winter. Rains are generally with high intensity, resulting in over flowing of seasonal streams, soil erosion and degradation. The entire zone has agriculture-based economy but is always deficient in food grains. Though, the farmers are hardworking, working most of the time in the field along with their spouse and children, they do not produce as much as to feed their family. In absence of optimum soil moisture and irrigation facilities; application of fertilizers, good crop seed and other inputs have little impact on crop productivity. The studies have shown that water management is the major factor, which can improve the crop productivity in the *kandi* zone. It is difficult to derive any benefit from the water from two rivers as they flow in hilly terrain and cost involved in lifting the water and construction of canals would be two high compared to the area available for irrigation in the immediate vicinity. Construction of small structures for rainwater harvesting during monsoon will be good preposition. Farmer´s participation in the whole programme is necessary for achieving the desired goals. Construction of small check-dams to divert the water to ponds will not only reduce the soil erosion but water can be utilized for life saving irrigation during winter. Besides, there is need to introduce such cropping pattern, which may reduce the run-off and help in ground water recharge. The paper discusses the feasibility of the check-dams, water storage reservoirs, soil conservation measures according to topography and judicious utilization of available water for higher crop productivity, resource management and environment conservation in kandi zone of Jammu Province.

HS02/11A/C24-013OP   Oral-Poster   1133

WATER RESOURCES MANAGEMENT AND PLANNING; THE NEED FOR MULTIDISCIPLINARY MODELLING APPROACHES

Islam Hamza ABOU EL-MAGD, Trevor TANTON (Civil & Environmental Engineering Departement, University of Southampton)

Water is a finite resource and the rapidly growing population in many arid and semi arid countries is placing excessive pressure on the limited water resources of these Countries. Unfortunately, it is predicted that many of these arid and semi arid countries will be the most seriously effected by a decline in water resources as a result of global warming. In most of these countries irrigated agriculture is the main consumptive user of water and unless water management is improved there will be a dramatic reduction in food production as a result. Typically most large irrigation schemes have an unimaginable wastage of water, with crop evapotranspiration accounting for only 20-35% of the water supplied, the remainder being wasted. Global warming will result in both increased evapotranspiration and reduced water resources and it is clear that if productivity is to be maintained water will have to be used more efficiently. Water allocation for irrigation is traditionally based on theoretical estimations of crop water requirements and rough estimations of canal losses, with the result that water supply rarely meets demand. Remotely sensed data is capable of supplying the planners with up to date data on the crops in the field and in measuring crop water requirements and wetland losses. This paper explores how remote sensed data is presently being used to improve water resource management in large irrigated catchments. It investigates the potentiality of spatial modelling of the real time data from satellite images, crop water demand from climatic data and irrigation information from the field to accurately allocate the irrigation water need in large irrigation scheme.

HS02/11A/C24-014OP   Oral-Poster   1137

THE SYSTEM FOR ECOLOGICAL AND ECONOMICAL ASSESSMENT OF USE, PRESERVATION AND RESTORATION OF URBAN WATER BODIES: ST. PETERSBURG AS A CASE STUDY

Sergey A. KONDRATYEV (Prof.)

The water surface area of 106 water bodies of St. Petersburg city is equal to about 21 km2. The urban water bodies reflect the level of environmental pollution of St. Petersburg. At present time only 2% of water bodies can be referred to pure, 18% - to polluted, and 80% - to dirty. The State is the owner of water resources, including urban water bodies. Its interests is to stop deterioration of water quality and degradation of water ecosystems, and to find money for restoration of water bodies. The potential water-user can rent water bodies for the aim to get money income. In this case he should be interested in preservation or restoration of water bodies being a natural basis of his business.At present study there is discussed the problem of a choice of optimum variants of urban water resources use without deterioration of water quality and ecological status of water bodies, and with financial profit for water-user.The system for ecological and economical assessment of use, preservation and restoration of water bodies has been developed. The basic stages of the system are the following:- Data bases load and GIS development.- Assessment of the investment appeal of urban water body. High level of environment pollution, industrial enterprises located in catchment, high level of anthropogenic impact on water body are the reasons for negative assessment. The below mentioned stages take place only for positive assessment of the investment appeal of water body. - Assessment of present suitability of water body for various kinds of use. The basis of assessment is the result of comparison of present parameters of water quality with critical limits of chemical substances in water and sediments. High level of water and sediment pollution is the reason for negative assessment.- Economical assessment of water body restoration. Various kinds of restoration methods are considered: internal (chemical, biological and engineering) and external (catchment changes). - Optimisation of water body use on the basis of mathematical modelling. - Assessment of sensitivity of results of modelling to change of parameters of water body (depth, volume, area of recreation zone, etc.). Results of assessment are the information for choice of scenario of parameters changes for maximization of financial profit of water use.- Economical assessment of water body parameters change.- Economical assessment of monitoring.- Final ecological and economical assessment of water body use taking into account costs of restoration, parameters change and monitoring. Application of the developed system has been made for urban water bodies. Results of application show that it is possible to use a number of water bodies with financial profit for water-user and without deterioration of water quality and degradation of ecosystems. The lists of water bodies with maximal and middle investment appeal are carried out.

OPTIMAL PRESSURE CONTROL IN SUPERVISORY WATER DISTRIBUTION NETWORK USING SHUFFLED COMPLEX EVOLUTION ALGORITHM

Haytham AWAD, Akira KAWAMURA, Kenji JINNO (Institute of Environmental Systems, Kyushu University, Fukuoka, Japan)

Obtaining an optimal control of the distribution of system service pressures in a municipal water distribution networks has always faced combinatorial problems due to its complexity, scale of the problem, variation of water demand and the difficulty in estimating the roughness coefficient of old pipes. Referring to the previous difficulties, the application of linear, non-linear, dynamic programming, simulated annealing and genetic algorithm have been investigated by many authors and used in recent years for the optimization programs of water distribution networks design, replacement and leakage minimization. Particularly, the application of genetic algorithm (GA) in water distribution networks optimization models has been known as the most successful method in this field. It works with a coding of the parameter set, direct the search to the improved solutions by probabilistic rules and working directly with the objective function requiring no additional knowledge.In this paper, we used an evolutionary optimization procedure known as Shuffled Complex Evolution - University of Arizona (SCE-UA) for searching for the optimal or near-optimal solution of valves setting for the pressure regulation of a water distribution network. The SCE-UA technique has been successfully used in the calibration of conceptual rainfall-runoff models and the identification of aquifer formation parameters in the area of surface and subsurface hydrology, respectively. However, this algorithm has never been used in the field of water distribution networks management and planning and this paper is our first attempt in this direction.The SCE-UA Method which is relatively new concept is a general purpose global optimization program which combines the strengths of the simplex procedure with (i) the concept of controlled random search; (ii) competitive evolution; and (iii) the concept of complex shuffling. The synthesis of these three concepts makes the SCE algorithm not only effective and robust, but also flexible and efficient. The main advantage of the SCE-UA method is that, for a given number of objective function evaluations, the SEC-UA have the highest probability of succeeding of finding the global optimum.To demonstrate the performance of the SCE-UA algorithm, A case study of a certain block of the supervisory Fukuoka City water distribution networks is presented showing the effectiveness of the algorithm to regulate the pressure at all the network nodes between upper and lower values and as near as a target

value. In Fukuoka City water distribution networks, electrically motor valves openings are adjusted by remote control to regulate pressures and flow rates on the basis of information provided by flow meters and pressure gauges attached to distribution pipes. Results show that pressures are well regulated by SCE-UA algorithm to a target value for a specified nodal demands and external inflows.

HS02/11A/C24-016OP   Oral-Poster   1145

BANK FILTRATION SYSTEMS AS COMBINED TECHNOLOGY FOR GROUNDWATER AND SURFACE WATER

Ekkehard O. HOLZBECHER (Humboldt University Berlin)

Bank filtration systems are of increasing importance for the supply of water for all kind of purposes. Worldwide water works extend old pumping well galleries, and increasingly new investments are directed to this technology. By bank filtration in most cases both surface water and groundwater resources are exploited, what has to be taken into account by the management of bank filtration facilities. Through the combination disadvantages of pure surface water or pure groundwater systems can be overcome. The technology of bank filtration makes the system less vulnerable to extreme events. The quality of the pumped mixture is higher than the water of the reservoir with lowest quality. Moreover surface water is significantly purified during the filtration passage from the surface water body to the pumping facility, so that the application of further water treatment may even become obsolete. An example is the water supply for the city of Berlin, Germany, which is studied in detail within the NASRI project (Natural and Artificial Systems for Recharge and Infiltration) since spring 2002. The aim of the project is to obtain a better understanding of such systems and to develop appropriate models and management tools - not only for the Berlin sites. The contribution to the conference provides an overview on the current state of the project. An introduction to the technology will be presented, followed by an overview on the activities of the NASRI project. Computer models will be demonstrated concerning the design and dimension of pumping well galleries and concerning the biogeochemical transformations during the passage of surface water through the porous medium. Finally follow some implications concerning the management of combined surface water and groundwater resources.

HS02/11A/C24-017OP   Oral-Poster   1149

REDUCING SHALLOW - WELL CONTAMINATION IN UGANDA

James MWAMI (Project Manager, Busoga Trust)

Despite an abundance of surface water in Uganda(18% of the land area), the predominantly rural (>70%) population relies almost exclusively on groundwater for a portable water supply. This dependence arises from the more widespread occurrence, superior quality and reduced susceptibility to contamination, of groundwater supplies compared to surface water resources. As a result, provision of safe water to rural communities in Uganda has depended primarily upon the construction of wells and protection of spring discharges. In Uganda, as with other regions in equatorial Africa, featuring extensive, weathered crystalline rocks, often referred to as he ˝basement complex˝ ground water development has targeted two main aquifer units: a deep aquifer of fractured bedrock and a shallow, muddy-sand aquifer comprising of detrital bedrock and alluvium. This paper depicts a case study taken in east and central Uganda. Particular attention has recently been directed at developing the shallow - well aquifer since the formation is less costly to develop and a recent study has found it to be more productive than the deeper, bedrock aquifer. However, monitoring of water quality in south eastern Uganda, a region of intense shallow - well development, shows that within months of installation, shallow groundwater commonly exhibit levels of coliform bacteria and nitrate exceeding W.H.O health guidelines. Human and livestock waste excreted in pit latrines, over land or in open-pit wells, called ˝scoop wells˝ may contain worms, protozoa, bacteria and viruses that if consumed, can lead to the contraction of hepatitis, typhoid, cholera and a variety of diarrhoea diseases. Wells and springs harvesting shallow groundwater are generally protected from these pathogens by a granular soil matrix which both filters bacteria, protozoa and worms due to their relatively large diameter (>0.5 um) in relation to the aquifer material, and adsorbs smaller viruses (0.07 um to 0.7 um) on account of their strong, negative surface charge. Despite this cleansing capacity, the presence of coliform group of bacteria in groundwater indicates that faecal contamination has occurred. The practice of siting shallow wells in the vicinity of existing scoop wells has been identified as a probable source of faecal contamination too shallow wells in Mukono District of South Eastern Uganda.   Simulations of groundwater flow in the shallow aquifer indicate that a well head protection area of 60m between wells and contaminant sources such as scoop wells, pit latrines and swamps is required to ensure the sustainability of this vital, potable source of water to rural communities.

WATER MANAGEMENT ON MEDITERRANEAN ISLANDS UNDER CHANGING CONDITIONS

Manfred A. LANGE (Center for Environmental Research, University of Muenster, Mendelstr. 11, D-48149 Muenster, GERMANY)

The availability of water in the Mediterranean in sufficient quantities and adequate quality represents a significant problem, particularly in light of possible changes in climatic conditions. This is due to a number of factors which include: the over-exploitation of existing aquifers by various users, insufficient recharge due to diminishing precipitation, excessive and inadequate use through agricultural activities or tourism, significant deficits in water management and distribution schemes and conflicting or unresolved demands and interests between various users, to name just a few. These problems are exacerbated on the islands in the Mediterranean because of their isolation and thus the impossibility to draw on more distant or more divers aquifers in general and because of the threat of saline intrusions, which reduce the utilisation of existing, near-shore aquifers in particular. While the availability, demand and distribution of water on each island are determined by specific conditions, there are a number of attributes common to all Mediterranean islands which call for the formulation of generic solutions to the above mentioned problems. Because most of these problems are mutually related and interdependent, solutions will only be obtained through holistic considerations that are carried out by an interdisciplinary research team. Equitable and acceptable strategies require a stakeholder-based participatory process that builds on the results of scientific investigations on the one hand and on the consent of major stakeholders on the other. These requirements are central to the EU-funded MEDIS project, which aims to contribute towards the sustainable use of water on islands of the Mediterranean where conflicting demand for water is combined with a wide range of hydrological, social and economic conditions. MEDIS is being carried out by a consortium of 12 institutions from seven countries and will involve detailed investigations in one typical catchment each on Corsica, Crete, Cyprus, Mallorca and Sicily. By carrying out this project on five islands that cover the Mediterranean from west to east and by enabling a dialogue between scientists and stakeholders as well as between principal stakeholders from each island, these recommendations will embrace generic solutions based on the collective experiences of the residents on all islands. We will report on the results of the first year of MEDIS, which include an extensive review of current conditions pertaining to water management on each island and the specification of a typology of water demand and supply relationships for the islands of the Mediterranean. In addition, we will consider water supply under future climate scenarios derived through a regional model for the Mediterranean and/or downscaling of GCM results from models of the Max Planck Institute Hamburg, Germany. These results will give rise to a set of recommendations for improved water management practices that will have to be discussed, modified and agreed-upon through a participatory process involving key stakeholders on each island in the future course of the project.

RELIABILITY ANALYSIS OF THE INTEGRATED MANAGEMENT OF WATER QUANTITY AND WATER QUALITY FOR WATER TRANSFER SYSTEM

Xiang ZHANG[1], Jun XIA[2] ([1]Dept. of Hydrology and Water Resources, Wuhan University, [2]2. Department of Hydrology and Water Resources, Institute of Geographical Science & natural Resource)

Water consuming around the world increased sharply in order to meet the demands of the rapid economic development. On the other hand, it is the economic development that courses the degeneracy of eco-enviromental system and the decrement of available water quantity, especially in the developing countries. It is necessary to consider the integrated management of water quantity and water quality in order to decrease the risk of water supply. In this paper, the integrated management of water quantity and water quality for the water transfer system is discussed. And based on the reliability theory, the method of reliability analysis is applied to assess quantitatively the operation reliability of water transfer system.Transferring water from the catchment with abundant water resources to the area in shortage of water, the water transfer system covering the different catchments plays an important role in solving the water shortage. Obviously it also influences the water quantity and water quality of the river in the water source area. In this paper, the importance and the method to consider the integrated management of water quantity and water quality are discussed and suggested. For the water quantity, the temporal and space variability of water resources in the water source area should be analyzed carefully in order to determine the amount of the available water. On the other hand, the influence to the water quality should also be considered thoroughly, including the pollutant source, the decrease of discharge in river resulting in the deterioration of water quality at the downstream and etc. In this paper, the environmental critical discharge, which is defined as the lowest required discharge to keep the water quality of the river to reach the standard of drinking water source, is used as a threshold for the management of water quality. It can be determined by using the river water quality mathematical model. At last, for the reliability of the integrated management of water quantity and water quality, the two reliability criteria, the temporal reliability and the volumetric reliability, are presented. The last part of this paper gives a case study about the water transfer system in Shenzhen city, Guangdong province. This system transfers water from the Dongjiang catchment to Shenzhen. Considering the integrated management of water quantity and water quality, not only the water quantity in the Xizhijiang and Dongjiang river is analyzed carefully, but the environmental critical flow is calculated. And the two reliability criteria are used to evaluate the operation of the system. The result shows the reliability analysis of the integration of water quantity and water quality can provide thorough decision making for the sustainable management of water transfer system.

HS02/11A/C24-020OP   Oral-Poster   1201

LATERITE - LOW COST REMEDIAL OPTION FOR HIGH ARSENIC GROUNDWATER

Rupa BHATTACHARYYA[1], Debashis CHATTERJEE[2], Yoshio TAKAHASHI[1] ([1]Department of Earth &Planetary Systems Science, Hiroshima University, [2]Department of Chemistry, University of Kalyani, India, [3]Department of Land & Water Resources Engineering, Royal Institute of Technology,KTH, Stockholm)

High arsenic groundwater has emerged as a niggling environmental problem in the recent decades. Elevated levels of groundwater arsenic (>>50ppb) in the Bengal Delta Plain (BDP) threatens the lives of millions of people. Large scale uncontrolled groundwater development may play a key role for such human suffering. The present study deals with the adsorption pattern of AsO_3^{3-} and AsO_3^{3-}, the predominant arsenic species in groundwater using Red Earth (Laterite) for the supply of potable water. Laterite is an indigenous, abundantly available, natural geological material enriched with amorphous ferric hydroxide (HFO)/ oxides. The mineralogical study of Laterite exhibits the predominance of iron and aluminium secondary phases. Chemical composition reveals that Laterite contains 30 - 35% iron oxides.Batch experiments indicate the Langmuir adsorption isotherm. The pHzpc of laterite is determined to be 8.5-8.6. The high pHzpc value supports a high positive surface charge of laterite over a wide pH range. The material, therefore acts as an effective adsorbent for several anionic contaminants. On the basis of the lab as well as field scale studies, laterite is used as a fixed bed filter media in an earthenware pitcher with a view to supply drinking water on the household basis. The results interpreter that the material is not only effective in adsorbing arsenic but also effectively removes iron from the groundwater. Cost calculated for the transportation of laterite approximates to Rs 750 /ton/km (US$ 16) whereas the treatment process estimates to Rs30/100L(US$ 0.6) contaminated water. Therefore fixed bed laterite can be successfully used for removal of arsenic from groundwater. Lab scale experiments are also executed to understand the efficacy of the system for removing heavy metals as well from the aquatic environment.

HS02/11A/C24-021OP   Oral-Poster   1205

LARGE DIAMETER WELLS AS A SOLUTION AGAINST THE RISK OF CONTAMINATION IN THE SEMI-ARID WORLD USING THE FILTER FACTOR CONCEPT

Sarma K. SEEMANAPALLI, Soniaeli P. CARVALHO, Silvestre L. NOBREGA, Alex M. NEYVES (Smith Research Corporation, Small Business Technological Center, LSU, Baton Rouge, LA)

Water is the life blood of living creatures on earth. Seventy percent of earth´s surface is covered with water. Despite much information available, groundwater movement, its quantity and quality remain a mystery. Groundwater levels decline due to intensive pumping and yearly below-normal precipitations, that accelerate the downward trend in water levels. Natural groundwater quality is affected by the materials it passes through on its way to the groundwater reservoir. Human activities also cause water quality degradation. serious enough to prevent the use of water for human consumption. Well location is a crucial factor, a well downhill from a source of bacterial contamination running greater risk of contamination than that on the uphill of pollution source. Minimum separation distances from potential sources of contamination are to be maintained. Proper well design reduces the risk of pollution by sealing the well from contaminants that enter from the surface. Bacterial contamination which cannot be detected by sight, smell or taste can result from a number of sources. Shallow wells and wells that do not have water-tight casings can be contaminated by bacteria infiltrating through the soil near the well. Soil remediation is a difficult, time-consuming and expensive operation and environmentalists select the most appropriate

technology for specific contaminated sites. Here-in is suggested one such method of soil remediation, using Large Diameter Wells (LDW) that are popular in the semiarid world. The simplicity and low cost in the construction and operation of such wells make their use viable for rural communities. The LDW is a viable alternative to tube wells to alleviate the problem of draughts and the risk of contamination in Paraiba state, Brazil. The filter factor concept, f_f, conceived by Sarma(1997) considers the relative effects of transmission and passage of water through bricks and cement mortar. Values of ff in function of well yield for given diameters and drawdown are presented. Criteria to avoid mutual interference due to simultaneous pumping of wells was also studied. Computer programs developed would prove useful in making the characteristics curves for LDWs constructed in aquifers with low transmissivity values. Unlike tube wells, in LDWs, water continues to get extracted from aquifer to the well even after the cessation of pumping, attesting LDWs as efficient in aquifers in the semi-arid world.. Using field data, calibration was effected adopting a 14/16 mesh for the LDW. The numerical method adopted here-in was the volume element method. The flexibility of the method permits implantation of desired well-diameters, change the network in the computer program, thus permitting to evaluate the drawdown-discharge-diameter relationships. Regional characteristic curves drawn between the variables facilitate practical application of these by agriculturists and engineers to explore rightly the aquifers, avoiding thus the risk of contamination of LDWs.

HS02/11A/C24-022OP Oral-Poster 1209

REDUCTION OF RISK OF AGROTOXICS BY DRAINAGE IN AGRICULTURAL LANDS USING INTERCEPTOR DRAINS

Sarma K. SEEMANAPALLI (Smith Research Corporation, Small Business Technological Center, LSU, Baton Rouge, LA)

About 80% of the sick and over 33% of the deaths in the third world countries are attributed to the clean water crises, caused by degradation in water quality. According to UNO, the disorderly distribution of available resources affects 20% of 3rd world countries. South America goes black-listed as a continent, threatened with water crisis. Brazil is however privileged because of its abundance of water, with its availability of 5000m3/year/capita, with a demand of only 200 m3/year in its NE region. Subsurface waters have distinct economic advantages over other components of the hydrological cycle. Groundwater can be used directly in most cases, without prior treatment. However, groundwater may also be polluted by way of natural or surface contamination. Because of the greater demand of groundwater, the confidence in the quality of potable water is posing doubts, its authenticity being questioned, once that major sources are already getting over-explored. Higher standards of water quality imply higher costs of water. Environmental scientists are concerned about groundwater contamination by way of agro-toxic substances entering the flow regime. The pollutants detected in shallow waters might reach the deeper strata of the aquifers. Here-in, an investigation is made about the effective use of interceptor drains in the irrigated perimeter in Sume in the Semiarid Paraiba State in Northeast Brazil, in function of their geometric, hydraulic and hydro-geologic parameters. Effective removal of chemical pollutants from aquifers through the use of interceptor drains is suggested to contain and even to remove subsurface pollutants from shallow aquifers. Interceptor Drain is a gravel trench excavated into a relatively impermeable soil layer and installed to collect and remove groundwater as it flows across the impermeable layer, which is typically placed across a contour of a slight to moderate sloping area to intercept groundwater. The potential theory used here-in and the concept of ground water divide conceived proved helpful to quantify the efficiency of interceptor drains. These drains offer concrete solutions to the problem of the control of subsurface water pollution in shallow aquifers. Such drains are used to capture the contaminants and to delimit the spreading of hazardous chemicals. Finite difference scheme used here-in was developed by Sarma e Alex (1997). For the totally and partially penetrating drains studied to know the effectiveness of such drains, spacing, widths and depths of drains varied. The drain discharge is treated as a function of the number of tubes that effectively enter into the drain. Recharge played an important role in the control of the pollutant movement, in delimiting the configuration of the phreatic surface, an increase in recharge rate correspondingly increasing the depth of the groundwater divide. Such water divides help one to forecast the contaminant movement and to quantify the same.

WATER QUALITY MANAGEMENT FOR CONJUCTIVE USE OF GROUND WATER AND WASTEWATER FROM AQUACULTURE : AN INDIAN OVERVIEW

Lalitkumar Pandit CHAUDHARI (Institute for sustainable development and research)

Aquafarming has emerged as one of the more promising industries in the world with considerable growth potential expected to contribute around the quarter of global fishery the year 2000 AD. The aquafarming has a multidimensional in perspective agricultural growth. It is a tool for utilizing land and water more economically and optimally for increasing the productivity of both natural resources, land and ground water through sustainable agriculture. The countries in the Asia -Pacific region have vast and varied aquafarming resources . Oftenly these are these are main source of Irrigation in this region. The overexploitation of ground water causes salinity problem in many countries reducing the cultivating area resulting reduction in agriculture reduction An attempt has been made in this paper to develop the plan for ground water management for the aquaculture and horticulture as well as drinking water from the river source adopting conjunctive use of irrigation water from Indian experience .The paper also evaluate the water quality criteria of ground water and irrigation water for increasing the agricultural productivity. The methodology is based on the economics of the conjunctive use of irrigation and ground water for horticulture and aquaculture and also for agriculture. The main aim is to utilize the ground water over saline land for aquafarming and to reduce the soil salinity in irrigated land to increase the productivity of the land and the water .Series of the observations were taken on the various aspects of irrigation and soil salinity management for aquafarming using different methods to maintain the quality of land and the ground water. Also the relative economics of aquafarming and horticulture system under alternative water conserving irrigation /rain water harvesting management options, has been compared with the resources available .The result obtain demonstrate the implication of increase in yield in horticulture including agriculture and indicate the necessity of optimal and suitable use of natural resources for increasing the agricultural productivity The result signify that the soil salinity can be managed using ground water management practices and the additional area can be brought down under agriculture. The result obtained also suggest that significant economic gains can be had from adopting conjunctive use of ground water to maintain the quality criteria for increased production in horticulture and agriculture as well as for dirnking water from the river source after discharge. Apart from results of drinking water quality, it also signifies that the increase in the production can be achieved through reuse of water alongwith the ground water as supplemental irrigation, reducing the soil salinity problems in command area .

ELEVATED DROUGHT RISK DUE TO MULTI-DECADAL CLIMATEVARIABILITY

Anthony S. KIEM, Stewart W. FRANKS (Department of Civil, Surveying and Environmental Engineering, University of Newcastle)

A number of previous studies have identified changes in the climateoccurring on decadal to multi-decadal timescales. Recent studies havealso revealed multi-decadal variability in the modulation of themagnitude of El Nino/Southern Oscillation (ENSO) impacts on rainfall andstreamflow in Australia and other areas.This study investigates the multi-decadal variability of drought risk byanalysing the performance of a water storage reservoir in NSW,Australia, during different climate epochs defined using theInter-decadal Pacific Oscillation (IPO) index. The performance of thereservoir is also analysed under three adaptive management techniquesand these are compared with the reservoir's performance using current'reactiveAEmanagement practices. Two of the three techniquesinvestigated use climate indicators to alter management procedures andinitiate them in advance of drier than average periods based on an ENSOforecast.The results indicate that IPO modulates both the magnitude and frequencyof ENSO events. This dual modulation of ENSO processes has the effect ofreducing and elevating drought risk on multi-decadal timescales. Theresults also confirm that adaptive reservoir management techniques,based on ENSO forecasts, can improve drought security and becomesignificantly more important during dry climate epochs. These resultshave marked implications for achieving drought security, despite climatevariability, for water storage reservoirs.

HS02/11P/C24-002 1415

ON THE CAUSES OF TAIWAN DROUGHT EPISODES

Fong-Chiau CHANG, Chung-Ho WANG (Institute of Earth Sciences, Academia Sinica, P.O.Box 1-55, Nankang, Taipei, Taiwan)

Droughts, prolonged deficit rainfall, affect the balance between water resources and demands. Atmospheric processes, sea surface temperature anomalies, land surface conditions, solar variability, sulfur-rich volcanic eruption and anthropogenic processes are all involved in their onset and maintenance. There is considerable debate on the role of anthropogenic process, natural forcing or natural variability in initiating droughts. Four major Taiwan drought episodes occurred during the 20th century. They are 1906-1910, 1961-1966, 1978-1982 and 1993-1995. These droughts appear synergistic phenomena with the 1907 Ksudach, 1963 Agung, 1980 St. Helen, and 1991 Mt Pinatubo eruptions. The higher frequency since 1960s seems related to both anthropogenic aerosols increases ensued from rapid economic development and urbanization in 1960s and four major sulfur-rich volcanic eruptions during the period from 1963 to 1991. This study examines 1) how monthly precipitation changes for each episode before and after the corresponding eruption, and 2) what are their respective characteristics.

HS02/11P/C24-003 1430

THE CHARACTERISTICS OF BASE-FLOW RECESSION COEFFICIENT AND ITS LONG TERM CHANGE ON MOUNTAINOUS WATERSHED OF RAPID FOREST RESTORATION

Junji SHIMOKURA, Hirofumi SHIBANO (Graduate School of Agricultural and Life Sciences, University of Tokyo)

This study aims at exploring the method that can directly assess water conservation by using watershed storage as an index, which is found from the base-flow recession coefficient; therefore this study only pays attention to the recession coefficient of discharge in non-precipitation terms. The influence of recession characteristics affected by evapotranspiration is taken into consideration in order to remove the influence of seasonal change. Properties of recession coefficient are analyzed through secular change and comparison between experimental watersheds.Ananomiya, Higashiyama and Shirasaka, experimental watersheds in the University Forest in Aichi, University of Tokyo, are elected as object watersheds for analysis. From the end of the 1800s, forests in the experimental watersheds and their surrounding areas had been cut. Consequently, forests including experimental watersheds had been denuded. When the observation started in1923, the forest in each experimental watershed, especially in Ananomiya, was in bad condition. The recent research showing an increase of stand volume and reduction of bare land rate concludes that forest in experimental watersheds is in the process of recovery. However, soil is still unripe. In the experimental watersheds, no tree logging has been conducted except for work on several streams and artificial reforestation in denuded areas. In August 1959, water dispersion work was performed in a large scale as an experiment to intercept hillside runoff and make water penetrate into Ananomiya. Daily data of discharge and precipitation, over a period of 70 years, is used for analysis. Non-precipitation terms, defined as days there is no precipitation continuously for more than 7 days, are extracted from the long-term daily data to estimate the recession coefficient. An equation expressing the runoff from an unconfined aquifer is used to estimate it. Estimated coefficients are large in Ananomiya where the forest condition is poor and small in Higashiyama and Shirasaka where the forest condition is good (a large coefficient means discharge recesses fast and a small one means the contrary). The coefficient averaged every month has seasonal changes, i.e. it's large in summer and small in winter. Evapotranspiration in non-precipitation terms is estimated by the Penman-Monteith equation. The recession coefficient has seasonal change, i.e. it is large in summer and small in winter, similar to that of estimated evapotranspiration. And there is positive correlation between the recession coefficient and evapotranspiration. Secular change of recession coefficient, analyzed by dividing a year into two seasons, has a downward tendency, however it temporarily increases in Ananomiya in the 1960s and has increased in all watersheds since the 1980s. The downward tendency is caused by development of forest soil, and it can be easily estimated that water reservation in the watershed has increased. The temporary increase in the 1960s in Ananomiya is based on the influence of water dispersion work and the increase in the 1980s is a future examination subject.

H

HS02/11P/C24-004   1445

IMPACT OF CLIMATE ON FLOW REGIMES OF THE UPPER REACHES OF STREAMS

Hironobu SUGIYAMA[1], Varawoot VUDHIVANICH[2], Andrew C. WHITAKER[1], Kosit LORSIRIRAT[3] ([1]Graduate School of Science and Technology, Niigata University, [2]Faculty of Engineering, Kasetsart University, Thailand, [3]Royal Irrigation Department, Thailand)

The objective of this paper is to compare flow regimes in the upper reaches of streams in the temperate zone (eastern Japan) and the tropical monsoon zone (western Thailand), and then to examine an index of low flow, aiming towards the synthesis of water resources evaluation. Research catchments were selected with the restriction that there are no regulation or diversion structures in the upper reaches of the streams. The range in catchment areas is 45.9-10,880 km^2, and the range in record lengths is 15-43 years. Firstly, the flow regimes of the upper reaches of streams are stochastically evaluated by applying the stochastic flow duration (SFD) curve. In Japan, the nonexceedance probability value of 10% (10 year probability) of the discharge exceeded 97% of time ($Q97_{10}$) has generally been recognized as a design flow for water resources facilities based on the severity of droughts. Then, by the comparison of values used from the SFD curve with the 10 year probability value, it is understood that the discharge exceeded 97% of time in the tropical monsoon zone is about one-fifteenth of the temperate zone. This difference indicates that this flow regime is uncomfortable for planning if a water resources planner evaluates a flow with the 10 year probability. It may be argued that a more severe probability of occurrence (i.e. longer than 10 years) should be adopted for the design of water resources facilities in the tropical monsoon zone. Secondly, the recession shape of the lower part of the flow duration curve is compared. From the examination of these shape characteristics, it is observed that the recession shape of the lower part of the flow duration curve is dependant on the strength of low flow persistence. By comparing the recession shape of the lower part of the flow duration curve, it is seen that the persistency of low flow in the temperate zone is stronger than that in the tropical monsoon zone. Finally, the index of low flow is discussed by examining the relation between the index used in Japan and that in the United States. In the United States, the value of the 10 year probability for annual minimum flow averaged over a consecutive period of 7 days ($Q_{10,7}$) of a given year has been used as an index of low flow. The relationship between $Q_{10,7}$ and $Q97_{10}$ is strong. This aspect implies that the 10 year probability value for the discharge exceeded 97% of time can be recognized as an index of low flow.

HS02/11P/C24-005   1500

ASSESSMENT OF DROUGHT IN THE CONDITIONS OF CLIMATE AND ECOSYSTEM CHANGES: CASE STUDY IN THE SOUTH - WEST REGION OF ROMANIA

Gheorghe STANCALIE, Elena SAVIN, Vasile CRACIUNESCU, Simona CATANA, Anisoara IORDACHE (National Institute of Meteorology and Hydrology, Bucharest, Romania)

The physiographic and biophysical characteristics of many regions change through time, due to natural or anthropogenic factors, thus increasing or lessening sensitivity to climate impacts. Among the various suspected causes of climate variability land cover/use modifications and environmental degradation (overgrazing, deforestation) constitute a major focus of interest. In the last 2 decades, the increase of the aridization trends under the conditions of drought having affected certain regions in south of Romania, where the mean yearly temperature is over 10°C, the mean yearly precipitation is under 500 mm and the aridity "de Martonne" index is under 25. The south of the country with temperate continental climate undergoes also more severe hydrological drought as against the others regions. Injurious consequences of drought are felt going to exhaustion of water resources, drainage of rivers and diminution of crops. The area of interest corresponds to the Oltenia region, situated in the south-west of Romania in which eight very severe droughts years were recorded during the last 20 years, and the annual mean runoff was constantly at least 50% lower than multiannual mean runoff. In this region there is the coal basin Motru, chosen as a relevant example for emphasizing the modifications, which affected the active surface, due to the human intervention. and analyzed on the basis of cartographic documents, aerial and satellite images. From the analysis of processed remotely sensed data an updated representation of the topography, as well as of the land cover/use has resulted. The modifications occurred in the land cover and use, led obviously to the modifications of the structure of the radiative field at the local an regional scale, due to the redistribution of the albedo values of different surface types, that in this case have suffered a weak increase. In analyzing the drought phenomena, the lack of rainfall and the hydrological regime were mainly considered but other parameters were also taken into account, such as the maximum temperature over 25°C, the potential evapotranspiration and the aridity "de Martonne" index. Studying the meteorological and hydrological factors, a natural aridization tendency, associated with the climate variability at regional scale has been observed. An integrated monitoring system was designed and implemented in order to emphasize the trends, extent and future evolution of the drought and aridization phenomena. This approach allows the combination of thematic layers for the modeling of the interactions between the physiographic, climatic and anthropogenic factors as well as for the determination of some complex parameters facilitating the surveillance of the vegetation-soil system and the water resources during the drought periods. The main conclusion of the study is that in order to increase ecosystems resistance at long drought effects due to climate change, stress elements as anthropogenic ones must be decreased, if not eliminated.

TOWARDS AN OPTIMUM WATER RESOURCES DEVELOPMENT IN THE NIGERIAN NIGER DELTA

Adepoju D. OLUSEGUN (Geography Department, Faculty of Social Sciences)

Man's interaction and interference with the environment in order to satisfy his socio-economic needs without adequate management plan always result in environmental degradation either in the short or long term since the effects of his actions are registered in the atmosphere, accumulates and it is only a matter of time before its manifestation. The present water problem in the Niger Delta area of Nigeria is a combination of tripartite factors of climate change, increasing population, and the global economy. The implication of the climate change is due to the fact that Nigeria through the Oil and gas activities especially flaring contributes a significant amount of carbon mono-oxides, carbon dioxides in the global atmosphere which play an important role in raising temperatures at both the local and regional levels; but the major effect of these is mostly felt by the local environment. One of the consequences of these actions is inundation through the saline water in55cursion into the freshwater environment thereby increasing water problem both in quality and quantity. Secondly, growing populations, associated urban development and intensifying pressures on small areas of land are creating new pressures on available water resources with conflicting water demands, occurring to a lesser extent across the Niger Delta area. The population continues to grow at an estimated 2.8 percent per annum while urbanisation increases even more rapidly at an estimated rate of 5.2 percent. A visible consequence of this is the increased competition between users leading to increased conflict between users. That Nigeria and in particular the Niger Delta is having a fair share of the impact of dynamic global economy cannot be overemphasised. Of the three standard categories of freshwater use - for Agriculture, industry, and domestic - industry (processing, exploration, exploitation activities etc) is dominating. As a result of Pollution of surface water from increasing oil exploration and exploitation, industrialisation, increased food production is reducing the quality and quantity of portable water thereby reinforcing the problem of scarcity. In this study monthly rainfall and temperature datasets from the period 1941-1990 was in order to evaluate climatic trends of basic water resources parameter useful for assessing proper water resources planning and development in the Niger Delta. Optimal strategic water resources scenarios was built towards a sound water resources of the Niger Delta using GIS techniques.

CURRENT CONSTRAINTS TO THE IMPLEMENTATION OF WATER DEMAND MANAGEMENT (WDM) IN URBAN CENTRES IN ZAMBIA

Daniel C.W. NKHUWA (School of Mines, University of Zambia)

Water is more than just a commodity but also an essential element that supports all forms of life. It is also basic to many socio-economic activities. In this regard, it is imperative to recognise its economic value in all policy and sector activities so that wise and efficient use of the resource is initiated and promoted in all sub-sectors, particularly in the large urban centres. However, the provision of adequate water supply and sanitation to the rapidly growing urban populations is increasingly becoming a problem for most cities and towns in Zambia. The continuing expansion of the numbers of people who need water and sanitation services and who cannot readily get the services by self provision continue to exert continuous pressure on either investment to create additional production capacity or to stretch the available supplies to serve more people. The predominant approach towards meeting these increasing water demands has been towards supply augmentation schemes. Undoubtedly, the cost of developing these new sources will get higher and higher as most accessible water, in terms of quality and quantity, has already been tapped. In places like Lusaka, the country's capital, where demand has outstripped demand, citizens have taken to indiscriminate drilling of boreholes. In places, this has caused aquifer over-abstraction, which has initiated lowering of the water table. If this trend persists, pumping charges may go up, thereby heightening the cost of supply. This may eventually affect the availability of water to the poor who may not be able to afford the new rates. It is in this regard that water demand management (WDM) becomes the preferred alternative in meeting increasing water demand in order to improve efficiency and sustainable use of water resources taking into account economic, social and environmental considerations. However, there are a number of constraints that have inhibited successful implementation of WDM. These include: Inadequate knowledge by consumers and water utility staff of the socio-economic benefits of implementing WDM Unfavourable pricing mechanisms Poor revenue collection rates, which have caused the water utility companies so severe financial constraints that they are unable to finance some of the routine operation and maintenance operations to the existing conveyance networks. Consideration of WDM as an inferior alternative to the construction and extension of new conveyance systems. Inadequate policy and legal frameworks, overlapping responsibilities among the water and sanitation sector institutions. Lack of clear sector policies, compatible legal framework, clear division of responsibilities and mandates, which has resulted in low priority assigned to operations and maintenance within the water sector. This paper will attempt to highlight what measures must be adopted to overcome these and other constraints to the implementation of WDM.

HS02/11P/C24-003OP   Oral-Poster   1523

PRECIPITATION ENHANCEMENT OPERATION ALONG THE YELLOW RIVER IN WESTERN CHINA BY WEATHER MODIFICATION METHOD

Xueliang GUO[1], Meiyuan HUANG[1], Tiezheng LI[2], Junsheng ZHANG[2] ([1]Institute of Atmospheric Physics, Chinese Academy of Sciences, [2]Yellow River Hydropower Co. of China)

This paper discussed the weather modification activities and their application to water resources management. The shortage of water supplies in the region along the Yellow River of western China has increased in recent years and is related to some decrease in annual precipitation, but mainly due to the increasing demand from the rapid growing population and industrialization in the region, which has seriously threaten the development of hydropower along the Yellow River. The precipitation enhancement activities have been conducted as an additional source of unconventional water supply for many years in the region. This work focused on clarifying the fundamental mechanism involved in precipitation enhancement by cloud seeding. We will introduce the climate condition that suitable for precipitation enhancement activities in the region as well as the efficacy of cloud seeding. In addition, a comparison study of cloud seeding was made with a current widely used seeding agent—silver iodide (AgI) and a newly developed seeding agent—liquid carbon dioxide (liquid CO2). Characteristics of cloud dynamics and microphysics and the interactions between them affected by the artificial seeding of AgI and liquid CO2 are examined using a 3D stratocumulus cloud model with seeding processes. The model results show that the liquid CO2 seeding in the region of high supercooled cloud water in the simulated cloud can generate shallow thermal convection and cause larger dynamic effect than that AgI seeding, and thus can significantly enhance surface precipitation. The seeded clouds by liquid CO2 show two prominent increases in maximum updraft. The first increase is directly produced by liquid CO2 seeding and the second is caused by downdraft outflow induced by falling precipitation in the boundary layer. The formed shallow thermal convection can produce many ice crystals. By the recirculation growth of these ice crystals transferred by the updraft of the thermal convection, they can consequently grow to precipitable particles such as snow and graupel.

HS02/11P/C24-004OP   Oral-Poster   1527

WATER RESOURCE MANGEMENT IN THE UPPER REACH OF THE GORAI RIVER OF BANGLADESH

Mohammad Monowar HOSSAIN, Mohammad Rashedul ISLAM (Department of Water Resources Engineering, Bangladesh University of Engg. & Technology)

Gorai river is the only distributaries of the river Ganges in Bangladesh. The Ganges is the second largest river in the Indian subcontinent. Gorai river is the prime source of freshwater to the South West Bangladesh, which covers an area of about 30% of area of the country. In recent times, the river was getting silted up at its mouth and for some distance downstream due to gradual decrease of the Ganges water. As a result very little water was available in the Gorai river during dry flow season. Tremendous environmental impacts were being felt in the Gorai dependent area due to this water shortage over the last few years. The Government undertook a program of dredging the Gorai for a distance of about 30 km from the mouth with a view to increasing the conveyance and attracting more flow in the river. The aim of this study is to examine the effectiveness of this dredging activity. The analysis has been conducted on the basis of dredge and post dredge observed bathymetry. The dredge bathymetry stands for the bathymetry measured immediately after the dredge and the post dredge bathymetry stands for the bathymetry after the passage of first year flood flows over the dredged Gorai. It is found from the analyses of these bathymetry that the normalized bed levels of the dredge bathymetry has been lowered all along the dredged Gorai while the bottom bed levels is found to have been raised. This implies that the pilot dredging has increased the high level conveying capacity of the Gorai while the low level conveying capacity has been decreased after the passage of first year flood flows over the dredged Gorai. Evidently this change in decreasing the low level conveying capacity of the dredged Gorai is due to the sedimentation in the deeper channel and therefore, the first year pilot dredging is not meaningfully effective in the sense of self-sustaining development for low flow augmentation. It is found that the bottom bed level of dredge channel has been raised close to the level of pre-dredge (post monsoon 1997) state after the passage of first year flood event over the dredged channel. Thus dredging may not be a sustainable means for management of water resources problems in the sediment-laden rivers of Bangladesh especially of the Gorai.

THE GENERAL PRINCIPLE FOR RESTORATION OF THE RIVER BASINS

Boris FASHCHEVSKY[1], Tatyana FASHCHEVSKAY[2] ([1]International Sakharov Environmental University, [2]Ufa State Aircraft University)

The first step to restore any water body has to be the assessment of its ecological troubles on the scale ˝norm-pathology˝ here the criteria must be established determining the notions ˝the norm˝ and the ˝the pathology˝. The main among such criteria are the following: First, these are indices of the basic hydrological characteristics: maximum and minimum discharges and levels of water, inside-year distribution of a river flow in different years of water capacity -5, 25, 50, 75, 95 % frequency and average annual discharges and levels of water, duration of floodplain flooding, temperature and ice regime, flow of sediments. Second, these are indices of water quality, characterized by major ions, oxygen and pH concentration, biogenic elements, organic matters and heavy metals. Third, the important criterion in assessment of a river state is the character of channel process development, which in the result of economic activity can be changed greatly in the terms of hydrography (slopes of rivers and basins, drainage density, tortuosity, area of swamping, area of lakes, area of forests, area of ploughed lands, area of urban, etc) and morphology (increase and decrease of depths, narrow or widening of channels, damming of floodplains, extraction of building materials from channels, dredging of waterways, etc) of rivers and their basins. Forth and often (but not always) a main and completing component is a biotic one of the river ecosystem, the influence by the first three components and includes: bacteria and viruses, alga and higher aquatic plants, invertebrates, fishes, amphibia and aquatic reptiles, waterfowl and semi-aquatic birds, aquatic and semi-aquatic mammals. As the ˝norm˝ of a river ecosystem is its state before the beginning of a human activity in this basin or the state of the river-analogue that are situated in analogous natural conditions but untouched by a human activity must be accepted. All above-mentioned hydrological, hydrochemical, hydrographical, morphological and biotic components have to be accepted for the norm and recalculated for a restorated basin in a special way. The restoration of a river basin can be produced: 1. Totally on all regime elements and bioproductivity of aquatic and semi-aquatic plants and animals. 2. Partially, only for the separate elements of regime and separate components of biotic ones. For example, restoration of only migratory fish, ignoring the phytophilous species, which need an obligatory flooding of floodplain. 3. Artificial creation of a new ecosystem in a given river system by the way of introduction and acclimatization new species of plants and animals which have never occurred in a given river but if there are favorable conditions for reproduction these species. The experience of such developments has obtained a wide dissemination in the world, including Japan, China, Australia, Chile, Norway, France, Russia and others countries.

MAÎRISE ET CONFLITS LIÉS À LA GESTION DES RESSOURCES EN EAU DANS LA BASSE VALL ÉE ET LE DELTA DU FLEUVE SÉNÉGAL

Alioune KANE (department of geography/ Faculty of Arts and Human Sciences/ University Cheikh Anta Diop)

L'int érêt port é à ces milieux de la zone tropicale sèche, caractérisés par l'extrême fragilité de leur équilibre écologique, se justifie par la demande en eau pressante d'une population en forte croissance, les saisons climatiques caractérisés avec une irrégularité pluviométrique marquée, imposant des contraintes sévères à l'environnement et un caractère aléatoire à cette ressource dont l'exploitation traditionnelle était très souvent rythmée par le régime hydrologique du fleuve. Depuis deux à trois décennies, de grands programmes d'aménagements hydro-agricoles ont été développés. Les barrages de Diama et de Manantali, ont complètement artificialisé le régime hydrologique du Sénégal., permis le desserrement de la contrainte de mobilisation de la ressource en eau., le fonctionnement du système est désormais tributaire de la pluviométrie dans le haut bassin et du mode de gestion. Ces programmes se traduisent par des modifications radicales du fonctionnement hydrologique naturel et des transformations très importantes affectent l'environnement. Ces bouleversements peuvent prendre un caractère particuliérement grave, notamment lorsqu'ils se conjuguent à des modifications climatiques qui fragilisent encore un milieu sensible du fait de sa position en bordure du Sahara. Souvent ces programmes d'aménagement des bassins versants ont mal évalué les impacts écologiques et sociaux, engendrant des dysfonctionnements dans les rapports homme-nature, et compromettant l'instauration d'un développement durable. La maî·rise hydraulique est imparfaite, les parcelles sont souvent mal planées. La qualité des eaux de drainage est une préoccupation majeure, la capacité du réseau s'est avérée limitée et insuffisante pour assurer une bonne vidange. Les déversements d'eaux de drainage ne sont plus acceptables, le degré de toxicité de ces eaux et les volumes en jeu ne sont pas connus. La maî·rise des eaux et le développement de la riziculture ont mis en contact les populations avec l'eau douce stagnante et différents vecteurs de maladies. Le grand effet purgatif du à l'invasion des eaux marines a disparu, les risques d'aggravation des maladies se sont multipliés. La prolifération de la végétation aquatique se pose. La construction des grands barrages ayant pour but d'atteindre l'autosuffisance alimentaire, se révèle mal maî·risée. Les efforts de modernisation agricole ont porté sur une conquête de l'espace et un développement de la riziculture irriguée. Les modifications du milieu résultent de la création des aménagements hydro-agricoles et des réserves d'eau douce, avec une recomposition d'une société paysanne multiforme, sans

aucune technicité ni moyens financiers appropriés, les éleveurs peul sont les grands perdants. Le partage des ressources en eau est un problème difficile entre états riverains aux intérêts divergents avec la revitalisation des vallées fossiles du Sénégal. La vallée du Sénégal n'est pas une région d'irrigation traditionnelle. Les dysfonctionnements notés au plan de l'environnement, hypothèquent lourdement l'avenir des aménagements.

RAINWATER MANAGEMENT TECHNOLOGY FOR CONJUNCTIVE USE IN ARID REGION, INDIA

M. A. KHAN (Central Arid Zone Research Institute)

In Indian arid zone of Rajasthan and elsewhere several kind of rainwater harvesting structures have been in vogue since many centuries. At field level runoff has been collected in natural depressions or in dug-out structures such as ponds, tankas and khadins. Till recently local wisdom, experiences and precedences guided the designing of such structures. However, for better storage, conservation and judicious use, CAZRI, Jodhpur provides details of design. Seepage proofing in ponds was found necessary in sandy soils where percolation rates are high. In western Rajasthan, dug-out ponds locally known as Nadi and tanka are used mainly for domestic water use and economically not viable option for surface irrigation. However, if recycling of rainwater primarily links more profitable cash yielding crops or tree component, potential water storage in these structures is likely to become highly attractive. Recently, tankas have been constructed on large scale in western Rajasthan for developing fruit orchards. Response of ber (Ziziphus nummularia) and pomegranate to supplemental irrigation from tanka was studied (1995-97) on a loamy soil at Jodhpur. Compared to control (no irrigation) increase in fruit yield with 2, 4 and 6 irrigation for ber was 46.,4%, 80.3% and 124%, whereas in the case of pomegranate it was 69.8%, 112.5% and 191.7%, respectively. Tankas have also been found useful in raising forest nurseries and establishment of trees in watershed. Khadin is an other method of water resources development, conservation and utilisation for crop production even in very low rainfall 150-300 mm. Rocky catchments with adjoining valley-filled lands are converted in khadin farm by constructing earthen embankment at lower periphery of field with suitable spillway arrangement. The system is very popular in hyper arid region of Rajasthan. Due to low rainfall, the catchment to command ratio is rather high ranging from 8 to 15. On khadin farms, even without agronomical practices and with no application of fertilizer the average of yield ranges from 20-30 q ha-1. Anicut, percolation tanks and sub-surface barrier are very effective water harvesting and recharge techniques to improve ground resources in depleted aquifers. With the construction of anicut in Ujalian watershed in Jodhpur district, the annual increase in static water level in wells located in the zone of influence ranges from 1.8 to 2.2 m as compared to wells located in the adjoining area. In Pali district, due to the presence of anicut groundwater recharge has increased from 5.2 to 38.5%. Percolation tanks for inducing recharge is being practiced in parts of India. The average rate of percolation from percolation tanks constructed in different geological formation ranges from 10 to 72 mm day-1. Similarly with the construction of sub-surface barrier across an ephemeral stream at Chauri-kalan in Jodhpur district, the rate of depletion has been reduced from 1.2 m year-1 to 0.3 m year-1, and water yield has increased from 60 m3year-1 to 125 m3 year-1. With the increased ground resources, over 15 ha area has been brought under well irrigation.

DECISION SUPPORT INFORMATION FOR WATERSHED MANAGEMENT OVER DROUGHT PRONE REGION

Nagarajan Ramakrishnan IYER (Center of Studies in Resources Engineering, Indian institute of Technology, Bombay)

An effective mitigation activity during drought situations offer support to the people, in carrying out their regular activities, without much stress on their existing water and food (if necessary) availability. Continuous monitoring of spatial and dynamic land resources and the vulnerable groups is important. Integrated analysis of rainfall, run-off and surface storage facilities and creation of demand and supply scenario during the summer months would help the water regulation planning. It is observed that some of the un-preparedness situation of the government agencies is mainly due to the lack of dynamic input into their preparedness planning. The individual subject experts broadly use deficit of rainfall amount, water supply, crop production and reduced purchase power in identifying a drought area. Even though meteorological drought is considered as the initiation of drought situation over an area, followed by deficit of water supply and crop production. A multi-criteria approach is warranted. An attempt has been made in the creation of drought intensity scenario (demand and supply approach) for group of settlements in a watershed located in the semi-arid region using integrated analysis of static and dynamic information. This study has adopted a methodology based on the rainfall and water requirement, in aiding the crisis situation and sustainable planning at local level. Time series analysis of annual rainfall of 100 years was used in identifying critical period. The inter-rainfall gap analysis was carried on 10 years of daily rainfall. Based on these results and the reported physical situation, a threshold of annual rainfall (below which scarcity begins) was established. Surface run-off was calculated using SCS method and the surface cover information changes were collected from the orbital India remote sensing satellite data. The water spread of the irrigation tanks was demarcated and used in the water availability estimation. Ground water level fluctuation information was collected and used in establishing relationship with rainfall over the years. Crop area and type and their inter-seasonal (winter/summer) and annual changes were deciphered from temporal satellite Revenue village Information on the human / animal population, crop type and area, water resources availability (ground water & surface water), natural vegetation cover, rainfall and temperature information, etc., were collected from the existing revenue records and updated from the interpretation of temporal IRS data. The demand from the crops (including the evapo-transpiration and transmission loss) and the settlements (human and animal) was calculated for individual settlement/villages. The supply position of the watershed by way of surface run-off and storage and their losses over seasons was estimated for a given rainfall event. A drought scenario situation for Jhod nadi watershed, tributary of Godavari River, located in Nanded District of Maharashtra, India, with an area of 196 km² was created. Probable drought severity of the settlements (about 40) was grouped in low to very High depending on their deficit percentage of demand-supply. An effective method for regular monitoring and preparedness is discussed in the paper.

USE OF GEOGRAPHIC INFORMATION AND REMOTELY SENSED DATA IN THE DECISION-MAKING SUPPORT SYSTEM FOR FLOOD MANAGEMENT IN ROMANIA

Corina PREDESCU, Gheorghe STANCALIE, Elena SAVIN (Remote Sensing and GIS Laboratory, INMH)

Floodings are an important risk in many areas around the globe and especially in Romania. In the latest years floodings occurred quite frequently in Romania, some of which isolated, others were affecting wide areas of the country's territory. The paper presents the elaboration of the cartographical documents on the flood risk regions over a pilot watershed

H

and the development of the GIS applications with a decision system for the crises management. A modern approach is used for the flooding risk indices estimation. These indices are associated to the physic-geographical, morpho-hydrographical and vulnerability characteristics of a region. The methodology was elaborated to determine the flooding risk, using risk indices at a scale compatible with a synthetic representation of the territory. There are stressed the facilities supplied by the Geographic Information System (GIS) and the remotely sensed data to manage flooding during their characteristic phases: before, during and after flooding. Accent is laid on the pre and post-crisis phases. An important research topic was the study of the parameters that can be extracted from satellite images in view of organizing a hierarchy of the geographical space versus the flooding risk. Information obtained from satellite images proved to be useful for the determination of certain parameters necessary to monitor flooding: hydrographic network, water accumulation, size of floodable surface, land impermeability degree, water absorption capacity over the basin surface, or resilience to in-soil water infiltration. The study encompassed both the risk degree levels related with various parameters, which influence and determine floodings and which takes into consideration the human presence in the sensitive areas. The application was developed for the Arges hydrographic basin in Romania, a critical area, keeping in mind that it withholds many localities, including the capital and also important economic centers. Advantages offered by this integrated system are: to manipulate and make available large databases, to easily update the information, to survey the temporary modifications, to establish the link between the measured/forecasted data and the GIS database. The database allows obtaining synthetic representations of the hydrologic risk for the Arges basin, through separate or combined use of the risk parameters as well as for interfacing with the hydrological models in view to improve them as regards recovering results and the possibility to achieve scenarios.

VELOCITY DISTRIBUTION DUE TO LAUNCHING APRON AROUND ABUTMENT

Mohammad Monowar HOSSAIN, Mohammad Salzar HOSSAIN, Mohammad Faheem SADEQUE (Department of Water Resources Engoneering, BUET)

Velocity distributions were measured in a small-scale riverbed model for vertical wall abutment constructed at the Hydraulics and River Engineering Laboratory of Bangladesh University of Engineering and Technology (BUET). A series of test run were conducted for five different apron-setting configurations and velocities were measured using a programmable 2-D electromagnetic liquid velocity meter. Comparison of velocity distribution in terms of velocity vectors with and without apron was made. It was observed that considerable displacement of velocity vectors occur due to different apron setting. Due to displacement of velocity vector, the scour depth was found to be affected significantly. Vertical velocity distribution at the maximum scour hole formed due to apron setting was also measured. The result obtained gives an indication of use of falling apron for protection of vertical abutment against failure due to scour.

URGENT WATER SUPPLY INTO ZHALONG WETLAND IN 2001 AND 2002

Shiguo XU[1], Lianwen DANG[2], Heyue LI[2] ([1]Department of Civil Engineering, Dalian University of Technology, [2]Songliao Water Resources Commission)

Nen River basin is located in northeast of China, where belongs to monsoon precipitation zones. There usually are short summers and long winters with spring draught and summer floods. Around lower reaches of Nen River, there exist many big wetlands, such as Zhalong, Xianghai and Momoge wetlands. Zhalong wetland is the biggest one with the area of 2100km2, 468 species of vegetations and 236 species of birds belonging to 48 families. The main protected bird is Red Crown Crane. It is one of 7 wetlands earliest accepted by Ramsar convention in China. Water is very important for wetland evolution. As the water resource development is gradually actualized on the upstream of rivers that flow into Zhalong wetland, water shortage problem has endangered the wetland ecological environment. Farther more, after the big flood in 1998, Nen River basin faced a four-year long draught series. At the begin of 2001, the area of water surface in Zhalong wetland was only 130km2, much less than the average area 800km2 and that in common dry year 300-400km2. The most part of the wetland draught up. Reeds couldn't grow up as usual. A lot of reed wetland became into grass wetland and the vegetal state degrades very seriously. It threats the habitation condition of Red Crown Cranes that make their nests and hatch small cranes in every earlier summer here. So as to maintain the condition to keep basic function of the wetland, an urgent water supply project from Nen River to Zhalong wetland is put into practice. In the later autumn of 2001, supplied 35?106 m3 of water into the wetland, and from the spring to summer of 2002, 300×106 m3 again. According to the investigation on site, water supply has achieved satisfactory results. In the end of April, the supplied water pours over the central area of the wetland. By recovering the ecologic condition of reed and fish, it helps Cranes and birds very much. This urgent water supply program provided a useful experience to rescue wetlands from a water shortage disaster. In the same time, an especial water resources plan of Zhalong wetland is under working to guarantee the water supply safety of it for a long term. A key project supported by National Natural Science Foundation of China is also come to operation, which studies the problems concerned with using floodwater to restore wetlands and using wetland to make floodwater a useful water resources.

MAXIMUM OVERLAND FLOW IN RIVER BASIN AND LANDUSE

Elena ASABINA (Russian Research Institute for Intergrated Water Management and Protection)

Present paper is the case of study of the basin where water resources for large city water supply are being formed. High economical activity in the basin transforms environment. Change of landuse structure such as transformation of forests into farmlands, meadows into pasture lands, bogs into meadows, etc. leads to changing of overland flow which presents the main component of river runoff. Solved problem is to assess how the values of overland flow depend on character of landscape. To prevent negative consequences of these

---

processes for runoff regime it needed to reveal the areas in the basin where main quantities of overland flow are to be generated and to protect them against possible landuse. Values of precipitation were almost equaled in different areas of studied basin. However, significant differentiation of overland flow in the space of the basin was found that is explained by differences of overland flow genesis such as characteristics of land surface. Character of landscape and soil type cause different conditions in the basin. Each of landscapes in combination with topography and soil can be considered as certain runoff-producing unit, which characteristic is uniform conditions of overland flow genesis. Hence, the river basin as a whole and its different areas were represented by combination of various runoff-producing units and overland flow was evaluated in different areas of the basin. Also, overland flow was assessed for different phases of hydrological regime such as winter low water, spring flood, and summer low water with rain floods. It was found that main amount of overland flow is being formed during spring flood and in upstream but not in downstream part of the basin as it was thought earlier. Obtained conclusion will allow providing optimal landuse practice in future.

ARTIFICIAL NEURAL NETWORK MODELING OF THE RAINFALL-RUNOFF EXTREME EVENTS

Dionysia PANAGOULIA, Nikos MARATOS (Department of Water Resources, Hydraulics and Maritime Engineering, National Technical Univercity of Athens)

An artificial neural network (ANN) is a reliable mathematical mechanism in modeling the complex nonlinear relationships between input and output timeseries. ANN models have been proven effective and efficient to model the rainfall-runoff relationship in situations where explicit features of the internal hydrological subprocesses are difficult to be described using physically based equations. A new algorithm using a combination of linear least squares and multistart simplex optimization is developed to show the mechanism and parameters of three-layer feed forward ANN models and the potential of such models for simulating and forecasting the high-and low-flow events over a mountainous catchment. The output "rain plus melt" from the snow accumulation and ablation model of the US National Weather Service (US NWS) applied on a medium-sized mountainous catchment. The Mesochora catchment in Central Greece was used as input to ANN model. The conceptual soil moisture accounting model (SMA) of the US NWS applied, as well, over the same catchment, for comparison of extreme values. The RMSE (root mean square error) and %VE (percent volume error) statistics, for each model, computed separately for flows above and below the 15-year meandaily flow and presented as a function of the total annual flow for eachdata year. Note that the five calibration years were the driest of the 15 data years. Clearly, RMSEA (root mean square error above-mean daily flow) performance of the SMA model is worse than that of ANN on all years. The results of the RMSEB statistic (root mean square error below-mean daily flow) indicate that ANN model performs best for all of the years. The %VEA (percent volume error for above-mean daily flow) statistic indicates thatthe ANN model consistently has the smallest bias, while the SMA performance is poor. The %VEB (percent volume error for below-mean daily flow) statistic shows the poor performance of SMA model. We should not point out that the poorperformance of the SMA model does not reflect so much on the ability of the model as it does on the calibration procedure used. In addition, an 'expert' would not allow the model error bias at various flow levels to deteriorate so much while minimizing the error variance. Although the ANN model developed here, by no means, could substitute a physically based conceptual model, the results indicate that the ANN model may provide best performance when only dry years of data are used for calibration.

DETERMINATION OF INSTANTENEOUS UNIT HYDROGRAPH WITH CLARK'S TECHNIQUE IN GIS

Musa YILMAZ, Nurunnisa USUL (Water Resources Lab. Department of Civil Eng. Middle East Technical University)

Determination of unit hydrographs for the basins is very important for the design of hydraulic structures. When there are observed rainfall-runoff data for the storms they are obtained by using these data, but when there are no observed data they are obtained by using synthetic unit hydrograph methods. In this study one such method is used together with Geographical Information Systems techniques. Application of Clark's synthetic unit hydrograph technique with GIS technology requires the estimation of three parameters of the original methodology. Time of concentration, Tc, is derived from SCS lag equation, reservoir storage coefficient, R, from an observed storm hydrograph and the time-area histogram is determined from the Digital Elevation Model of the basin. The translation hydrograph is then derived from time-area graph by applying a unit excess rainfall over the basin. After performing a linear reservoir routing, the translation hydrograph is routed to the basin outlet and the Instantaneous Unit Hydrograph of the basin is obtained. It can be used to obtain any duration unit hydrograph and then storm hydrographs for this basin. Such a study is performed for two different size basins in Turkey and the results are compared with the observed unit hydrographs of the basins and a discussion is given.

ARIDIFICATION AND THE INCREASE OF FLOOD EVENTS IN CENTRAL EUROPE

János RAKONCZAI, Katalin BÓDIS, Ferenc KOVÁCS (Department of Physical Geography, University of Szeged)

Hydrological events in Central Europe (including the more thoroughly analyzed Hungary) began to show a strange kind of controversy in the past decades. It is clearly visible through statistics that precipitation has decreased significantly (with about 10 %), at the same time however, the number of flood events shows a remarkable increase. In the year 2000 the situation was really peculiar, because in the beginning of a persistent drought significant flood prevention efforts had to be made along the Tisza riveri. e. drought and flood at the same time!We demonstrate the characteristics and consequences of the aridification process from several aspects. Beginning as early as 1910 precipitation in Hungary is dropping constantly. Statistical analyses show that the reduction did not bring about the decrease of variability; fluctuation was merely transferred into a lower range of values, clearly showing the decrease in the average amount of precipitation. The persevering drop of precipitation has produced a significant decline in the amount of groundwater. This process became obvious since the early 0-s. We have determined through detailed GIS analysis the spatial and temporal changes in the level of groundwater and the total deficiency in subsurface waters. One of the most important consequences of the analysis is that in some areas even the significantly rainy years could not stop the decrease of groundwater meaning that the drop of precipitation clearly appears in subsurface waters. (It is important to bear in mind that the decrease of subsurface waters in closely connected to relief: in plain areas that are higher than their surroundings the decrease is more significant.) To determine the reaction of foliage to aridification we executed spatial analysis based on Remote Sensing methods.Throughout the world, floods became more frequent in the past decades. This is

caused by both natural processes as well as the changes in social and economical structures. Extensive growth of agriculture became possible by creating arable lands through massive river regulation works. However population growth can also cause people to move into areas that are endangered by floods. Floods are thus just the products of natural processes in such areas. The truth is however, that due to human interventions, areas of potential flood-risk has expanded as well. The higher water levels in regulated rivers or the huge amount of water stored in large reservoirs both lead to flood risks to get higher than they would naturally be. In addition to the above, meteorological extremities also augment the possibilities for floods. The flood disasters of recent years all over the world and in Central Europe clearly demonstrate this as well. In this lecture we will, through demonstrating several floods, evaluate their natural and social background. It can be said that now floods can appear in any part of the year due to climatic changes, nature can produce quite peculiar extremities (extraordinary amounts of precipitation; record breaking flood levels along the Tisza river in four consecutive years), as well as the way human actions affect natural processes.

DEVELOPMENT OF NEW TECHNOLOGIES OF FLOOD SIMULATION AND FORECASTING IN REAL-TIME

Sandra Gabriela GARCIA (Technical University of Cartagena. Department of Thermic Engineering and Fluids)

The flash floods constitute one of the main problems of the Mediterranean semiarid zones of Spain. The convective storms of high intensity, typical of these zones, produce hydrological events that can turn out to be catastrophic. Due to the scanty existing time between the runoff hydrograph peak and the associated rainfall, the warning of flooding must be based on meteorological and hydrological forecasting. The coordination among the responsible authorities in the operational flood management, needs real-time operative decision support system. The use of Geographical Information Systems (GIS) in the development of these support tools, it constitutes a foreseeable direction. The GIS allow an efficient integration of information with a high spatiotemporal resolution, and spatially distributed hydrologic models oriented to runoff simulation and prediction in real time. The development of new methodologies and tools that allows the operative integration of radar rainfall fields and short term quantitative rainfall forecasting as input to distributed spatially rainfall-runoff models, are proposed. Finally, it is to be underlined that this work incorporates the use of new technologies (GIS, remote sensing, Digital Elevation Models) and the most recent developments in aspects of estimation and treatment of the spatial distribution of soil moisture and the flow in the unsaturated zone. The main objective is to improve the forecasts of flash floods applying a decision support tool in real-time named *Shyska*, developed with GIS-embedded functions.

SPATIAL-TEMPORAL APPROPRIATENESSES OF EXTREME PROCESSES FORMATION IN RIVERS SYSTEMS OF REGIONS WITH SHARP CONTINENTAL CLIMATE

Leonid M. KORYTNYI, N. V. KICHIGINA (Institute of Geography Siberian Branch Russian Academy of Sciences)

Spatial-temporal appropriatenesses of floods and shallows formation in main basins of East Siberia- the Enisey, Angara, Lena rivers, Lake Baikal are researched.Genetic and statistical regional analysis considers the specific of physiography conditions and also the peculiarities of sharp continental climate that has a tendency to change for the last ten years. Long-term series of flow on 120 hydrological gauge lines are the basis. Floods and shallows characteristics are determined: causes of extreme situations, their recurrence, geophysical and hydroengineering factors. Zoning of East Siberia on floods risk is implemented and statistic analysis of flow´ extremes and curves of maximum flow distribution as well. Researches are directed to decrease extreme situations in water resources´ systems. Effectiveness of different gear of risk management, the system of ecological insurance in particular is considered. For a number of regions the risk areas in the valleys of main extreme flood rivers is marked out and regulations of economic activity in these valleys are worked out. In the base of regulations there is the combination of four types of arrangements: geoecological, economical, engineering, and legal.

DEVELOPMENT OF WATERSHED RAINFALL-RUNOFF MODEL BASED ON THE PARTIAL CONTRIBUTING AREA CONCEPT

Chin-Hsin CHANG[1] ([1]Department of River and Harbor Engineering, National Taiwan Ocean University, [2]Department of River and Harbor Engineering, National Taiwan Ocean University)

The objective of this study is to develop a rainfall-runoff model based on the partial contributing area (Betson, 1964; PCA) concept. The influence factors of the PCA phenomena were investigated. The size of the PCA during storm is derived from TOPMODEL theory and estimated by using a digital elevation model (DEM). The PCA concept was then combined with a kinematic-wave based geomorphic instantaneous unit hydrograph model (Lee and Yen, 1997; KW-GIUH) for rainfall-runoff simulation. In the KW-GIUH runoff simulation considering PCA concept, the surface runoff mechanism was simulated by Manning's formula, and the subsurface runoff was approximated by Darcy's law.The Hen-Chi watershed in northern Taiwan was used to demonstrate the capability of the proposed model. The PCA size and geomorphic factors of the study watershed were obtained using a DEM, and SPOT satellite images were adopted for land cover analysis to obtain the roughness coefficient. The results showed that significant improvements were found in the simulation of rising and recession hydrographs.

REAL TIME FLOOD FORECASTING: A CASE STUDY OF THE JHELUM RIVER, PAKISTAN

Sajjad AHMAD (Department of Urban and Regional Planning, University of California, Irvine)

A modeling system is developed for real-time flood and reservoir inflow forecasting. It comprises a lumped conceptual rainfall runoff model, a hydrodynamic model for river routing, and an up dating procedure for real time operation of reservoirs. The model is implemented for the Jhelum River Basin in Pakistan, with watershed area of 14860 km2 and the Mangla Reservoir situated at the down stream end. The model is calibrated and verified at five gauging stations using daily rainfall data from twelve rain gauges and daily discharge data from three stream gauging stations for the period 1985 to 1991. Statistical parameters are used to evaluate the performance of the model. Real time forecasts of historic floods of 1976 and 1992 are performed with 24 hour and 6 hour lead times respectively. Sensitivity analysis on quantitative precipitation forecast (QPF) is made. The model performance for short term forecasts that is, 6 to 24 hours indicate robust system behavior in real time inflow prediction. Results indicate that if the accuracy of precipitation forecast is greater than 60 %, the error in the forecasted stream flow is less than 25 % for huge flood events. Sensitivity analyses show that large historic floods are highly sensitive to QPF.

REVISITING 1992 FLOODS IN PAKISTAN: OPERATION OF MANGLA RESERVOIR

Sajjad AHMAD (Department of Urban and Regional Planning, University of California, Irvine)

Occurrence of floods is a natural phenomenon all over the world. With the increase in population and human activity in the floodplains, flood damages represent escalating hazard in many countries, despite increasing investments in flood control measures. Reservoirs are important structural measures to reduce damages caused by floods. Reservoir operation during large flood events is crucial in utilizing reservoirs as flood damage reduction options. In 1992 a catastrophic flood passed through the Mangla Reservoir on the Jhelum River in Pakistan. Operation of reservoir resulted in severe flooding of down stream areas causing damages to lives and property. A reservoir operation model is developed for the Mangla Reservoir. Model is calibrated for the flood event of 1976. The simulation model is used to investigate the water levels in the Mangla reservoir that would have resulted in 1992 with releases of 5700 m3/s (safe passage down stream) and 8500 m3/s (high flooding conditions down stream). Simulations revealed that it was possible to accommodate a considerable volume of the 1992 flood in the reservoir. However, to operate the reservoir in this way, difficult decisions have to be made during the flood. This can only be done with a full overview of the flood situation and in close cooperation with the concerned agencies. It also requires that the procedures for the reservoir operation for such a situation be already developed.

STOCHASTIC MODEL OF THE RUNOFF FLUCTUATIONSOF THE RIVERS WITH A FLOOD FLOW REGIME

Andrei V. KHRISTOFOROV[1], Taras V. SAMBORSKY[2] ([1]Department of Hydrology, University of Moscow, [2]Department of Oceanology, University of Moscow)

The stochastic model of fluctuations of a runoff during a flood period is offered. It includes a stochastic model of the hydrograph of a flood season and stochastic model of the annual fluctuations of its characteristics. The stochastic model of the hydrograph is based on the approximation of the individual hydrographs of separate flood peaks and base flow and their superposition into the unit hydrograph of the whole flood period. The parametres of the approximation - base flow, number of flood peaks, dates of their passage, their maximums, durations of the growth and intensity of recession. All these characteristics are considered to be the random variables. The sequence of flood peaks during a flood period is described by a model of Poisson process. The model of annual fluctuations includes the description of probability distribution of hydrograph elements, correlation between them, autocorrelation of their annual fluctuations, their probable climatic and man-made regular changes. The number of flood peaks is the major characteristic of flood season. It can be considered as an index of flood forming situations of the year. The realization of model includes the Monte-Carlo method and theoretical formulas suggested for transition from model elements to any river flow characteristics of flood season. In a case of some regular changes caused by climate or economic activity the principles of correction of the parameters of probability distribution of model elements are suggested. The adequacy of the model was succesfully tested on a base of hydrolodic data for 68 rivers of the world. These are the rivers of the Amur basin and Northern Caucasus in Russia, North Korea, Ukrainian Carpathians, Georgia, USA, Algeria and Surinam. The statistical stability of the model is rather high. The basic parameters of the model can be estimated with the errors no more than 5-10% already in a case of 10-15 years of hydrologic observations. The model is intended for the hydrologic computations of any characteristics of the river flow of flood season for a weakly studied rivers in a case when a lack of hydrometeorologic observations don't allows to use the models of river flow formation. The model permits to increase the accuracy of hydrological computations by a factor of 1,5 - 2 and more in comparison with normative methods used now. The application of the model is not limited by the traditional problems of hydrologic computations. This is confirmed by an example of model application for the analysis of the systematic increase of the annual river flow which was discovered for the rivers of Mid-Atlantic of USA from the beginning of 70-ties.

IMPACT OF POPULATION GROWTH AND THE CLIMATE CHANGE ON THE QUANTITY OF WATER RESOURCES IN NORTH EASTERN REGION OF INDIA

Uttam C. SHARMA (Indian Council of Agricultural Research)

The north-eastern region of India, comprising seven states, has a geographical area of 255,090 sq km. The region is extremely rich in water resources but continuous increase in human interference and mismanagement has rendered these resources in fragile state. The region receives about 510 cubic km of water as annual rainfall. It has two major river basins viz. Brahamputra and Barak, which drain 194413 and 78150 sq km area with an annual runoff of 537.0 and 59.8 cubic km, respectively. The region has a total surface and ground water potential of 1064.8 and 16.6 cubic km. The scenario appears to be quite encouraging but indiscriminate use of water resources has caused land and environmental degradation in the region. Against an irrigation potential of 3.68 million ha, only 10.6% has been exploited. The population in the region has increased from 10.5 million in 1951 to 40.3 million in 2001, that is, it has grown 4 folds in 50 years, thereby exerting tremendous pressure on land and water resources. More than 82% of the population is rural based, whose main occupation is agriculture. Prevalence of shifting cultivation has resulted in deforestation and annual soil loss of 88.3 million tonnes through run-off from hill slopes, causing silting of river beds and frequent occurrence of floods. Due to population pressure, more and more forest area is being brought under plough, putting whole ecology in peril. The declining trend in rainfall and frequent temperature fluctuations are a signal for climate change. The demand for water for domestic use has suddenly increased due to fast population growth and change in life lifestyle of the people. At present, about 2.9 and 20.0 cubic km of water is required for domestic and irrigation use and 1.5 cubic km each for energy, industry and other miscellaneous uses. In towns, generally the raw rainwater is supplied for domestic use while the people in rural areas have to depend on stream or pond water collected during monsoon. Seasonal rainfall flushes the catchments earlier charged with polluted environment. This polluted water results in frequent occurrence of diseases like cholera, jaundice, diarrhea and typhoid. Water demand is high and the supply does not commensurate with it. Due to mismanagement of rainwater, about 3586 thousand ha of land has become prone to floods. Further, the quality of water has also deteriorated due to its being polluted with nitrates, chlorides and sulphates with increased use of fertilizers and pesticides in an effort to increase crop productivity in the region. If the rate of population increase remains unabated, the water resources are likely to dwindle further as also deterioration in the quality of water. A multidisciplinary study, based on watershed approach, is in progress since 1983, to evolve new farming system to replace

shifting cultivation, judicious management of rain-water and monitoring of soil, nutrients and water yield through surface and base flows. Lot of useful data has been generated which will help in planning, developing and improving the water resources in the region.

MANAGEMENT OF WATER RESOURCES IN KANDI (DROUGHT PRONE) ZONE OF JAMMU PROVINCE FOR HIGHER CROP PRODUCTIVITY

Vikas SHARMA (S.K. UNIVERSITY OF AGRICULTURAL SCIENCES AND TECHNOLOGY-JAMMU)

The *kandi* zone of Jammu province of Jammu and Kashmir state of India is characterized by low rainfall ($<$650 mm), deep water table, undulating topography, poor soil fertility with land surface full of sand stones, soil moisture stress, frequent droughts and acute scarcity of water for domestic use and crop production. The *kandi* zone has two major river basins *viz.* Chenab and Tawi, which pass through deep gorges and undulating terrain, draining entire Jammu region. About 3.5 to 5.0 km³ of water is received as annual rainfall, mostly during July and August. Rest of the period during the year remains dry except few showers during winter. Rains are generally with high intensity, resulting in over flowing of seasonal streams, soil erosion and degradation. The entire zone has agriculture-based economy but is always deficient in food grains. Though, the farmers are hardworking, working most of the time in the field along with their spouse and children, they do not produce as much as to feed their family. In absence of optimum soil moisture and irrigation facilities; application of fertilizers, good crop seed and other inputs have little impact on crop productivity. The studies have shown that water management is the major factor, which can improve the crop productivity in the *kandi* zone. It is difficult to derive any benefit from the water from two rivers as they flow in hilly terrain and cost involved in lifting the water and construction of canals would be two high compared to the area available for irrigation in the immediate vicinity. Construction of small structures for rainwater harvesting during monsoon will be good preposition. Farmer´s participation in the whole programme is necessary for achieving the desired goals. Construction of small check-dams to divert the water to ponds will not only reduce the soil erosion but water can be utilized for life saving irrigation during winter. Besides, there is need to introduce such cropping pattern, which may reduce the run-off and help in ground water recharge. The paper discusses the feasibility of the check-dams, water storage reservoirs, soil conservation measures according to topography and judicious utilization of available water for higher crop productivity, resource management and environment conservation in kandi zone of Jammu Province.

WATER RESOURCES MANAGEMENT AND PLANNING; THE NEED FOR MULTIDISCIPLINARY MODELLING APPROACHES

Islam Hamza ABOU EL-MAGD, Trevor TANTON (Civil & Environmental Engineering Departement, University of Southampton)

Water is a finite resource and the rapidly growing population in many arid and semi arid countries is placing excessive pressure on the limited water resources of these Countries. Unfortunately, it is predicted that many of these arid and semi arid countries will be the most seriously effected by a decline in water resources as a result of global warming. In most of these countries irrigated agriculture is the main consumptive user of water and unless water management is improved there will be a dramatic reduction in food production as a result. Typically most large irrigation schemes have an unimaginable wastage of water, with crop evapotranspiration accounting for only 20-35% of the water supplied, the remainder being wasted. Global warming will result in both increased evapotranspiration and reduced water resources and it is clear that if productivity is to be maintained water will have to be used more efficiently. Water allocation for irrigation is traditionally based on theoretical estimations of crop water requirements and rough estimations of canal losses, with the result that water supply rarely meets demand. Remotely sensed data is capable of supplying the planners with up to date data on the crops in the field and in measuring crop water requirements and wetland losses. This paper explores how remote sensed data is presently being used to improve water resource management in large irrigated catchments. It investigates the potentiality of spatial modelling of the real time data from satellite images, crop water demand from climatic data and irrigation information from the field to accurately allocate the irrigation water need in large irrigation scheme.

THE SYSTEM FOR ECOLOGICAL AND ECONOMICAL ASSESSMENT OF USE, PRESERVATION AND RESTORATION OF URBAN WATER BODIES: ST. PETERSBURG AS A CASE STUDY

Sergey A. KONDRATYEV (Prof.)

The water surface area of 106 water bodies of St. Petersburg city is equal to about 21 km2. The urban water bodies reflect the level of environmental pollution of St. Petersburg. At present time only 2% of water bodies can be referred to pure, 18% - to polluted, and 80% - to dirty.The State is the owner of water resources, including urban water bodies. Its interests are to stop deterioration of water quality and degradation of water ecosystems, and to find money for restoration of water bodies. The potential water-user can rent water bodies for the aim to get money income. In this case he should be interested in preservation or restoration of water bodies being a natural basis of his business.At present study there is discussed the problem of a choice of optimum variants of urban water resources use without deterioration of water quality and ecological status of water bodies, and with financial profit for water-user.The system for ecological and economical assessment of use, preservation and restoration of water bodies has been developed. The basic stages of the system are the following:- Data bases load and GIS development.- Assessment of the investment appeal of urban water body. High level of environment pollution, industrial enterprises located in catchment, high level of anthropogenic impact on water body are the reasons for negative assessment. The below mentioned stages take place only for positive assessment of the investment appeal of water body. - Assessment of present suitability of water body for various kinds of use. The basis of assessment is the result of comparison of present parameters of water quality with critical limits of chemical substances in water and sediments. High level of water and sediment pollution is the reason for negative assessment.- Economical assessment of water body restoration. Various kinds of restoration methods are considered: internal (chemical, biological and engineering) and external (catchment changes). - Optimisation of water body use on the basis of mathematical modelling. - Assessment of sensitivity of results of modelling to change of parameters of water body (depth, volume, area of recreation zone, etc.). Results of assessment are the information for choice of scenario of parameters changes for maximization of financial profit of water use.- Economical assessment of water body parameters change.- Economical assessment of monitoring.- Final ecological and economical assessment of water body use taking into account costs of restoration, parameters change and monitoring. Application of the developed system has been made for urban water bodies. Results of application show that it is possible to use a number of water bodies with financial profit for water-user and

without deterioration of water quality and degradation of ecosystems. The lists of water bodies with maximal and middle investment appeal are carried out.

OPTIMAL PRESSURE CONTROL IN SUPERVISORY WATER DISTRIBUTION NETWORK USING SHUFFLED COMPLEX EVOLUTION ALGORITHM

Haytham AWAD, Akira KAWAMURA, Kenji JINNO (Institute of Environmental Systems, Kyushu University, Fukuoka, Japan)

Obtaining an optimal control of the distribution of system service pressures in a municipal water distribution networks has always faced combinatorial problems due to its complexity, scale of the problem, variation of water demand and the difficulty in estimating the roughness coefficient of old pipes. Referring to the previous difficulties, the application of linear, non-linear, dynamic programming, simulated annealing and genetic algorithm have been investigated by many authors and used in recent years for the optimization programs of water distribution networks design, replacement and leakage minimization. Particularly, the application of genetic algorithm (GA) in water distribution networks optimization models has been known as the most successful method in this field. It works with a coding of the parameter set, direct the search to the improved solutions by probabilistic rules and working directly with the objective function requiring no additional knowledge.In this paper, we used an evolutionary optimization procedure known as Shuffled Complex Evolution - University of Arizona (SCE-UA) for searching for the optimal or near-optimal solution of valves setting for the pressure regulation of a water distribution network. The SCE-UA technique has been successfully used in the calibration of conceptual rainfall-runoff models and the identification of aquifer formation parameters in the area of surface and subsurface hydrology, respectively. However, this algorithm has never been used in the field of water distribution networks management and planning and this paper is our first attempt in this direction.The SCE-UA Method which is relatively new concept is a general purpose global optimization program which combines the strengths of the simplex procedure with (i) the concept of controlled random search; (ii) competitive evolution; and (iii) the concept of complex shuffling. The synthesis of these three concepts makes the SCE algorithm not only effective and robust, but also flexible and efficient. The main advantage of the SCE-UA method is that, for a given number of objective function evaluations, the SEC-UA have the highest probability of succeeding of finding the global optimum.To demonstrate the performance of the SCE-UA algorithm, A case study of a certain block of the supervisory Fukuoka City water distribution networks is presented showing the effectiveness of the algorithm to regulate the pressure at all the network nodes between upper and lower values and as near as a target value. In Fukuoka City water distribution networks, electrically motor valves openings are adjusted by remote control to regulate pressures and flow rates on the basis of information provided by flow meters and pressure gauges attached to distribution pipes. Results show that pressures are well regulated by SCE-UA algorithm to a target value for a specified nodal demands and external inflows.

BANK FILTRATION SYSTEMS AS COMBINED TECHNOLOGY FOR GROUNDWATER AND SURFACE WATER

Ekkehard O. HOLZBECHER (Humboldt University Berlin)

Bank filtration systems are of increasing importance for the supply of water for all kind of purposes. Worldwide water works extend old pumping well galleries, and increasingly new investments are directed to this technology. By bank filtration in most cases both surface water and groundwater resources are exploited, what has to be taken into account by the management of bank filtration facilities. Through the combination disadvantages of pure surface water or pure groundwater systems can be overcome. The technology of bank filtration makes the system less vulnerable to extreme events. The quality of the pumped mixture is higher than the water of the reservoir with lowest quality. Moreover surface water is significantly purified during the filtration passage from the surface water body to the pumping facility, so that the application of further water treatment may even become obsolete. An example is the water supply for the city of Berlin, Germany, which is studied in detail within the NASRI project (Natural and Artificial Systems for Recharge and Infiltration) since spring 2002. The aim of the project is to obtain a better understanding of such systems and to develop appropriate models and management tools - not only for the Berlin sites. The contribution to the conference provides an overview on the current state of the project. An introduction to the technology will be presented, followed by an overview on the activities of the NASRI project. Computer models will be demonstrated concerning the design and dimension of pumping well galleries and concerning the biogeochemical transformations during the passage of surface water through the porous medium. Finally follow some implications concerning the management of combined surface water and groundwater resources.

REDUCING SHALLOW - WELL CONTAMINATION IN UGANDA

James MWAMI (Project Manager, Busoga Trust)

Despite an abundance of surface water in Uganda(18% of the land area), the predominantly rural ($>$70%) population relies almost exclusively on groundwater for a portable water supply. This dependence arises from the more widespread occurrence, superior quality and reduced susceptibility to contamination, of groundwater supplies compared to surface water resources. As a result, provision of safe water to rural communities in Uganda has depended primarily upon the construction of wells and protection of spring discharges. In Uganda, as with other regions in equatorial Africa, featuring extensive, weathered crystalline rocks, often referred to as he ˝basement complex˝ ground water development has targeted two main aquifer units: a deep aquifer of fractured bedrock and a shallow, muddy-sand aquifer comprising of detrital bedrock and alluvium. This paper depicts a case study taken in east and central Uganda. Particular attention has recently been directed at developing the shallow - well aquifer since the formation is less costly to develop and a recent study has found it to be more productive than the deeper, bedrock aquifer. However, monitoring of water quality in south eastern Uganda, a region of intense shallow - well development, shows that within months of installation, shallow groundwater commonly exhibit levels of coliform bacteria and nitrate exceeding W.H.O health guidelines. Human and livestock waste excreted in pit latrines, over land or in open-pit wells, called ˝scoop wells˝ may contain worms, protozoa, bacteria and viruses that if consumed, can lead to the contraction of hepatitis, typhoid, cholera and a variety of diarrhoea diseases. Wells and springs harvesting shallow groundwater are generally protected from these pathogens by a granular soil matrix which both filters bacteria, protozoa and worms due to their relatively large diameter ($>$0.5 um) in relation to the aquifer material, and adsorbs smaller viruses (0.07 um to 0.7 um) on account of their strong, negative surface charge. Despite this cleansing capacity, the presence of coliform group of bacteria in groundwater indicates that faecal contamination has occurred. The practice of siting shallow wells in the vicinity of existing scoop wells has been identified as a probable source of faecal contamination too shallow wells in Mukono

District of South Eastern Uganda. Simulations of groundwater flow in the shallow aquifer indicate that a well head protection area of 60m between wells and contaminant sources such as scoop wells, pit latrines and swamps is required to ensure the sustainability of this vital, potable source of water to rural communities.

WATER MANAGEMENT ON MEDITERRANEAN ISLANDS UNDER CHANGING CONDITIONS

Manfred A. LANGE (Center for Environmental Research, University of Muenster, Mendelstr. 11, D-48149 Muenster, GERMANY)

The availability of water in the Mediterranean in sufficient quantities and adequate quality represents a significant problem, particularly in light of possible changes in climatic conditions. This is due to a number of factors which include: the over-exploitation of existing aquifers by various users, insufficient recharge due to diminishing precipitation, excessive and inadequate use through agricultural activities or tourism, significant deficits in water management and distribution schemes and conflicting or unresolved demands and interests between various users, to name just a few. These problems are exacerbated on the islands in the Mediterranean because of their isolation and thus the impossibility to draw on more distant or more divers aquifers in general and because of the threat of saline intrusions, which reduce the utilisation of existing, near-shore aquifers in particular. While the availability, demand and distribution of water on each island are determined by specific conditions, there are a number of attributes common to all Mediterranean islands which call for the formulation of generic solutions to the above mentioned problems. Because most of these problems are mutually related and interdependent, solutions will only be obtained through holistic considerations that are carried out by an interdisciplinary research team. Equitable and acceptable strategies require a stakeholder-based participatory process that builds on the results of scientific investigations on the one hand and on the consent of major stakeholders on the other. These requirements are central to the EU-funded MEDIS project, which aims to contribute towards the sustainable use of water on islands of the Mediterranean where conflicting demand for water is combined with a wide range of hydrological, social and economic conditions. MEDIS is being carried out by a consortium of 12 institutions from seven countries and will involve detailed investigations in one typical catchment each on Corsica, Crete, Cyprus, Mallorca and Sicily. By carrying out this project on five islands that cover the Mediterranean from west to east and by enabling a dialogue between scientists and stakeholders as well as between principal stakeholders from each island, these recommendations will embrace generic solutions based on the collective experiences of the residents on all islands. We will report on the results of the first year of MEDIS, which include an extensive review of current conditions pertaining to water management on each island and the specification of a typology of water demand and supply relationships for the islands of the Mediterranean. In addition, we will consider water supply under future climate scenarios derived through a regional model for the Mediterranean and/or downscaling of GCM results from models of the Max Planck Institute Hamburg, Germany. These results will give rise to a set of recommendations for improved water management practices that will have to be discussed, modified and agreed-upon through a participatory process involving key stakeholders on each island in the future course of the project.

RELIABILITY ANALYSIS OF THE INTEGRATED MANAGEMENT OF WATER QUANTITY AND WATER QUALITY FOR WATER TRANSFER SYSTEM

Xiang ZHANG[1], Jun XIA[2] ([1]Dept. of Hydrology and Water Resources, Wuhan University, [2]2. Department of Hydrology and Water Resources, Institute of Geographical Science & natural Resource)

Water consuming around the world increased sharply in order to meet the demands of the rapid economic development. On the other hand, it is the economic development that courses the degeneracy of eco-enviromental system and the decrement of available water quantity, especially in the developing countries. It is necessary to consider the integrated management of water quantity and water quality in order to decrease the risk of water supply. In this paper, the integrated management of water quantity and water quality for the water transfer system is discussed. And based on the reliability theory, the method of reliability analysis is applied to assess quantitatively the operation reliability of water transfer system.Transferring water from the catchment with abundant water resources to the area in shortage of water, the water transfer system covering the different catchments plays an important role in solving the water shortage. Obviously it also influences the water quantity and water quality of the river in the water source area. In this paper, the importance and the method to consider the integrated management of water quantity and water quality are discussed and suggested. For the water quantity, the temporal and space variability of water resources in the water source area should be analyzed carefully in order to determine the amount of the available water. On the other hand, the influence to the water quality should also be considered thoroughly, including the pollutant source, the decrease of discharge in river resulting in the deterioration of water quality at the downstream and etc. In this paper, the environmental critical discharge, which is defined as the lowest required discharge to keep the water quality of the river to reach the standard of drinking water source, is used as a threshold for the management of water quality. It can be determined by using the river water quality mathematical model. At last, for the reliability of the integrated management of water quantity and water quality, the two reliability criteria, the temporal reliability and the volumetric reliability, are presented. The last part of this paper gives a case study about the water transfer system in Shenzhen city, Guangdong province. This system transfers water from the Dongjiang catchment to Shenzhen. Considering the integrated management of water quantity and water quality, not only the water quantity in the Xizhijiang and Dongjiang river is analyzed carefully, but the environmental critical flow is calculated. And the two reliability criteria are used to evaluate the operation of the system. The result shows the reliability analysis of the integration of water quantity and water quality can provide thorough decision making for the sustainable management of water transfer system.

HS02c/11P/D-020   Poster   **1630-118**

LATERITE - LOW COST REMEDIAL OPTION FOR HIGH ARSENIC GROUNDWATER

Rupa BHATTACHARYYA[1], Debashis CHATTERJEE[2], Yoshio TAKAHASHI[1] ([1]Department of Earth &Planetary Systems Science, Hiroshima University, [2]Department of Chemistry, University of Kalyani, India, [3]Department of Land & Water Resources Engineering, Royal Institute of Technology,KTH, Stockholm)

High arsenic groundwater has emerged as a niggling environmental problem in the recent decades. Elevated levels of groundwater arsenic ($>>$50ppb) in the Bengal Delta Plain (BDP) threatens the lives of millions of people. Large scale uncontrolled groundwater development may play a key role for such human suffering. The present study deals with the adsorption pattern of AsO_4^{3-} and AsO_3^{3-}, the predominant arsenic species in groundwater using Red Earth (Laterite) for the supply of potable water. Laterite is an indigenous,

abundantly available, natural geological material enriched with amorphous ferric hydroxide (HFO)/ oxides. The mineralogical study of Laterite exhibits the predominance of iron and aluminium secondary phases. Chemical composition reveals that Laterite contains 30 - 35% iron oxides.Batch experiments indicate the Langmuir adsorption isotherm. The pHzpc of laterite is determined to be 8.5-8.6. The high pHzpc value supports a high positive surface charge of laterite over a wide pH range. The material, therefore acts as an effective adsorbent for several anionic contaminants. On the basis of the lab as well as field scale studies, laterite is used as a fixed bed filter media in an earthenware pitcher with a view to supply drinking water on the household basis. The results interpreter that the material is not only effective in adsorbing arsenic but also effective removes iron from the groundwater. Cost calculated for the transportation of laterite approximates to Rs 750 /ton/km (US$ 16) whereas the treatment process estimates to Rs30/100L(US$ 0.6) contaminated water. Therefore fixed bed laterite can be successfully used for removal of arsenic from groundwater. Lab scale experiments are also executed to understand the efficacy of the system for removing heavy metals as well from the aquatic environment.

LARGE DIAMETER WELLS AS A SOLUTION AGAINST THE RISK OF CONTAMINATION IN THE SEMI-ARID WORLD USING THE FILTER FACTOR CONCEPT

Sarma K. SEEMANAPALLI, Soniaeli P. CARVALHO, Silvestre L. NOBREGA, Alex M. NEYVES (Smith Research Corporation, Small Business Technological Center, LSU, Baton Rouge, LA)

Water is the life blood of living creatures on earth. Seventy percent of earth´s surface is covered with water. Despite much information available, groundwater movement, its quantity and quality remain a mystery. Groundwater levels decline due to intensive pumping and yearly below-normal precipitations, that accelerate the downward trend in water levels. Natural groundwater quality is affected by the materials it passes through on its way to the groundwater reservoir. Human activities also cause water quality degradation. serious enough to prevent the use of water for human consumption. Well location is a crucial factor, a well downhill from a source of bacterial contamination running greater risk of contamination than that on the uphill of pollution source. Minimum separation distances from potential sources of contamination are to be maintained. Proper well design reduces the risk of pollution by sealing the well from contaminants that enter from the surface. Bacterial contamination which cannot be detected by sight, smell or taste can result from a number of sources. Shallow wells and wells that do not have water-tight casings can be contaminated by bacteria infiltrating through the soil near the well. Soil remediation is a difficult, time-consuming and expensive operation and environmentalists select the most appropriate technology for specific contaminated sites. Here-in is suggested one such method of soil remediation, using Large Diameter Wells (LDW) that are popular in the semiarid world. The simplicity and low cost in the construction and operation of such wells make their use viable for rural communities. The LDW is a viable alternative to tube wells to alleviate the problem of draughts and the risk of contamination in Paraiba state, Brazil. The filter factor concept, f_1, conceived by Sarma(1997) considers the relative effects of transmission and passage of water through bricks and cement mortar. Values of ff in function of well yield for given diameters and drawdown are presented. Criteria to avoid mutual interference due to simultaneous pumping of wells was also studied. Computer programs developed would prove useful in making the characteristics curves for LDWs constructed in aquifers with low transmissivity values. Unlike tube wells, in LDWs, water continues to get extracted from aquifer to the well even after the cessation of pumping, attesting LDWs as efficient in aquifers in the semi-arid world.. Using field data, calibration was effected adopting a 14/16 mesh for the LDW. The numerical method adopted here-in was the volume element method. The flexibility of the method permits implantation of desired well-diameters, change the network in the computer program, thus permitting to evaluate the drawdown-discharge-diameter relationships. Regional characteristic curves drawn between the variables facilitate practical application of these by agriculturists and engineers to explore rightly the aquifers, avoiding thus the risk of contamination of LDWs.

REDUCTION OF RISK OF AGROTOXICS BY DRAINAGE IN AGRICULTURAL LANDS USING INTERCEPTOR DRAINS

Sarma K. SEEMANAPALLI (Smith Research Corporation, Small Business Technological Center, LSU, Baton Rouge, LA)

About 80% of the sick and over 33% of the deaths in the third world countries are attributed to the clean water crises, caused by degradation in water quality. According to UNO, the disorderly distribution of available resources affects 20% of 3rd world countries. South America goes black-listed as a continent, threatened with water crisis. Brazil is however privileged because of its abundance of water, with its availability of 5000m3/year/capita, with a demand of only 200 m3/year in its NE region. Subsurface waters have distinct economic advantages over other components of the hydrological cycle. Groundwater can be used directly in most cases, without prior treatment. However, groundwater may also be polluted by way of natural or surface contamination. Because of the greater demand of groundwater, the confidence in the quality of potable water is posing doubts, its authenticity being questioned, once that major sources are already getting over-explored. Higher standards of water quality imply higher costs of water. Environmental scientists are concerned about groundwater contamination by way of agro-toxic substances entering the flow regime. The pollutants detected in shallow waters might reach the deeper strata of the aquifers. Here-in, an investigation is made about the effective use of interceptor drains in the irrigated perimeter in Sume in the Semiarid Paraiba State in Northeast Brazil, in function of their geometric, hydraulic and hydro-geologic parameters. Effective removal of chemical pollutants from aquifers through the use of interceptor drains is suggested to contain and even to remove subsurface pollutants from shallow aquifers. Interceptor Drain is a gravel trench excavated into a relatively impermeable soil layer and installed to collect and remove groundwater as it flows across the impermeable layer, which is typically placed across a contour of a slight to moderate sloping area to intercept groundwater. The potential theory used here-in and the concept of ground water divide conceived proved helpful to quantify the efficiency of interceptor drains. These drains offer concrete solutions to the problem of the control of subsurface water pollution in shallow aquifers. Such drains are used to capture the contaminants and to delimit the spreading of hazardous chemicals. Finite difference scheme used here-in was developed by Sarma e Alex (1997). For the totally and partially penetrating drains studied to know the effectiveness of such drains, spacing, widths and depths of drains varied. The drain discharge is treated as a function of the number of tubes that effectively enter into the drain. Recharge played an important role in the control of the pollutant movement, in delimiting the configuration of the phreatic surface, an increase in recharge rate correspondingly increasing the depth of the groundwater divide. Such water divides help one to forecast the contaminant movement and to quantify the same.

WATER QUALITY MANAGEMENT FOR CONJUCTIVE USE OF GROUND WATER AND WASTEWATER FROM AQUACULTURE : AN INDIAN OVERVIEW

Lalitkumar Pandit CHAUDHARI (Institute for sustainable development and research)

Aquafarming has emerged as one of the more promising industries in the world with considerable growth potential expected to contribute around the quarter of global fishery the year 2000 AD. The aquafarming has a multidimensional in perspective agricultural growth. It is a tool for utilizing land and water more economically and optimally for increasing the productivity of both natural resources , land and ground water through sustainable agriculture. The countries in the Asia -Pacific region have vast and varied aquafarming resources . Oftenly these are these are main source of Irrigation in this region. The overexploitation of ground water causes salinity problem in many countries reducing the cultivating area resulting reduction in agriculture reduction An attempt has been made in this paper to develop the plan for ground water management for the aquaculture and horticulture as well as drinking water from the river source adopting conjunctive use of irrigation water from Indian experience .The paper also evaluate the water quality criteria of ground water and irrigation water for increasing the agricultural productivity. The. methodology is based on the economics of the conjunctive use of irrigation and ground water for horticulture and aquaculture and also for agriculture. The main aim is to utilize the ground water over saline land for aquafarming and to reduce the soil salinity in irrigated land to increase the productivity of the land and the water .Series of the observations were taken on the various aspects of irrigation and soil salinity management for aquafarming using different methods to maintain the quality of land and the ground water .Also the relative economics of aquafarming and horticulture system under alternative water conserving irrigation /rain water harvesting management options , has been compared with the resources available .The result obtain demonstrate the implication of increase in yield in horticulture including agriculture and indicate the necessity of optimal and suitable use of natural resources for increasing the agricultural productivity The result signify that the soil salinity can be managed using ground water management practices and the additional area can be brought down under agriculture . The result obtained also suggest that significant economic gains can be had from adopting conjunctive use of ground water to maintain the quality criteria for increased production in horticulture and agriculture as well as for dirnking water from the river source after discharge. Apart from results of drinking water quality, it also signifies that the increase in the production can be achieved through reuse of water alongwith the ground water as supplemental irrigation, reducing the soil salinity problems in command area.

TOWARDS AN OPTIMUM WATER RESOURCES DEVELOPMENT IN THE NIGERIAN NIGER DELTA

Adepoju D. OLUSEGUN (Geography Department, Faculty of Social Sciences)

Man's interaction and interference with the environment in order to satisfy his socio-economic needs without adequate management plan always result in environmental degradation either in the short or long term since the effects of his actions are registered in the atmosphere, accumulates and it is only a matter of time before its manifestation. The present water problem in the Niger Delta area of Nigeria is a combination of tripartite factors of climate change, increasing population, and the global economy. The implication of the climate change is due to the fact that Nigeria through the Oil and gas activities especially flaring contributes a significant amount of carbon mono-oxides, carbon dioxides in the global atmosphere which play an important role in raising temperatures at both the local and regional levels; but the major effect of these is mostly felt by the local environment. One of the consequences of these actions is inundation through the saline water in55cursion into the freshwater environment thereby increasing water problem both in quality and quantity. Secondly, growing populations, associated urban development and intensifying pressures on small areas of land are creating new pressures on available water resources with conflicting water demands, occurring to a lesser extent across the Niger Delta area. The population continues to grow at an estimated 2.8 percent per annum while urbanisation increases even more rapidly at an estimated rate of 5.2 percent. A visible consequence of this is the increased competition between users leading to increased conflict between users. That Nigeria and in particular the Niger Delta is having a fair share of the impact of dynamic global economy cannot be overemphasised. Of the three standard categories of freshwater use - for Agriculture, industry, and domestic - industry (processing, exploration, exploitation activities etc) is dominating. As a result of Pollution of surface water from increasing oil exploration and exploitation, industrialisation, increased food production is reducing the quality and quantity of portable water thereby reinforcing the problem of scarcity. In this study monthly rainfall and temperature datasets from the period 1941-1990 was in order to evaluate climatic trends of basic water resources parameter useful for assessing proper water resources planning and development in the Niger Delta. Optimal strategic water resources scenarios was built towards a sound water resources of the Niger Delta using GIS techniques.

CURRENT CONSTRAINTS TO THE IMPLEMENTATION OF WATER DEMAND MANAGEMENT (WDM) IN URBAN CENTRES IN ZAMBIA

Daniel C.W. NKHUWA (School of Mines, University of Zambia)

Water is more than just a commodity but also an essential element that supports all forms of life. It is also basic to many socio-economic activities. In this regard, it is imperative to recognise its economic value in all policy and sector activities so that wise and efficient use of the resource is initiated and promoted in all sub-sectors, particularly in the large urban centres. However, the provision of adequate water supply and sanitation to the rapidly growing urban populations is increasingly becoming a problem for most cities and towns in Zambia. The continuing expansion of the numbers of people who need water and sanitation services and who cannot readily get the services by self provision continue to exert continuous pressure on either investment to create additional production capacity or to stretch the available supplies to serve more people. The predominant approach towards meeting these increasing water demands has been towards supply augmentation schemes. Undoubtedly, the cost of developing these new sources will get higher and higher as most accessible water, in terms of quality and quantity, has already been tapped. In places like Lusaka, the country's capital, where demand has outstripped demand, citizens have taken to indiscriminate drilling of boreholes. In places, this has caused aquifer over-abstraction, which has initiated lowering of the water table. If this trend persists, pumping charges may go up, thereby heightening the cost of supply. This may eventually affect the availability of water to the poor who may not be able to afford the new rates. It is in this regard that water demand management (WDM) becomes the preferred alternative in meeting increasing water demand in order to improve efficiency and sustainable use of water resources taking into account economic, social and environmental considerations. However, there are a number of constraints that have inhibited successful implementation of WDM. These include: • Inadequate knowledge by consumers and water utility staff of the socio-economic benefits of

implementing WDM Unfavourable pricing mechanisms Poor revenue collection rates, which have caused the water utility companies so severe financial constraints that they are unable to finance some of the routine operation and maintenance operations to the existing conveyance networks. Consideration of WDM as an inferior alternative to the construction and extension of new conveyance systems. Inadequate policy and legal frameworks, overlapping responsibilities among the water and sanitation sector institutions. Lack of clear sector policies, compatible legal framework, clear division of responsibilities and mandates, which has resulted in low priority assigned to operations and maintenance within the water sector. This paper will attempt to highlight what measures must be adopted to overcome these and other constraints to the implementation of WDM.

PRECIPITATION ENHANCEMENT OPERATION ALONG THE YELLOW RIVER IN WESTERN CHINA BY WEATHER MODIFICATION METHOD

Xueliang GUO[1], Meiyuan HUANG[1], Tiezheng LI[2], Junsheng ZHANG[2] ([1]Institute of Atmospheric Physics, Chinese Academy of Sciences, [2]Yellow River Hydropower Co. of China)

This paper discussed the weather modification activities and their application to water resources management. The shortage of water supplies in the region along the Yellow River of western China has increased in recent years and is related to some decrease in annual precipitation, but mainly due to the increasing demand from the rapid growing population and industrialization in the region, which has seriously threaten the development of hydropower along the Yellow River. The precipitation enhancement activities have been conducted as an additional source of unconventional water supply for many years in the region. This work focused on clarifying the fundamental mechanism involved in precipitation enhancement by cloud seeding. We will introduce the climate condition that suitable for precipitation enhancement activities in the region as well as the efficacy of cloud seeding. In addition, a comparison study of cloud seeding was made with a current widely used seeding agent— silver iodide (AgI) and a newly developed seeding agent—liquid carbon dioxide (liquid CO2). Characteristics of cloud dynamics and microphysics and the interactions between them affected by the artificial seeding of AgI and liquid CO2 are examined using a 3D stratocumulus cloud model with seeding processes. The model results show that the liquid CO2 seeding in the region of high supercooled cloud water in the simulated cloud can generate shallow thermal convection and cause larger dynamic effect than that AgI seeding, and thus can significantly enhance surface precipitation. The seeded clouds by liquid CO2 show two prominent increases in maximum updraft. The first increase is directly produced by liquid CO2 seeding and the second is caused by downdraft outflow induced by falling precipitation in the boundary layer. The formed shallow thermal convection can produce many ice crystals. By the recirculation growth of these ice crystals transferred by the updraft of the thermal convection, they can consequently grow to precipitable particles such as snow and graupel.

WATER RESOURCE MANGEMENT IN THE UPPER REACH OF THE GORAI RIVER OF BANGLADESH

Mohammad Monowar HOSSAIN, Mohammad Rashedul ISLAM (Department of Water Resources Engineering, Bangladesh University of Engg. & Technology)

Gorai river is the only distributaries of the river Ganges in Bangladesh. The Ganges is the second largest river in the Indian subcontinent. Gorai river is the prime source of freshwater to the South West Bangladesh, which covers an area of about 30% of area of the country. In recent times, the river was getting silted up at its mouth and for some distance downstream due to gradual decrease of the Ganges water. As a result very little water was available in the Gorai river during dry flow season. Tremendous environmental impacts were being felt in the Gorai dependent area due to this water shortage over the last few years. The Government undertook a program of dredging the Gorai for a distance of about 30 km from the mouth with a view to increasing the conveyance and attracting more flow in the river. The aim of this study is to examine the effectiveness of this dredging activity. The analysis has been conducted on the basis of dredge and post dredge observed bathymetry. The dredge bathymetry stands for the bathymetry measured immediately after the dredge and the post dredge bathymetry stands for the bathymetry after the passage of first year flood flows over the dredged Gorai. It is found from the analyses of these bathymetry that the normalized bed levels of the dredge bathymetry has been lowered all along the dredged Gorai while the bottom bed levels is found to have been raised. This implies that the pilot dredging has increased the high level conveying capacity of the Gorai while the low level conveying capacity has been decreased after the passage of first year flood flows over the dredged Gorai. Evidently this change in decreasing the low level conveying capacity of the dredged Gorai is due to the sedimentation in the deeper channel and therefore, the first year pilot dredging is not meaningfully effective in the sense of self-sustaining development for low flow augmentation. It is found that the bottom bed level of dredge channel has been raised close to the level of pre-dredge (post monsoon 1997) state after the passage of first year flood event over the dredged channel. Thus dredging may not be a sustainable means for management of water resources problems in the sediment-laden rivers of Bangladesh especially of the Gorai.

THE GENERAL PRINCIPLE FOR RESTORATION OF THE RIVER BASINS

Boris FASHCHEVSKY[1], Tatyana FASHCHEVSKAY[2] ([1]International Sakharov Environmental University, [2]Ufa State Aircraft University)

The first step to restore any water body has to be the assessment of its ecological troubles on the scale ˝norm-pathology˝ here the criteria must be established determining the notions ˝the norm˝ and the ˝the pathology˝. The main among such criteria are the following: First, these are indices of the basic hydrological characteristics: maximum and minimum discharges and levels of water, inside-year distribution of a river flow in different years of water capacity -5, 25, 50, 75, 95 % frequency and average annual discharges and levels of water, duration of floodplain flooding, temperature and ice regime, flow of sediments. Second, these are indices of water quality, characterized by major ions, oxygen and pH concentration, biogenic elements, organic matters and heavy metals. Third, the important criterion in assessment of a river state is the character of channel process development, which in the result of economic activity can be changed greatly in the terms of hydrography (slopes of rivers and basins, drainage density, tortuosity, area of swamping, area of lakes, area of forests, area of ploughed lands, area of urban, etc) and morphology (increase and decrease of depths, narrow or widening of channels, damming of floodplains, extraction of building materials from channels, dredging of waterways, etc) of rivers and their basins. Forth and often (but not always) a main and completing component is a biotic one of the river ecosystem, the influence by the first three components and includes: bacteria and viruses, alga and higher aquatic plants, invertebrates, fishes, amphibia and aquatic reptiles, waterfowl and semi-aquatic birds, aquatic and semi-aquatic mammals. As the ˝norm˝ of a river ecosystem is its state before the beginning of a human activity in this basin or the state

of the river-analogue that are situated in analogous natural conditions but untouched by a human activity must be accepted. All above-mentioned hydrological, hydrochemical, hydrographical, morphological and biotic components have to be accepted for the norm and recalculated for a restorated basin in a special way. The restoration of a river basin can be produced: 1. Totally on all regime elements and bioproductivity of aquatic and semi-aquatic plants and animals. 2. Partially, only for the separate elements of regime and separate components of biotic ones. For example, restoration of only migratory fish, ignoring the phytophilous species, which need an obligatory flooding of floodplain. 3. Artificial creation of a new ecosystem in a given river system by the way of introduction and acclimatization new species of plants and animals which have never occurred in a given river but if there are favorable conditions for reproduction these species. The experience of such developments has obtained a wide dissemination in the world, including Japan, China, Australia, Chile, Norway, France, Russia and others countries.

MAÎRISE ET CONFLITS LI ÉS À LA GESTION DES RESSOURCES EN EAU DANS LA BASSE VALL ÉE ET LE DELTA DU FLEUVE SÉNÉGAL

Alioune KANE (department of geography/ Faculty of Arts and Human Sciences/ University Cheikh Anta Diop)

L'int érêt port é à ces milieux de la zone tropicale sèche, caractérisés par l'extrême fragilité de leur équilibre écologique, se justifie par la demande en eau pressante d'une population en forte croissance, les saisons climatiques contrastées avec une irrégularité pluviométrique marquée, imposant des contraintes sévéres à l'environnement et un caractère aléatoire à cette ressource dont l'exploitation traditionnelle était très souvent rythmée par le régime hydrologique du fleuve. Depuis deux à trois décennies, de grands programmes d'aménagements hydro-agricoles ont été développés. Les barrages de Diama et de Manantali, ont complètement artificialisé le régime hydrologique du Sénégal., permis le desserrement de la contrainte de mobilisation de la ressource en eau., le fonctionnement du systéme est désormais tributaire de la pluviométrie dans le haut bassin et du mode de gestion. Ces programmes se traduisent par des modifications radicales du fonctionnement hydrologique naturel et des transformations très importantes affectent l'environnement. Ces bouleversements peuvent prendre un caractère particuliérement grave, notamment lorsqu'ils se conjuguent à des modifications climatiques qui fragilisent encore un milieu sensible du fait de sa position en bordure du Sahara. Souvent ces programmes d'aménagement des bassins versants ont mal évalué les impacts écologiques et sociaux, engendrant des dysfonctionnements dans les rapports homme-nature, et compromettant l'instauration d'un développement durable. La maû'rise hydraulique est imparfaite, les parcelles sont souvent mal planées. La qualité des eaux de drainage est une préoccupation majeure, la capacité du réseau s'est avérée limitée et insuffisante pour assurer une bonne vidange. Les déversements d'eaux de drainage ne sont plus acceptables, le degré de toxicité de ces eaux et les volumes en jeu ne sont pas connus. La maû 'rise des eaux et le développement de la riziculture ont mis en contact les populations avec l'eau douce stagnante et différents vecteurs de maladies. Le grand effet purgatif du à l'invasion des eaux marines a disparu, les risques d'aggravation des maladies se sont multipliés. La prolifération de la végétation aquatique se pose. La construction des grands barrages ayant pour but d'atteindre l'autosuffisance alimentaire, se révèle mal maû 'risée. Les efforts de modernisation agricole ont porté sur une conquête de l'espace et un développement de la riziculture irriguée. Les modifications du milieu résultent de la création des aménagements hydro-agricoles et des réserves d'eau douce, avec une recomposition d'une société paysanne multiforme, sans aucune technicité ni moyens financiers appropriés, les éleveurs peul sont les grands perdants. Le partage des ressources en eau est un problème difficile entre états riverains aux intérêts divergents avec la revitalisation des vallées fossiles du Sénégal. La vallée du Sénégal n'est pas une région d'irrigation traditionnelle. Les dysfonctionnements notés au plan de l'environnement, hypothèquent lourdement l'avenir des aménagements.

RAINWATER MANAGEMENT TECHNOLOGY FOR CONJUNCTIVE USE IN ARID REGION, INDIA

M. A. KHAN (Central Arid Zone Research Institute)

In Indian arid zone of Rajasthan and elsewhere several kind of rainwater harvesting structures have been in vogue since many centuries. At field level runoff has been collected in natural depressions or in dug-out structures such as ponds, tankas, and khadins. Till recently local wisdom, experiences and precedences guided the designing of such structures. However, for better storage, conservation and judicious use, CAZRI, Jodhpur provides details of design. Seepage proofing in ponds was found necessary in sandy soils where percolation rates are high. In western Rajasthan, dug-out ponds locally known as Nadi and tanka are used mainly for domestic water use and economically not viable option for surface irrigation. However, if recycling of rainwater primarily links more profitable cash yielding crops or tree component, potential water storage in these structures is likely to become highly attractive. Recently, tankas have been constructed on large scale in western Rajasthan for developing fruit orchards. Response of ber (Ziziphus nummularia) and pomegranate to supplemental irrigation from tanka was studied (1995-97) on a loamy soil at Jodhpur. Compared to control (no irrigation) increase in fruit yield with 2, 4 and 6 irrigation for ber was 46.,4%, 80.3% and 124%, whereas in the case of pomegranate it was 69.8%, 112.5% and 191.7%, respectively. Tankas have also been found useful in raising forest nurseries and establishment of trees in watershed. Khadin is an other method of water resources development, conservation and utilisation for crop production even in very low rainfall 150-300 mm. Rocky catchments with adjoining valley-filled lands are converted in khadin farm by constructing earthen embankment at lower periphery of field with suitable spillway arrangement. The system is very popular in hyper arid region of Rajasthan. Due to low rainfall, the catchment to command ratio is rather high ranging from 8 to 15. On khadin farms, even without agronomical practices and with no application of fertilizer the average of yield ranges from 20-30 q ha-1. Anicut, percolation tanks and sub-surface barrier are very effective water harvesting and recharge techniques to improve ground resources in depleted aquifers. With the construction of anicut in Ujalian watershed in Jodhpur district, the annual increase in static water level in wells located in the zone of influence ranges from 1.8 to 2.2 m as compared to wells located in the adjoining area. In Pali district, due to the presence of anicut groundwater recharge has increased from 5.2 to 38.5%. Percolation tanks for inducing recharge is being practiced in parts of India. The average rate of percolation from percolation tanks constructed in different geological formation ranges from 10 to 72 mm day-1. Similarly with the construction of sub-surface barrier across an ephemeral stream at Chauri-kalan in Jodhpur district, the rate of depletion has been reduced from 1.2 m year-1 to 0.3 m year-1, and water yield has increased from 60 m3year-1 to 125 m3 year-1. With the increased ground resources, over 15 ha area has been brought under well irrigation.

DECISION SUPPORT INFORMATION FOR WATERSHED MANAGEMENT OVER DROUGHT PRONE REGION

Nagarajan Ramakrishnan IYER (Center of Studies in Resources Engineering, Indian institute of Technology, Bombay)

An effective mitigation activity during drought situations offer support to the people, in carrying out their regular activities, without much stress on their existing water and food (if necessary) availability. Continuous monitoring of spatial and dynamic land resources and the vulnerable groups is important. Integrated analysis of rainfall, run-off and surface storage facilities and creation of demand and supply scenario during the summer months would help the water regulation planning. It is observed that some of the un-preparedness situation of the government agencies is mainly due to the lack of dynamic input into their preparedness planning. The individual subject experts broadly use deficit of rainfall amount, water supply, crop production and reduced purchase power in identifying a drought area. Even though meteorological drought is considered as the initiation of drought situation over an area, followed by deficit of water supply and crop production. A multi-criteria approach is warranted. An attempt has been made in the creation of drought intensity scenario (demand and supply approach) for group of settlements located in a watershed located in the semi-arid region using integrated analysis of static and dynamic information. This study has adopted a methodology based on the rainfall and water requirement, in aiding the crisis situation and sustainable planning at local level. Time series analysis of annual rainfall of 100 years was used in identifying critical period. The inter-rainfall gap analysis was carried on 10 years of daily rainfall. Based on these results and the reported physical situation, a threshold of annual rainfall (below which scarcity begins) was established. Surface run-off was calculated using SCS method and the surface cover information changes were collected from the orbital India remote sensing satellite data. The water spread of the irrigation tanks was demarcated and used in the water availability estimation. Ground water level fluctuation information was collected and used in establishing relationship with rainfall over the years. Crop area and type and their inter-seasonal (winter/summer) and annual changes were deciphered from temporal satellite Revenue village Information on the human / animal population, crop type and area, water resources availability (ground water & surface water), natural vegetation cover, rainfall and temperature information, etc., were collected from the existing revenue records and updated from the interpretation of temporal IRS data. The demand from the crops (including the evapo-transpiration and transmission loss) and the settlements (human and animal) was calculated for individual settlement/villages. The supply position of the watershed by way of surface run-off and storage and their losses over seasons was estimated for a given rainfall event. A drought scenario situation for Jhod nadi watershed, tributary of Godavari River, located in Nanded District of Maharashtra, India, with an area of 196 km² was created. Probable drought severity of the settlements (about 40) was grouped in low to very High depending on their deficit percentage of demand-supply. An effective method for regular monitoring and preparedness is discussed in the paper.

USE OF GEOGRAPHIC INFORMATION AND REMOTELY SENSED DATA IN THE DECISION-MAKING SUPPORT SYSTEM FOR FLOOD MANAGEMENT IN ROMANIA

Corina PREDESCU, Gheorghe STANCALIE, Elena SAVIN (Remote Sensing and GIS Laboratory, INMH)

Floodings are an important risk in many areas around the globe and especially in Romania. In the latest years floodings occurred quite frequently in Romania, some of which isolated, others were affecting wide areas of the country's territory. The paper presents the elaboration of the cartographical documents on the flood risk regions over a pilot watershed and the development of the GIS applications with a decision system for the crises management. A modern approach is used for the flooding risk indices estimation. These indices are associated to the physic-geographical, morpho-hydrographical and vulnerability characteristics of a region. The methodology was elaborated to determine the flooding risk, using risk indices at a scale compatible with a synthetic representation of the territory. There are stressed the facilities supplied by the Geographic Information System (GIS) and the remotely sensed data to manage flooding during their characteristic phases: before, during and after flooding. Accent is laid on the pre and post-crisis phases. An important research topic was the study of the parameters that can be extracted from satellite images in view of organizing a hierarchy of the geographical space versus the flooding risk. Information obtained from satellite images proved to be useful for the determination of certain parameters necessary to monitor flooding: hydrographic network, water accumulation, size of floodable land, land impermeability degree, water absorption capacity over the basin surface, or resilience to in-soil water infiltration. The study encompassed both the risk degree levels related with various parameters, which influence and determine floodings and which takes into consideration the human presence in the sensitive areas. The application was developed for the Arges hydrographic basin in Romania, a critical area, keeping in mind that it withholds many localities, including the capital and also important economic centers. Advantages offered by this integrated system are: to manipulate and make available large databases, to easily update the information, to survey the temporary modifications, to establish the link between the measured/forecasted data and the GIS database. The database allows obtaining synthetic representations of the hydrologic risk for the Arges basin, through separate or combined use of the risk parameters as well as for interfacing with the hydrological models in view to improve them as regards recovering results and the possibility to achieve scenarios.

VELOCITY DISTRIBUTION DUE TO LAUNCHING APRON AROUND ABUTMENT

Mohammad Monowar HOSSAIN, Mohammad Salzar HOSSAIN, Mohammad Faheem SADEQUE (Department of Water Resources Engoneering, BUET)

Velocity distributions were measured in a small-scale riverbed model for vertical wall abutment constructed at the Hydraulics and River Engineering Laboratory of Bangladesh University of Engineering and Technology (BUET). A series of test run were conducted for five different apron-setting configurations and velocities were measured using a programmable 2-D electromagnetic liquid velocity meter. Comparison of velocity distribution in terms of velocity vectors with and without apron was made. It was observed that considerable displacement of velocity vectors occur due to different apron setting. Due to displacement of velocity vector, the scour depth was found to be affected significantly. Vertical velocity distribution at the maximum scour hole formed due to apron setting was also measured. The result obtained gives an indication of use of falling apron for protection of vertical abutment against failure due to scour.

URGENT WATER SUPPLY INTO ZHALONG WETLAND IN 2001 AND 2002

Shiguo XU[1], Lianwen DANG[2], Heyue LI[2] ([1]Department of Civil Engineering, Dalian University of Technology, [2]Songliao Water Resources Commission)

Nen River basin is located in northeast of China, where belongs to monsoon precipitation zones. There usually are short summers and long winters with spring draught and summer floods. Around lower reaches of Nen River, there exist many big wetlands, such as Zhalong, Xianghai and Momoge wetlands. Zhalong wetland is the biggest one with the area of 2100km2, 468 species of vegetations and 236 species of birds belonging to 48 families. The main protected bird is Red Crown Crane. It is one of 7 wetlands earliest accepted by Ramsar convention in China. Water is very important for wetland evolution. As the water resource development is gradually actualized on the upstream of rivers that flow into Zhalong wetland, water shortage problem has endangered the wetland ecological environment. Farther more, after the big flood in 1998, Nen River basin faced a four-year long draught series. At the begin of 2001, the area of water surface in Zhalong wetland was only 130km2, much less than the average area 800km2 and that in common dry year 300-400km2. The most part of the wetland draught up. Reeds couldn't grow up as usual. A lot of reed wetland became into grass wetland and the vegetal state degrades very seriously. It threats the habitation condition of Red Crown Cranes that make their nests and hatch small cranes in every earlier summer here. So as to maintain the condition to keep basic function of the wetland, an urgent water supply project from Nen River to Zhalong wetland is put into practice. In the later autumn of 2001, supplied 35×106 m3 of water into the wetland, and from the spring to summer of 2002, 300×106 m3 again. According to the investigation on site, water supply has achieved satisfactory results. In the end of April, the supplied water pours over the central area of the wetland. By recovering the ecologic condition of reed and fish, it helps Cranes and birds very much. This urgent water supply program provided a useful experience to rescue wetlands from a water shortage disaster. In the same time, an especial water resources plan of Zhalong wetland is under working to guarantee the water supply safety of it for a long term. A key project supported by National Natural Science Foundation of China is also come to operation, which studies the problems concerned with using floodwater to restore wetlands and using wetland to make floodwater a useful water resources.

ASSESSMENT OF UNCERTAINTY IN DISTRIBUTED HYDROLOGICAL MODELING

HS03/07A/C26-001   Invited   0900

A METHODOLOGY FOR ASSESSING THE UTILITY OF DISTRIBUTED MODEL FORECAST APPLICATIONS IN AN OPERATIONAL ENVIRONMENT

Konstantine P. GEORGAKAKOS, Theresa M. CARPENTER (HYDROLOGIC RESEARCH CENTER)

Modern day deployment of weather radars in the US and abroad, and the availability of high-resolution distributed digital spatial databases have accelerated the development of a variety of new hydrologic models with distributed parameters and input. These models range from process-based to statistical and from time-continuous to event based. Distributed models have long been viewed as beneficial for hydrologic forecasting. However, errors in the precipitation data and model parameters may diminish any gains in prediction accuracy realized by accounting for the spatial variation of precipitation and parameters. Application of these models for the purposes of reliable flow simulation using observed spatially distributed precipitation data requires the resolution of the issue of balancing model complexity (as measured for example by the requirements for parameter estimation) with distributed-input uncertainty. The present paper exemplifies a probabilistic methodology to address this issue. A distributed model with components used in the operational forecasting of streamflow in the US is utilized to produce flow predictions for a typical catchment in a semi arid environment (Blue River in Oklahoma, USA). Models of uncertainty for input data and model parameters are identified, the latter based on consistent calibration procedures. Ensemble flow forecasts are produced at the outlet of the catchment for a number of forcing and parameter uncertainty scenarios and for a high and low spatial resolution model configuration. Kolmogorov-Smirnov test analysis is then performed to assess whether the results of the low and high resolution models can be distinguished at a given confidence level. Assessments of the implications regarding accuracy under operational forecast conditions are given.

HS03/07A/C26-002   0930

PROPAGATION OF PRECIPITATION UNCERTAINTYTHROUGH FLOOD FORECASTING MODEL

SHREEDHAR MASKEY[1], VINCENT GUINOT[2], ROLAND K. PRICE[1] ([1]IHE-Delft,PO Box 3015, 2601 DA, Delft, Netherlands, [2]Universite Montpellier 2, Maison des Sciences de l'Eau, 34095 ontpellier Cedex 5, France)

Over the last decade significant progresses have been made in quantitative forecast of precipitation by the use of sophisticated radar technology. The imprecision in the forecast precipitation however remains one of the major sources of uncertainty in real time flood forecasting. The uncertainty in the forecast precipitation generally comprises of (i) the imprecision in the quantity of forecast precipitation (Pq), (ii) the imprecision in the temporal distribution of the precipitation over the forecast horizon (Pt), and (iii) the imprecision in the spatial distribution of the precipitation over the watershed (Ps). This paper presents a methodology for the propagation of precipitation uncertainty (Pq, Pt and Ps) through a real time flood forecasting model. The imprecision Pt is represented by assuming a 3-valued forecast precipitation (minimum, most credible and maximum) for the period of a forecast horizon. A typical triangular fuzzy membership function is constructed based on the 3-valued forecast. A number of precipitation patterns are considered representing the possible distributions of each forecast precipitation over the forecast horizon and over the sub-basins. This is meant to treat the uncertainty due to Pt and Ps. The uncertainty in the forecast flood

due to the uncertainty in the forecast precipitation is computed applying the extension principle of the fuzzy set theory assisted by a genetic algorithm (GA). The idea here is basically to search for the maximum and minimum possible model-simulated floods for the given range of forecast precipitation and for the given possible precipitation patterns distributed both in time and space. The methodology was applied to a watershed model for flood forecasting that was developed using the HEC-1 software. The result of the analysis comprises of a band of minimum and maximum flood values associated with the forecasted flood. This is analogous to the confidence intervals in the probability theory-based uncertainty analysis. The method also provides a fuzzy membership function of each forecasted flood. The result shows good potential of this method for modelling precipitation uncertainty in flood forecasting models.

COMBINING PHYSICALLY BASED AND CONCEPTUAL APPROACHES IN THE DEVELOPMENT AND PARAMETERIZATION OF A DISTRIBUTED SYSTEM

Victor I. KOREN, Seann REED, Michael SMITH, Ziya ZHANG (Department of Commerce, NOAA/NWS/OHD)

Gridded precipitation estimates from a radar-gage analysis (NEXRAD) are now available for operational use by the National Weather Service (NWS) of the United States. While these estimates provide high temporal and spatial resolution data, it is not clear how the NWS can most effectively utilize these data to improve its river forecasts. One possibility is to incorporate high resolution NEXRAD precipitation into an existing lumped modeling framework. Two such approaches were tested: use of dynamical distribution functions of precipitation in addition to a basin average rainfall, and downscaling a rainfall-runoff model to capture the spatial pattern of rainfall. The tests suggested that while these approaches have potential in capturing the spatial variability of precipitation, they failed to improve upon 'basic' lumped simulations consistently. At the same time, they increased requirements on parameterization procedures. Another possibility, use of fully distributed physically based models, is also not as strait forward. Most distributed models are based on point process equations, and their spatially variable parameters are less identifiable from hydrograph analysis because they represent local properties. Recently, the Hydrology Laboratory of the NWS has developed a grid-based Research Modeling System (HL-RMS) that combines lumped conceptual and distributed model features. The HL-RMS consists of a conceptual water balance model (well tested over wide range of basins and climates) applied on a regular spatial grid and physically based kinematic hillslope and channel routing models. GIS-based algorithms are used to derive grid connectivity, overland and channel slopes from a digital elevation model. Experience with lumped and distributed models suggests that practical benefit from any rainfall-runoff model depends significantly on the availability of advanced parameter estimation procedures. Such a procedure is being developed for the HL-RMS. The procedure is based on combined analyses of distributed basin properties and the integrated basin response at the outlet. Initial (a priori) water balance model parameter grids are generated using high resolution soil-vegetation data. Uniform adjustment of a priori parameter grids is performed using results of lumped calibration at selected outlets. To remove scale effects, further fine tuning is achieved comparing simulated and observed hydrographs by a trial-and-error process. Spatially variable channel routing parameters are estimated from discharge measurement information at the basin outlet and geomorphological properties at each grid cell. HL-RMS tests have been conducted for a few headwater basins which have hourly NEXRAD precipitation estimates for nine years with a 4x4 km resolution. The tests showed that while the HL-RMS yields results comparable to well calibrated lumped model simulations, it outperforms a lumped model over basins where the effect of rainfall variability is significant. Combining outlet information and spatially variable basin properties provides a reliable procedure to estimate distributed model parameters. While uniform adjustment of water balance model parameters provides reasonable results at basin outlets, the problem of removing scale effects in nested basins is still a challenge.

IMPROVING A PRIORI ESTIMATES OF HYDRAULIC PARAMETERS IN A DISTRIBUTED ROUTING MODEL VIA VARIATIONAL ASSIMILATION OF LONG-TERM STREAMFLOW DATA

Dong-Jun SEO, Victor KOREN, Seann REED (Hydrology Laboratory, National Weather Service)

Due to the typically very large dimensionality of the problem, exhaustive estimation of distributed parameters in hydraulic routing models is highly impractical (if not infeasible). For this reason, much attention has been given in recent years to improving, with the aid of GIS, estimation of a priori distributed parameters from all available spatial data sources. Such a priori estimates of distributed routing parameters, however, are subject to various sources of error, and hence may not necessarily be dynamically consistent in the hydraulic sense. The purpose of this work is to develop a procedure for systematic improvement, or refinement, of a priori distributed hydraulic parameters in a kinematic wave routing model via variational assimilation (VAR) of long-term streamflow observations. Conceptually, the task amounts to solving a distributed inverse problem of downscaling the sensitivity of the streamflow observations to hydraulic parameters from the basin scale (O(1,000 sq km)) to the model grid scale (O(10 sq km)) through the distributed routing model of choice. Calculation of the gradient (i.e., the sensitivity of the streamflow to some parameter at some grid) for the least squares minimization is obtained from the adjoint of the distributed kinematic wave routing model of the National Weather Service Hydrology Laboratory´s (NWS/HL) Research Modeling System (RMS). To evaluate the marginal value of parameter improvement, the baseline distributed model in RMS consisting of a gridded Sacramento soil moisture accounting model with kinematic hillslope and channel routing is run with the a priori and the refined routing parameters for selected basins used in the Distributed Model Intercomparison Project (DMIP). The results are presented and the issues are described.

DISTRIBUTED MODEL FLOW SENSITIVITY TO UNCERTAINTY IN RADAR RAINFALL INPUT

Theresa M. CARPENTER, Konstantine P. GEORGAKAKOS (HYDROLOGIC RESEARCH CENTER)

The high spatial and temporal resolution of precipitation estimates afforded by weather radar has lead to increased research on distributed hydrologic models that can utilize these radar precipitation estimates, along with other high-resolution, spatial data on terrain, land use, land cover, and soil characteristics. HRCDHM is a catchment-based, distributed model that ingests radar precipitation estimates from the U.S. National Weather Service's WSR-88D radar and produces runoff and channel flow estimates for sub-catchmentsof a watershed of interest. The sub-catchments are delineated through GIS-processing of digital terrain and land use/land cover databases. The focus in the development of HRCDHM is on distributed hydrologic modeling suitable for use in an operational flow-forecasting environment. Thus, HRCDHM assumes operationally available input databases and includes components based

on operational hydrologic models. The aim of the current research is to assess the sensitivity of flow simulations produced by the distributed model under various definitions of uncertainty in the radar rainfall estimates.The distributed model is applied to several watersheds in the Midwestern UnitedStates. Generally, the basins are mildly sloping, with silty-loam soils, and range in contributing drainage area from 1,000 to 2,500 km2. The catchment delineation yielded sub-catchments with average sizes on the order of 60-80km2. Hydrologic model parameters were calibrated based on uniform distribution of parameters within each watershed and with distributed rainfall input. This yielded good agreement with observed flow records, with cross-correlation of hourly flow on the order of 85% and small bias. Available soils databases werethen used to distribute hydrologic model parameters with each watershed based on average soil properties such as available water content and permeability. Thus, the distributed model was applied with both distributed precipitation forcing and distributed hydrologic model parameters. The resulting variation of parameters across the study watersheds was not great, and the flow simulations with distributed parameters were similar to those with uniform parameters.A Monte Carlo simulation framework was used to examine the sensitivity of the flows produced by the distributed model to uncertainty in the radar rainfall estimates. For each watershed, various historical events were selected and modeled with 100 Monte Carlo simulations runs for each event and for various definitions of radar-rainfall uncertainty (uniform, exponential and radar-pixel scale). The variation in the resulting flow simulations were summarized in terms the maximum range of simulated flow for several watershed locations including interior locations and the watershed outlet. These results consistently show scale-dependence in the flow prediction uncertainty for a given radar rainfall uncertainty definition.

HS03/07A/C26-006   1045

DISTRIBUTED HYDROLOGICAL MODELING IN THE YATA WATERSHED USING THE WEP MODEL AND PROPAGATION OF RAINFALL ESTIMATION ERROR

Yangwen JIA, Tsuyoshi KINOUCHI, Junichi YOSHITANI (Hydrologic Engineering Team, Hydraulic Engineering Research Group, Public Works Research Institute)

Distributed hydrological modeling is highly required for hydrological prediction in watersheds with heterogeneous land surfaces, soils and aquifers under uneven distribution conditions of rainfall. A robust distributed hydrological model should be applicable to both long-term prediction of water budgets and short-term prediction of flood with satisfied accuracy. In this study, the WEP (Water and Energy transfer Processes) model is applied to simulate the hydrological changes in the Yata watershed in the past 25 years (1976-2001) and the impact of rainfall estimation error and rainfall spatial distribution on river discharge prediction is also evaluated. The Yata watershed is located in the northwest of Ibaraki prefecture, Japan, and has an area of 166km^2 of which agricultural landuse and forest accounts for about 70%. Urbanization in the watershed started in 1970's with the development of the Tsukuba city, and now as a part of a new railway development plan, 5 regions with a total area of 13km^2 are scheduled for various kind of urban development. Though several institutions had ever carried out some field investigations of groundwater and river discharges in the watershed in 1970's, PWRI and the local government began to monitor water and heat fluxes, river discharges and groundwater levels in 1999 and periodically carry out field investigations of river water and groundwater quality. In comparison with the observed results of 1970's, it is found that the river peak discharges become bigger and the groundwater levels become a few meters lower. The WEP model is first validated using the observation data in 2000 and 2001 and then applied to the long-term simulation from 1976 to 2001 in a time step of 1 hour and a grid cell size of 100m. The simulation results have good matching with the observation ones in both low river flow and flood peaks. The simulation results also show the same trend of groundwater level changes with that of the observed results. The sensitivity analysis of soil hydraulic conductivity and time step of flow routing is also conducted. It is found that the time step of 10 minutes for flood routing of river flow and overland flow can give satisfied results in the watershed. Finally, the impact of rainfall estimation error and rainfall spatial distribution on river discharge prediction is also studied. The simulation shows that during typhoon seasons, spatial distribution of rainfall has a great impact on river discharge prediction in the watershed because of its unevenness even at sites a few kilometers away.

THE EFFECTS OF RADAR-DERIVED RAINFALL UNCERTAINTIES ON FORECASTS FROM A DISTRIBUTED HYDROLOGIC MODEL

Jonathan J. GOURLEY[1], Baxter E. VIEUX[2] ([1]National Severe Storms Laboratory, Univ. of Oklahoma, [2]Univ. of Oklahoma)

The advent of weather radar has provided the potential to estimate rainfall accurately at high spatial and temporal resolutions. When these estimates are input to a distributed hydrologic model, forecasts of stream flow may be used to anticipate and thus mitigate the potential hazards associated with a flash flood. In hydrologic modeling, forecast uncertainties have traditionally been a function of the uncertainty in the model parameters, and in some cases the model structure. The study presented here uses a physics-based, distributed hydrologic model (that is based on the University of Oklahoma's *r.water.fea* model with modifications) to address the impact of uncertainties in the input rainfall estimates on stream flow predictions. Specifically, extension of the Generalized Likelihood Uncertainty Estimation methodology allows us 1) to assess prediction uncertainties by including uncertainties in the rainfall estimates and 2) to evaluate the accuracy of different rainfall algorithms independently at the scale of an integrating watershed. The study plan and some initial results will be presented for several events in the U.S.

HS03/07A/C26-008   1115

REAL-TIME ASSIMILATION OF RADAR-BASED PRECIPITATION DATA AND STREAMFLOW OBSERVATIONS INTO A DISTRIBUTED HYDROLOGIC MODEL

DONG-JUN SEO, Victor KOREN, Neftali CAJINA (Hydrology Laboratory, National Weather Service)

Along with the uncertainty in Quantitative Precipitation Forecast (QPF), the uncertainties in Quantitative Precipitation Estimate (QPE) and in soil moisture states represent arguably the biggest source of error in real-time hydrologic prediction. To reduce the uncertainty in the soil moisture states, much attention has been given in recent years to state-updating techniques that assimilate streamflow observations in real time. Though a number of such techniques appear in the literature in the context of lumped modeling, it is not clear whether the applicability extends to situations of significant biases in radar-based QPE and to distributed models. The purpose of this work is to explore real-time assimilation of radar-based QPE and streamflow observations into a distributed hydrologic model using variational assimilation (VAR) techniques. Experience with VAR in a lumped setting indicates that, being a primitive non-recursive filter (compared to, e.g., Kalman filter), VAR is well-suited for assimilation of QPE that is subject to significant biases, and offers much insight into the formulation and parameterization of the assimilation procedure (be it VAR or Kalman filter). The VAR formulation in this work solves the inverse problem of perturbing the grid-specific initial model soil moisture states and the grid-specific QPE over the time window

commensurate to the basin response time, based on the real-time streamflow observations. The hydrologic model is the gridded application of the Sacramento soil moisture accounting model in the National Weather Service Hydrology Laboratory´s (NWS/HL) Research Modeling System (RMS). To evaluate the technique, VAR-aided forecasts (under clairvoyant QPF) are compared with raw forecasts for selected basins used in the Distributed Model Intercomparison Project (DMIP). The results are presented and the issues are described.

HS03/07A/C26-009   1130

IMPACT OF ONLINE CALIBRATION OF RADAR-MEASURED RAINFALL IN HYDROLOGICAL FORECASTING USING DISTRIBUTED HYDROLOGICAL MODEL

Minjiao LU[1], Norio HAYAKAWA[2] ([1]Dept. of Civil and Environ. Eng. Michigan State University, [2]Nagaoka University of Technology)

In order to find a more effective way to use both gauge-measured and radar-measured rainfall data in hydrological forecasting, a runoff analysis using a distributed hydrological model is carried out over Uono River basin (355 square kilometers), a tributary of Shinano River, the longest in Japan. In order to take into account the spatially distributed information on rainfall and hilly topography of the study basin, a distributed hydrological model is constructed by using our distributed hydrological modeling system. This model computes runoff generated in all grid cells, 100x100m square areas from rainfall data using XinAnJiang model, and routes the runoff from all grid cells to the basin outlet through a channel network delineated from a DEM (Digital Elevation Model). Calculated hydrographs can be derived at all interested grid points, central points of grid cells near by the hydrological stations. Before running the distributed model, the rainfall data derived by using operational radar constants are compared with rainfall data from rain gauges. It´s shown that both point rainfall and the basin average rainfall from radar-measured rainfall data are over-estimated. This may be caused by radar constants determined improperly at logarithmic scale. In order to correctly consider the water budget over the basin, we determine the radar constants at normal scale using non-linear optimization. However, these constants are not always the best. The radar constants vary largely from storm to storm in all 16 selected heavy storms, and even vary largely during a storm. An algorithm is developed to make online calibration of radar-measured rainfall data by using gauge-measured rainfall data. The impact of this online calibration is investigated by using above distributed hydrological model. It is shown that online calibration can combine low-accuracy and high-density radar-measured rainfall and high-accuracy and low-density gauge-measured rainfall well and improve the accuracy of hydrological forecasting.

HS03/07A/C26-010   1145

A NEW COMPOSITE APPROACH OF PHYSICAL AND GEOSTATISTICAL ASPECTS TO GROUNDWATER MODELING

Toshio HAMAGUCHI (Disaster Prevention Research Institute, Kyoto University)

A new groundwater model in conjunction with spatial uncertainty is proposed in this paper. Modeling errors, which is typically included in spatial uncertainty components, cannot be completely covered by physical modeling in details. Geostatistical approaches using trend and random functions in space-time are founded on deterministic and stochastic models. Most of trend functions are, in general, represented as just a deterministic form based on the corresponding and well-known physical law, whereas a new additional component of uncertainty such as a geostatistical bias of a so-called `drift´ is introduced in this approach. It consists of a constant in space but changes with the lapse of time. A random function at each time is indirectly described through a stochastic form of an appropriate error covariance model with spatical uncertainty. For the sake of the best agreement with actual behavior by physical modeling, parameter identification with high accuracy is needed. A highly efficient scheme for numerically solving inverse problems, the extended Kalman filter-FEM, is herein employed. This tool filters out uncertainty components as a set of system noises by using observed data. It can easily identify the most likelihood model that is represented by a set of the equivalent uniform materials in zones even though the true structure gets unknown. Attempts to estimate model parameters of permeabilities are numerically tested in some hypothetical aquifers, which are designed to allow testing various aspects of the modeling problem. The true and hypothetical aquifers of interest are subdivided into two, four and twenty constant-permeability zones, respectively. Convergence on the inverse solution can be achieved with high accuracy. The changes in the water levels to be calibrated are assesed in the several cases based on permeability zonation. The model errors at observed points are then obtained with uncertainty. It is now assumed that they have a geostatistical structure with a spatial bias. Their geostatistical distribution is mapped by a constant drift and the error covariance function, which is chosen a sphere type in this work. As mentioned above, the proposed method to eliminate modeling errors is demonstrated through all of the case studies. The greater effectiveness of the geostatistical bias in this work can be seen from a reciprocal of the absolute coefficient of variation in transition. The dependent relationship of such coefficients to a drift is investigated from the their transient reciprocal, which gets larger in strongly depending on the drift term for the statistical model and becomes smaller in weakly depending on that. Finally all the results to be discussed can be then shown that the composite estimates are reasonable and successfully in best agreement with the true ones.

WEATHER RADAR INFORMATION FOR HYDROLOGICAL PREDICTION

HS03/07P/C26-001   1400

EFFECT OF RADAR BEAM GEOMETRY ON RADAR RAINFALL ESTIMATION

Siriluk CHUMCHEAN[1], Alan SEED[2], Ashish SHARMA[1] ([1]School of Civil and Environmental Engineering, The University of New South Wales, [2]Bureau of Meteorology and CRC for Catchment Hydrology)

The frequency, accuracy and resolution of hydrologic records is a major limitation in the accurate modelling of hydrologic events. The weather radar provides real-time spatially continuous measurements covering a large area at short time intervals. However, considerable uncertainty still remains in the procedures used to estimate the rainfall from weather radar observations. This uncertainty may be caused by the variability of raindrop size distribution, the variation of reflectivity with height and with range and the temporal and spatial resolutions adopted for sampling the radar reflectivity. This paper accounts for the effect of the radar beam geometry as a function of distance. The conical shape of the radar beam causes the observed volume to increase with range from the radar, leading to both bias and an increase in the standard error associated with the measured reflectivity as a

function of range. To remove the bias caused by the radar beam spreading, a simple-scaling transformation is proposed. The results show that the transformed reflectivity becomes relatively free from range dependent bias, which leads to more accurate relations with the measured ground rainfall than what is obtained otherwise. Formulation of relations between rainfall and reflectivity implicitly assumes that the reliability of the reflectivity measurements does not change with distance from the radar. This is far from true in practice. A procedure is developed to estimate the standard error associated with reflectivity measurements as a function of range. This is then used to develop reflectivity-rainfall relationships that take the uncertainty of reflectivity measurements specifically into account. A 6-month long rainfall-reflectivity record from the Kurnell radar at Sydney, Australia is used to illustrate the efficiency and applicability of the reflectivity scaling transformation and the consideration of reliability in reflectivity measurements, compared to radar rainfall algorithms used conventionally.

HS03/07P/C26-002   1415

EVALUATION OF DUAL POLARIZATION RADAR FOR RAINFALL-RUNOFF MODELING - A CASE STUDY IN SYDNEY, AUSTRALIA

Phillip W. JORDAN[1], Alan W. SEED[2], Tom D. KEENAN[2], Peter T. MAY[2] ([1]Hydrology Unit, Bureau of Meteorology, Australia, [2]Bureau of Meteorology Research Centre, Australia)

The routine use of radar for rainfall measurement and short-term forecasting in flood forecasting and other hydrological applications is increasing. Dual polarisation radars have a theoretical advantage for rainfall rate estimation over conventional radars because the radiation returned by the horizontal and vertical polarised beams provide several additional parameters of the rainfall field that can be combined into an estimate of rainfall intensity. The Bureau of Meteorology Research Centre operated a 5.3 cm wavelength dual polarisation radar at Badgery´s Creek, 44 km West of Sydney Australia, for the period from September 2000 to June 2001. The aim of this paper is to analyse and optimise the performance of a C-Band dual polarisation radar for forecasting of floods in rural and urban catchments. Hourly rainfall data from a network of 239 tipping bucket raingauges, located within 110 km of the radar, has been utilised in the analysis. The Bureau of Meteorology is responsible for preparing flood warnings for the Georges River, which flows through the Western suburbs of Sydney. The URBS semi-distributed rainfall runoff routing model is used to predict flood inflows from the 350 km[2] catchment area upstream of the urban area. Accurate measurement of rainfall across the catchment is critical for timely and accurate flood forecasts on the Georges River. The paper compares rainfall accumulation estimates across the Georges River catchment from: 1. raingauge networks of varying density, 2. single polarisation (reflectivity only) radar, 3. reflectivity with attenuation correction calculated using dual polarisation algorithms, 4. several multi-parameter algorithms that implement measurements from the dual polarisation radar, such as reflectivity at dual polarisation, attenuation and specific differential phase, and 5. single or dual polarisation radar combined with raingauge networks of varying density. The paper then goes on to analyse the effect of each of the rainfall measurement strategies on the accuracy of prediction of the flood hydrograph from the catchment. Inferences are drawn about selection and optimisation of parameter values for the rainfall runoff routing model for use with rainfall data from each of the various sources.

HS03/07P/C26-003   1430

RADAR RAINGAUGE WITH VOLUME SCANNING FUNCTION

Takeo KINOSITA[1], Minoru IRISAWA[2] ([1]The Representative of Suimon Kankyo, [2]Ministry of Land, Infrastructure and Transport)

CAPPI is the abbreviation of Constant Altitude PPI while PPI means Plane Position Indication of a radar. The radar equipped with CAPPI has been operated since 10 years ago at the top of Mt.Akagi which is about 100 km northwest of Tokyo. It can monitor rainclouds three-dimensionally every 15 minutes. It has 20 kinds of angles and observes rainfall 200 km radius.The authors try to develop the availability of the CAPPI radar for operational use, especially to operation of multi-purpose reservoirs. The followings show the steps of development of CAPPI radar application to reservoir operation and monitoring of heavy rainfall disasters. 1) Parameter developmentThe empirical formula Z=BR βis used for calculation of rainfall R from the radar reflectivity Z where B and β are determined by the observed data. The data for determination of B and β are selected from the adequate mesh point data of the radar and the good conditioned ground raingauge. 2) Selection of the altitudeFor monitoring of rainfall on the ground, the radar beam must be as low as possible. Since there are high mountains around Mt. Akagi, and the cloud producing heavy rainff is more than 3000 m height, the 3000 m level is chosen as the best altitude. It may be changing season by season. 3) Variable B and β methodThe parameters B and β are revised every hour both by the reflectivity at the constant altitude and rainfall in raingauges. Every next hour the revised parameters are successively adopted for accurate estimation of rainfall. B and β are not fixed. 4) Bright band eliminationA bright band sometimes appears in PPI observation. It is like a doughnut on the PPI picture because the radar beam forms a conic plane and a bright band exists at the 0° level of the atmosphere. The variable B and β method based on the CAPPI observation is not affected by the bright band because a) the reflectivity on the 0°level can be avoided by the selection of the advantageous altitude, or b) the variable B and β method can find the best B and β even if the bright band appears. 5) Vertical profileThe vertical profile of the raincloud can be drawn at any section by CAPPI method due to three dimensional data acquisition. Therefore a winter storm, a Baiu rain, a thunderstorm etc are characterized by their cloud profile. This picture gives us the important information such as rainfall potential, heavy rainfall monitoring and prediction of a downburst. The authors developed the variable B and β method by using the CAPPI radar, then implemented successfully rainfall observation by the radar. They would like to improve in the future the software of CAPPI analysis for reservoir operation, and prevention of disaster caused by heavy rainfall.

HS03/07P/C26-004   1445

EVALUATION OF THE APPLICABILITY OF RADAR RAINFALL INFORMATION TO OPERATIONAL HYDROLOGY

Tadashi MATSUURA, Kazuhiko FUKAMI, Junichi YOSHITANI (Hydraulic Engineering Research Group, Public Works Research Institute)

This paper proposes a framework for evaluating usefulness of radar rainfall information by different usage, and discusses prospect and limitation of further development of the radar system. First, effectiveness of radar data online calibration for accuracy improvement was discussed. Second, an appropriate evaluation method for observation accuracy according to each usage purpose was suggested after reviewing various reports on evaluation methods. Radar usage purposes include weather forecast, flood forecast, sediment disaster warning, reservoir management, and traffic management. Last, the authors demonstrated case studies to show advantages of the use of different evaluation methods according to usage purpose and evaluated the usefulness of the radar rainfall system from multi-functional aspects. Two different online calibration schemes are commonly used in the present Japan.

The process of the development of the two schemes and their effectiveness for accuracy improvement were reviewed and analyzed in terms of difference in radar data usage intentions. Generally-used evaluation method of radar observation accuracy is comparison of the ground point rainfall and the mesh radar rainfall right above the station. Studies employing this comparison to show the accuracy of radar data have reported high correlation between hourly ground point rainfall and the radar mesh rainfall right above the station; correlation coefficient sometimes exceeds 0.8 in studies conducted in Japan. Another evaluation method is comparison of ground point rainfall and a mesh radar rainfall in the vicinity of the mesh right above the ground station. This evaluation could be better when falling raindrops in the atmosphere drift, and could avoid unreasonable judgment that the radar rain system has low accuracy and no use. For the purpose of flood forecasting, Matsuura et al. have proposed rainfall averaged over the river basin instead of ground point rainfall as an index to show the radar observation accuracy. They showed that radar observation for several extreme rain events including the devastating 2000 Tokai storm could be considered to have very high accuracy which could not be shown by comparison with ground point rainfall. Then, critics that flood forecasting with direct input of radar rainfall alone has less reliable than one with ground rain input could be reconsidered by checking the accuracy of radar rainfall by more appropriate index. In the same way, accuracy of radar rainfall data for each purpose was discussed. Synthesizing these accuracy evaluations from multi-functional aspects, the authors discuss the usefulness of the radar system.

WEATHER RADAR DISTRIBUTED HYDROLOGICIC MODEING, CASE STUDY IN INDUS BASIN

Shaukat Ali AWAN (Pakistan Meteorological Department)

Tropical cyclone and depression and associated rainfall over the catchment areas of the rivers which generates rainfall runoff resulting in flooding in the rivers. The radar rainfall estimation through echo reflectivity in decibels (dB) delineates heavy precipitation areas. The uncertainty occurs because of the beam width and the location of the vertex. The limited area calibration sensors help in ground truth and radar estimation. However, keeping in view the continuity equation for hydrological aspects better results can be obtained particularly in rainfall amounts in three categories i.e; (a) Less than 50 mm, (b) 50 mm to 100 mm and (c) More than 100 mm. Doppler weather radar plays a significant role in tracking down the tropical storms and depressions. Since its effective hydrological range is 240 Km as such at least 1 to 2 days in advance the information with specific direction of movement and internal structure of the clouds embedded with heavy precipitation are obtained. The intensity of the rainfall as depicted quantitatively through decibel variations with Pseudo coloring technique can pinpoint the areas of intense rainfall, and with appropriate software CAPPI (Constant Altitude Plain Position Indicator) the volumemax Analysis over a particular place (determined through Echotop capability) and its intensity value provides a time lapse and cumulative information in three dimensions which is extremely important for Hydrological/Flood Forecasting. With regard to catchment area of rivers which lies beyond our borders and from where hardly any ground information is available; this remote sensing equipment played extremely vital role in disaster monitoring i.e. Flood Forecasting and its assessment for subsequent mitigation as applied to Pakistan River basins on real -time basis. The vertical wind shear profiler coupled with X-Y cross-section gives the areal distribution of precipitation with altitude depiction pin pointing the potential vorticity area max (PVA max) essential for flash flooding giving a quantitative assessment essential for area under threat for issuing early flood alert. A consequential application of both Radar estimation and rainfall runoff was made in Indus River sub-basin, the runoff was with in an accuracy of 20 %. However it did save life, cattle and property particularly evacuation was carried out in riverbed areas. The flow channel was estimated 60,000 cusecs whereas the actual was 45,000 cusecs. Relief and Flood Mitigation authorities appreciated the community coordination.

HS03/07P/C26-006   1515

RADAR PRECIPITATION FOR WINTER HYDROLOGICAL MODELLING

Steven R. FASSNACHT[1], Eric D. SOULIS[2], Nicholas KOUWEN[2] ([1]Colorado State University, [2]University of Waterloo)

Weather radar has been successfully used for estimating rainfall to drive hydrological models for watersheds of numerous sizes, and has been applied to temporal resolutions from individual storm events to seasonal to annual periods. However, the use of weather radar for snowfall estimation has focussed primarily on short time intervals, such as hourly and sub-hourly, to single storm events lasting up to two days. The emphasis has been to improve radar estimates using ground-based measurements as truth. This paper illustrates the use of weather radar snowfall estimation for seasonal hydrological modelling purposes. In this paper weather radar data are used for winter precipitation estimation. The estimates are compared to gauge measurements (corrected for wind undercatch) to illustrate the improvement in the radar data as the length of accumulation increases. The radar data and interpolated ground based measurements are used to drive a physically based hydrological model (WATCLASS). Post-processing of the radar data has been undertaken to consider a local scaling issue, underestimation due to the use of winter radar coefficient for winter rain, and variability in reflectivity based on snow particle shape. The study area is the Upper Grand River Basin in central southwestern Ontario, Canada and the study period is the winter from 1993 through 1997. For four of the five year, the radar data provided precipitation estimates that were better than those provided by the gauge data, in terms of simulated runoff volumes. For the winter of 1995, the gauge data yielded better precipitation estimates for runoff volume modelling than the gauge data. The significant over-estimation of the radar data compared to gauge point estimates for 1995 was also observed by radar operating in Michigan, USA. Along with runoff volumes, peak streamflows were more closely estimated from radar precipitation than gauge precipitation. Gauge estimates consistently yielded lower than observed peak streamflows.

HS03/07P/C26-007   1545

NUMERICAL STUDY OF RAINFALL-TOPOGRAPHY RELATIONSHIPS IN MOUNTAINOUS REGIONS OF JAPAN USING A MESOSCALE METEOROLOGICAL MODEL

Yoshiharu SUZUKI[1], Eiichi NAKAKITA[2], Shuichi IKEBUCHI[3] ([1]Department of Architecture and Civil Engineering, Faculty of Engineering, Utsunomiya University, [2]Department of Global Environment Engineering, Graduate School of Engineering, Kyoto University, [3]Water Resources Research Center, Disaster Prevention Research Institute, Kyoto University)

From the standpoint of hydrological applications and water resources management, it has been required to determine the spatial and temporal structures of rainfall distribution with consideration to topographic properties in a watershed. Especially, it is much difficult to understand the nature of the relationship between rainfall distribution and topography in mountainous regions like in Japan. For the purpose of determining the mechanism of topographic effects on rainfall and making a stochastic model of rainfall distribution, this study researched the relationship through the following two approaches: analyzing long-term

rainfall information from a weather radar in Japan, and running numerical simulations of precipitation using the mesoscale meteorological model named MM5. First, for a quantitative estimation of topographic effects on rainfall distribution, rainfall-elevation relationships were determined through the analysis of data from a weather radar on the basis of the Dependence Line on Topographic Elevation (DLTE), one of the models which represent the correlation between rainfall distribution and topographic elevation. The condition required for establishing the relation of DLTE was determined by analyzing various cases of rainfall distribution which have various time scales of accumulation. Furthermore, some investigations were also conducted on the basis of DLTE to determine the temporal accumulation process of rainfall distribution (TAPR), which explains how properties of rainfall distribution fluctuate with temporal accumulation. It is one of important standpoints which should be taken into consideration to make a stochastic model of rainfall distribution. Next, DLTE and TAPR were analyzed by running numerical simulations using the MM5, which is the mesoscale model constructed in the Pennsylvania State University - National Center for Atmospheric Research (PSU-NCAR), to determine the mechanism of topographic effects on rainfall distribution. In testing simulations, it was verified by comparison with the raingauge data in some areas of Japan that rainfall distribution could be simulated with reasonable accuracy, and that the relation of DLTE and the process of TAPR were also hold in such numerical simulations. By running simulations under the topographic conditions which have various scales of resolution, it was investigated what influence the scales had on the process of TAPR. The relationship between the scales of topographic resolution and the degree of topographic effects was made clear, and it was found that the degree depended largely on the scale of mountains. On the other hand, an attention was focused on the slope of DLTE, and the relationship between the slope and the wind on a synoptic scale was investigated to determine the influence of wind speed and direction on rainfall-elevation relationships. It was found that linear correlation was hold overall between the slope of DLTE and horizontal wind speed although vertical wind speed and wind direction had no definite correlation with the properties of rainfall distribution.

SIMULATION OF PRECIPITATION CAUSED BY A BAIU FRONT: AN EVALUATION STUDY WITH RADAR DATA

Soichiro SUGIMOTO, Hiromaru HIRAKUCHI (Central Research Institute of Electric Power Industry)

Remarkable improvements of a mesoscale model allow its potential applications for short-term precipitation forecasting to be wider range. The objective of this study is to investigate the capability of a mesoscale model to reproduce the spatial variability of precipitation and the associated wind field at mesoscale. To evaluate the ability of a mesoscale model, a simulation of precipitation system embedded in the Baiu (Mei-yu in Chinese) front is performed. A west-east oriented rainbelt along the front was prominent and a few precipitation centers were found in the event. Simulated results are compared with 3-h accumulated precipitation amount from Radar-AMeDAS, which is calibrated using operational C-band radar data and surface rainfall data collected by the automated meteorological acquisition system of Japan Meteorological Agency. Horizontal wind field in an orographic region estimated by the extended volume velocity processing (EVVP) using radial velocities from Doppler radar is also used for evaluation of wind field in meso-beta scale. The model for this study is the nonhydrostatic version of the Pennsylvania State University - National Center for Atmospheric Research Mesoscale Model version 5.3.4 (MM5v3.4). In all simulations, the coarsest grid has a spacing of 81 km, the middle grids 27 km and 9 km, and the finest grid 3 km. The model is initialized using both archived analyses from the European Center for Medium-Range Weather Forecasts (ECMWF) and Reynolds sea surface temperature (SST) from the National Oceanic and Atmospheric Administration (NOAA), from which first-guess fields are generated. 3- and 9-km domains are nested within a 27-km domain using one-way interfaces, and two-way interactive nested grid system is adopted between 27- and 81-km domains. Model results indicate that the MM5 can provide a general description of mesoscale features such as the rainbelt and more local strong precipitation centers of the frontal system observed by Radar-AMeDAS. The southward propagation of rainbelt and the eastward movement of the embedded system can be also well simulated by the model. The major deficiencies of the model are its underestimation of rainfall amount and to fail in reproducing localized rainbands in a mountainous region of Japan. These deficiencies are associated with the model's limit that the model cannot resolve the convergence zones of EVVP-based wind field affected by complex terrain. These findings suggest that mesoscale data assimilation should be required for additional improvements particularly in applying to mountainous regions and that radar data may represent a potentially valuable source of upper-air data suitable for four-dimensional data assimilation.

RAINSTORM CHARACTERISTICS IN TEMPERATE AREAS DERIVED FROM MULTIPLE TIME SERIES OF WEATHER RADAR IMAGES

Gabrielle J.M. DE LANNOY, Inge L.M. DE JONGH, Niko E.C. VERHOEST, François P. DE TROCH (Laboratory of Hydrology and Water Management, Ghent University)

In order to define the spatial and temporal characteristics of rainstorms, 20 time series of weather radar images over The Netherlands and Belgium are analysed. The velocity of rainfall events and the direction of movement are determined for the 1632 available radar images using the cross-correlation technique. After a thorough statistical analysis, theoretical probability distribution functions could be fitted to the histograms of these two rainfall characteristics. To discriminate single rainstorms within a radar image, a new technique was developed. Spatial characteristics, like the area and the perimeter of the rainstorms are determined and theoretical distributions were fitted to the data. Different methods to define the dimension of a rainstorm are proposed and worked out. A statistical analysis revealed that the dimensions of rainstorms in the direction of the rainfall movement are significantly different from the dimensions in the direction perpendicular to the movement. Rainstorms are composed of several rain cells which are clustered together. Due to the spatial resolution of the radar images, individual rain cells cannot be identified. In order to describe the occurence of cell clusters, a technique was developed for localizing cluster centra within a radar image. The method is based on level slicing the image and detecting connected areas which have a rainfall intensity above a preset threshold. A statistical analysis revealed that the positions of the cluster centra in the two perpendicular directions (i.e. along and across the rainfall movement) follow a Poisson distribution.

HS03/07P/C26-010   1630

STOCHASTIC MODELING OF ERROR STRUCTURE OF REAL-TIME PREDICTED RAINFALL AND RAINFALL FIELD GENERATION

Yasuto TACHIKAWA[1], Yoshimitsu KOMATSU[1], Kaoru TAKARA[1], Michiharu SHIIBA[2] ([1]Disaster Prevention Research Institute, Kyoto University, [2]Department of Civil Engineering Systems, Kyoto University)

To evaluate the uncertainty of a real-time river discharge prediction with a distributed rainfall runoff model, an error structure of real-time rainfall prediction by a translation model is modeled as a spatial random field and predicted rainfall fields are simulated according to the characteristics of the prediction error structure. At first, absolute prediction error fields and relative prediction error fields between radar observed rainfall and predicted rainfall by a translation model are statistically analyzed. Kolmogorov-Smirnov test shows that the relative prediction error of 1 hour ahead mean precipitation with 3km spatial resolution fits to a lognormal distribution. Also spatial correlation of relative prediction error is found to be modeled using Gaussian model and the correlation length takes almost same value during one precipitation term. Thereby a lognormal spatial random field is selected to represent the prediction error structure. Then a method to generate a lognormal spatial random field is developed, which uses a matrix factorization technique of a covariance matrix decomposition into its square root matrix approximately by using the Chebyshev polynomials. Finally, rainfall fields with the uncertainty having lognormal spatial random field characteristics are generated by using the method. The generated rainfall fields will be used to evaluate the uncertainty of real-time river discharge predictions with a distributed rainfall runoff model on a Monte Calro simulation framework.

ON THE MODELING OF TEMPORAL CORRELATIONS IN SPATIAL-CASCADE RAINFALL DOWNSCALING

Assela PATHIRANA[1], Srikantha HERATH[2], Tadashi YAMADA[1] ([1]Chuo University, [2]University of Tokyo)

Using cascade theories to spatially-distribute global or mesoscale rainfall forcing for watershed scale run-off simulations, has a number of attractive features compared with the traditional approaches (e.g. Thiessen polygons), where the adequacy of the ability to mimic the spatial variability and discontinuity as in observed rainfall is a major concern. In last two decades, a number of multiplicative cascade based downscaling models and techniques have been developed. In spite of these numerous advances in cascading theories and techniques, the applications of the principal in run-off studies has been rare. A rainfall product needs to be accurate in the temporal-persistence, in addition to the spatial features for it to qualify as a candidate for run-off studies. Most of the past efforts of multifractal analysis and cascade modeling of rainfall have been limited to either temporal or spatial dimension. On the other hand, even a crude maintenance of both spatial and temporal correlations is a pre-requisite for distributed run-off modeling. Thus, the lack of reliable means of maintenance of the temporal-persistence in spatial models is perhaps a main reason for the lack of appeal to apply cascade downscaling to run-off studies. One theoretically attractive way of overcoming this inadequacy is to model rainfall as a full spatiotemporal process. This involves transformation of the temporal dimension in to a third spatial dimension by multiplying with a hypothetical velocity factor, derived empirically from observed rainfall. Alternatively, we propose that a simpler time-series approach combined with the cascade schemes can be used with relative ease, to model the temporal-correlations observed in rainfall in to spatial downscaling schemes. We interpret the scaling of rainfall in space as the combined effect of a spatial multiplicative cascade process based on large-scale forcing and a number of time-series processes that relate rainfall intensity at a given cascade level to that of the past time steps or the history. Thus, the model is capable of mimicking the temporal-persistence at all spatial scales involved in the problem at hand. We use a number of Markov processes to model the time-series process. The ability of a cascade scheme to treat the zero rainfalls explicitly (e.g. Over and Gupta 1996) may be of particular interest to the run-off analyst. In addition to the intensity, data analyses shows that zero rainfall at various spatial scales, also have a strong temporal correlations. In the present model, zero rainfall persistence is modeled based on a simple conditional probability scheme. After developing the theoretical framework for the proposal based on the features of spatial rainfall, the model is verified using hourly radar based spatial rainfall observations for the central part of Japan.

ASSESSMENT OF PERFORMANCE IN DISTRIBUTED HYDROLOGICAL MODELING

HS03/08A/C26-001   Invited   0830

DISTRIBUTED HYDROLOGIC MODELING: WHAT ACCURACY IS ACHIEVABLE?

Baxter E. VIEUX[1], Fekadu G. MOREDA[2] ([1]School of Civil Engineering and Environmental Sci., University of Oklahoma, [2]National Weather Service, National Atmospheric Administration)

Distributed parameter watershed models that are physics-based offer distinct advantages over conceptual rainfall-runoff models. Spatially distributed parameters derived from soil properties, land use/cover, topography, and input from radar rainfall require new methods of adjustment in order to minimize differences between simulated and observed hydrographs. Distributed hydrologic models based on conservation laws have identifiable optimal values and expected behavior and interaction during calibration. This paper describes a calibration method that exploits these model characteristics and presents results for two river basins: the Illinois River (2300 km²) and Blue River basins (1142 km²) in Oklahoma. The calibration scheme presented is an ordered physics-based parameter adjustment (OPPA) method. Two river basins are simulated with volume errors with good agreement in volume for a series of twenty storm events over each basin. Within a subset, high accuracy is achieved, while for other event subsets, departures of simulated from observed volume and discharge are much larger. Realistic parameter values are obtained for both basins using a storm subset. As storm events are added to the calibration set, stability in the optimal parameter set is examined.

MODEL BEHAVIOR OF DISTRIBUTED HYDROLOGICAL MODELING WITH DIFFERENT FORCING DATA RESOLUTIONS

Roshan K. SHRESTHA, Yasuto TACHIKAWA, Kaoru TAKARA (DPRI, Kyoto University)

Hydrological modeling with distributed approach lacks popularity in practical application due to problems with data rather than modeling principles. On the other hand, the advantages of distributed modeling approach, for example its ability to evaluate the effects of spatially variable human and natural impacts, make it very attractive and an essential tool. General Circulation Models (GCMs) are one of the major data source in distributed hydrological modeling for gauged and un-gauged basins. However, the available grid resolution of GCM data should resemble to the need of hydrological model's spatial resolution, which largely depends on catchments size. Observing the behavior of spatial resolution in distributed

hydrologic modeling, data requirement criterion with respect to catchments size is investigated by evaluating IC Ratio (ratio between catchments area and input data resolution) expecting massive use of GCM data and coupled atmospheric and hydrologic model in near future. A macro scale distributed hydrological model is developed using object oriented hydrological modeling system (OHyMoS) and test simulations are conducted for the case of Huaihe River Basin (132000 sq. km.), in China and its two sub-basins Wangjiaba (29800 sq. km.) and Suiping (2093 sq. km.). A 10 minute spatial resolution data set is generated using the 1.25 degree GAME Reanalysis Data Version 1.1 referring the spatial pattern of 5 minute HUBEX EEWB Data, a field measurement based distributed data set. The newly created data has improved the modeling result. Later on, the generated 10 minute spatial data is converted to 20 minute, 30 minute and so on. Feeding these generated data into the model separately for discharge simulation keeping all other parameters same as before, its model performances are experimented. The change behavior of simulation result displayed a rapid improvement on model result with finer resolution. The improvement in model performance saturates afterward which suggests an existence of a threshold value of IC Ratio. Optimal simulation results are observed while the IC Ratios are around 1:10 ~ 1:20. Geo-statistics has revealed that the input data with greater spatial variability displays significant improvement in performance otherwise spatial pattern of input data has feeble sensitivity. Higher sensitivity in model performance due to spatial resolution is observed in smaller catchments in both presence and absence of routing models than that of larger catchments.

HS03/08A/C26-003   0915

INVESTIGATING THE EFFECT OF CATCHMENT CHARACTERISTICS ON THE RESPONSE TIME SCALE USING DISTRIBUTED MODEL AND WEATHER RADAR INFORMATION

Efrat MORIN[1], Konstantine P. GEORGAKAKOS[2], Uri SHAMIR[3], Rami GARTI[4], Yehouda ENZEL[5] ([1]Hydrology and Water Resources, University of Arizona, Tucson, AZ 85721, [2]Hydrologic Research Center, 12780 High Bluff Drive, Ste. 250, San Diego, CA 92130, USA, [3]Civil Engineering and Nancy Grant Water Research Institute, Technion, Haifa 32000, Israel, [4]Soil Erosion Research Stations, Emek Hefer 40250, Israel, [5]Institute of Earth Sciences, The Hebrew University of Jerusalem, Jerusalem 91904, Israel)

The Response Time Scale (RTS) is a characteristic time scale of the catchment that represents the amount of smoothing performed by the hydrological system in transforming the rainfall input into runoff. The identification of the RTS involves analysis of time series of rainfall and runoff and does not require information about the hydrological system. In our study we use weather radar rainfall data, rain gauge data and runoff data to identify the RTS of five small catchments (10-150 km2) in Israel and Panama. The results indicate that the RTS is stable for a given catchment and it depends on the catchment characteristics. For example, the RTS of the urban and arid catchments is considerably lower than the RTS of the rural catchments. In order to study the relationships of the catchment characteristics to the RTS a physically based, non-calibrated distributed hydrological model is applied to one of the studied catchments. The radar rainfall data are used to obtain the computed runoff hydrographs, and these computed data are then used to derive the RTS of the modeled catchment. The effect of several catchment parameters (such as length, slope and roughness of hillslopes and channels) on the RTS is examined by altering each parameter and deriving the RTS for each case. The effect of the different parameters on the time scale characteristics of the catchment hydrological response is investigated. Special emphasis is placed on comparing hillslope vs. channel processes. The results indicate that the effect of hillslope processes on the response time scale is greater than the effect of the channel processes.

HS03/08A/C26-004   0930

EFFECT OF SPATIAL AND TEMPORAL RESOLUTION OF PRECIPITATION DATA ON ACCURACY OF THE LONG-TERM RUNOFF SIMULATION

Hiroshi ISHIDAIRA[1], Kuniyoshi TAKEUCHI[1], Zongxue XU[1], Tianqi AO[2], Jun MAGOME[3], Makoto KUDO[3] ([1]Graduate School of Engineering, Yamanashi University, [2]Public Works Research Institute, [3]Graduate Student, Yamanashi University)

The precipitation is usually dramatically distributed with time and space within a basin. In physically-based distributed model, the precipitation data with rational resolution to represent the variability of precipitation is needed for accurate estimation of the river discharge. However, it is not yet clear that with what resolution will the runoff be estimated with rational accuracy at different time scales. The objective of this study is to identify the effect of spatial and temporal resolution of precipitation data on the accuracy of long-term runoff simulation. The hourly Radar-AMeDAS precipitation data with 5km x 5km spatial resolution is used in this study. The original Radar-AMeDAS data is averaged over different spatial and temporal scales, and both original and the averaged data are used as the input for hydrological model. The rainfall-runoff simulation is carried out in Fuji River basin by using the Block-wise use of TOPMODEL with Muskingum-Cunge method (BTOPMC). The difference between the simulated daily hydrographs using original precipitation and the averaged ones are investigated through the comparison of Nash efficiency and the total runoff volume ratio for each simulation. In addition, same analyses are also carried out for hydrographs at other time scales, and the influence of spatial and temporal resolution of precipitation data on the accuracy of the hydrological simulation was identified.

HS03/08A/C26-005   0945

EFFECT OF PRECIPITATION SPATIAL DISTRIBUTION ON THE HYDROLOGICAL RESPONSE IN THE UPPER TONE RIVER OF JAPAN

Dawen YANG, Toshio KOIKE, Hiro TANISAWA (Department of Civil Engineering, University of Tokyo)

Distributed physically-based hydrological models give a detailed and potentially more correct description of the hydrological processes in a catchment than do other model types. Moreover, they are able to make effective use of available information and knowledge concerning the catchment, and the Geographic information systems (GIS) and remote sensing have been widely used in the advanced hydrological modeling. Besides the information from land surface, the spatial distribution of precipitation is usually a key factor to the accuracy of hydrological simulations. With development of the weather radar technique, it is possible incorporate the radar measurement with the distributed model for investigating on the hydrological response, especially for the flood events. This research aims at evaluating the effect of spatial rainfall distribution on the hydrological response in the upper Tone River basin of Japan. The spatial rainfall distributions are generated by two ways. One is the traditional Thiessen Polygon Method based on the point measurements. Another method is integration of the point observations and the weather radar measurements. The results are compared for the long term hydrological responses and several flood events.

HS03/08A/C26-006   1000

GRID-BASED DAM INFLOW PREDICTION ON A LARGE RIVER BASIN USING THIESSEN POLYGON AND SPATIALLY DISTRIBUTED RAINFALL DATA

Seong-Joon KIM, Hyung-Joong KWON, In-Kyun JUNG, Geun-Ae PARK (Department of Rural Engineering, Konkuk University)

The surface runoff and streamflow responses between Thiessen average rainfall controlled by rainfall stations (T) and spatially distributed rainfall that is cell by cell units (R) would be different each other. To identify the effects quantitatively, the grid-based kinematic wave storm runoff model (Kim, 1998; Kim et al., 1998) that predicts temporal variation and spatial distribution of overland flow, subsurface flow and stream flow, was developed. The model adopts single overland flowpath algorithm and simulates surface and/or subsurface water depth at each cell by using water balance of hydrologic components. The model programmed by C-language uses ASCII-formatted map data supported by the irregular gridded map of the GRASS (USACERL, 1993) GIS and generates the spatial distribution maps of discharge, flow depth and soil moisture of the watershed. The model was tested for the above rainfall conditions to Yeoncheondam watershed (1,875 km2) that has just 4 available rainfall stations in South Korea. We found that there were big temporal and spatial surface runoff/discharge differences between T and R when the rainfall is moving from north to south direction rather than moving from east to west direction because the watershed width is relatively narrow in shape.

HS03/08A/C26-007   1030

APPLICATION OF RADAR-MEASURED RAIN DATA IN HYDROLOGICAL PROCESSES MODELING DURING THE IOP OF HUBEX

Liliang REN, Chunhong LI, Meirong WANG (Dept. of Hydrology & Water Resources, Hohai University)

On the basis of Digital Elevation Model (DEM) data, raster flow vectors, watershed delineation, and spatial topological relationship, are generated by Martz and Garbrecht method for the upper area of Huangnizhuang station in the Shihe Catchment with 805 sq. km. of area, intensified observation field for the HUBEX/GAME Project. Then, the Xin'anjiang Model is applied for runoff production in each grid element where rain data measured by radar at Fuyang Station is utilized as the input of hydrological model. Those elements are connected by flow vector to the outlet of drainage catchment where runoff is routed by the Muskingum method from each grid element to the outlet according to the length between each grid and the outlet. The Nash-Sutcliffe model efficiency coefficient is 92.41% from May 31st to August 3rd in 1998, and 85.64%, 86.62%, 92.57%, 83.91%, respectively for 1st, 2nd, 3rd, 4th flood event during the whole computational period. As compared with the case where rain-gauge data were used in simulating hourly hydrograph at Huangnizhuang station in the Shihe Catchment, the index of model efficiency improvement is positive from 27.56 % to 69.39 %. That justifies that radar-measured data is superior to rain-gauge data as the input of hydrological modeling. As a result, grid-based hydrological model provides a good platform for runoff computation, in which radar-measured rain data with highly spatiotemporal resolution are taken as the input of hydrological model.

HS03/08A/C26-008   1045

APPLICATION OF MODELS WITH DIFFERENT TYPES OF MODELING METHODOLOGIES FORRIVER FLOW FORECASTING

Hapu Arachchige Prasantha HAPUARACHCHI[1], Li ZHIJIA[1], F. A. WOLFGANG[2] ([1]Hohai University, [2]International Water Management Institute)

A number of watershed modeling methodologies are available at present. Basically they can be divided into three categories as conceptual modeling, distributed modeling and ˝black box˝type modeling. In the present study, a conceptual model, a distributed model, and an artificial neural network (ANN) have been applied for river flow forecasting in the *Kalu* river upper catchment in Sri Lanka. The Xinanjiang watershed model, which is widely applied in China for flood and river flow forecasting has been used as a conceptual watershed model and the SWAT (2000) model has been used with spatial data as a distributed model. ANN has been applied as a ˝black box˝type modeling methodology. Two types of ANN architectures, namely multi-layer perceptron network (MLP) and a radial basis function network (RBF) have been implemented. Based on the application results, it seems that the conceptual watershed model could perform slightly better than the distributed model and the ANN for this watershed. It was clearly noted that the performance of distributed models strictly depend on the quality of data. Therefore the application of distributed models is bounded to the availability and quality of data. ANNs are good in many practical situations where the main concern is with making reasonable predictions at specific locations where less data are available. On the other hand the performance of conceptual models strictly depend on the calibration and the input data. However the results obtained using above three methods are conceptually realistic and acceptable.

HS03/08A/C26-009   1100

EFFECTS OF SUB-BASIN SCALE ON RUNOFF SIMULATION IN DISTRIBUTED HYDROLOGICAL MODEL: BTOPMC

Tianqi AO[1], Junich YOSHITANI[1], Kuniyoshi TAKEUCHI[2], Kazuhiko FUKAMI[1], Tadashi MATSUURA[1], Hiroshi ISHITAIRA[2] ([1]Hydrologic Engineering Research Team, Public Works Research Institute (PWRI), [2]Institute of Material and Environment Technology, Graduate School, Yamanashi University)

It has been widely recognized that the scale problem of distributed hydrological models is a very difficult and serious question; it affects model accuracy and reliability a great deal, yet is far from any form of solution. Model parameter dependence on sub-basin and/or grid cell size selection is an example. In the case of physically based distributed hydrological model, BTOPMC (Block-wise use of TOPMODEL with Muskingum-Cunge method), topographic scale including both sub-basin and grid cell size is closely related to runoff to be generated. In this study their effects, particularly that of sub-basin scale on runoff simulation were investigated, attempting to identify the quantitative relationship between model parameters and basin characteristics, so that the model can be applied to large watersheds especially to ungauged/data-poor basins. In BTOPMC, runoff generation is based on TOPMODEL; flow routing is carried out by the Muskingum-Cunge method; drainage networks are generated using the Ao automated pit-removal method; study basins are automatically subdivided into either rectangular blocks or natural sub-basins over which groundwater balance was taken (the latter by the Pefafstetter numbering system); model parameters are automatically calibrated using the SCE-UA optimization algorithm (Shuffled Complex Evolution Method for Global Optimization-the University of Arizona). Using this BTOPMC, the 3,500km2 Fuji-kawa basin and the 3,270km2 Nakagawa basin of Japan were subdivided into natural sub-basins of different sizes. In order to focus on the effects of sub-basin scale, soil type and vegetation were assumed homogeneous. Hourly precipitation data and 30˝X30˝ GTOPO30 DEM (digital

elevation model) were used for simulation. Simulated were the floods of the Fuji-kawa basin in September 1993 and its annual runoff of 1990-1991, and the flood of the Nakagawa basin in 1989. The preliminary results indicate that in the case of floods, smaller sub-basin scale will generally result in higher peak discharge, a little earlier peak time, larger base flow and larger total runoff. Such behavior is considered as an effect of averaging scale of the topographic index used in calculating surface and base flow in the model. On the other hand, in the case of annual runoff, the effects on peak discharges do not show any determined tendency; the effects on peak time, total runoff and flow components are not obvious or negligible. Furthermore, when average sub-basin size is smaller than about 1/150 of the entire basin (say, around 25km^2 for the two basins), simulation results seems stabilized, indicating that there may exist a proper sub-basin scale for BTOPMC, at which uncertainty due to topographic scale in modeling can be reduced to quite a low level. This sub-basin size might be used as a referential scale for catchment subdivision both in modeling large river basins and in establishing the relationship between model parameter values and basin features. Key words scale issue; model parameters; physically based distributed hydrological model BTOPMC model; Pfafstetter numbering; SCE-UA optimization; Fuji-kawa;Nakagawa

HS03/08A/C26-010   1115

A GRID-CELL BASED DISTRIBUTED FLOOD RUNOFF MODEL AND ITS PERFORMANCE

Toshiharu KOJIMA, Kaoru TAKARA (Disaster Prevention Research Institute, Kyoto University)

Distributed parameter runoff models are recently developed and expected to be used in practice. They can take into account spatial distribution of rainfall, land surface conditions and their changes, which affect the runoff from river basin. This paper introduces a grid-cell based distributed rainfall-runoff model that was developed by the authors in 1997. The model uses geographic information such as digital elevation models (DEM), land cover/use based on either the National Land Information developed by Geological Survey Institute (GSI) or remote sensing imageries. The model has the following features. 1) A d-m square area centering on a node point of a d-m DEM is a sub basin, which is called a cell, and many cells constitute a river basin. 2) A DEM produces a drainage path, and the discharge from a cell to another cell flows to only one direction. 3) In each cell, the total amount of outflows from upper cells is the inflow to the cell, and an outflow from the cell is calculated using the kinematic wave model. The objective of this paper is to compare this distributed runoff model with two models conventionally used in Japan: the storage function model and the slope-channel system kinematic wave model. This paper discusses some problems to improve the precision of the distributed runoff model and to put it to practical use, by comparing each model on the basis of the indices for the model parameter sensitivity, such as the difference in peak time, peak discharge and hydorograph shape between observed and simulated hydrographs. The slope-channel system kinematic wave model can reproduce the observed hydrographs well with the optimum model parameters, which are almost the same as the conventionally recommended values. Although the grid-cell based distributed model also can reproduce the observed hydrographs well, it has a tendency to give earlier peak than the observed one. Further investigation is necessary to improve this tendency by adjusting the roughness coefficient of channel much affecting the peak time. In the storage function model, the optimum parameters depend on flood events. Variation in optimum parameters is greater than other runoff models. This paper also discusses about the effect of spatial resolution of the grid-cell based distribution runoff model. The authors compare the 50-m grid-cell based runoff model with the 250-m model in terms of the model parameter sensitivity. The optimum model parameters of the coarse-resolution runoff model have a tendency to become larger than the higher resolution model, and the model parameters of the coarse-model are more sensitive than the high-resolution model.

HS03/08A/C26-011   1130

EVALUATING LAND USE CHANGE EFFECTS ON FLOOD PEAK USING DISTRIBUTED RAINFALL RUNOFF MODEL IN YASU RIVER, JAPAN

Tumaini Anderson KIMARO[1], Yasuto TACHIKAWA[2], Kaoru TAKARA[2] ([1]Graduate School of Civil Engineering Kyoto University, [2]Disaster Prevention Research Institute Kyoto University)

The effects of land use changes on flood peaks in Yasu River basin are investigated using a distributed rainfall runoff model. The land use changes over a 20 year period are determined using 100 m spatial resolution data of 1976 and 1997. The main land use classes in the basin are forest, paddy fields, urban and water bodies. As compared to 1976 there is decrease in areal coverage by forests of 2.5% and paddy fields by 1.4%. The coverage of urban area increased by 2% and that of agricultural land by 0.2%. A new land use ″Golf courses″ emerged in 1997 covering 2.3% of mostly forested area in 1976. Simulation results shows that 1997 land use data produces higher flood peaks by 6% and faster travel times by 16 minutes as compared to 1976 land use data. The changes detected indicate the gradual effects of urbanization in the study basin.

APPLICATION OF DISTRIBUTED HYDROLOGICAL MODELS IN WATERSHED MANAGEMENT

HS03/08P/C26-001   1400

OPERATIONAL DEPLOYMENT OF A PHYSICS-BASED DISTRIBUTED RAINFALL-RUNOFF MODEL FOR FLOOD FORECASTING IN TAIWAN

Baxter E. VIEUX[1], Jean E. VIEUX[1], Chiarong CHEN[2], Keneth W. HOWARD[3] ([1]Vieux & Associates, Inc. Norman, OK 73072 USA, [2]Central Weather Bureau, Taiwan, [3]NOAA National Severe Storms Laboratory)

The Central Weather Bureau of Taiwan in cooperation with the Water Resources Agency, among others, seeks to improve technology used to forecast rainfall-runoff throughout Taiwan. Forecasting technology is needed for the specific hazards of floods, debris flow, and landslide for all of Taiwan. This initiative for the development of a flood alert and water resources system is expected to unify forecasting of floods on a single system enhancing the accuracy and efficiency of flood information for dissemination from the central government to the public, and to regional and local agencies. Operational deployment of a physics-based distributed rainfall-runoff model, coupled in real-time with quantitative precipitation estimate (QPE) from radar, satellite and rain gauges, allows distributed prediction of flooding at any location. Coupling and deployment of Vflo™ along with integrated quantitative precipitation estimates from multiple sensors provides unique opportunities for improved prediction of flood hazards. Addition of a rainfall-runoff model, Vflo™, coupled with quantitative precipitation estimates provides improved flood information in real-time. Vflo™ relies on digital elevation and other geographic information to predict discharge and stage at any selected location. This model relies on the QPE derived from a system developed by the US

NOAA-National Severe Storms Laboratory called QPESUMS. The Vflo™ system and QPESUMS were installed this year and was operational during Typhoon Rammasan as well as other events in 2002. One of the most damaging events of 2001, Typhoon Nari, is the subject of post-analysis event re-construction. Typhoon Nari left 93 dead and 10 people missing and caused extensive damage to the northern part of the island and to the City of Taipei. Besides an overview of the flood warning system design and operational features, a sensitivity study and simulation of river stage compared with observed stream flow will be presented.

HS03/08P/C26-002   1415

APPLYING RADAR RAINFALL DATA IN BASIN HYDROLOGIC MODELING

Oscar KALINGA, Thian Yew GAN, Jiancang Xie (Department of Civil and Environmental Engineering, University of Alberta)

To overcome the limitation of point measurements from rain gauges, there is a growing interest in utilizing radar data for basin-scale hydrologic modeling. Since radar rainfall data are derived from radar echoes, there is also a need to analyze errors associated with precipitation estimated from different radar processing techniques. This study uses the WSR-88D level III hourly rainfall estimates supplied by Hydrology Laboratory (HL) of the National Weather Service (NWS) office, USA, meteorological data of Oklahoma Mesonet, and a semi-distributed hydrologic model, DPHM-RS developed by Biftu and Gan (2001). Major sources of errors affecting the WSR-88D level III hourly rainfall estimates are radar electronic calibration, the Z-R relationship, rainfall attenuation, radar range effect, anomalous propagation, ground cluster, beam filling, and the radar sampling strategy, and techniques used to produce stage III data from stage II products, such as averaging the overlapping radar bins. In general, more spatially and temporally variable spring and summer convective rainfall is better represented by radar data than the sparse rain gauges, while the less variable stratiform winter precipitation could be well captured by sparse rain gauges. This study focuses on the following objectives: (1) To assess the advantage of basin-scale hydrologic modeling gained from using radar rainfall data as input over the standard input of gauge measurements in terms of basin subdivision and radar data resolution; (2) To integrate radar rainfall fields with gauged rainfall data via a statistical objective analysis scheme as an effort to reduce errors in terms of storm type (i.e. convective and stratiform storms), and storm size.

A DISTRIBUTED HYDROLOGICAL MODELING APPLIED TO HEIHE MOUNTAINOUS BASIN IN WESTERN CHINA

Jun XIA, Wang GANGSHENG, Tan GE (Insititute of Geographical Science & natural Resources Research, Chinese Academy of Science)

The Western China Development is confronted with a quite serious and realistic problem on water resources because of the water cycle´s district characteristics, the ecosystem´s vulnerability and the increasing demand of water resources. Based on the traits and existent problem of water cycle in western China, the key scientific issues of water cycle in western China has been studied in this paper. Main contribution in this paper is to develop a distributed hydrological modeling coupled physical process grids with a Time Varian Gain Model (TVGM) that was developed for system approach in University College of Galway, Ireland for river flow forecasting (1995). This model has three advantages: (a) it can be available to the case of input information imperfection such as the lack of enough precipitation and evaporation observations for distribution modeling; (b) it can be coupled the present physical process units or conceptual models with hydrological system approach such as TVGM, where time variant gain factor, G(t), could be linked with RS information to extend easily to application of hydrological prediction in basin scale; (c) Parameter sets of the distributed hydrological model can be estimated in terms of system identification approach to reduce uncertainry By preliminary application and examination in the Heihe River Basin of Guansu Province with area 1300km2 in arid & semi arid region, it was found that this model is successful with more advantages than conditional distributed model applied in China. Moreover, the new problems were addressed in the paper.

HS03/08P/C26-004   1445

DEVELOPMENT OF DISTRIBUTED RED SOIL RUNOFF MODEL USING RADAR DATA

Yutaka ICHIKAWA[1], Katsuhiro NAKAGAWA[2], Kazuki FUJIWARA[1], Michiharu SHIIBA[1], Shuichi IKEBUCHI[3] ([1]Graduate School of Global Environmental Studies, Kyoto University, [2]Okinawa Subtropical Environment Remote-Sensing Center, Communications Research Laboratory, [3]Disaster Prevention Research Institute, Kyoto University)

Okinawa region is located at the south-west end of Japan andconsists of a number of islands. The region has been suffering from theproblems caused by severe red soil runoff. The red soil of Okinawaregion is called as Kunigami Maaji. It is quite erosive and has mediumhydraulic conductivity. Okinawa region has much rainfall and is oftenattacked by typhoons occurred at south sea, especially in summer andautumn. The heavy rainfall causes overland flow and soil erosion. Thesoil particle of Kunigami Maaji is very fine and will not sink once thesoil is eroded and involved into water flow. The muddy water containingred soil particles pollutes the shores and coasts, and it gives heavydamage to ecosystems of the sea, farming and tourism. The final goal ofthis study is to develop a distributed red soil runoff model using radardata, and to investigate the effective countermeasures to prevent ormitigate red soil runoff. As a preliminary study, we developed adistributed red soil runoff model based on a kinematic wave flow modeland a digital topographic model. This model describes erosion process ofplane soil surface due to overland flow. A study basin is described as aset of small rectangular plane. The kinematic wave flow modelconsidering field capacity of surface soil layer is applied to eachrectangular plane, and water flow is routed from upstream todownstream. This kinematic wave flow model is a model of subsurface flow - saturated overland flow and also describes a process that a part ofwater infiltrated into surface soil layer is captured by capillary forceof the soil. The erosion of surface soil is assumed to occur at a pointwhere overland flow occurs, and the rate of erosion is calculated byusing the friction velocity at the point, which is determined from waterdepth of overland flow. The model was applied to Taiho River basin (24km^2), which is located at the north part of Okinawa main island. Theresults of simulations showed good agreements with observations, whilethe model needed tuning of a parameter which greatly affected the rate ofsoil erosion. This model is now using rainfall data observed at raingauges, however it can also use radar rainfall data as input. Then weare planning to use rainfall data obtained by a bistatic radar which isnow being installed by Communications Research Laboratory (CRL). Thisradar will observe rainfall intensity and distribution of precipitationparticle size. The latter will give us quite important information tomodel soil detachment process due to raindrop impact.

A FLASH FLOOD FORECAST MODEL FOR THE THREE GORGES BASIN USING GIS AND REMOTE SENSING DATA

Yangbo CHEN[1], Jiaxi HU[2], Jie YU[3] ([1]Department of Urban and Resource Planning, Sun Yat-sen University, [2]Department of Management, Three Gorges University, [3]Cascade Dispatching Center, CTGPC)

This paper presents a physically-based, distributed hydrologic model for the flash flood forecasting of Three Gorges Basin, which uses GIS technique and remote sensing data, including digital weather radar estimated precipitation and satellite sensed DEM and vegetation. This model is divided into several sub-models, which include the Basin Digitization Model(BDM), Precipitation Feeding Model(PFM), Evapotranspiration Model(EM), Runoff Production Model(RPM) and Runoff Routing Model(RRM).In the BDM, a Square-Grid Network DEM is employed to discrete the whole basin into a number of squared cells, and every cell is considered as a basin(called mini-basin), which is divided into three layers: the Canopy Layer(CL), the Soil Layer(SL) and the Underground Layer(UL). To every cell, there are unique vegetation type and leaf area index. The flow direction, flow accumulation, slope, flow length of every cell are calculated by ArcView based on the DEM. The PFM is used to treat the precipitation measured from both the digital weather radar and rain gauges. The input digital weather radar rainfall reflectivity is first transferred into the precipitation and assigned to every cell. The precipitation measured from the rain gauges is assigned to every cell using the Theissen Polygon. In this study as the current digital weather radar can not cover the whole Three Gorges Basin, so the precipitation from both the weather radar and the rain gauges are used. The EM is used to calculate the cell evapotranspiration, which is down based on the vegetation type and the leaf area index. The RPM is used to determine the runoff produced upon the precipitation which is down by the Xinanjiang Model at the cell scale. That means the runoff will be and will only be produced after the soil is saturated. The runoff is then divided into surface runoff and underground runoff according to the steady infiltration rate. The RRM is used to route the runoff to the basin outlet. In this study as the focus is on the flash flood forecast, so the underground runoff is considered steady, and the runoff routing is mainly the surface runoff routing which is further divided into hill slope routing that routes the surface runoff at the cell, and the river routing that routes the surface runoff in the river channel. The routing is controlled by the runoff flow velocity, the river routing velocity is derived from the Manning equation, and the hill slope routing velocity is governed by the Darcy-Weisbach equation, and a equation for deciding the velocity is derived also. The 2001 summer flooding of Three Gorges Basin is studied using the model presented in this paper, and satisfactory results was found. This model mainly relys on the remotely sensed data to physically derive model parameters, so it is particularly useful in the ungauged or poorly gauged basins.

PERFORMANCE ASSESSMENT OF BTOPMC MODEL IN NEPALESE DRAINAGE BASIN

Nawa Raj PRADHAN[1], Raghunath JHA[2] ([1]DPRI, Kyoto University, [2]Department of Civil Engineering, Institute of Engineering, Pulchowk Campus)

Nepal, with an area of 147,181 sq. km. has more than 6000 rivers stretching from the Great Himalayas with an elevation of more than 8800m to the southern plain called ˝Terai˝with an elevation of 100m within a mere 200 km width. This provides a dense network of rivers with steep topographical conditions and concentration of 80% of the total annual rainfall in a relatively short period of about four months. These peculiar characteristics lead to a set of hazards including frequent floods. In view of the important role that water resource can play in Nepal and the need to harness it in a sustainable manner, it is essential to know the various facets of water resource. Depending on the situation, different approaches to its use needed to be designed, sometimes to ´keep the water away from the people´ and the other times ´keep the people away from the water´ Suitably selected models can help to identify issues which are useful for planning various development projects with minimum risk of flood disasters, alerting people to keep away from such disasters in time and providing planners an information about water for use in various development projects like hydropower, irrigation etc. But at the same time, evaluation of rainfall-runoff models that incorporates all the challenges- non availability of hydrological `data itself, rugged terrain, a large part of catchment lying in Tibetan Plateau where the information of the data is not available-become one of the most significant themes in the context of Himalayan kingdom of Nepal. More suitable types of model include distributed models but they are data demanding. BTOPMC - a physically based distributed hydrological model based on the blockwise use of TOPMODEL with Muskingum-Cung flow routing method- was selected to evaluate the applicability in Nepalese catchment. The major rivers of Nepal like the Sun Kosi river originates from the Tibetan plateau where the data information is not available. Thus to cope with this problem further modification in the model was suggested that lead to the development of BTOPMC version II. The quality of simulation is classically judged by comparing the simulated flow with observed flow. Sensitivity analyses was performed as an effective means of coping with the inherent complexities of catchment modeling, including the associated parameter uncertainties. Model performance was judged by a range of quantitative and qualitative measures of fit applied to both the calibration and validation periods. The regression analysis for saturation deficit and discharge was performed. The daily stream flow estimation in Sun Kosi river basin was promising. BTOPMC being a distributed hydrological model uses a few numbers of parameter and can simultaneously simulate low flow or flood runoff for multiple subcatchments in large watersheds with DEM and other GIS oriented data. BTOPMC can be successfully used as a tool for integrated water resources investigation in large watershed, mountain physiographic region, of Nepal.

HS03/08P/C26-007   **1545**

COUPLING OF MODFLOW AND WATFLOOD IN HYDROLOGICAL MODELING OF A SMALL WATERSHED

Sayed-Farhad MOUSAVI[1], Nicholas KOUWEN[2] ([1]College of Agriculture, [2]Department of Civil Engineering, Univ of Waterloo)

In water resources assessment, coupling of watershed and groundwater models is a process to integrate surface water and groundwater components. In this research, the coupling process was performed by applying the recharge component of the WATFLOOD hydrologic model to the MODFLOW groundwater model in the Laurel Creek watershed, Ontario, Canada. Net groundwater leakage computed by MODFLOW was combined with WATFLOOD surface flow and interflow and routed down the creek. The flows obtained by the coupling of the two models were compared with flows computed by the WATFLOOD model. Several runs were performed using radar-rainfall data and the hourly-measured stream flow for the period of 1993-1999. The results showed that use of adjusted radar precipitation improved the predicted stream flows. Running the MODFLOW model for 28 years of consecutive data showed that it takes about 20 years for the system to reach equilibrium, regardless of the starting heads. A simple lower-zone function (in WATFLOOD) was substituted for the MODFLOW to predict the stream flows without degrading the computed stream flow.

PREDICTION OF EVAPOTRANSPIRATION AND STREAM FLOW WITH A DISTRIBUTED MODEL OVER THE LARGE WUDING RIVER BASIN

Xingguo MO[1], Suxia LIU[1], Zhonghui LIN[1], Weimin ZHAO[2] ([1]Institute of Geographical Sciences and Natural Resources Research, Chinese Academy of Sciences, [2]Bureau of Hydrology, Yellow River Conservancy Commission)

A process-based distributed model, LISFLOOD, is used to simulate the temporal and spatial variation of evapotranspiration and discharge over the Wudinghe basin in China. The climate of Wudinghe basin is arid with an annual precipitation of 450 mm, but there are usually heavy storm in the summer that may cause disastrous flooding. The basin is divided into 32000 square grids with a resolution of 1 km x 1 km. Channel pattern and slope gradient derived from digital elevation data of the basin are corrected by real pattern in the Geographical Information System. Recordings of 40 rain gauges and 10 meteorological stations are spatially interpolated with an inverse distance square method to all the grids in the basin. Remotely sensed normalized difference vegetation index (NDVI) of NOAA-AVHRR and the land use/cover data are used to retrieve the distribution of vegetation leaf area index (LAI). The model is applied to predict the discharge and evapotranspiration in two time periods 1984-1986 and 1994-1996. The predicted daily discharges are compared with the observed at five sub-catchments. It is shown that predicted discharges agree well with the measured in most of the sub-catchments, but obvious biases exist in some extreme discharge conditions. In this large, arid basin, it is found that the contributions of discharge are mainly from subsurface runoff, rather than surface fast runoff. Spatial patterns of evapotranspiration and its components in these two periods are also compared to distinguish the effect of land cover change on the hydrological cycle in this basin.

HS03/08P/C26-009   **1615**

A CATCHMENT SURFACE RUNOFF SIMULATION FOR LAND SURFACE MODEL STUDY

Shufen SUN, Weiping DENG (LASG, Institute of Atmospheric Physics, Chinese Academy of Sciences)

The main focus of this paper is to numerically simulate the surface runoff process in a catchment in China based on the TOPMODEL. The catchment is located in western China with area of around 2300 km2. In the paper, the basic principle and relevant problems of the TOPMODEL will be described and discussed. The long term more than 40 years observation data in the catchment is used to compare with the model output and thus verify the TOPMODEL function. The result shows that there is a good agreement between the observation data and model prediction. It is indicated that the TOPMODEL can be extended for land surface model in the region with runoff process controlled mainly by topography.

APPROACHING REALISTIC SOIL MOISTURE STATUS WITH AN IMPROVED MESO-SCALE NUMERICAL WEATHER PREDICTION MODEL

Suxia LIU[1], Lance LESLIE[1], Milton SPEER[2], Rees BUNKER[3], Russel MORISON[1] ([1]Institute of Geographical Sciences and Natural Resources Research, Chinese Academy of Sciences, [2]Bureau of Meteorology, Sydney, Australia, [3]Rural Fire Office, NSW, Australia, [4]Inst of Geographical Sciences and Natural Resources Research,Chinese Academy of Sciences, Beijing)

Much research has focussed on the development of high resolution Limited Area meso-scale weather Models (LAM) to improve operational guidance for the prediction of meteorological variables including those associated with high levels of bushfire risk. Forest Fire Danger Index (FFDI) in Australia is one of the main indices used as guidance by fire weather forecasters to issue fire weather warnings. Most schemes that calculate a fire danger index are based on values of air temperature, relative humidity, wind speed and a factor that represents the dryness of the vegetation based on the number of days since precipitation has occurred. However, few schemes have yet considered soil moisture status, especially root zone soil moisture status, which is a key factor to consider for the outbreak of bushfires. The weak link between the land surface scheme and the atmosphere in LAMs is one of the reasons for the deficiency. To address this deficiency, this paper outlines a method to couple a self-nested HIgh RESolution meso-scale atmospheric LAM (HIRES) developed by one of the authors (LL) to a hydrological model. By considering the moisture status in the whole of the root zone with a five layer soil division, the Force-Restore scheme used in original version of HIRES is replaced with the Richards Equation, as used in other land surface process models. Attention is also focused on how to effect the correct two-way transfer of soil moisture in the nesting, the setting of suitable boundary conditions, and other processes in the LAM that are affected by soil moisture. The model is validated with both gauge-observed precipitation and weather radar information. Use of both rainfall records together with radar data is important for validation as it has been shown that the spatial pattern of precipitation over the Goulburn River catchment is very important in shaping the hydrograph. By applying the coupled HIRES modelling system to the Goulburn River catchment in the Hunter Valley, NSW, Australia prior to and following a large bushfire in the catchment (November 97/December 97) for a sufficiently long enough period, improvements in surface soil moisture values are investigated. By including the improved regional scale soil moisture field, improvements in the HIRES model predictions of FFDI over the fire weather season can then be assessed. In previous work there was no effect of 1997/98 fires found on streamflow in the Goulburn River catchment. This contrasts with conclusions reported from extensive studies on catchments by other authors who have reported an immediate increase in streamflow after fire based on a variety of techniques including experimental analyses, paired-catchment analyses and modelling studies.

AGRICULTURAL USE OF TREATED WASTEWATER: THE NEED FOR A PARADIGM SHIFT IN SANITATION & TREATMENT

Jules B. VAN LIER (Sub-department of Environmental Technology, Wageningen University)

Shortages in irrigation water in and around urban areas calls for alternative sources in particularly the (sub)tropical zones. Domestic sewage represents such alternative source and its nutritional value is known by the farmers since long times. In many situations, even (diluted) raw domestic sewage is used for agricultural purposes, especially in those areas that cannot afford sewerage and treatment systems. However, discharge or reuse of non-treated effluents, give rise to serious environmental problems, including human health threats. Nonetheless, in most cases, the master plan of big cities reveals the conventional approach to deal with domestic and municipal wastewater, i.e., the construction of large-scale sewage collection systems including pumping stations and ideally a centralised treatment system. Unfortunately, such approach is not affordable for most of the developing countries and solutions between needs, requirements and socio-economic feasibility are paralysed. Decentralisation will play an important role in looking for alternative solutions since large-scale infra-structural investment can be avoided. Also with respect to the available treatment techniques, economic sustainability is often disregarded in making the final choices. Amongst the available compact technologies for wastewater treatment, the anaerobic (pre-)treatment can be regarded as an appropriate technology of which its potential is hardly utilised. In addition, anaerobic treatment is ideal to be implemented in a decentralised mode, i.e., reducing the required sewerage. The products of anaerobic treatment consist of nutrient-rich effluents, stabilised digested sludge and energy rich biogas. Particularly, the former two can be beneficially be used by the local farmers, whereas the produced biogas can be used on the site if it is produced in sufficient quantities. The key-note lecture discusses the various options for anaerobic (pre-)treatment, embedded in centralised and decentralised treatment & reuse concepts. Its cost-effectiveness may lead to a more rapid implementation of productive sewage reclamation, while the environmental problems are concomitantly addressed.

HS04/07A/C30-002   1005

ASSESSMENT METHOD FOR RISK OF GROUNDWATER QUALITY DETERIORATION WHERE RECLAIMED WATER IS STORED IN AQUIFERS

Peter J. DILLON[1], Russell MARTIN[2], Simon TOZE[1], Paul PAVELIC[1], Karen RATTRAY[1], Ray CORRELL[1], Ros MILLER[1] ([1]CSIRO Land and Water, [2]SA Dept for Water, Land and Biodiversity Conservation)

A five year research project involving laboratory and field investigations of aquifer storage and recovery with municipal sewage effluent treated to a quality suitable for unrestricted irrigation is drawing to a close. This has involved studies of the fate of various components of injected water including natural organic carbon, nutrients, disinfection byproducts, and pathogens. Seventeen observation wells up to 160m deep enabled studies of heterogeneous aquifer properties, hydraulics, clogging, mixing, recovery efficiency and geochemistry, as well as attenuation of constituents over two periods when a total of 360,000 cu.m. of reclaimed water was injected. The results give clear support for an ecosystems view of attenuation processes and enable confidence in prediction of risk associated with fate of contaminants. Consequently a simple screening model has been developed to predict the risk of unacceptable water quality being recovered at production wells. The paper will focus on the development and application of this risk assessment tool as a means of predicting impacts of injection of reclaimed water on groundwater quality.

HS04/07A/C30-003   1130

FATE AND TRANSPORT OF ORGANIC CONSTITUENTS DURING SOIL-AQUIFER TREATMENT LEADING TO INDIRECT POTABLE REUSE

Jorg Eckard DREWES (Colorado School of Mines)

One major water quality issue associated with soil-aquifer treatment (SAT) leading to indirect potable or non-potable reuse of wastewater effluents is the fate and transport of organic constituents. The objective of this study was to investigate the fate and transport of bulk and trace organics associated with potential adverse health effects in reclaimed water used for indirect potable reuse. The fate of organics during SAT was investigated using controlled biodegradation studies in adapted soil-columns and full-scale infiltration facilities in Arizona and California. The study design followed a watershed guided approach considering hydraulically corresponding samples of drinking water sources, SAT-applied wastewater effluents, and subsequent post-SAT samples representing a series of different travel times in the subsurface. Extensive characterization of organic carbon in the different samples was performed using state-of-the-art analytical techniques and biomass/bioactivity measurements in order to distinguish between primary removal mechanisms (biodegradation vs. adsorption). The results generally demonstrated that naturally-derived and effluent-derived organic matter after SAT overlap extensively in molecular weight distribution, amount and distribution of hydrophobic and hydrophilic carbon fractions, and chemical characteristics based on elemental analysis and structural analysis. However, the residual portion of the DOC contained both effluent-derived organic matter and natural organic matter. The study revealed that the stimulant caffeine, analgesic/anti-inflammatory drugs and blood lipid regulators were efficiently removed to concentrations near or below the detection limit of the analytical method after retention times of less than 6 months during ground water recharge. The antiepileptics carbamazepine and primidone were not removed during ground water recharge under either anoxic saturated or aerobic unsaturated flow conditions during travel times of up to eight years. Organic iodine showed a partial removal only under anoxic, saturated conditions as compared to aerobic conditions and persisted in the recharged ground water.

CASE STUDIES

HS04/07P/C30-001   1405

ASSESSMENT OF RE-USE OF WASTEWATER FOR IRRIGATION: A CASE IN PUNJAB, PAKISTAN

Yutaka MATSUNO[1], Jeroen ENSINK[2], Robert SIMMONS[2], Wim VAN DER HOEK[2], Sarfraz MUNIR[2], Rizwan ASLAM[2] ([1]Department of International Resources Management, School of Agriculture, Kinki University, [2]International Water Management Institute)

Farmers often take advantage of using wastewater for irrigation in arid regions of developing countries as it is a reliable water source and contains rich nutrients. However, its negative impact on health, environment, and sustainability needs to be taken into account. In addition, as a country develops, the risk of industrial pollution in irrigated fields increase. In most cities in Pakistan, untreated wastewater is used directly for irrigating crops in urban and peri-urban areas. A study to assess the environmental and health risks associated with using untreated wastewater for irrigation was carried out in two cities; Faisalabad and Haroonabad, in the Punjab province of Pakistan. The two cities have distinct characteristics: Haroonabad has a population of 67,000 and no major industries, while Faisalabad is one of the bigger cities in Pakistan with a population of over 2,000,000 and has major industries. In Faisalabad, inadequate and inconsistent original irrigation supply and in particular a significantly restricted command area due to drought/re-allocation induced reduction in flows has resulted in partial and in most cases 100% reliance on wastewater for irrigation. The study consisted of hydrological analysis of wastewater irrigation and chemical analysis of wastewater, soil, and groundwater, in addition to field inspections and interviews with farmers and officials from the respective Municipalities and the Irrigation Department. In order to establish management alternatives, the information collected was categorized to evaluate the risk of current practices and its impacts on the environment. The results confirmed that, due to an excessive application of wastewater, the nitrogen and phosphorus concentrations in the groundwater under the wastewater irrigated sites were much higher than those concentrations in fields irrigated with normal canal water. Soil heavy metal contents in wastewater irrigated areas of Faisalabad indicate significantly elevated heavy metal loading rates, which pose a risk for both sustainable production and human/livestock health. In comparison, soil heavy metal concentrations in Haroonabad were within internationally established 'safe' limits. Salinity problems have also been reported in some fields in Faisalabad due to the high content of salt in the wastewater. In addition, crop diversity and quality has steadily declined following long-term wastewater application. In Faisalabad and Haroonabad, positive impacts of wastewater utilization to farmers include the provision of a reliable source of irrigation and the ability to produce cash crops with high cropping intensity and less fertilizer inputs. Consequently in both cities, wastewater utilization is fundamental to maintaining current rural livelihoods. Owing to the present financial constraints and institutional settings of the cities, it is difficult to foresee an introduction of a treatment system in the near future. In this circumstance, it is very important to develop and apply comprehensive methods of wastewater irrigation management that would facilitate the sustainable use of soil and ground water resources, preserve environmental integrity and improve rural livelihoods on a long-term basis.

HS04/07P/C30-002   1435

ON THE IDENTIFICATION OF NITRATE POLLUTION IN GROUNDWATER IN A WASTEWATER IRRIGATED FIELD

Jianyao CHEN, Changyuan TANG, Yasuo SAKURA, Yanjun SHEN (Hydrology Group, Department of Earth Sciences, Chiba University)

Wastewater is widely used for irrigation in arid and/or semi- arid area, especially in the suburb of the big city. As a special water resource with respect to its nutrients and toxic chemicals, wastewater, particularly non-treated must be used with care to prevent nitrate pollution in groundwater. Luancheng County, nearby Shijiazhuang, the capital city of Hebei Province in the North China Plain, was selected as a case study area, where non-treated wastewater from a non-proof canal had been used for more than 40 years. Direct irrigation with wastewater and seepage from the canal flowing from the north to the south, were two approaches for contaminating the local aquifer. Local people use groundwater as drinking water without any treatment from the aquifer, which flows from the northwest to the southeast according to the groundwater table and topography. Field surveys and the measurement of major ions of groundwater show that hardness (Ca+Mg) in groundwater increases in recent years, indicating the effects of long-term wastewater irrigation. Groundwater table of the study area remains relatively stable and shows no seasonal fluctuation in comparison to the intensive seasonal change in the vicinity without exterior water. Though low hardness and no nitrate was found in the wastewater, nitrate was detected for all groundwater samples in the wastewater irrigated area with about 50% higher than the drinking water standard (45 mg NO3/l) of WHO. The concentration of NO3 decreased with the distance from the canal and the highest of 124 mg NO3/l was found in a well near the canal. Good linear relationship between CL and NO3 indicated that nitrate in groundwater in the area had the same source associated with a dilution process. Stable isotopes, O-18,D and N-15 were also used as tracers to identify the source of pollution and the related physical and chemical processes. In order to identify the sources and distribution of nitrate in groundwater, physical factors, such as water balance components and groundwater flow system ought to be integrated well with chemical contents and isotopes as well in a comprehensive manner.

HS04/07P/C30-003   1505

LONG TERM EFFECT OF IRRIGATION WITH WASTEWATER ON NITRATE IN GROUNDWATER OF NORTH CHINA PLAIN

Changyuan TANG, Jianyao CHEN, Yuanjun SHEN (Graduate School of Science and Technology)

Because urban wastewater or groundwater has been used for irrigation in the regions where water is scarce and re-use of wastewaters is a challenging possibility to manage regional water resources, it is important to re-assess the long-term impacts of wastewater irrigation practices on regional groundwater quality. As wastewaters contain elements and compounds that may damage environmental quality, if deposited at a wrong location and time at a too high rate, wastewater can be dealt with in terms of water cycle and chemicals migration in groundwater. At first, history of wastewater irrigation practices in North China Plain (NCP) after 1950s was reviewed. With the urbanization in NCP, huge tons of wastewater was disposal from cities as an alternative source of irrigation water for agricultural development. With its average annual precipitation less than 600mm, 80% of irrigation water used in the farmland near big cities of NCP is urban wastewater. As a result, surface water and groundwater quality problems have been very serious. Then, nitrate problem in groundwater quality caused by wastewater irrigation has been discussed. A case study in the North China Plain was shown. There are three ways for nitrate entering into the groundwater system, i.e.

H

seepage of wastewater at the bottom of the canal, infiltration of wastewater in the wastewater-irrigated croplands, and infiltration of fertilizers used in the groundwater-irrigated croplands. It was found that the wastewater canal controls the local groundwater flow system, and concentrations of nitrate in most wells with depths of less than 40 m are higher than the drinking water standard set by WHO. In the croplands irrigated by wastewater, NO3- concentration ranges from 50 to 130 mg/L, but in the croplands irrigated by pumping wells away from the canal, NO3- concentrations are less than 35 mg/L. Clustering analysis was used to classify the spatial distribution of nitrates resulting from the wastewater. Identification of chemical patterns is found to be effective for the comprehensive assessment of spatial distribution of groundwater quality. As a result, poor management of wastewater transport systems may cause leakage of wastewaters to groundwater resulting in a serious deterioration of its quality. Monitoring of the chemical composition of groundwater quality yields information that can be used to find trends in groundwater quality. Finally, statistical analysis was used to identify effects of pumping irrigation and wastewater irrigation on nitrate distributions in groundwater of the study region, respectively. It was found that there is a higher possibility of nitrate concentration detectable in wastewater irrigation area than that in pumping-irrigation. It is also emphasized that the wastewater controls nitrate distribution in groundwater, and should be used carefully to protect both soil and groundwater from nitrate pollution. Effluent-soil-plant system is necessary for the development of appropriate irrigation-fertilization-cropping management system.

HS04/07P/C30-004   1555

DETERMINATION OF WATER QUALITY IMPROVEMENTS DUE TO THE ARTIFICIAL RECHARGE OF TREATED EFFLUENT

Simon TOZE[1], Jon HANNA[1], Tony SMITH[1], Lindsay EDMONDS[1], Adrian MCCROW[2] ([1]CSIRO Land and Water, [2]Water Corporation WA)

An indirect wastewater reuse project was established at a wastewater treatment plant to determine the effectiveness of obtaining reclaimed water of suitable quality and low risk for the irrigation of parks and gardens. Treated sewage effluent was infiltrated to a shallow limestone aquifer and recovered by two recovery wells situated 80 and 100 m from the infiltration basins. A monitoring and research program was established to ensure that the water recovered from the production bores meet environmental and health guidelines for water reuse in irrigation. The monitoring program consisted of monthly sampling of the two production bores, an in-line water storage tank, treated effluent in the infiltration ponds and native groundwater. The collected samples were analysed for a range of physical, chemical and microbiological analytes. Results of the monitoring program indicated that the the recovered water quality was well below the Western Australian guideline limits for effluent reuse and suitable for irrigation purposes. The reclaimed water was found to be physically, chemically and microbiologically different from both the treated effluent in the infiltration basins and the native groundwater. The reclaimed water had consistently low inorganic nitrogen and phosphate concentrations and significantly lower electrical condictivity than the native groundwater. Total organic carbon concentrations in the reclaimed water were much lower than in either the treated effluent or native groundwater. No bacteriophage or enteroviruses and only intermittent very small numbers of *E. coli* cells were detected in the recovered water at any time during the monitoring program. As these microorganisms were frequently detected in the treated effluent this indicated that there was removal during infiltration and in the aquifer. An assessment of the hydrogeology in the region of the infiltration ponds found that the limestone aquifer was highly transmissive, under tidal influences and had a very flat hydraulic gradient. Modelling of the groundwater flowpaths and the effect of secondary porosity in the aquifer determined that the infiltrated effluent would remain within the general limits of the wastewater treatment plant. An additional study of pathogen survival potential indicated that bacterial pathogens and indicators had very limited survival in the aquifer with 90% removal times within ten days. Viral pathogens had a greater survival potential than the bacteria but still had 90% removal times of less than 17 days. The results of this study have shown that indirect reclamation in shallow limestone aquifers within Western Australia is a viable means of obtaining reclaimed water of suitable quality for irrigation purposes and that there would thus, be a limited impact on groundwater quality in the surrounding area.

HS04/07P/C30-005   1625

IMPACT OF UNINTENDED RECHARGE OF ASSAMRA WASTEWATER STABILIZATION PONDS ON THE SHALLOW AQUIFER IN WADI DHULEIL BASIN

Nizar KLhalil AL-HALASAH (Environmental Research Centre, Royal Scientific Society)

This paper tackles the impact of Assamra Wastewater Stabilization Ponds (AWSPs) and the discharge effluent from the treatment plant on the groundwater quality of the shallow aquifer in the area. AWSPs is considered as one of the largest treatment plants in the world, it is located about (40 Km) northeast Amman. To study the impact of infiltrated wastewater on the groundwater, twelve wells were monitored during the period from March 1994 to March 2002. Two wells upstream the plant, six wells adjacent wadi Dhuleil where AWSPs discharge its effluent, and five wells to the south-east of plant. It is clearly noticed that wells adjacent to wadi Dhuleil contain higher concentrations of TDS, SO4, NH4, NO3, Cl, Na, TH, B, PV, in addition to TCC and TTCC than the wellslocated upstream and south-east the plant this trend attenuates along the groundwater flow direction (East-West). Physical, chemical and microbiological analyses show that there are several sources of pollution in the study area like, agricultural activities, overpumping rates and AWSPs.

TREATED URBAN WASTEWATER REUSE FOR IRRIGATION OF A GOLF COURSE AND IMPACT ON SOIL AND GROUNDWATER

Lucila CANDELA[1], Jordi MAS[2] ([1]Dep. of Geotechnical Engineering and Geoscience-UPC, [2]Dep. of Microbiology. UAB.)

Starting in July 2000, treated wastewater of urban origin has been used for the irrigation of the ″Serres de Pals″ golf course (Girona-Spain). To evaluate if the soil and the aquifer underneath are affected by the utilization of this type of water, samples have been taken along a period of several months from the wastewater treatment plant, the stabilization lagoon and soil profiles. Analyses have been performed for total coliforms and aerobic bacteria, soil water pressure and soil water content as well as chemical analyses of the irrigation water and water of the vadose zone. Soil profiles taken at several times during the study indicate the absence of coliforms except for a short period during summer. In the vadose zone and the aquifer a significant increase in salinity was detected 10 months after starting the application.

THE NUTRIENT EXPORT RISK MATRIX (THE NERM) FOR STRATEGIC APPLICATION OF BIOSOLIDS TO AGRICULTURAL LAND

Louise HEATHWAITE[1], Sean BURKE[1], Paul QUINN[2], David LERNER[3], Paul WHITEHEAD[4], Adrian SAUL[3], Neil PREEDY[4] ([1]Department of Geography, University of Sheffield, [2]Department of Civil Engineering, University of Newcastle, [3]Department of Civil & Structural Engineering, University of Sheffield, [4]Department of Geography, University of Reading)

Diffuse phosphorus (P) export from land is a key driver of the eutrophication of surface waters (Dils & Heathwaite, 2000) and may contaminate groundwater resources. High risk diffuse P sources include animal manures and biosolids: both carry the enhanced environmental risk associated with microbial contamination of waters. Biosolids recycling to land in the UK is projected to double by 2006 but the security of this route is threatened by environmental concerns and health scares. Soil P saturation is already being documented in some areas and may further elevate P losses to surface and groundwaters. The SEAL Research Project: Strategic Management of Non-Point Source Pollution from Sewage Sludge is evaluating the environmental risk of contaminant export from biosolids recycling to land. Our basic premise is not all land has an equal risk of contributing diffuse contaminants to receiving waters. We believe high risk is associated with critical source areas of diffuse pollution where source and transport risks coincide (Heathwaite & Sharpley, 1999). We are focusing on colloidal-size particles, which have been shown to be mobile in subsurface environments and important for virus and bacterial transport. We are investigating the extent to which colloids facilitate the transport of strongly sorbing pollutants such as P. This work is tied to the development of a predictive and spatially-sensitive semi-distributed model of critical thresholds for biosolids application that goes beyond traditional 'end-of-pipeAEor 'edge-of-fieldAEmodelling, to include hydrological delivery to receiving waters from diffuse sources at the catchment scale. The research output from this project is being synthesised into a risk advice matrix (the Nutrient Export Risk Matrix or NERM) for our end-users on the project which include water utilities: Thames Water plc, North West Water plc, Yorkshire Water plc and their research arm: UKWIR (UK Water Industries Research), the Environment Agency and DEFRA (the Department of Environment, Food and Rural Affairs). The NERM will help determine the most appropriate form and frequency of spatially-sensitive biosolids application to land to achieve sustainable biosolids management without detriment to the environment and receiving water quality, whilst being of net benefit to farmers.Dils, R.M & Heathwaite, A.L. (2000). Tracing P movement in agricultural soils. In Foster, I. (Ed) Tracers in Geomorphology. Wiley, 259-276. Heathwaite, A.L. & Sharpley, A.N. (1999) Evaluating measures to control the impact of agricultural P on water quality. Water Science & Technology 39, 149-155.

VARIATION OF CHEMICAL SPECIES INFILTRATING TREATED SEWAGE WATER USING THE MULTI-COMPONENT SOLUTE TRANSPORT MODEL

Gingging De Castro GUERRA, Kenji JINNO, Yoshinari HIROSHIRO (Insititute of Environmental Systems, Kyushu University)

For the conservation of water resources, the re-use of treated sewage water should be considered. However treated sewage waters contain elements and compounds that may damage environmental quality. The relevant physical, chemical and biochemical processes in the soil must be understood in order to determine the state and movement of groundwater contaminants. To simulate the mechanisms responsible for the movement of chemical species through soils and aquifers predictive tools in the form of mathematical models have been developed by several researchers. This study deals on the processes and chemical transport in an aqueous soil similar to paddy field, where successive reduction reactions occur like denitrification, cation exchange reactions and oxidation and reduction reactions. Oxidation and reduction reactions play an important role in the spatial distribution of chemical species in soils like O_2, NO_3, Mn^{2+}, and Fe^{2+}. To examine the behavior of the different chemical species infiltrating secondary treated sewage water, a two-soil column experiment was conducted using columns of different thickness of plow layers. Glass beads were used as oxidized layer at 15 cm for both the two soil columns. Treated sewage water was constantly supplied up to 5 cm at the top of the soil column in order to reproduce the redox condition similar to paddy field situation. In order to more fully understand chemical and biochemical processes, a solute transport model that takes into consideration the biochemical reactions and cation exchange reactions was developed in this study. The multi-component solute transport model simulates solute transport and computes changes in concentration over time caused by the processes such as advection, dispersion, biochemical reactions and cation exchange reactions. The soil column experiment and solute transport model had produced interesting observations on the behavior of different chemical species infiltrating treated sewage water. The measured cation concentrations correlated fairly well with the simulated cation concentrations. The most rapid bacterial growth occurred at the top of the column where O_2 and CH_2O concentrations are present. NO_3 concentration decreased due to denitrification while Mn^{2+} and Fe^{2+} increased due to dissolution of Mn- and Fe-hydroxides. The simulated concentrations approximately agreed with the measured concentrations and the sequences of reduction reactions can be reproduce by the developed solute transport model.

SATURATED MODELING OF EFFLUENT RECHARGE AND ITS IMPACT ON GROUNDWATER QUALITY

Shutang ZHU[1], Gang ZHAO[1], Yueqiang LIU[1], Keke PENG[1], Xuan ZHAO[1], Xiaojing YANG[1], Yuanle MA[1], Yiping GAN[2] ([1]Institute of Nuclear Energy Technology, Tsinghua University, [2]Gaobeidian Wastewater Treatment Plant)

This paper presents numerical modeling on saturated flow and reactive transport of groundwater recharge with secondary effluent. To alleviate the shortage of water supply in North China and maintain the sustainable development, reuse of treated wastewater through groundwater recharge must be considered as an integral part of water and wastewater management. Based on such a background, a demonstration project of groundwater recharge with secondary effluent at Gaobeidian Wastewater Treat Plant (WWTP) will be implemented. As the wastewater may bring pollution to surface water, if the artificial recharge is dealt with improperly, it may also bring serious contamination to the groundwater. To avoid the effluent recharge bringing additional pollution to groundwater system and deteriorating the water quality, complex and deep-going investigations including laboratory experiments, numerical simulations as well as pilot tests are required before the practical operation. Processes of groundwater movement and contaminants transport

should be simulated while the impact on the quality of groundwater resource must be assessed. The present study focuses on the numerical model, which is used to simulate contaminants transport including convection-dispersion, adsorption / de-sorption, dissolve / precipitate and / or biodegradation and to assess the impact of such recharge on the quality of groundwater resource. The groundwater movement is modeled based on the saturated flow assumption and Bossinesq approximation. The soil field is divided into two zones with different characteristics: the inertial zone above the water table and the saturated zone below the water table. It is assume that the effluent directly drops to the water table after recharged. A new method is developed to deal with the varying water table and the discretized matrix equation is solved using the Pre-conditioned Jacobi Conjugate Gradient method (PJCG). Operator-splitting techniques are applied to the reactive transport model while an implicit upwind finite difference scheme is developed to solve the convection-dispersion equations. Explicit solutions with small time step, which can be considered as exact solutions, are also computed to demonstrate the validity of the present method. With the numerical predictions, the scheme of practical operations for the demonstration project is drawn up. The detailed descriptions on the solution procedure for the reactive transport model are given in an accompanying paper (Zhu et al.)

WASTWATER RE-USE POLYCY

HS04/08A/C30-004   1100
ASSESSMENT OF WASTE WATER GENERATION, MANAGEMENTPATTERN AND ITS RE-USE POTENTIAL IN URBAN INDIA

R. B. SINGH (Department of Geography, University of Delhi)

Cities and towns in India are exposed to water pollution. Indiscriminate discharge of domestic and industrial waste water has polluted water resources. Ground water reserves are under risk of pollution as a result of seepage of surface pollutants. Estimates of access to excreta disposal systems vary between 48 per cent to 70 per cent. Out of 300 cities having population of 100,000, about 70 have partial sewage systems and sewage treatment facilities. Levels of sewage treatment is very low. Thus the untreated and partially treated municipal waste water finds its way into precious water sources such as rivers, lakes and ground water, causing water pollution. Recently untreated such water is being used for urban agriculture etc. As per the study conducted by the central Pollution control Board during 1994-95, the total waste-water generated in 300 class-I cities is about 15,800 million litres a day (mld), while the treatment capacity is hardly 3,750 mld. In the 23 metropolitan cities, over 9000 litres of sewage is generated daily, of which about 60 per cent is generated in the 4 mega cities such as Mumbai, Kolkata, Delhi and Chennai. In the metro cities, only 30 per cent waste water is treated before disposal..Most of the cities have only primary treatment facilities. The situation of industrial waste water is also problematic. Waste water management system is the framework within which all activities associated with generation, storage, collection, transfer, processing and disposal of waste water. This includes other activities designed to reduce the amount of waste water at all points. Waste water can be categorized according to the sources from which it emanates such as household, commercial, institutional like hospitals and industrial etc. Waste water can be reduced through pre-consumer recycling (during production process, household level, transport, re-use and recycling. In Indian situation sustainability of waste water management includes minimization of waste water production, maximization of re-use and recycling and its financial viability, efficiency in terms of clean and healthy neighbourhood. Keeping within the absorption capacity of local sinks for waste water, level of facilities need to be improved for protection of soil and ground water from pollution. It is very important that waste water produced by enterprises should be re-use or recycled within the same. Public involvement through ENGOs and DNGOs and resident association will go a long way in achieving the sustainability. Contents of linkages for partnership between local government and communities include discussions, consultations, negotiation, sharing of functions and decision taking power etc. The Central Pollution Control Board strengthened the monitoring of water quality of national aquatic resources through a network of 414 stations on rivers, 25 on ground water, 38 on lakes and 30 on canals, creeks, drains and ponds etc.

HS04/08A/C30-005   1130
ASPECTS OF GROUND WATER ENRICHMENT BY WASTEWATER REUSEIN THE PALESTINIAN TERRITORIES

Rebhy Ata EL SHEIKH[1], Sami Mahmoud HAMDAN[2], Ashraf Sobhy ABO SHAMMALA[3] ([1]Technical Directorate, Palestinian Water Authority, [2]Information department, Palestinian Water Authority, [3]Engineering Unit, UNDP)

The Palestinian population amounts to 1.2 Million in Gaza and 2.1 Million in the West Bank. Water is mainly supplied for Gaza Strip from the coastal aquifer at the rate of 130-135 MCM/year. The annual renewable quantity for the coastal aquifer is about 98MCM out of which 46MCM are infiltrated directly from rain water and the remainder is from the irrigation return flow, wastewater leakage and brackish trans boundary flow. This allows for sea water intrusion. In the West Bank the annual renewable quantities of groundwater in the Western, Northeastern, and Eastern basins in addition to springs are estimated at 691-811 MCM/year. Out of that only 143 MCM/year are accessible by the Palestinians in the West Bank due to the political situation. On the wastewater side, only 50% of the Gaza strip is covered by collection networks where only secondary treatment is available for 20%. Meanwhile more than 80% of the West Bank area is not sewered. Generally, the water quality is continuously deteriorating as a result of over abstraction and infiltration of both the wastewater and the return flow polluted with pesticides and detergents recharged form agriculture. Samples taken from the ground water aquifer down stream from wastewater treatment plants and in unsewered areas where septic tanks for sewage are used show relatively high Nitrate concentration. Although recovery wells drilled at a safe distance from the recharging sites indicate improved water quality, still a psychological barrier exists for local residents in the vicinity of a waste water treatment plant that the quality of extracted ground water is affected by the plant effluent infiltration.By the time recharge to the aquifer and reuse of treated wastewater in agriculture are key points in the Palestinian water sector policy especially since the agriculture sector consumes about 80% of the total abstraction, it is still not an easy task to apply on a large scale due to high investment requirements to improve the effluent characteristics, to build the required infrastructure and to overcome the psychological problem. Nevertheless a pilot project is under preparation in Gaza Strip.

HS04/08A/C30-006   1200
GROUNDWATER QUALITY DETERIORATION - A MAJOR THREAT TO WATER RESOURCES

Hillel RUBIN (Department of Civil Engineering, Technion - Israel Institute of Technology)

About 50 years ago the Israeli Water Law was established, stating that all water resources available with the State of Israel belong to the nation. This law allowed the National Water Carrier and the Coastal Drainage that avoids loss of groundwater into the sea, etc. However,

presently the Israeli Water Law cannot compete with contemporary water quality problems. For many years cotton was the major crop irrigated by treated wastewater. Due to the government decision of raising the price of treated wastewater raising cotton disappeared, and large quantities of treated wastewater flow into the sea. A group of professors has claimed that irrigation with treated wastewater is extremely dangerous to groundwater quality, and only treatment to drinking water quality is acceptable. The Water Commission has no capability to compete with this issue. Eventually, this topic is of purely agricultural nature. Also here some examples indicate that often privatization with limited governmental control give results much better than provided by the big government. Some urban communities have been released from payments of the ″balance payment″ (is imposed by the Water Law) if they pump and reclaim groundwater contaminated by nitrate, micropollutants, etc. So, they built groundwater treatment plants. The Water Commission is presently pushing the construction of big desalination plants to overcome the water needs. However, in Florida many urban communities have built such plants with no government involvement. Why do Israeli urban communities need the Commissioner involvement? Why should not they obtain reclaimed groundwater? If the urban communities can sell treated wastewater to farmers for irrigation, why do they need the pricing of the Water Commission? The operation of the Coastal Drainage plant, resulted in a continuous increase of contaminants in groundwater. Mass conservation law implies such a result. Therefore, quantities of these contaminants should be taken out from the aquifer, to balance the mass input and output. It is appropriate to encourage use of reclaimed groundwater rather than desalination of sea water, wherever it is possible. The government should allow communities to choose the best option for their water supply source. Probably they will pick up the optimal solution much better than it can be done by the Water Commission. There are also good chances that communities have better capability than the Water Commission to avoid the contamination of their aquifer and to identify the individuals responsible for the contamination of groundwater.

CONSERVATION OF WATER RESOURCES IN BERLIN (GERMANY) THROUGH DIFFERENT RE-USE OF WATER

Birgit FRITZ[1], Stephanie RINCK-PFEIFFER[1], Thomas HEBERER[2], Asaf PEKDEGER[3] ([1]Centre of Competence for Water Berlin, [2]Technical University Berlin, [3]Free University Berlin)

The inhabitants of Berlin, just about 3.4 million, are supplied with drinkingwater by its own groundwater resources exclusively. In order to conserve the natural available groundwater, it is enriched intensively by bank filtration from surface waters and artificial recharge. In addition, some of in the past intensively used sewage farms are still in function. Hence, the volume of the groundwater storage, its quality and the proportion of artificial recharged or bank filtered water are of significantimportance for a sustainable water management in Berlin. A partly closed water cycle is a result of the usage the treatment and recycling of water in Berlin. Advanced treated wastewater is discharged into the surface waters. To predict increasing loads of nutrients in the surface water, phosphorus is removed upstream in a phosphorous removal plant (up to 0.02 mg/l). The production wells of the water supply system are located in a short distance (10-600 m away) around the lakes and rivers, which are affected by the input of the above described treated water. The surface waters are also used for artificial recharge through infiltration ponds. Nevertheless, there is no need for further treatment after abstracting the bank-filtered water. The only treatment consists of an aeration step for removal of manganese and iron. The natural pre-treatment in the aquifer (Soil-aquifer treatment) during bank filtration and artificial recharge is one of the most important parts within this water cycle. Intensive investigations started to study the efficiency of the removal processes. Former studies have shown that the oxygen consumption and the most important geochemical processes are taking place in the first few centimetres to meters in the aquifer. Redox sequences can be observed as described in the marine environment also in the groundwater, where oxygenated river water infiltrates to an anoxic aquifer. On of the main topics of this research programme is the removal of bacteria, drug residues, algae toxins and organics and the hydrogeochemical and biological interaction in the sediment/water layer. Mathematical models for flow and transport can be used to simulate possible changes of chemical loads, flow velocities or through the performance of the supply system.

WATER AND SEDIMENT PATHWAYS FROM TERRESTRIAL TO FLUVIAL SYSTEMS: THE KEY TO ASSESSING LAND USE

Roy C. SIDLE (Disaaster Prevention Research Institute, Kyoto University)

Understanding the pathways of water and sediment from the hillslope to the stream, and subsequently within stream systems is essential to evaluate the spatial and temporal effects of land uses. Headwater catchments are sources of sediments, nutrients, and biota for larger streams, yet the hydrologic pathways that transport these materials remain unclear. Most of the research on hydrologic and sediment modeling that has attempted to incorporate processes, still greatly simplifies the complexity of hydrologic and geomorphic pathways. To understand the movement of sediments and water from source to sink, it is necessary to link hydrologic processes with their respective geomorphic setting and vice versa. One paradigm that has been proposed is the hydrogeomorphic concept of stormflow generation, whereby catchments are partitioned into landform attributes based on their unique hydrologic response. For example, in steep forested hillslopes, storm runoff occurs largely as subsurface flow, comprised of dynamic proportions from the matrix flow and preferential flow paths depending on antecedent wetness. The relatively flat riparian corridor generates saturated overland flow due to the perennially high water table. The extent of saturated overland flow depends on the width of the riparian zone. Geomorphic hollows are also important dynamic sources of storm runoff, as well as landslide sediment, in many steep catchments. Runoff from hollows appears to initiate when a threshold on groundwater has accumulated and thus the timing of response is related to soil depth. Each of these three sources may have different chemical signatures, but sorting out the pathways based solely on these signatures can be misleading due to mixing and exchange that occurs as water moves to stream channels. Sediment pathways are more obvious than hydrologic pathways, but are still poorly understood. To assess the effects of land use practices on soil loss and

sediment transport, a clear distinction needs to be drawn between surface erosion processes (surface wash) and mass wasting. Surface erosion is typically initiated when contiguous areas of hillslopes are compacted and disturbed. In temperate forests where organic horizons are relatively thick, sites may be able to withstand a certain level of disturbance before surface erosion links directly to streams; however, in tropical environments where decomposition rates are high and in sparsely vegetated dry sites, such erosion linkages can be dramatic. Mass wasting occurs in many steep environments and often links directly to channels, but the dynamics of sediment loading to streams is difficult to assess due to the episodic nature of these processes. Geomorphic hollows are sites of recurrent landsliding and sometimes initiation of debris flows depending on failure volumes and channel linkages. Assessment of this suite of hydrogeomorphic processes and pathways is necessary for the planning of land use activities.

HW01/09A/C26-002   **0930**

IMPACT OF URBAN GROWTH ON INDIA'S SURFACE AND GROUNDWATER QUALITY

Sitharama Murty KOTTAPALLI (Coordinator of Geoarchives, International Commission on the History of Geological Sciences (INHIGEO))

Urbanization has become a global phenomenon and its ramifications are more pronounced in developing countries. Natural growth of population, reclassification of habitation and migration trends are important factors contributing to the unmitigated increase of urban growth and population in India. Urban population of India was 217 million as per 1991 census, accounting for about 26 per cent of its total population, in 3768 urban agglomerations and towns. This is likely to rise in 442 million (38 per cent) of the country's population by 2006 - 2007 A.D. The first attempts at a survey of water supplies and sewerage systems in India was made in 1944 which revealed that the urban population as also the rural population that could bank upon safe water supplies was 6.6 per cent in Madras, 7.3 per cent in Bengal, and 4.1 per cent in U.P. It was then proposed that 90 per cent of the population should obtain water supply and sanitation facilities within 40 years. The number of metropolis increased from 12 in 1981 to 23 in 1991. in the initial period of planning (first five year plan) the outlay on urban drinking water was relatively substantial in relation to the urban population (17.3 % to 19.9 %). The outlay was 1.28 % which has risen to 1.38 %. Correspondingly, the outlay on rural water supply rose from 0.18 % to 2.47 % from 1951 to 1992 - 97 plans. In the eighth plan, an Accelerated Urban Water Supply Programme (AUWSP) was launched, targeted to small towns (population less than 20,000 - 1991), with a modest outlay of Rs. 500 million and 50:50 contribution by the Central and State Governments. Out of 2151 eligible towns project reports have been approved for 225 towns at an estimated cost of Rs. 2129.00 million. In India, the availability of water (both surface and ground) varies extremely in the various regions of the country. Rajasthan, for example, has 8 % of the country's population, but has only 1 % of the total water resources of the country, while Bihar with 10 % of the country's population has 5 % of the water resources. Until recently, an ordinary Indian was satisfied with availability of water, but today he wants water that is devoid of chemical and bacteriological contamination. Groundwater in the coastal tracts of Saurashtra is brackish due to over exploitation. Fluoride level is high in vast tracts of Andhra Pradesh, Haryana, Rajasthan, parts of Uttar Pradesh, Punjab, Karnataka and Tamil Nadu. Iron content is higher in major parts of northeastern States and many parts of Bengal have high arsenic content in the groundwater. The surface and groundwater sources have been affected by indiscriminate use of pesticides, release of wastes and industrial affluents into the surface and groundwater zones. A modified Model Bill of the Central Ministry of Water Resources in groundwater exploration is there for the consideration of the State Governments and many of them have enacted the necessary legislation.

HW01/09A/C26-003   **0950**

THE CHANGE OF SPRING WATER QUALITY CAUSED BY URBANIZATION IN UPLAND AREA

Atsuko TERAZONO[1], Hiroo OHMORI[2] ([1]Graduate Student, Department of Natural Environmental Studies, The University of Tokyo, [2]Department of Natural Environmental Studies, The University of Tokyo)

In recent years, land use/cover changes due to urbanization have been followed by the changes in quality of spring waters and shallow groundwater, in the uplands and hilly lands, in metropolitan areas. The deterioration of hydrological environment has been emphasized, and it is needed to put forward an adequate policy for urbanization. However, the actual state of material loads from diffuse land use is still unclear yet. This study aimed to clarify the relationship between the spatial differences of spring water quality and various diffuse land use. The study area is the upland located in the northwest part in Chiba Prefecture. There various land uses have been developed. The landforms consist of upland surfaces with an altitude of 15~30m and alluvial lowland (2~9m). There are many water springs along the small rivers. The altitudes of spring points vary with upland and valley landforms. The upland consists of four units of geological strata, indicating that the aquifers of spring water are controlled by geology. A total of 60 springs were surveyed in Jul. 2002. In the field, water temperature, electronic conductivity, pH, and alkalinity were measured. Major ion concentrations were analyzed in laboratory by high performance liquid chromatography. Silica concentration was determined using spectrophotometer. Using the Detailed Digital Information maps, land use in drainage basin was analyzed. Firstly, basic water quality originated from geology was examined. Along the increase in relative height between spring points and upland surface, the silica concentration increases. Concentrations of inorganic ions show the same tendency. There is no relationship between the relative height and the land use in drainage basins. Thus, the basic water quality is formed in the process of groundwater flow through geology by dissolving of carbonate minerals in layers. The rest of the loads are controlled by land use development in drainage basins. The spatial difference of the additional loads is larger than that of the basic loads. There are clear relationships between the additional loads and land use. When forests occupy a large part of the drainage basin, the concentration of major ions is low. In the area with fields, the concentration and the proportions of Mg^{2+}, Ca^{2+}, SO_4^{2-} and NO_3^- are high. In residential area, the ion concentration is basically low but Mg^{2+} and NO_3^- show high proportion. Ca^{2+} and HCO_3^- concentrations become high for the developed drainage basins. When the land use consists of fields and residential area, the load is explained by taking the components of fields and residential area into account. Thus, the spring water quality is controlled mainly by land use in drainage basin.

HW01/09A/C26-004   **1010**

NITRATE TRANSPORT IN UNSATURATED ZONE NEAR A SMALL STREAM IN AN AGRICULTURAL AREA

Fumi SUGITA[1], Michael ENGLISH[2], Sherry SCHIFF[3] ([1]Chiba University of Commerce, [2]Department of Geography and Environmental Studies, Wilfrid Laurier University, Ontario Canada, [3]Department of Earth Sciences, University of Waterloo, Ontario Canada)

Nitrate contamination in groundwater and surface water caused by agricultural activities is one of major environmental concerns in many countries. Due to non-point nature of the source distribution, the nitrate transport processes and its pathways in soil are not clearly understood. In this study, nitrate concentration of soil water in five different land uses near a small stream (Strawberry Creek) in an agricultural area were investigated and compared with that of stream water. The purposes of this study are to identify major nitrate contributing land-uses into underground in the watershed and also to estimate its major pathways to the stream. The study area is located approximately 100km southwest of Toronto, Ontario. The watershed (3.5km²) is covered mainly with various croplands, and also with patches of woodland and narrow stripes of uncultivated land along the creek. Intensive land use and very narrow riparian zone are resulted in high nitrate concentration in the stream water(NO_3-N ≈10mg/l) in this area. In the growing season of 1999, several soil cores were obtained from 0.2m below the ground surface to the saturated zone which was around 1.2m below the surface in barely field, corn field, soy bean field, woodland and riparian zone along the creek. The soil water was extracted and was analyzed for NO_3, NH_4^+, Cl^- and DOC concentrations. Stream water and groundwater beneath the streambed were also sampled and analyzed for the same components listed above. The differences between the stream water head and that of under streambed indicated groundwater was discharging into the creak in most part along the creek. The NO_3 concentrations typically found in the groundwater were lower than those found in stream water except small upstream part. The highest NO_3 concentrations were found at the top (0.2m below the surface) of the soil profiles of barely and cornfields and the concentration decrease with depth. The concentrations found in the rest of the field were relatively low, suggesting corn and barely fields were the main nitrates contributing area. Along with the groundwater in the upstream, the tile drains which are facilitated about 0.7m below the surface in some part of this watershed give shortcut for nitrate to flow from upper unsaturated zone to the stream and may be contributing to the high nitrate concentrations found in the stream water. Depletion of NO_3 with depth is mainly due to denitrification that could take place in anaerobic loam patches exist in the zone. The average denitrification rates obtained by curve fitting were 0.0108 mg/l/day for the barley and 0.0064 mg/l/day for the corn. Though these rates are almost one-order of magnitude smaller than most fond in saturated zone, they suggest considerable denitrification is taking place even in unsaturated zone and this process is not negligible.

HW01/09A/C26-005   **1030**

EFFECTS OF LAND USE AND SOIL TYPE ON MANGANESE MOBILISATION FROM UPLAND SOILS

Kate Victoria HEAL[1], Alasdair Macdonald HARDIE[2], Allan LILLY[3] ([1]School of GeoSciences, University of Edinburgh, [2]Scottish Environment Protection Agency, East Kilbride, [3]Macaulay Land Use Research Institute, Aberdeen)

Concentrations of the trace metal manganese (Mn) in water supplies in excess of the drinking water standard of 0.05 mg L[-1] cause aesthetic and structural problems and have been linked with neurological health effects. The majority of Scotland´s drinking water is supplied from upland catchments and Mn concentrations in a number of these water supplies appear to have increased since the 1970s. We investigated two hypotheses to explain the observed increases in Mn concentrations: 1) Land use change: recent extensive conifer afforestation in many upland water supply catchments could cause elevated Mn concentrations in surface waters, for example, by enhanced leaching from tree foliage and from soils due to increased acidification; 2) Changes in soil moisture regime: increased Mn concentrations are particularly evident during autumn following unusually dry summer conditions so Mn may be mobilised when rewetting of dried soils occurs. The two hypotheses were tested in the Ballochbeatties Burn catchment, a 0.86 km² sub-catchment of the Loch Bradan water supply reservoir, southwest Scotland, in which Mn concentrations frequently exceed the drinking water standard. Soil water chemistry and soil hydrology were monitored for 18 months at six locations in the catchment, selected to represent the major upland land uses of Sitka spruce (*Picea sitchensis*) plantation and a dwarf shrub/grass moorland and the major soil types found in upland Scotland (Histosols, Histic Gleysols and Histic Podzols). No significant difference was observed in Mn concentrations in soil water under Sitka spruce plantation and moorland, indicating that this land use change is not responsible for increased Mn concentrations in surface waters. There was no evidence of Mn release into soil water from the rewetting of dried soil but this was attributed to the absence of extended drying conditions during the field programme. Laboratory controlled experiments were conducted, using soil cores taken from the horizons of the soils investigated in the field, to examine whether Mn release into soil water would occur following prolonged drying. The experimental results showed that Mn mobilisation into soil water occurred in organo-mineral horizons two weeks after re-wetting. To determine whether catchment soils could have dried sufficiently to promote Mn mobilisation and account for elevated Mn concentrations measured in surface waters in autumn 1995, a process-based soil water simulation model (WAVE) was used to hindcast catchment soil moisture regime. The simulation results showed a greater degree of soil drying during 1995 than we measured in the field or in the soil core experiments, indicating that changes in soil moisture regime can account for elevated Mn concentrations in surface waters. Although the processes responsible for Mn mobilisation during the rewetting of dry upland soils are not known, these conditions may occur more frequently in the future due to increased climatic variability, resulting in drinking water supplies regularly exceeding the standard for Mn.

HW01/09A/C26-006   **1110**

EFFECTS OF LAND USE CHANGE ON HYDROLOGICAL CYCLE: A CASE STUDY ON CHAOBAIHE RIVER BASIN IN NORTH CHINA

Gang-sheng WANG[1], Jun XIA[2] ([1]Institute of Geographical Sciences and Natural Resources Research,Chinese Academy of Sciences,China, [2]School of Water Resource and Hydropower,Wuhan University,430072,China)

The issure of water shortage and related eco-environmental degradation in North China is one of the major emergency problems in China. As runoff generated from mountainous area is significantly decreased and water resources are over developed, serious water and eco-environmental problems have arisen, such as drying-up of river system, ground water decline, lake and wetland degradation, and water pollution in plain area, etc. Based on the traits and existent problem of water cycle in North China, a distributed hydrological modeling has been developed. This model, so-called DTVGM (Distributed Time Variant Gain Model), can be coupled the present physical process units or conceptual models with hydrological system approach such as TVGM (Time Variant Gain Model), where time variant gain factor, *G(t)*, could be linked with RS information to extend easily to application of hydrological simulation in basin scale. DTVGM picks up the information, such as the gradient of the slope, the direction of the slope, the water current path, as well as the boundaries of the river network and the watershed of the land surface units with DEM by establishing itself on the basis of GIS/DEM. It simulates the movement of the water in the soil-vegetation-atmosphere (SVAT) system, describes the relation between the cellular grids in the horizontal direction, and it performs mathematical calculations of the surface water and the subsurface water on the watershed cellular grids divided by DEM. DTVGM combines runoff generation process and flow routing process by soil moisture content. At present, the runoff generation process is divided into two layers in the vertical direction: the upper layer is the surface flow based on the concept of TVGM; the lower layer is the subsurface flow developed through a control

volume approach, including a water balance equation and a storage-outflow equation. On the other hand, the kinematic wave models are applied to simulate the flow routing process. DTVGM can simulate the effects of human activities such as land use change on hydrological cycle by establishing the relationship between *G(t)* and land use types. A case study on Chaobaihe River Basin, controlled by Miyun Reservoir in North China, is implemented by applying DTVGM. The basin, with area about 13,846 km², is divided into 55,444 grid elements; and the grids are partitioned into different ranks for flow routing. The land use types of the basin include forest, meadow, river, reservoir, construction area, arable land area and naked land. By preliminary application and examination in Chaobaihe River Basin, it was found that DTVGM is successful with more advantages than conditional distributed model applied in China; and the increase of forest area could cause the decrease of runoff in this basin. Moreover, the new problems were addressed in the paper.

HW01/09A/C26-007   1130
BIOMASS BURNING AEROSOLS AND RAINWATER CHEMISTRY IN SOUTHEAST BRAZIL

L.B.L.S. LARA[1], P.B. CAMARGO[1], P. ARTAXO[2], L.A. MARTINELLI[1], E.S.B. FERRAZ[1] ([1]Lab. Ecologia Isotopica, Centro de Energia Nuclear na Agricultura (CENA, [2]Instituto de Fúeica, Universidade de Sao Paulo Brazil)

The acidification of precipitation by H_2SO_4 and HNO_3 and subsequent high N deposition rates has been taken place in Southeast Brazil. Besides, the biomass burning, which occurs around 6 months in every year, has increased the inhalable particles as well as black carbon concentrations in this region. In order to understand how the anthropogenic activities could be changing the rainwater and aerosol chemical composition, during one year we have collected and analyzed aerosols and rainwater samples in three different sites in State of São Paulo (Southeast Brazil), with different kind of anthropogenic activities: pristine area with original forest, biomass burning and industrial activities and pasture area. The origin of the free acidity in rainwater is different in each site and come out to be linked to the land-use Organic acids appear to control the acidity in pristine areas, while in other sites, mineral acids (mainly nitrate), dominate rainwater acidity. According to the Factor and Cluster Analyses, the composition of rainwater in the two sites appears to be controlled mostly by two sources: biomass burning and industrial emissions, and in the pristine area by biogenic emissions and marine influence, due to the proximity to the sea.   High levels of pollutants have been measured during biomass burning season in southeast Brazil, the annual PM_{10} concentration (57.1∀45.2µgm⁻³) exceeds the other urban and industrialized areas and the BC concentration is significantly higher during the biomass burning season - dry season (4.2∀2.2 µgm⁻³) than the wet season (2.0∀1.0 µgm⁻³). A detailed aerosol source apportionment study was performed in these three sites. A complex system of air pollution sources modulates the pollutants concentration in the Southeast Brazil. Principal component analysis results showed that the main source of fine aerosol is biomass burning which is generated into the State (sugarcane burning) or coming from fires in the Amazon Basin. The other main sources are soil dust, industrial emissions and oil combustion. Resuspended soil is the main source of coarse mode followed by industrial emissions. The sampling and analytical procedures applied in this study showed that the biomass burning and agricultural practices are dominating the chemical composition of the rainwater and aerosols in Southeast Brazil, possibly altering the biogeochemical cycles. Besides, if in the future, urbanization and industrialization process continues to grown in this rate we can expect significant climate changes.

HW01/09A/C26-008   1150
EFFECTS OF VEGETATION AND LANDUSE ON THE HYDROLOGIC CYCLE OF SEMI-ARID CANADIAN PRAIRIES

Masaki HAYASHI, Garth VAN DER KAMP (Department of Geology and Geophysics, University of Calgary)

In the semi-arid northern plains of North America there are millions of small wetlands, also called ˝prairie potholes˝ or ˝sloughs˝, which play an important role in the hydrology of the region and provide important breeding habitat for migratory waterfowl. At the St. Denis National Wildlife Area in the prairie region of southern Saskatchewan, Canada, water levels in over 100 wetlands have been monitored since 1968. Most of the wetlands, located in closed drainage basins, have no permanent inflow and outflow streams. As a result the water balance of the wetlands is primarily controlled by snowmelt runoff, summer precipitation, and evapotranspiration from open water and the riparian fringe. The underlying glacial deposits consist largely of clay-rich glacial till with low permeability. Therefore, groundwater flow is generally slow and represents a minor component of the water balance although it may play a decisive role in controlling the chemical mass balance. Between 1980 and 1983 about one-third of the 4 km2 area was converted from cultivation to a permanent cover of brome grass in order to provide dense nesting cover for waterfowl. A few years after this conversion all the wetlands within the area of grass dried out and have remained dry since, while wetlands in adjacent cultivated lands have held water as before. Field measurements show that introduction of permanent grass reduces water input to the wetlands mainly through a combination of efficient snow trapping and enhanced infiltration into frozen soil. In winter the tall brome grass traps most of the snowfall whereas in the cultivated fields more wind transport of snow occurs, especially for short stubble and fallow fields. Single-ring infiltration tests were conducted during snowmelt while the soil was still frozen and again in summer. The infiltrability of the frozen soil in the grassland is high enough to absorb most or all of the snowmelt, while in the cultivated fields infiltration into the frozen soil is limited and significant runoff occurs. In summer the grassland maintains a much higher infiltrability than the cultivated land. The development of enhanced infiltrability takes several years after the conversion from cultivation to grass and is likely due to the gradual development of macropores such as root holes, desiccation cracks and animal burrows.

HW01/09A/C26-009   1210
INFLUENCE OF ANTHROPOGENIC ACTIVITY TO EROSION PROCESSES IN THE CHANNELS OF THE BELAYA AND UFA RIVERS

Tatyana FASHCHEVSKAYA[1], Nicolay OSIPOV[2] ([1]Department of Ecology, Ufa State Aircraft University, [2]Hydrometeorological centre, Bashkirian hydrometeorological service)

The Belaya river is situated in limitations of South Ural and is one of main tributary of the Volga river with area catchment equal 142000 km². The length of the Belaya river is 1430 km. The Ufa river is the main tributary of the Belaya river. Its length is 918 km. There are intensive economic activities at floodplain and at channels nowadays, especially at middle and lower reaches of river. As a result of these activities the river makes active erosion processes. First of all is extract of sand-gravel materials from channel that is used for production of asphalt-concrete mixture, roads repairing and for building. The depth and the width of some quarries may be compared with the depth and the width of rivers. The second direction of anthropogenic exploitation of rives channels is intensive dredging for navigation. River transport development (carrying, intensity) promoted improvement of water ways and

increasing of navigation water depths. Every year much soil is withdrawn from river channel in order to restore or to support the fairway. Today the navigation distance in the Belaya River is 670 km, in the Ufa River - 305 km. The third important factor which increases river erosion activity considerably is construction of reservoirs. The intensive channel wash-out happens in downstream of reservoir. In 1961 year the Pavlovskoye reservoir was built at the Ufa River (water volume is 1,41 km³). The influence of the reservoir is being observed till inflow of the Ufa river into the Belaya River, i.e. 170 km. In that place the channel had been scoured and the water level was decreased till scale that could be compared with navigation water depth. The analysis of the dynamics of suspended load before and after building of Pavlovskoye reservoir showed considerable decreasing of entering of them into downstream because of accumulation them in the upstream. As a result of the research it became clear decreasing of water level while water discharge was invariable. In the Ufa River, where it inflows into the Belaya River the decreasing is 100cm, in the Belaya River is 156cm. As a result of the decreasing of water level we have: 1.Undertaking pipelines and intakes, those were made on the bottom of the river, became stripped, and their exploitation was violated; 2. Navigation conditions got worse; 3.Duration of the flooding of floodplain decreased, that is why the spawning grounds of fishes have degraded, the crop capacity of floodplain meadow reduced, the conditions nesting of birds and mammals have aggravated.

MODELLING STREAM WATER CHEMISTRY USING RIVER BASIN LANDUSE CHARACTERISTICS

Chandra Sekhar MATLI, Surender REDDY (Department of Civil Engineering, Regional Engineering College)

The study of water quality is fundamental to understanding a water resource, as it gives insight into the benefits derived from water management. Urbanization and industrialization are recognized to be main causes for water quality degradation for quite some time. Hence, assessment of non-point (diffuse) pollution, which arises from the river basin, has to some extent been overshadowed by the urgent need for treatment of domestic and industrial wastewater (point sources).   The River Krishna and its tributaries drain three important states of South India. The river water plays a very important role in the overall socioeconomic development of Andhra Pradesh. The river water is used for drinking, industry, power generation and predominantly for irrigation in the basin, which has a tropical climate. From available literature, it is evident that the river receives pollutants from non-point sources, in addition to point sources. In large river basins monitoring non-point sources pollution is rather difficult and expensive and is subjected to analytical errors. Hence, modeling water quality using landuse data of the basin is attempted in the present study.The results of the study indicated the impact of landuse on water quality of the tributaries of River Krishna. The seasonality in river flows and concentrations of dissolved solids is explained with the help of variations in flow patterns that is due to unequal rainfall distribution in the basin over the year. Agriculture is the dominant landuse in all the sub-basins. Correlation studies explain the relationships, between dissolved solids concentration and landuse of the basins. The multiple regression models accounted for significant variation in concentrations for majority of dissolved solids. The predicted concentrations are in good agreement with the observed values. However, some of the deviations can be explained by dynamic nature of the landuse patterns. The proposed models can be useful for planning landuse controls in integrated water quality management program. As water quality of flowing water is closely linked to the landuse in the basin, it is essential to include water quality management in future river basin planning.

HW01/09P/D-002   Poster   1400-193
THE BENEFIT BROUGHT BY SOIL AND WATER CONSERVATION IN CHINA

Ge TAN, Jun XIA (Hydrology Studio, Institute of Geographical Sciences and Natural Resources Research, CAS.)

Soil and Water Conservation (SWC) approach can reduce the runoff and sediments of rivers, these functions should be estimated and quantified. There are two kinds of traditional estimating ways: one is called hydrological way and the other is called water conservation way.   Aimed at the biggest rivers of China, Yangtse River and Yellow River, two typical heavy eroded catchments are selected as study areas, these areas have been harnessed for some years, and can be choose as study object. In this paper, the Jialingjiang catchment (upper course catchment of Yangtse River) and middle course catchment of Yellow River will be studied to find out the influence of SWC approach on water resources. Though analyzing, we can make latter conclusions: The soil and water conservation can reduce more runoff and sediment of arider area than that of humid area. (1) With the implement of soil and water conservation measure, the condition of catchment runoff and sediment will be better. When the harness reaches a certain degree, there will be a balance of wash and silt. (2)The study of typical catchment show that: since 90s, reasons of the reduce of sediment amount included precipitation decrease and SWC, the former make 16% of the runoff and sediment reduce, the latter make the left 84% reduce. (3) Using the precipitation data, runoff data and sediment date of before-harness area to build a experience model, and then using this model to simulate the benefit of harness project, this is a better analysis method until now. The key point is whether the sediment rules of harnessed area can be really reflected by the experience model which is based on the data of before-harness area. According to the change of runoff of Yellow River under SWC influence: (1) Reservoir can adjust the river annual and year-to-year runoff. LongYangXia and LiuJiaXia reservoir made the runoff distribution change greatly, the runoff increased in low-water season and decreased in high-water season. According the observation data, the runoff increased 10~20% in low-water season. (2) Analyze from the aspect of water loss, because of the reservoir the water surface area is increased, the evaporation is increased accordingly. By statistic of the main reservoirs of China, the evaporation increased 77×108m3(not included plain reservoirs), account for 1.3% of the natural runoff of Yellow River. (3) According to the analyses of the change reason of the runoff in the Hekou-Longkou area and catchments of the Jinghe, the Luohe, the Weihe and the Fenhe ,the measurements of SWC is one of the elements which affect the amount water entering the Yellow River, which has decreased about 10.9×108 m3.The affections of SWC and the irrigation measurements are almost the same, but the irrigation measurement is the main means in catchments of the Jinghe, the Luohe, the

Weihe and the Fenhe, where the contribution of SWC approaches to reduce the runoff of Yellow River is about 10%.

HW01/09P/D-003 Poster 1400-194

IMPACT OF INDUSTRIAL EFFLUENT ON WATER QUALITY IN KORBA AND ENVIRONS, CHHATISGARH, INDIA

L. P. CHOURASIA (Department of Applied Geology,Dr. H.S. Gour Univ)

The impact of multiple industrial pollution sources on the groundwater system were evaluated in the industrial complex at Korba of Chhatisgarh State of India. The quality of groundwater in the region has been affected negatively due to the discharge of effluents on open land and into ponds, tanks and streams. Water samples from surface water bodies and due wells were analyzed for their major ion concentrations of Na^+, Ca^{2+}, Cl^- and $HCO3^-$ indicate the impact of industrial effects on water quality. Based on the hydro chemistry, the groundwater is classified into various types such as sodium chloride, sodium-bicarbonate calcium chloride, and magnesium-chloride etc. Its suitability for dinking and irrigation purposes has been assessed. The ground water quality in and around Korba has become hazardous. Some possible remedial measures are suggested.

HW01/09P/D-004 Poster 1400-195

GROUNDWATER AS AN ALTERNATIVE SOURCE OF SUPPLY FOR URBAN AREAS IN RUSSIA

Igor Semenovich ZEKTSER (Department of Hydrogeology, Water Problems Institute, Russian Academy of Sciences)

Groundwater represents a valuable source of public drinking water in many parts of the Russian Federation but its use varies widely across the country. In part this reflects differences in the hydrological and hydrogeological settings that govern groundwater recharge and safe groundwater yield. However, in some regions, groundwater development is constrained by water management organizations that simply ignore available and well-protected groundwater resources in favor of surface water supply. Locally, significant human impacts on groundwater quality and quantity have been documented. In many populated areas, for example, groundwater recharge has been artificially enhanced and safe yield has increased; in other cases, aquifers have been drained and safe yield has been depleted. It is important that these impacts be understood if future problems are to be resolved. In particular, a full knowledge of the extent to which human activity impacts groundwater resources is essential for adequate assessment of safe yield. Safe yield assessment allows changes in surface runoff and fluctuations of the water table to be predicted; however, an inadequate representation of human influences on annual recharge and discharge will lead to serious error. The depletion of groundwater resources and safe yield is generally localized. The effects of anthropogenic pollution on groundwater also tend to be local. Pollution is most prevalent in the uppermost aquifers, particularly in urbanized and agricultural areas and in river valleys. Deeper confined aquifers used for centralized withdrawal normally produce water of good quality. Where pollution of confined aquifers occurs, it is normally caused by inadequate protection of well capture zones or by the poor design of the water-supply wells.

HW01/09P/D-005 Poster 1400-196

THE EFFECT OF LAND USE CHANGES ON FLOW REGIME

Richard P. SILBERSTEIN, Tim GARGETT (IAHS)

Clearing of native vegetation for agriculture in Western Australia has resulted in enormous environmental problems. The irony is stark in a region generally considered dry and lacking in water for much of the year, we have a problem caused by too much water accumulating in local areas. The native deep rooted perennial vegetation used virtually all the available rainfall, and maintained a very deep watertable or ensured there was no watertable at all. Salt accumulated from the rainfall in the root zone in huge amounts. Shallow rooted annual agricultural crops and pastures do not use all the rainfall, and each winter a small amount drains through the soil until it reaches the now rising watertable. The result on stream flow has been a complete change on flow characteristics, with ephemeral streams now flowing continuously, and with high salinity, so they are no longer drinkable. In catchments subject to detailed analysis there has been a much lesser impact on extreme flows than on low flows. Conversely, when cleared catchments are planted to trees, there is a reduction in streamflow, and potentially a big impact on water resources. This paper shows the extent to which flow regime has been modified by the rising watertables resulting from the clearing for agriculture. We discuss time scales for these changes to become apparent and for them to reach their maximum expression; and what impact might be expected of recovery attempts by reafforesting catchments. In this work we seek a general solution to the prediction of changes to flow regime resulting from land use changes. Flow frequency and salinity frequency distribution curves are analysed and represented as parametric curves, with the parameters linked to catchment and climate characteristics.

HW01/09P/D-006 Poster 1400-197

ENVIRONMENTAL CONDITIONS EFFECT ON THE FLUVIAL TRANSPORT CHANGES IN SOME CATCHMENTS OF THE VISTULA AND BUG INTERFLUVE

Andriej TUCKI, Andrzej SWIECA (Department of Regional Geography, Maria Curie-Skeodowska University)

The purpose of this study was to determine the influence of environmental conditions and economic activities on the nature and quality of solute and suspended sediment transported by the rivers in the middle and southern parts of the Vistula and Bug interfluve. The above-mentioned problems were studied in the four catchments with different natural conditions and anthropogenic impact (Fig. 1.) The upper Wieprz river catchment up-stream of the gauging station at Zwierzyniec (405 km²) is situated in Tomaszow Roztocze. Its geological structure is distinctly different; the Upper Cretaceous opokas and gaizes occur often on the surface as well as loess. The Quaternary sandy deposits are wide spatial expended too. The forestage is significantly high (36% of the catchment area), whereas arable land covers 59.9% of this area. The mean annual amount of drained off sewage during 1989-1992 was 0.2 million m³, which was 0,4% the river yield. The Por river catchment - the Wieprz river left tributary - 590.3 km² in size - is situated mainly in Goraj Roztocze. The MWMI gauging station at Sułłow closes this catchment (571 km² - 96.7%). The Upper Cretaceous marl and opokas, mainly overlaid by loess are in the basement complex. The arable land in this catchment is 66.3%, whereas the forest - 18.7% of the catchment area. The amount of municipal and industrial wastewater is small. The mean annual amount of drained off sewage during 1989-1992 was 0.1 mln m³, which was 0.1% of the river runoff. The Labunka river catchment - the Wieprz right tributary - up-stream of the gauging station at Krzak is 416 km² in size - 81%; the catchment is 513.5 km². It largely comprises the area of the Zamosc Basin. Of Quaternary formations, mineral-organic ones lining the valley bottom of the

---

Labunka river and its tributaries are the most widely-distributed. The cropland covers 79.3% of the area, in it meadows and grassland constitute 16.2%. Forests cover about 12.3% of the Labunka river catchment. During 1989-1992 the surface waters were polluted with 6.5 million m³ of municipal and industry sewage. The Uherka catchment - the Bug river right tributary - up-stream of the MWMI gauging station at Ruda Opalin is 432 km² in size, which constitutes 75% of the Uherka river catchment. The catchment is situated mainly in Lublin Upland and Polesie Plain. Soft limestones of the Upper Cretaceous rocks, which are related to spread depression, predominate in the basement complex. Whereas more resistant rocks of the same age (marl and marly opokas) are related to inselberg heights. In the basin up-stream of the MWMI gauging station at Ruda Opalin, forests cover 12% of area, meadows and grassland - 11%; whereas the arable land - 69%. The surface waters are polluted mainly with municipal and industry sewage (during 1989-1992 they were polluted with 7.7 million m³ of sewage).

HW01/09P/D-007 Poster 1400-198

CHARACTERISTICS, CHANGING TRENDS AND CLASSIFICATIONS OF NITRATE-NITRITE IN HOKKAIDO

Xuan-Zhu YANG (Ueyama-Sisui Earth Consultant Co. Ltd)

Nitrogen (ammonium-, nitrite-, and nitrate-nitrogen) is inputted to the land from various sources (fertilizers, atmospheric deposition, animal wastes and wastewater) during the past decades years in Hokkaido. Most common drinking water pollutant in groundwater is caused by agricultural watersheds and wastewater of nitrogen. Elevated nitrate-nitrate concentration in groundwater have raised serious human-health and ecological concerns. The degree of pollution in agricultural and urban area is not easily determined because of overprinting by numerous subsequent processes. It is possible for us to determine that concentrations of nitrate-nitrite vary systemically with an increase in time. The purpose of study is that understand their characteristics and changing tendencies, and then suggest some countermeasures about pollution. The combined results of this study indicate that the nitrate-nitrite concentrations in Hokkaido have responded to increased or decreased nitrogen loads from various sources in agricultural and urban area over the last few decades. Six significant changing trends of nitrate-nitrite concentrations, corresponding to an increase of time, may be identified on the basis of mode of their characteristics in Hokkaido. Type 1 is characterized by lower concentration ($<$10ppm) and a gradual increase in nitrate- nitrite . Type 2 shows remarkable higher concentration ($>$10ppm) and a gradual increase in nitrate-nitrite. Type 3 is characterized by lower concentrations ($<$10ppm) and a gradual decrease in nitrate- nitrite. Type 4 show remarkable higher concentrations ($>$10ppm) and a gradual drop in nitrate- nitrate. Type 5 and Type 6 indicate that concentrations of nitrate-nitrite essentially is stable, although there may be slight concentration variation. Because of the severe environmental effects, removal of the various forms of nitrogen from soil, water and wastewater has become mandatory in resent years. The data presented in this study provide insights into such significant events as pollution countermeasure. The result of study indicates that pollution countermeasure is necessary to Type 1 and Type 2. It is suggested that previous survey of pollution conditions is very important before consideration of countermeasure. Nitrate-nitrite pollution must be controlled if we are to improve significantly nitrogen input to the land from various sources.

HW01/09P/D-008 Poster 1400-199

GEOCHEMISTRY OF GROUNDWATER IN MINE-AFFECTED ZONES OF SALEM, TAMIL NADU, SOUTHERN INDIA

Palanivel Periakali GOUNDER, Manavalan Sathya NARAYANAN (DEPARTMENT OF APPLIED GEOLOGY, UNIVERSITY OF MADRAS)

Mineralogic, hydrogeologic and geochemical data of ultrabasic - Peninsular gneiss rocks of Salem covering an area extent of about 194 sq.Km around Salem magnesite mine area were used to determine the source of solutes to groundwater and to assess the chemical weathering processes. The results indicate that the flux of dissolved solids from the abandoned mines are controlled by interaction between ultrabasic rocks and materials derived from local bedrock. Mass balance calculations indicate that dissolution of feldspar and ferromagnesian minerals release Na, Ca and Mg. The average denudation rate was found to vary from 0.3 to 4.2 tons/km2/yr for a discharge of 5.3×10^8 l/yr, and from 0.5 to 8 tons/km2/yr for a discharge of 10×10^8 l/yr. Mineral solubility study of Mg-phase in the system shows that serpentine is the dominant Mg^{2+} contributor. The distribution of several dissolved species in groundwater over the ultrabasic rocks - Peninsular gneissic complex explain the significance of water-rock interactions. Input-output budgets for major chemical species show an increase in the concentration of (Na+K) and TDS towards downgradient. Weathering of plagioclase feldspar and biotite in the Peninsular gneiss could be the source of (Na+K) to the groundwater. There is a net export of major cations, silica and bicarbonate from the magnesite mine area, reflecting the weathering of bedrock. Bedrock in magnesite mine is ultrabasic rocks comprised of dunites, peridotites, shonkinites, missourites, yogites and syenites. While Ni and Co are within the tolerable limits in most of the area, the concentration of total Cr was observed to be about 3-4 times more than the permissible limit. Though chromium is an essential trace element in the metabolism of lipids and proteins and is vital for the maintenance of a normal glucose tolerance factor, excess of chromium uptake damages mucous membranes, causes renal damages and has been classified carcinogenic to humans by the International Agency for Research on Cancer. Our preliminary studies have shown, the incidence of breast cancer among the inhabitants in the study area. From the chromium speciation studies, it was observed that the trivalent chromium concentration was below the permissible level (50 ppb), but carcinogenic hexavalent chromium ranges from 0 to 228 ppb during summer and 3 to 186 ppb during winter. The concentration of hexavalent chromium is about three times greater than the permissible limit (50 ppb) rendering the groundwater unfit for drinking and domestic use. Hexavalent chromium shows positive correlation with pH and most of the major ions. Shaded colour contour diagram were prepared which showed that an area of 145 sq.Km was affected by hexavalent chromium contamination during summer and 132 sq.Km during winter.

HW01/09P/D-009 Poster 1400-200

WATER QUALITY ENHANCEMENT THROUGH IN-LAKE MODIFICATION

Byeong-Chan KIM, Sang-il LEE (Department of Civil and Environmental Engineering, University of Dongguk)

The quality of reservoirs and lakes is gradually deteriorating due to social and environmental changes. Since the construction of new dams gets increasingly difficult owing to environmental concerns, rehabilitation of existing water bodies become necessary. In order to achieve this scientifically challenging task, Herculean efforts are being made. This paper presents the issue of improving the water quality of a lake by modifying its shape. Lake Sihwa, located in the midwest of the Korean Peninsula, is an artificial water body created as a result of the construction of an embankment in 1994 to secure agricultural water for the region. Besides the freshwater lake having 56.5km² of surface area, a reclaimed land of 173km² and 330 million m³ volume was also created. However, due to the cut-off of tidal

currents and the rapid increase of population and industrial waste loads from factories in the neighborhood, the water quality of Lake Sihwa has deteriorated immediately after the construction. Various measures based on both hydrodynamic and environmental approaches have been proposed and implemented thus far to improve the water quality of the lake. External measures include the creation of artificial marsh, conduit works for collecting stormwater, and the construction of treatment plants for wastewater from livestock. But these measures have intrinsic limitations both in technical and operational aspects. There also exists a practical need for an in-lake approach: the sluice gates at the embankment are being operated for the purpose of flood control and water quality improvement. Accordingly, seawater flows into the lake and the downstream part of the lake has lost the function of freshwater impoundment. Thus the plan of zoing and partial reclamation of the lake has been highlighted. While the waterway is channeled through reclamation, the water body is divided into three zones by two submerged dams. The middle zone is expected to supply some portion of water demand for the future industrial complex nearly. To estimate the daily inflow for a watershed where hydrologic data are insufficient, a methodology based on the inflow weight factor has been devised. Numerical analysis was performed for water quality prediction, utilizing the daily inflow estimates and biochemical information acquired from field measurements. Results showed that the water quality of modified Lake Sihwa would be enhanced up to the level of both agricultural and industrial use. Acknowledgment: This work was partially supported by a grant (H00018) from Korea Research Foundation.

HW01/09P/D-010   Poster   1400-201

EFFECT OF URBANIZATION ON FLOOD RUNOFF

Tokuo KISHII[1], Michiko HAYANO[2], Yasuhisa KUZUHA[2] ([1]National Research Institute for Earth Science and Disaster Prevention and University of Tsukuba, [2]Natinal Research Institute for Earth Science and Disaster Prevention)

In this research, the change of flood runoff characteristics, that is, the flood runoff ratio and the time of concentration etc. are investigated, on the Shakujii River which flows from west to east on the Musashino Terrace in the northern part of Tokyo Metropolis. The basin area of the river is 48 km2 in area with a total channel length of 19 km. The surface geology of the area is the volcanic ash of high permeability, called Kanto Loam. After 1950's, this basin has been urbanized rapidly and in 1975 it had over 50% of impermeable area and a population of 590 thousands. On this river there are available data of rainfall and discharge of floods which occurred through twenty years and the data have made it possible to investigate the change in flood runoff characteristics in these years.As a result, no considerable difference in runoff ratio was found between each year. From this it is considered that the surface geology of high permeability influences much more than the urbanization does. The time of concentration was reduced remarkably to about a half after urbanization. This is supposed to have been caused by the decrease of roughness in the basin and the channel. Concerning runoff coefficient of Rational Formula, no conspicuous difference is seen. Because the shortening on time of concentration causes high rainfall intensity the time of concentration and the increase of peak discharge, consequently, the runoff coefficient is not so different year by year.These results were derived only from data of the period of twenty years, in which period only a few floods were recorded. Further investigation of flood runoff ratio and runoff coefficient of Rational Formula with enough records of big floods is expected.

LOW COST TREATMENT TECHNOLOGIES FOR RECLAMATION OF CONTAMINATED SOILS AND POLLUTED GROUNDWATERS

Zareen KHAN, Anjaneyulu Y. (Center for environment, Jawaharlal Nehru Technological University)

Currently approximately 155 cubic yards of soil is contaminated with hazardous organics at Patancheru industrial estate, Hyderabad, (A.P.) India. These hazardous organic contaminants are frequently part of wastes disposed on land and the study of waste site interaction is key to assess the potential for onsite contamination of soil and groundwaters and their interference in the biogeochemical cycles. Phenol and substituted phenols are selected as the test contaminants in the present study. The data on nature of organics, soil organic content, free iron and aluminium oxides of soils which are known to influence the adsorption and desorption process of hazardous orgnics on soils are presented. Desorption isotherms of soil adsorbed hazardous organics exhibited hysterisis at higher initial concentration indicating the degree of irreversibility of adsorption-desorption process. Leaching potential of the hazardous organics decreases with their increasing hydrophobicity and soil organic content while their persistence in terms of half life time (DT50) increases. By adopting low cost treatment methods like bioremediation have demonstrated that phenols can be degraded by the concerted activity of microbial consortia under optimized conditions. Continuous monitoring of percent COD reduction, microbial count and hazardous organic concentration revealed that there is considerable decrease in the amount of organics.

STUDYIND CONTAMINATION RISK TO A DRINKING WATER SOURCE THROUGH GROUNDWATER FLOW ACROSS A DYKE IN A GRANITIC AREA NEAR HIMAYATSAGAR, HYDERABAD, INDIIA

Ratan L. DHAR[1], S. SANKARAN[2], R. RANGARAJAN[2], M.R.K. SARMA[2], V.S. SINGH[2] ([1]Groundwater Exploration & Management Group, National Geophysical Research Institute,Hyderabad, India, [2]National Geophysical Research Institute)

In order to examine the hydraulic behaviour of a dolerite dyke and its impact on the groundwater flow, multi-parameter geophysical and hydrogeological investigations were carried out. This would in turn reflect on the possibility of contamination of a drinking water source downstream of the dyke due to discharge of effluents from an oil industry. The investigations included water level monitoring, pumping tests, magnetic, electrical, resistivity and tracer studies. Groundwater flow inferred from the water level contour maps clearly indicates the existence of flow across the dyke. However, it was not possible to draw any conclusions from the pumping test because of (i) the large distance between the observation and pumping wells and (ii) pumping of the wells for irrigation is a continuous process in the area and interferes with the water level recovery monitoring in the observation wells. The tracer tests have also been inconclusive for the same reason. However, the similarity of background iodide levels of well water samples upstream and downstream side of the dyke suggests continuity of groundwater flow across the dyke. The groundwater electrical conductivity and chloride data wells located across the dyke also suggest a similar nature. Electrical resistivity and magnetic investigations have indicated that the dyke is weathered and, therefore, capable of transmitting groundwater. There is no significant contrast between the resistivity of the dyke and the surrounding granite. Low resistivity values are observed over parts of the dyke. Electrical resistivity soundings have revealed the weathered nature of dyke with the thickness of weathering varying from place to place. Magnetic studies also indicate the dyke to be weathered. The interpretation of magnetic and resistivity data estmate the depth to the hard dyke to be 6-31 m along the investigated profiles. The depth to the hard dyke could vary considerably from place to place and so also

the degree of weathering. From the results of multi-parameter investigations carried out in the area, it is concluded that hydraulic connectivity exists across the dolerite dyke facilitating the groundwater movement. A bore well drilled right into the dyke has been found to have a sustained yield. The oil industry located upstream of the drinking water source has been closed as a result of the findings of these investigations.

MONITORING OF WATER POLLUTION OF A HYDROMORPHIC ENVIRONS

Hari Shanker GUPTA (Department of Geography, University college, M. D. University, Rohtak 124 001, INDIA)

The future life support system of mankind is being threatened by the rate at which we deplete and degrade our fresh aquatic resources. The rise in human population exploits more of natural resources and this met through the growth of industries; chemical and petrochemical, urbanisation, desertification, deforestation and intensive agriculture. The industrial and urban solid and liquid waste is discharged into the rivers. The deforestation process itself aggravates the sedimentation transport into the streams. And use of chemicals in the crops contaminates groundwater through percolation, rivers and lakes through surface run-off. All these sporadic degrading activities have lead to gradual deterioration in the quality of surface and sub-surface water causing health hazards and death of human, livestock, aquatic lives, crop failure and loss of aesthetics.Keeping in view the importance of good water quality, the Central Pollution Control Board (CPCB) has initiated a series of integrated river basin studies, and established the water quality monitoring (WQM) network all over the country. The present study is taken up for measures of water pollution control in a hydrogeomorphic region (about 19388 km2, which is 7.2% of the total catchment area) with the help of GIS. A spatial GIS model has been put into analysis to monitor water quality. GIS database has been generated for storage and retrieval of attribute data for water quality. The hydrogeomorphic zonation has been suggested in terms of spatial coverage and pollution controls.Key Words: Pollutants, Hydromorphic unit, and Water Quality Monitoring

HW01/09P/D-014   Poster   1400-205

THE REDUCTION OF RADIOACTIVE CONTAMINATION FLOW BY A WATERWAY BEYOND THE BOUNDS OF THE CHERNOBYL NPP EXCLUSION ZONE

Dmitri I. GUDKOV[1], Valery V. DEREVETS[2], Sergey I. KIREEV[2], Alexander B. NAZAROV[2] ([1]Department of Radioecology, Institute of Hydrobiology, [2]SSSPE Chernobyl Radioecological Centre)

In 1986 after the termination of aerosol emissions from destroyed unit of theChernobyl nuclear power plant (NPP) the basic migration of radionuclides beyond the bounds of the exclusion zone occurs by a waterway. During 1986–2002 about132 TBq (tera-becquerel) of caesium-137 and 159 TBq of strontium-90 has flow into Kiev reservoir by Pripyat River – the main waterway of the exclusion zone.Getting into reservoir radionuclides are distributed on all cascade of Dnieper Riverreservoirs. The flow of radionuclides into the rivers influences increase on radiationdoze of the population of Ukraine at water consumption. In this connection the necessity of the careful control behind the radionuclide contents in water,estimation of its transference into Dnieper River reservoirs, and also for ecastingand prevention of such transference is obvious.The main purposes of the submitted researches were: the analysis of results ofsurface waters radioecological monitoring within territory of the Chernobyl NPPexclusion zone; the determination of the basic sources of radio active contamination of Pripyat River; the assessment of efficiency of operation mode of water-protection structures interfering of radionuclide flow into Pripyat River; the evaluation of radioactive contamination distribution beyond the bounds of the exclusion zone,as well as development and duly introduction of measures on its minimization.The greatest contribution in radionuclide contamination of Pripyat River and the formation of transference of radionuclides in Dnieper River reservoirs system bringsin radionuclide migration from periodically flooded sites of Pripyat River flood-lands,with the basic inflows of the river, and also from cooling-pond of the Chernobyl NPP. To the basic sources concern also Uzh River, which flows into Pripyat River and Braginka River flowing into Kiev reservoir.The analysis of operation of water-protection structures and radiation condition ofwater objects within exclusion zone during postaccident period shows that apriority direction at realization of water-protection measures should be creation ofdams, which protect the most contaminated territory from flooding and radionuclideflow into the river systems. To the basic tasks of radioecological monitoring o fsurface waters for the nearest period it is necessary to include the solution of aproblem of increased radionuclide flow from the territory of the left-bank flood-landsof Pripy at River due to over-wetting of these territories in connection with change ofa mode of the flow natural formation. Not less important the development of the possible scripts of decrease of water level in a cooling-pond of the Chernobyl NPPand evaluation of impact of these measures on a radioecological condition of waterobjects is occurred.

HW01/09P/D-015   Poster   1400-206

ASSESSMENT OF THE HYDROLOGIC CYCLE CONDITION IN SAPPORO

Yoshinari HAMAHARA[1], Makoto NAKATSUGAWA[2] ([1]FUKUDA Hydrologic Center CO.,LTD., [2]Civil Engineering Research Institute of Hokkaido)

The Toyohira River runs through Sapporo, Hokkaido. The upper reaches of the basin are densely forested, and the river merges at its lower reaches with the main stream. Sapporo (pop. 1.82 million) lies on an alluvial fan formed by the Toyohira River. The city has relied on the Toyohira for most of its water resources for drinking and hydroelectric power. However, population increases have necessitated the development of artificial elements in the hydrologic cycle, such as the public water supply system and the sewerage network. In recent years, rivers in northern Sapporo have experienced drought and have experienced water quality deterioration. We researched the hydrologic cycle in Sapporo toward finding solutions to these water environment problems, focusing on the artificial elements of the hydrologic cycle, such as the public water supply system and the sewerage network, for quantitative and qualitative assessment. The assessment revealed the following characteristics of the hydrologic cycle in Sapporo: 1) There are two dams at the upper reaches of the Toyohira River. Their presence makes for a ratio of annual mean discharge to 355 day discharge, which indicates dry stage, of 3.9, versus an estimated value of 6.7 if these dams were absent. This suggests that the dams contribute to stable supply of water from the Toyohira River. 2) The water quality (BOD) of the Toyohira River was assessed based on the per capita volume of organic matter in the municipal water system. Although the two dams mitigate drought, the BOD required for native fish species including salmon to live in the river and migrate up it is 3.0 mg/L or less. To meet this requirement, the river discharge must be approximately three times the wastewater discharge from the municipal water system, to allow the river water to dilute the municipal wastewater. For the Toyohira River to satisfy the above environmental requirement and to receive all the municipal water emitted from Sapporo, the catchment basin at the upper reaches would need to be 2.3 times its current size. 3) 2/3 the volume of wastewater discharge from the municipal water system is channeled into other rivers, and the remaining 1/3 into the Toyohira River. The load on the Toyohira River is reduced in this way to meet the above environmental requirement. 4) The Barato River, which runs through low flatlands in northern Sapporo, receives 1/3 the volume

H

of wastewater discharge from the municipal water system. Construction of sewerage facilities has enabled the reduction of organic pollutant emission, but eutrophication remains a problem. Based on the population and water hydrologic of Sapporo, we have clarified how the water environment in the river basin is maintained and the problems in maintaining that environment.

HW01/09P/D-016   Poster   1400-207

EFFECTIVENESS OF HYDROGEL IN WATER AND FERTILISER RETENTION

Manta Devi NOWBUTH[1], Nivedita GOKOOL[2] ([1]Department of Civil Engineering, Faculty of Engineering, University of Mauritius; [2]Faculty of Agriculture, University of Mauritius)

Hydrogels (gel forming polymers) were introduced in agriculture because of their water retaining properties. This particular study was carried out to evaluate the effectiveness of hydrogels with soluble fertilisers in highly permeable soils. Tests carried out on the hydrogels showed that the gels have a much lower absorptive capacity when dissolved salts are present in the solution. The tests carried out, clearly confirm that hydrogels dohelp significantly in retaining both water and fertilisers, and releasing them at a reasonable pace for the plant development. An experiment carried out under protected conditions, revealed that the best treatment for the particular soil, was obtained when the hydrogel was soaked in tap water and solid granular fertiliser was mixed separately in the soil. Though results indicate that there is not much increase in productivity, but as far as water requirement is concerned, the results do confirmed that hydrogels extend irrigation intervals to a reasonably economic level. Destructive tests carried out at the end of the experiment noted that a higher concentration of fertilisers within the soil with the presence of hydrogels.

HW01/09P/D-017   Poster   1400-208

THE IMPACT OF LAND-USE PATTERN ON GROUNDWATER RECHARGE AND ALTERNATIVES FOR MITIGATION

Subrahmanyam KAMBHAMPATI (National Geophysical Research Institute)

Hyderabad, the capital city of Andhra Pradesh in India is underlain by hard rock aquifers. During the past three decades a lot of developmental activities took place, the most important being the construction of building complexes, establishment of new industries and increased demand for domestic water consumption. The rainfall data for more than two decades indicates that the average annual rainfall oscillates around 900 mm. Many foreshore areas of irrigation tanks are presently occupied by housing colonies. Thus urbanization of the city has lessened the scope for natural recharge and increased pollutant loads. There is a drastic decline in the natural recharge as observed from a network of observation wells. This has caused hydrological degradation, particularly over the last 30 years. Factors responsible for this hydrological degradation include: decreased agricultural areas, changes in land use, increased drainage and groundwater abstraction, and quality changes due to indiscriminate disposal of effluents into surface water structures. The changes in landscape include the destruction of hillocks, resulting in hydraulic head losses, causing more evaporation than run-off and infiltration. The situation is becoming alarming and the only alternative is monsoon water harnessing through roof-water collection, and construction of artificial structures for enhancement of recharge. The possible structures and mitigation methodologies are suggested.

CARRYING CAPACITY BASED SUSTAINABLE DEVELOPMENT: A HOLISTIC TOOL AS APPLIED TO WATER RESOURCES FOR CENTRAL KERALA STATE

Balchand N. ALUNGAL (IAPSO)

The State of Kerala on the west coast of Indian peninsular region is blessed with numerous rivers and waterways. The southwest monsoon (June September) mainly regulates the water balance for this region followed by a scanty northwest monsoon (October November) giving rise to a bimodal distribution. The 3000 mm rainfall on this tropical belt is no exception but that the steep slopes of Western Ghats run down major portion of the precipitation along the narrow width of the state and very shallow coastal plains to the Arabian Sea. Through decades, regarded very crucial are the transport of nutrient rich waters embedded with particulates that paves the way for high productivity coastal waters. More recently, events such as river sand mining, changes in catchments characteristics, damming of flow, inter-basin transfers, abstraction for human use and accelerated agricultural practices have upset the inter relations and periodic cycling processes of this region. The resultant impacts on the water resources are well reflected in supply demand mechanisms, inabilities in adjusting to mild climatic extremities, altered status of nutrient/particulate loadings and more importantly, the failure to resolve watershed issues by correct management techniques now warrant judicious, policy backed developmental initiatives. The matured techniques exemplified towards sustainable development based on the concepts of Carrying Capacity are applied to this region as a holistic tool such that (1) the multi decadal biogeochemical cycles and currently prevailing scenario are critically assessed (2) watershed management in the realm of water resources are re-defined (3) human activities stand quantified and impacts listed and (4) locally practiced traditional techniques are integrated with new technologies to utilize as well as conserve the waters which is backed by models in the structured carrying capacity approaches.

HW01/09P/D-019   Poster   1400-210

ENVIRONMENTAL GEOCHEMISTRY OF DAMODAR RIVER BASIN: IMPACT EVALUATION OF COAL MINING AND ALLIED INDUSTRY ON WATER AND SEDIMENT QUALITY

Abhay Kumar SINGH (Geo-environment Division, Central Mining Research Institute, Barwa Road, Dhanbad -826 001, India)

Geochemical cycling has received wide attention due to the need for understanding the pathways of pollutants through our present environment. River processes form a major link in the geochemical cycle. Nearly 90% of the natural weathered, as well as man-made materials that are transported both in dissolved and particulate phase are delivered to the oceans by rivers. Geochemical study of river basins thus reveals the nature of weathering on a basin scale and helps us to understand the exogenic cycles of elements in the continent-river-ocean system. The present study deals with the elemental chemistry of medium sized river basin – Damodar River. The Damodar River Basin is sub basin and part of the master Ganga River Basin, spreading over am area of about 23,370 km^2. It flows through a vast track of rich mineralized zones of eastern India with variable topography and geology. The river flows through the countries richest coal bearing zones in its upper catchments and through alluvial and agricultural area in the lower stretch. A large number of coal based industries i.e.- coal washeries, steel plants, fertilizer, thermal power etc. are located in the Damodar basin, besides large mining activities. The major objective of the study is to evaluate the controlling factors and impact of coal mining and allied industry on the water

and sediment quality in the Damodar River basin. Na and Ca dominate the water chemistry of the Damodar River basin in the cationic abundance and HCO_3 and SO_4 in the anionic composition. Water chemistry strongly reflects the dominance of continental weathering aided by atmospheric and anthropogenic activities in the catchment area. High concentrations of SO_4 and PO_4 at some sites indicate impact of mining and anthropogenic on water quality. The high concentration of dissolved silica, relatively high (Na+K)/TZ+ ratio (0.2-0.4) and low equivalent ratio of (Ca+Mg)/(Na+K) indicates significant contribution of dissolved ions by the weathering of aluminosilicate minerals of crystalline rocks. The seasonal data show minimum ionic concentrations in the monsoon season, reflecting the influence of atmospheric precipitation on TDS contents. The suspended sediments show positive correlation with discharge and both discharge and suspended load reaches their maximum value during the monsoon season. The elemental composition of the sediments is characterised by the dominance of Si, Al, K, Fe and Na, constituting 75% of the elemental abundance. The suspended sediments show increased concentrations with respect to the bed sediments for the elements Al, Mg, Fe, Ti, and Ni and reduced concentrations with respect to Si, Na, Ca and K. The suspended sediments are finer and richer in multiple hydroxide coatings and heavy metal scavenging clays, so they carry higher heavy metals loads compared to the bed sediments. The concentration of heavy metals in the finer size fraction (<37 µm) is significantly higher than the bulk composition. The Igeo value calculated for Fe, Mn, Zn, Ni and Cr is well below '0' grade suggesting that there is no pollution with respect to these metals in Damodar River sediments.

HW01/09P/D-020   Poster   1400-211

OCCURENCE AND CONSEQUENT HAZARDS OF EXCESSIVELY NUTRIENT SEDIMENT IN ARTIFICIAL RESERVOIRS

Kazuo OKUNISHI (Japan Institute of Land and Environmental Studies)

Excessively nutrient sediment found in freshwater bodies of any dimension and in estuaries has been referred to as "Hedoro" in Japanese and has been translated in English simply as sludge. It is commonly muddy and very loose with much pore water which is in anaerobic condition. Hedoro was comprehensively recognized as different from natural nutrient mud at first in Japan when it occurred in the estuaries affected by an industtrial complex in 1950's causing serious environmental hazards. Sometimes, hedoro involved such poisonous substances as organic mercury that caused Minamata Disease (mud hatter´s disease). Hedoro has been frequently found in the freshwater bodies of different sizes that receive untreated sewage water. The hazards caused by hedoro in artificial reservoirs had been recognized only locally until the ecosystem of the Kurobe River, Japan, was badly spoiled by hedoro, when the sediment in one of the upstream dam was flushed in order to recover its storage capacity. Here I will compile the result of the research of Japan Institute of Land and Environmental Studies into the environmental problems of the hedoro that occur in the Tonoyama Reservoirs in an upstream reach of the Hiki River, Wakayama Prefecture, Japan. The Hiki River has recorded hazardous floods 11 times in 74 years between 1984 and 1957. After the construction of the Tonoyama dam, the equivalent floods occurred 22 times between 1958 and 2002, with the biological hazard caused by the hedoro involved in the flood water. A laboratory experiment proved that the ponding of water with hedoro suspended in it reduced the harvest of rice by 27% in weight while the ponding of clear water presented a reduction of 10%. Analysis of the composition of different species of diatom in the samples of hedoro taken from the flooded rice field in the downstream part of the drainage basin and from the bottom of the reservoir, and in the mud adhering the channel bed boulders in the tributary rivers showed that most of the diatom in the flood deposit in the downstream areas had come from the bottom of the reservoir, not from the tributary rivers or upstream rivers pouring to the reservoir. Although the samples of hedoro from the bottom of the reservoir contained relatively small amount of organic matter, the cavities commonly found in it suggest that the deposit was subject to the anaerobic fermentation with emission of methane. A local citizen group working in the area of Kurobe River has found that the collective deposition of sediment involves much quantity of fallen leaves, which becomes harmful to the aquatic ecosystem when disintegrated biochemically under anaerobic conditions. Taking this finding into account, the influx of organic material in excess of the oxygen supply needed for its aerobic disintegration can be a major cause of the generation of hedoro in the reservoir and consequent environmental hazards.

HW01/09P/D-021   Poster   1400-212

WATER SHED DEGRADATION AND WATER CONSERVATION CHALLENGES IN RIAANA RIVER CATCHMENT WITHIN THE VICTORIA DRAINAGE BASIN IN KENYA

George ONGWENYI, JOHN M. NYANGARA (Post-graduate programme in Hydrology, Faculty of Science, University of Nairobi)

Watershed degradation problems are worldwide in extent, leaving no continent unaffected. It is global in its environmental and socio-economic impacts. The need to address the global problem of watershed degradation is increasingly urgent as it is a major cause and mechanism of global loss of productive land resources in particular water resources. It can lead to economic instability and political unrest in the affected areas. The management of water resources possess several challenges to water resource planners, policymakers, politicians, researchers and academicians woldover-The major challengers include inadequate or lack of hydrological and hydrometeorogical networks, leading to poor river regime forecasting and subsequent determination of water resource quantities. Technical mistakes during design and construction of water abstraction structures, upstream downstream water use conflicts, individual vs community, and institutional vs individual or community conflicts, legal and water pollution challenges adds to the long list of possible challenges. It is important that these challenges are addressed urgently to ensure availability of sufficient water for use by mankind. This paper addresses water management challenges to ensure in Kericho District in Western Kenya. Conclusive Recommendations for solving some of the challenges and the way-forward are suggested.

HW01/09P/D-022   Poster   1400-213

CONTAMINANT ARRIVAL-TIME DISTRIBUTIONS FROM A RANDOM WALK MODEL OF HYPORHEIC TRANSPORT

William Earl BARDSLEY (Department of Earth Sciences. University of Waikato)

A simple random walk model is used to approximate a pulse of conservative contaminant released into stream water which interchanges with sub-channel groundwater. It is assumed there is steady stream flow and minimal longitudinal channel variation between the release point and a monitoring point at some distance x downstream. In a unit of time a contaminant particle in the channel water either advances downstream a small fixed distance b, or moves vertically down into the hyporheic zone a small fixed distance c. The respective movement probabilities are defined as p and $1-p$. A contaminant particle which has previously entered the hyporheic zone moves the (vertical) distance c in unit time, upward or downward, which may or may not return the particle back to the channel. The upward and downward movement probabilities are respectively defined as p and $1-p$. No constraint is placed on the relative sizes of b and c, although c is likely to be small relative to b. The use of p in both

vertical and horizontal contexts gives rise to contaminant arrival-times which are mathematically equivalent to a simple 1-dimensional random walk model with probabilities of steps to the right or left of p and $1-p$ respectively, where rightward movement represents the downstream direction. The resulting contaminant arrival-time distributions at the monitoring point are as follows: For $p \neq 0.5$ the arrival-time distribution is inverse Gaussian, which tends toward a normal distribution limit for sufficiently large x. For $p = 0.5$ the arrival-time distribution is a highly-skewed form which is distance-invariant and characterised by a long right tail with the log of contaminant concentration decreasing linearly with gradient $-3/2$ against log of time. This is illustrated with an example data set from a tracer experiment. The skewed distribution corresponds to an equivalent model of Brownian particle arrival times with zero drift, which predicts that the waiting time for contaminant concentration to decline to less than a specified value will increase with travel distance as $x^{2/3}$. For $p < 0.5$ some of the contaminant particles never escape the hyporheic zone and the proportion of permanently lost particles increases with travel distance as $[1 - \exp(-kx)]$, where k is a positive constant. The random-walk model is capable of further extension, such as placing a reflecting barrier at the base of the hyporheic zone.

STABLE ISOTOPES IN LEKE STECHLIN CATCHMENT AND ITS VICINITY

Ekkehard O. HOLZBECHER[1], Andrea KNAPPE[2], Asaf PEKDEGER[2], Gunnar N-ZMANN[1] ([1]Humboldt University Berlin, [2]Free University Berlin)

An extended observation campaign was undertaken in the watershed of Lake Stechlin watershed and its vicinity, sampling several chemical species, including stable isotopes D and O^{18}. Measurements are available from precipitation, from seepage water and groundwater at different depths, and from various surface water bodies. Data show that local meteoric and evaporation lines can be clearly identified in the ΔO^{18}-ΔD diagram. A part of the hydrological cycle can be traced, following seepage water and groundwater to lake water - the lake is almost entirely fed by groundwater. The concentrations of stable isotopes (ΔO^{18}=-2 per mille),measured in Lake Stechlin surface water, is unexpectedly high. It is still an open question, whether this can be attributed to the operation of the now abandoned atomic power plant. During operation of the plant the lake was utilized as part of the external cooling cycle. In the contribution it is attempted to answer this and other questions by a model, which is currently being set-up. The model takes advantage from the fact that a data-base of environmental parameters is available for Lake Stechlin from past observation campaigns and research activities, which accompagnied already the planning of the power plant in the 1960s. Nevertheless, stable isotopes were neglected, and the newest measurements open the chance, to confront former assumptions and results with new data.

HW01/09P/D-024	Poster	1400-215

INFLUENCE OF INTENTIONAL WATER STORAGES AND RELEASES ON HYDROLOGICAL PROCESSES OF DIFFERENT REGIONS IN THE MEKONG RIVER BASIN

Nmns Bandara NAWARATHNA, So KAZAMA, Masaki SAWAMOTO (Department of Civil Engineering, Tohoku University)

Controlled water storage and release activities in reservoirs and irrigated crop fields affect the hydrological cycle of large-scale watersheds. Water storing devices have been constructed to meet water demands especially for agriculture and power supply with increasing population. However, some of those human activities have adversely resulted in insufficient water resources and harmful environmental impacts in downstream locations. Availability of Geographical Information System (GIS) data sets of watershed physical properties such as land use, soil types, geology and the advancements gained in obtaining distributed meteorological variables with the help of GIS have stimulated the development of physically based hydrological models. Introduction of block wise approach to the TOPMODEL with Muskingum-Cunge flow routing method (BTOPMC) has enhanced the applicability of TOPMODEL from hundreds of square kilometers to several ten thousands square kilometres river basins. In the block wise approach, a watershed is divided into blocks and local saturation deficit which controls the depth to the saturation zone is calculated with respect to the block average saturation deficit value. The optimum number of blocks, which results in maximum simulation efficiencies produces the maximum standard deviation of block average soil topographic index. The BTOPMC model is used to simulate hydrological processes in the effective watershed of 277,000 square kilometers from Luang Prabang to Pakse in Lao PDR along the Mekong River. Model parameters are assigned as functions of watersheds physical properties. Reservoir activities in the watershed are taken into account using simplified ruling curves determined by the purposes of the operation and catchment area. Water storages and releases from irrigated crop fields are taken into account by introducing desirable water level function to the relevant grids. The Manning's coefficient along the main stream and tributaries are assigned as a function of slope and the best Manning's coefficient value at the most downstream location. Average Manning's coefficient values found for both the main river and tributaries are 0.029 and 0.034, respectively. Nash-Sutcliffe coefficient was used to evaluate the simulation accuracy. The efficiency coefficients were estimated for five gauging stations along the main stream. The value ranges from 93.5% to 95.4%. Simulation accuracy has significantly improved after considering intentional water storages and releases activities in the watershed. Hydrological processes are thoroughly studied at different climatic regions of the basin. Sub-basins annual evapotranspiration ranges from 470 mm to 620 mm. It was found that in lesser rainfall areas, 95% of the days in a year produce daily runoff that is less than that of basin average. The figures are 88% and 57% for an average and higher rainfall areas respectively. It has been found that there is sufficient water resources in mountainous areas in Lao PDR whereas flat irrigated fields in Thailand need to get water from nearest potential locations to meet their requirement.

GENERATION OF DATA BASE FOR EROSION PREDICTION OF HYDROLOGICAL BASINS

Hari Shanker GUPTA (Department of Geography, University College, M. D. University, Rohtak, 124 001 India)

Geographic Information System (GIS) coupled with Remote Sensing has proved as a powerful tool in the field of land evaluation and management. Various studies have been reported across the world, illustrating the application of GIS in the evaluation and management of landform, soil and water resources. In the present study, GIS capabilities have been utilized to understand the erosion potential and slop stability characteristics of a small catchments zone from a highly important terrain segment of bio-diversity hot spots in peninsular India. A multi- thematic analysis based on different physical factors has been adopted to generate integrated maps on erosion proneness as well as on critical slope under a GIS platform for terrain evaluation. The spatial data on erosion proneness has demonstrated that 17.62 Square Km. Area, out of –140 Square Km. in the catchments zone, needs careful attention for Eco- restoration. In the critical slope map four land stability

---

classes have been demarcated. The area represented as unstable and moderately stable is found to be important for slope stability problems. Temporal change as well as the extent of loss in the perennial status of tributaries has been recorded to evaluate the landform changes. A catchment's treatment plan has also been suggested.Key Words: Spatial Data, Critical slop, and Temporal change

HW01/09P/D-026	Poster	1400-217

AN ENHANCED MONITORING METHODOLOGY OF THE RIVERBED MORPHOLOGICAL CHANGES, APPLIED ON THE LOWER COURSE OF THE DANUBE RIVER

Constantin Stefan SAVA (National Institute of Marine Geology and Geoecology - GeoEcoMar, Bucharest - Constanta, Romania)

In the frame of the PHARE project 'MMorphological Changes and Abatement of Negative Effects on a Selected Part of the Danube River scientists and specialists from Austria, Bulgaria and Romania carried out a surveying experiment in the Zimnichea-Svistov research pilot sector. The main task of this project is the assessment of geo-morphologic changes of the River Danube. For that purpose it is necessary to compare the situation in different epochs and to assess the occurring differences. This comparison can be done quantitatively by derivation of certain geometric properties (for instance volume differences) or qualitatively. Qualitative comparisons aim to detect if changes have occurred and if yes, what kind of changes. Quantitative assessment tries to give an exact measure of these changes. The aim of the experiment was the surveying and mapping of this selected reach of the river, applying new technologies, in order to establish the preconditions for remedial actions:- Development and application of modern methodology and technology including GPS use for surveying and mapping of the Danube River;- Generation of precise maps of the riverbed from historical and current measurements;- Assessment of morphological and hydrological situation and its development for planning of remedial actions based on a common view and perception of the major processes. It is proposed that all Danubian countries should use a uniform co-ordinate and height systems for all control points, benchmarks and gauges, situated along the river banks and on the islands. The bases of these systems are EUREF and EUVN. Results, such as maps of the Danube River, GIS-applications, etc. have to be prepared in Lambert conic map projection. This system is named System 2000. Optimal values of the parameters are derived.

HW01/09P/D-027	Poster	1400-218

MEASURING VERTICAL WATER FLUX AND CONVECTIVE SOLUTE TRANSPORT IN FOREST SOIL WITH CONTROLLED-SUCTION-PERIOD LYSIMETER

Ken'ichirou KOSUGI, Akihito YOSHINO, Masanori KATSUYAMA (Graduate School of Agriculture, Kyoto Univ.)

The unsaturated infiltration of rain and irrigation water and solute transport in the vadose zone are major processes in hydrological and biogeochemical cycles. They are important for understanding groundwater quality and material balances in ecosystem. Although the convective chemical transport in the vadose zone can be quantified by measuring both the unsaturated water flux and the solute concentration of flowing water, few studies have accurately measured convective chemical fluxes in the field. This is partly because the existing techniques for sampling unsaturated soil water are not necessarily appropriate, considering the mechanism of soil water flow. This study evaluated the long-term performance of a recently developed controlled-suction-period lysimeter in the field. The lysimeter consists of two tensiometers and a porous plate connected to a vacuum system. The soil matric pressure heads immediately above the horizontally-buried porous plate, and at the same depth in the natural soil profile, are measured at 3-second intervals. The vacuum system is automatically controlled so that the readings of the two tensiometers match. The lysimeter was installed at a sampling depth of 30 cm in a sparse mixed evergreen and deciduous broadleaved forest, and at a sampling depth of 50 cm in a evergreen coniferous forest. At both monitoring sites, the lysimeter succeeded in maintaining the soil moisture condition in the sampling profile as about the same as that in the natural soil profile for most of the monitoring period, and water extraction by the lysimeter did not cause remarkable convergence or divergence in the soil water flow. The water-loss due to evapotranspiration estimated from the water-sampling rate showed a reasonable seasonal trend, as compared with the evapotranspiration rate. Combining the soil water flux data measured by the lysimeter with the results of chemical analyses of the sampled water, convective chemical fluxes in the vadose zone were quantified. Since the lysimeter minimized the disturbance of soil moisture in the sampling profile, the physical soil environment in the sampling profile, which affects biological and chemical reactions, was maintained at a similar state to that in the natural soil profile. At the sparse mixed forest, a sinusoidal seasonal trend was found in the dissolved silica concentration of the sampled water which corresponded to the seasonal trend in soil temperature. Although no nitrate was detected in the sampled water at the sparse mixed forest, the nitrate concentration of the sampled water at the coniferous forest showed a seasonal trend affected by the balance between litter-decomposition and uptake by plants. As a result, data observed with the controlled-suction-period lysimeter could be used effectively to analyze material balances in the vadose zone, and to validate numerical simulations, thereby contributing to the prevention of soil and groundwater contamination.

HW01/09P/D-028	Poster	1400-219

STATISTICAL MODELLING AND ESTIMATING THE IRRIGATION AND MAN-MADE EFFECTS ON ANNUAL RUNOFF AND WATER RESOURCES

Natalie LOBODA (Department of Hydrology & Water Resources, Odessa State Environmental University (OSEU))

The modern land use activity and necessity of governing by complex water systems in order to provide a rational use stimulate so called the technological direction in the hydrology science. It is supposed a calculation and estimate of changing the river runoff due to the land use activity and anthropogenic effect. Use of the water resources for needs of collective farm, irrigation and other ones is possible due to the using the annual runoff of rivers which are regulated by the pond and water reservoirs. Differential estimate of the annual runoff changing due to the irrigate and artificial water reservoirs effect is possible under availability of sufficiently long sets of natural runoff and detailed information about dynamics of factors which determine the level of the watershed technological use. As a rule, such data are available only for large river basin. For little and middle rivers an account of the water use is carried out non systematically or absent entirely. So, it is of a great importance a carrying out the imitative numeric models for runoff on the basis of modelling runoff sets with the use of initially known parameters of the functioning technological water systems. In our paper a new techniques is developed to carry out modelling the pond, reservoir and irrigation effects on the statistical parameters of annual runoff time series and state of water resources. We started from new statistical models, which are presented in (Loboda, NATO Advanced Research Workshop, Moscow, 1998). An effect of the land use activity on the water resources is provided by nature factors (speech is about link with climate stochastic vibrations) and by the land use activity level. In order to model an influence of ponds and

H

reservoirs as artificial land shaft objects, it is used a modified balance equation for the annual runoff layer under availability of the ponds and reservoirs in the watershed. The key physical parameters are taken into account, in particular, ; parameters of the artificial water reservoirs, atmosphere precipitation, the watershed parameters etc. It is also considered more complicated and adequate balance approach, based on the generalized memory functions formalism. A modelling of the annual runoff sets is carried out on the basis of balance equation by means the Monte-Carlo methods. Necessary parameters for the annual runoff set generation are the norm, variation and asymmetry coefficients and also information about inside set correlation. As example, we present the results of calculation for the effect of anthropogenic activity on annual runoff features for rivers of territory of Ukrainian south and republic of Moldavia. The effect of anthropogenic activity is in significant degree defined by the moisture of studied territories. Under consideration of the more acid territories the natural water resources are decreased and the anthropogenic factor role is increased.

TRANSFORMATION OF GROUNDWATER QUALITY UNDER ACID RAIN IMPACT

Anna P. BELOUSOVA (Water Problems Institute of RAS)

If in humid zones an evolution process in the direction of groundwater acidification under the impact of acid rain, then in semiarid zones in oil field this process develops successively in two opposite directions from alkalization to acidification of neutral groundwater. It is known that hydrocarbonate groundwater possesses a high protective natural geochemical potential, supporting neutralization of acid atmospheric precipitation. Natural hydrocarbonate water undergoes three stage of anthropogenic transformation caused by acid atmospheric precipitation over more than 50 years of oil field development. The first stage is transformation of neutral hydrocarbonate water into alkaline water and high alkaline water, accompanied by calcite precipitation and sodium carbonate dissolution from the unsaturated zone. The second stage is transformation of alkaline water into neutral hydrocarbonate water; the carbonate content, being lessthan the lower limit for background concentrations, showed reduced water buffering properties or protective potential relative to acid pecipitation. The third stage is transformation of neutral hydrocarbonate water into acidic water, with a complete loss of protective geochemical potential. This unfavorable ecological situation with groundwater showsthat even natural hydrocarbonate groundwater less protected from the impact of acid atmospheric precipitation an oil field in the semiarid zone.

CHANGE OF GROUNDWATER REGIMES IN RESPONSE TO URBANIZATION

Jiu J. JIAO (Department of Earth Sciences, University of Hong Kong)

Steep terrain in Hong Kong has forced around six million people to congregate in only about 165 km ^{2} near the coast, creating the highest population density and tallest buildings in the world. The construction of high-rise buildings requires extensive deep foundation and ground engineering work including large bored pilings and diaphragm walls. Consequently, the natural soil to depths of a few tens of meters, usually a zone with the most active groundwater flow, is largely replaced by concrete and other construction materials. This paper studies the change of extensively urbanized area of about 6 km ^{2} located on the north facing slopes of Hong Kong Island. This area consists of volcanic and granite rocks overlain by colluvium and residual soils and has a history of instability owing to the steep topography. A long history of engineering activities, including housing and road construction and slope work, has resulted in a wealth of data on the geology, hydrology, and geotechnical engineering of the area. A three-dimensional geological model is constructed based on information from over 400 boreholes. A review of the historical information indicates that numerous springs located in the lower part of the hillslope were extinguished in the process of urbanization. In recent 20 years, the seepage zone at the hillslope has moved uphill by several tens of meters to over 100 meters. A groundwater flow numerical model along a typical section is established and calibrated by comparing the simulated water levels with the observed ones. The modeling results show that the hydraulic conductivity in the shallow zone of the lower part of the slope is about one order of magnitude lower than that in the upper natural slope. The significant decrease in the hydraulic conductivity may reflect the modification of the natural aquifer system due to deep foundations of the extremely crowded buildings in the urbanized area. This paper goes on to discuss the possible undesirable engineering and environmental effects due to extensive urbanization, a process rapidly affecting many coastal areas of the world.

DENUDATION AND TRANSPORT OF TERRESTRIAL MATERIALS FROM A TROPICAL (KAOPING) RIVER WATERSHED

Jia-Jang HUNG, C.-Y. YANG (Institute of Marine Geology and Chemistry, National Sun Yat-Sen University)

Recent studies have demonstrated the importance of river fluxes from western Pacific islands in contributing to the global riverine material flux. The Kaoping River is a tropical, island-type river with the largest drainage area in Taiwan. In order to understand the denudation rates of river basin, the temporal and spatial distributions of hydrochemical parameters, total suspended matter (TSM), major ions, dissolved and particulate species of carbon in the Kaoping River were measured from August 1999 to August 2000. The total, physical and chemical weathering rates were estimated to be 7368, 5985 and 1383 g/m^2/yr, respectively. Such physical and chemical weathering rates are much higher than those reported from world rivers. The generation of total carbon (DIC+DOC+PIC+POC) from the Kaoping drainage basin was about 176 gC/m^2/yr. The yields of DIC, DOC, PIC and POC were 110 (63%), 2.27 (1.2%), 18.4 (10.4%) and 45.4 (25.4%) gC/m^2/yr, respectively. These carbon yields are very high in comparison with ones obtained from the Langyang River in northern Taiwan and the other major rivers in the world. The annual fluxes of riverine of DIC, DOC, PIC, POC and TC from the Kaoping River were about 34.5, 0.71, 6.02, 14.7 and 63.2 x 10^{10} g C, respectively. Regarding the nutrient loads, the fluxes of total dissolved nitrogen (TDN) and phosphorus (TDP) were 2.3 x 10^9 and 3.4 x 10^7 mole/yr, respectively. More than 80% TDN and 60% TDP were derived from anthropogenic sources. Human activities appear to play a major role on affecting the generation, transport and transformation of terrestrial materials in the Kaoping drainage basin. This study confirms that small mountainous rivers may contribute significantly to global fluxes of terrestrial materials.

STUDY ON TRANSPORT MECHANISM OF AL IN FOREST WATERSHED OF A SUB-URBAN FOREST IN JAPAN

Min-Sik KIM[1], Chisato TAKENAKA[1], Kyoji YOSHIDA[2], Ho-Taek PARK[3] ([1]Graduate School of Bioagricultural Sciences, Nagoya University, [2]Aichi Environmental Research Center, [3]Aichi science

and technology foundation, Aichi Industrial Institute)

Concentration of aluminum ion in soil water is considered as an indicator of soil acidification. Even so, the concentration decreases through infiltration process in soil layer with increase in pH value and reaches quite low level in stream water. In case of Foresta Hills in Aichi prefecture, high concentrations of aluminum (above 0.07mM) have been observed in the stream water although the pH value is almost neutral. In this work, in order to clarify the mechanism of aluminum runoff, spatial and temporal changes of chemical property of soil water and stream water were observed in Foresta Hills. Foresta Hills is located in Toyota city, Aichi-prefecture, Japan (137° 11´27˝E, 35° 02´00˝N.L.) and varies from 40m to 105m in altitude. The surveyed area belongs to a temperate secondary forest, where the dominant tree species are *Quercus serrata*, *Q. variabilis* and *Evodiopanax innovans*. The soil originated from granite bed rock. In the study area, the annual precipitation is 1272mm and the mean temperature is 16.8°C in 2001. The soil type is slightly dry brown forest soil (Bd). Sampling of stream water were done at 5 sites and that of soil water at one site. Performed sampling was once every week from May 9, 2002 to January 17, 2003 in Foresta Hills. Samples of stream water were collected at 20 m intervals from the sampling site of soil water. The pH and EC values were measured using a model WM-22WP (TOA, Japan). After filtration with a 0.45μm membrane filter, cations were analyzed using a Nippon Jarrell Ash IRIS Inductively Coupled Plasma Spectrophotometer (Na+, Mg^{2+}, Ca^{2+}, K+, Fe, Mn, Zn, Cu, Si, Al). Anions (Cl-, NO$_3$-, SO$_4$$^{2-}$) were analyzed using a Shimadzu PIA-1000 Ion Chromatography. During the study period, pH values of stream water ranged between 6.14 and 6.99(average of 6.52) and had statistically a little difference among season. However, the pH values of soil water in the upper stream ranged from 5.73 to 6.54(average of 6.10) and were lower than those of stream water. The mean concentrations of aluminum in stream water and soil water were 0.046mmol/L and 0.063mmol/L respectively, and higher values were observed at high discharge event. The concentrations of aluminum decreased from upper-stream to down-stream by intervals. The aluminum concentrations showed significantly correlation with Fe and Si concentrations in stream water and soil water. These results indicate that the high aluminum concentrations were derived from the weathering of bed rock. Therefore, the chemical species of aluminum in the neutral stream water would be clarified.

CHANGE OF SULFATE BUDGET AND FLUX BY PARTIAL DISTURBANCE WITH PINE WILT DISEASE

Su-Jin KIM, Nobuhito OHTE, Masatoshi KAWASAKI (Division of Environmental Sciences & Technology, Graduate School of Agriculture, Kyoto University)

Sulfur is found in a wide variety of inorganic and organic forms in forest ecosystems. Sulfur is an important element in the biogeochemistry of forest ecosystems because its role as an essential plant nutrient, and the contribution of sulfate as a counter ion in altering the flux of other elements, especially basic cations in soil solutions. Overload of sulfuric deposition can disturb terrestrial ecosystems not only plant physiology, but nutrients dynamics in soil. With economic and populational growth of Asia, it is considered that release of this local S oxide increases to 44TgS/yr in 2020. This overload may affect the nutrient cycle in forested ecosystems in eastern Asia. However, there is little information on S dynamics in a forest ecosystem compare with other nutrient in Japan. To evaluate response of sulfate dynamics to partial disturbance with pine wilt disease in a temperate forest catchment, we conducted a series of field experiments. Sulfate concentration in soil solutions were increased after peak of nitrate concentration at disturbed area. It suggested that nitrate seasonality is originated by lost of uptake and the influence on nitrate leaching following the unusual decomposition associating with pine-wilt. It is also considered that these results were due to pH depression originated by increase of nitrate concentration way enhanced sulfate adsorption to anion exchange site. Sulfate budget in upper soil layers (0-30cm) were larger than deeper layers (40-100cm). Sulfate budget in surface soil layer at disturbed area was largest than other layers. It may assume that mineralization of organic S from humus and retention of inorganic sulfate by soil. Moreover, 20-30 cm layer at disturbed area was showed increasing of sulfate budget. Increases of sulfate budget suggested that result from decomposition of root, which is residue due to pine wilt disease. While, deeper layers were showed different trend comparing to surface layers. Sulfate budget in 90-100 cm layer at unsaturated area increased, however the same layer at disturbed area decreased. It suggests that increase of sulfate budget at unsaturated area resulted from retention of sulfate by adsorption, because adsorbed sulfate concentration in 90-100 cm layer at unsaturated area highly increased comparing to surface soil. Consequently, disturbed area has low retention ability resulting from low adsorption of sulfate, and has large movement of sulfate with soil water infiltration. Sulfate concentration increased with depth, whereas nitrate concentration decreased with the depth of the groundwater at saturated area. Discharges from high concentrations of nitrate in shallow groundwater increased stream nitrate. During the winter, when groundwater levels were low, stream flow was dominated by deeper groundwater, which increased streamwater sulfate concentration. These results suggest that hydrological processes are important to clarify sulfate discharge to forest disturbances.

THE ROLE OF HORTONEAN OVERLANDFLOW IN STORM RUNOFF IN HINOKI PLANTATION, MIE, JAPAN

Yuichi ONDA[1], Maki TSUJIMURA[1], Daiji Harada HARADA[2], Taijiro FUKUYAMA[3] ([1]Institute of Geoscience, University of Tsukuba, [2]Department of Emvironmental Earth Science, Aichi University of Education, [3]Graduate School of Bioagricultural Sciences, Nagoya University)

The field evidence collected in the 1970's showed that in forested hillslopes, infiltration capacities almost always exceeds the rainfall intensities. In Japan, Hinoki (*Chamecyparis Obtusa*) plantation distributes widely because of the expensive log price. In unmanaged Hinoki plantations, understory vegetation decreases and the litter of Hinoki is known to be likely to move downward. Therefore, from the field observation, Hortonean overlandflow may occur. In addition, the soil erosion in Hinoki plantation has been the serious problems in Japan. In this study, we monitored the runoff in small catchments in unmanaged Hinoki plantations to understand the importance of Hortonean overland flow for understanding the human impact on hillslope stormflow path in Japan. The study catchments locate in Ohmiya village, Mie Prefecture, central Japan. We installed two Parshall flumes in unmanaged Hinoki plantations, and one in broad leave tree area. Electrical conductivity of runoff water is monitored continuously and in selected storm events, in situ water sampling was conducted 1 or 2 hour interval and dissolved ions were analyzed. When the rainfall intensities were high, runoff peaks coincide with rainfall peak in unmanaged Hinoki plantations, but runoff peaks were low and sometimes delayed to the rainfall peak in the broad-leaf forest. The storm hydrograph in Hinoki plantations were separated into two or three components, using electrical conductivity and Cl ions. When rainfall intensity was high, rainfall components occupied 49-67% of the storm hydrograph. This shows that the importance of the rainfall components in overland flow during rainstorm in unmanaged Hinoki plantations.

HW01/09P/D-035   Poster   1400-226

SPATIAL VARIATION OF AEOLIAN AND BEDROCK MATERIALS IN THE SURFACE SOIL ALONG A SLOPE IN THE KAWAKAMI BASIN, CENTRAL JAPAN

Yoriko YOKOO[1], Takanori NOKANO[2] ([1]Institute of Geoscience, University of Tsukuba, [2]The Graduate School of Life and Environmental Sciences, University of Tsukuba)

Elements in soil are partitioned into various phases such as soil minerals, organic matter, and soil solution. A-horizon with dominant organic mater constitutes an important soil component to elucidate and predict the response of recent changes of atmospheric environment on forest ecosystems, because it provides active sites for the interaction and circulation of elements between plants and exchangeable components in the soil. Soils on volcanic rock substrate, termed as kuroboku from its black color, are widely distributed in Japan. In order to evaluate the provenance of soil minerals and their relationship to vegetation, we determined Sr-Nd isotopic ratios and elemental compositions of andesite soils and their coarse-grained and fine-grained minerals along a small slope in the Kawakami forested basin of central Japan, which is divided by a valley in the lower and a woodland path in the upper. Sr and Nd in dehydrated soil is mainly contained in minerals and its $^{87}Sr/^{86}Sr$ ratio varies widely from 0.7044 to 0.7070 along the slope. However, coarse-grained minerals (>20 μm) in the soil have relatively homogeneous $^{87}Sr/^{86}Sr$ (0.7042-0.7046) and $^{143}Nd/^{144}Nd$ (0.5125-0.5127). As the values are slightly higher than the $^{87}Sr/^{86}Sr$ and lower than the $^{143}Nd/^{144}Nd$ of original andesite (0.7040 and 0.5128) but are indistinguishable from those of strongly altered andesite, it is assumed that the coarse-grained minerals were largely originated from the chemical weathering of bedrock minerals through which the atmospheric Sr of high $^{87}Sr/^{86}Sr$ (0.708 in the annual average) and REE were mixed. In contrast, the fine-grained minerals (<2 μm), mainly composed of illite and quartz, have high $^{87}Sr/^{86}Sr$ (0.710- 0.714) and low $^{143}Nd/^{144}Nd$ (0.5122-0.5125) due to an incorporation of aeolian minerals (~0.720 and 0.5120) originated from arid areas in northern China. It is estimated that the proportion of the aeolian minerals in the fine-grained soil minerals and in the bulk soil range from 14 to 22% and 6 to 19%, respectively. These data indicate that the Sr-Nd isotopic compositions of aeolian minerals do not change in the soil environment, demonstrating their usefulness as provenance tracers. In the upper slope, the aeolian-mineral contribution tends to decrease systematically with elevations from 20% down to 10%. This systematic decrease is caused by the input of secondary minerals of bedrock origin which was supplied from the regolith discarded at the construction of woodland path. This is consistent with elemental patterns which show that elements (Si, Al, Ga, Cu) normalized to Ti, an immobile element, tend to increase upward. The $^{87}Sr/^{86}Sr$ of vegetation and soil solution and their variation pattern along the slope are entirely different from those of soil minerals, showing no vital exchange of Sr and other elements between the two components.

HW01/09P/D-036   Poster   1400-227

ANTHROPOGENIC EVOLUTIONS OF PEAT SOILS AND CHANGES OF THEIR HYDROPHYSICAL PROPERTIES

Elena N. ROVDAN (Belarus, 10, Staroborisovsky tr., Minsk, 220114, BELARUS)

Natural evolution of the most ancient peat soils of Belarus Polesye took place during the last post-glacial period-holocene. Anthropogenic evolution of meliorated peat soil proceeds much quicker   and going on no longer that 300 years and most often during last tens years. Drainage amelioration changed natural orientation of geochemical processes in soils, which are expressed in partial destruction of soils organogenic layer due to mineralization and erosion processes, humus content decrease and variation of its qualitative composition. Agricultural utilization of the soils leads to mixture the peat with underlying sand soils. As results the great territories of peatlands have been turned into anthropogenic organic-mineral formations, requiring both special study and special use methods. Genezis and properties of peat soils stipulate the unfaivorable thermal rezime for grow and development of plants on the organic soils as compare with mineral soils. The sand application to drained peat soils is one of the methods to protect these soils from fast decomposition of organic matter and to change their hydrothermal regime. In spite of wide usage of the method there is lack of investigations about affect of the sand application on hydrophysical properties of peatKnowledge of soil hydraulic conductivity and water retention is required for quantitative description and prediction of water and solute transport processes, to quantify effects of land use, soil management on soil structure related processes, to predict the impact of human influences on the environment.The hydraulic conductivity of peat soils at different stages of organic matter transformation, peat, sand and their mixtures have been investigated by using TDR and instantaneous profile methods. Transformation of the peat soils as results of drainage and utilization leads to change in porosity, pore size distribution, bulk density, ash content, water retention, saturated and unsaturated hydraulic conductivity. Peat soils at aerobic conditions contain the greatest quantity of water at the saturation, but it gives its water more easily with increasing water potential. The water retention capacity of the drained peat soils which have reached a more advance stage of decomposition is lower, and the loss of water with increasing the water potential are also smaller. The surface peat layers do not show similar regularity with regards to their hydraulic conductivity as to deeper peat layers but the difference between the hydraulic conductivity is not large. Hydrophysical properties of peat sand mixtures are strongly depends from relation of organic and mineral parts. The most drastic changes in water retention of peat sand mixtures takes place in the region of the small quantity of organic matter content in systems (up to 20 % of organic matter content). The results obtained have been generalized using Mualem-Van Genuchten equation and parameters of the model have been defined.

HW01/09P/D-037   Poster   1400-228

SPATIAL VARIABILITY OF HYDROCHEMICAL DYNAMICS IN WEATHERED GRANITE CATCHMENTS

Masanori KATSUYAMA, Masayuki ITOH, Nobuhito OHTE, Hiroshi ITOH, Makoto TANI (Graduate School of Agriculture, Kyoto University)

To understand the differences of the hydrochemical processes between catchments, the variability of the catchment scales must be considered. In this study, the hydrochemical dynamics from headwaters to a 2-order catchment are examined at the Kiryu Experimental Watershed (KEW) located in Central Japan (34°58´N, 136°00´E). The entire area of KEW consists of weathered granitic rock and the vegetation mainly consists of afforested stands of Japanese cypress. Hydrochemical observations were conducted at the outlet of the KEW (K; 5.99ha), 4 subcatchments (A;0.086ha, H;0.40ha, M;0.68ha, R;1.75ha) and a 0-order hillslope plot within A catchment (AP; 0.024ha). The discharge rates in each catchment have been measured continuously and the streamwater for chemical analyses was sampled once two or three week. The discharges were perennial except for those of H and AP. The saturated throughflow generation processes during rainstorms have been observed at AP. Annual rainfall was 1179.4mm at 2002, much dryer than the mean value from 1972 to 2001 (1645.0mm). Some stonemasonry dams constructed here to prevent soil erosion. Upslope from the dam, the groundwater bodies are formed under the soil sedimentation areas in the headwater catchments (A, H, M, and R), and a small wetland is formed along the main

stream. The area of the wetland corresponds to 0.5% of the area of K. Considering the water budget from June to November 2002, the total discharge was increased in larger catchment. Based on the water budget at AP, a large proportion of rainfall seeped into the bedrock at hillslope and less contributed to the stream runoff at headwaters. The contributions of this bedrock groundwater to the stream runoff increased with increasing of catchment area. The SiO_2 concentrations of the streamwater of each catchment increased and $NO3^-$ concentrations decreased at larger catchment. The bedrock groundwater has high SiO_2 concentrations and low NO_3^- concentrations, thus, the variations of concentrations between the catchments depend on the contributions of this component. However, NO_3^- concentrations in the K streamwater were increased again. NO_3^- concentration of mainstream surface water decreased during passing through the wetland. NO_3^- concentrations were nearly zero except for the surface in the vertical profiles of the wetland soilwater. Thus, the surface water NO_3^- removed by instream processes such as denitrification under the reduced conditions. Therefore NO_3^- increase at K streamwater was caused by the runoff component from the hillside of the stream channel and instream hydro-biogeochemical processes. Depend on the catchment scales, the proportion of the constituent elements of catchment (hillslope, stream channel, wetland, etc.) may change. In addition, the existence of erosion control dams may form the wetlands along the stream. To clarify the hydrochemical mechanisms in various spatial scales, it is necessary considering the roles of the each constituent element.

HW01/09P/D-038   Poster   1400-229

THE SPATIAL AND TEMPORAL VARIATION OF METHANE FLUX OF TEMPERATE FOREST WATERSHED

Masayuki ITOH, Nobuhito OHTE, Masanori KATSUYAMA, Masatoshi KAWASAKI (Graduate School of Agriculture, Kyoto UnivUniversity)

Methane is considered to be one of the significant greenhouse gases, and is produced in soils as the end product of the anaerobic decomposition of organic matter. Soil methane emissions are taken place in the anaerobic soils such as natural wetlands, landfills, and rice paddies. On the other hand, under the aerobic conditions such as forest soil in hillside, methane is oxidized to carbon dioxide. So it is believed that the forest catchments function as a sink for methane. However, in temperate forest region, there are usually wetlands in riparian zones around streams, ponds. And it is possible that methane emissions in such wetlands exceed uptake in forest soil. It still has been not fully understood whether the forest catchment site is a net sink or source for methane. The in site observation was conducted at wetlands and dry hill slope around wetlands in the Kiryu Experimental Watershed (KEW), central Japan, covered by mixed stands of secondary broad-leaved deciduous trees and planted coniferous trees. Several wetlands are located along the main stream in KEW. The area of KEW and the total area of wetlands are 59900 m^2 and 300 m^2 respectively. To elucidate the temporal and spatial variability of methane uptake and emission, methane flux was observed regularly by closed chamber method at both the hillslope sites and wetland sites, coupling with surveys on soil physical and nutrient status. Methane was emitted through the year in the wetlands and showed strong seasonality. The emission rate was strongly depending on soil temperature, showed highest in summer (330 mg-CH_4 m^{-2} d^{-1}) and lowest in winter (0.1 mg-CH_4 m^{-2} d^{-1}). Spatial distribution within the wetland was highly heterogeneous, depending on soil water content and ground water level. While methane emission showed strong seasonality, methane uptake showed almost constant rate through the year (0-0.2 mg-CH_4 m^{-2} d^{-1}), and independent of soil temperature change. Estimated methane flux in watershed-scale varied seasonally from 2.97 g-CH_4 d^{-1} in Nov.2000 to 58.38 g-CH_4 d^{-1} in June 2001. This indicates that a small wetland which shares 0.05% of entire catchment area play important role for controlling the watershed-scale methane budget.

HW01/09P/D-039   Poster   1400-230

SPATIAL AND SEASONAL DISTRIBUTIONS OF DENITRIFICATION ZONE IN A FORESTED HEADWATER CATCHMENT IN CENTRAL JAPAN

Ken'ichi OSAKA[1], Nobuhito OHTE[1], Keisuke KOBA[2], Takuo NAKAJIMA[3], Masanori KATSUYAMA[1], Masatoshi KAWASAKI[1] ([1]Graduate School of Agriculture, Kyoto University, [2]Graduate School of Informatics, Kyoto University, [3]Lake Biwa Research Institute)

To clarify nitrogen loss from the forested headwater catchment, we investigated spatial and seasonal distribution of denitrification process by measuring N_2O concentration of soil gass and it's dissolved phase of groundwater in situ condition. Field investigation has been conducted at an unchanneled headwater catchment (0.68 ha) in the Kiryu Experimental Watershed (KEW) covered by mixed stands of secondary broad-leaved deciduous trees and planted coniferous trees. The concentrations of N_2O in the soil gas and the groundwater were measured with temperature, moisture content that potentially affect denitrification. We measured gaseous and dissolved N_2O at four site in the hillslope part of catchment, that is relatively shallow and wet soil layer above the groundwater body (G1), deep soil layer at the upper side of groundwater body (G34), deep and dry soil layer (G27), shallow and dry soil layer where saturated subsurface flow was occasionally generated during rainfall (G28). At the spring point, where the most wet part of catchment, we measured N_2O emission by closed chamber method. In the groundwater body, concentration of dissolved N_2O is generally higher in shallower potion than deeper potion. Correspondingly, the NO_3^- concentration decreased with depth in the groundwater body. Especially concentration of dissolved N_2O in groundwater was higher in July-August when it recorded the highest soil temperature: max concentration was 1296nM in shallowest groundwater. It was about 150 times higher than ambient concentration. The concentration of dissolved N_2O in stream water was relatively equivalent to ambient concentration. At the spring point concentration of dissolved N_2O was constantly high and emission of N_2O was large with intense correlation to soil temperature. These indicate that N_2O generated in shallower groundwater body was emitted at the spring point. At the hillside part of the catchment, where covered relatively dry forest soil, the concentration of gaseous N_2O in soil was relatively high at G1: max was 718ppbv in August. The concentration was gradually decreased with the decline of the soil temperature. On the other site in the hillside, the N_2O concentration was equivalent to ambient concentration. However at G28, where is generally dry part of the catchment, high concentration of dissolved N_2O was detected when saturated subsurface flow was generated during rainfall. These observed results suggest that the complete saturation by water was one of the most critical factors for determining the denitrification zone of this catchment. Moreover, denitrification might be highly variable depend upon temporal changes of groundwater condition.

HW01/09P/D-040   Poster   1400-231

THE ROLE OF FOREST VEGETATION ON THE SEASONALITY OF NITRATE CONCENTRATIONS IN STEEP HILLSLOPES

Yuko ASANO, Taro UCHIDA, Nobuhito OHTE, Masatoshi KAWASAKI (Graduate school of Agriculture, Kyoto University)

Understanding the factors influencing nitrate concentrations in mountainous headwater streams is important for the stream ecosystem and water resources management. Land-use

can strongly influences N export from hillslopes, however, the interactions between land-use and hydrological processes on the stream nitrate concentrations have been poorly understood. Spatially intensive observations within a hillslope, which is recharging a small stream will be useful in understanding the relationship between land-use and N export. Here we compare the seasonality of nitrate concentrations in soil solution, groundwater, spring from bedrock fracture and stream for two adjacent granitic hillslopes with contrasting land use. One hillslope is poorly vegetated, almost bare with thin soils and no organic layer due to forest cutting more than 1000 years ago (Rachidani: disturbed hillslope, 0.18ha), and the other covered with undisturbed forest (mixed stand of cypress and oaks) with developed forest soils (Fudoji: mature forest, 0.1 ha), in Tanakami Mountains, central Japan. Previous studies showed that the dominant source of stream during baseflow was from bedrock in both hillslopes. Dissolved N in stream was dominated by nitrate. The dominant N spices in those stream was nitrate. In mature forest, the mean nitrate concentrations in soil solution at 10 and 40 cm depths were 2.35 and 2.90 mg NO_3-N L^{-1} respectively, and quite variable. The concentration in transiently formed groundwaters ranged from 1.12 to 2.07 mg NO_3-N L^{-1}. The bedrock spring showed the lowest and least variable concentrations of 0.43 mg NO_3-N L^{-1}. The nitrate concentration in mature forest decreased with increasing sampling depth. Further, the nitrate concentration in stream was 0.67 mg NO_3-N L^{-1}, less than 60% of transient groundwater. In disturbed hillslope, the mean nitrate concentration in soil solution was 0.34 mg NO_3-N L^{-1} and concentrations in transient groudwaters ranged from 0.14 to 0.19 mg NO_3-N L^{-1}. The nitrate concentration slightly decreased with depth and the concentration in the stream (0.16 mg NO_3-N L^{-1}) was almost the same as the transient groundwater. Transient groundwater in mature forest showed relatively high nitrate concentrations in winter and low concentrations in summer, however, the stream showed no distinct seasonal pattern. In disturbed hillslope, both the transient groundwater and stream showed similar seasonality and stream nitrate concentration decreased with stream temperature. The seasonal patterns indicate the effect of biological activity, in particular, plant uptake of N during the growing season. In mature forest, nitrate concentrations in stream decreased with increasing bedrock groundwater contribution, which was estimated using SiO_2 concentrations. These results show that although disturbed hillslopes are covered with poor vegetation, plant uptake appears to play an important role in seasonal nitrate dynamics. In contrast, nitrate fluxes from the mature forest are strongly influenced by hydrological mixing. For mature forest, we suggest that signal of biological activity on N was extinguished in stream because of combination of two reasons, 1) large differences in nitrate concentrations between soil and bedrock water component, and 2) large contribution and variation of bedrock groundwater to stream.

THE GROUNDWATER RECHARGE MECHANISM REVEALED BY STABLE ISOTOPES AND CHEMICAL SOLUTIONS ANALYSIS IN AN ARID AREA, WESTERN CHINA

Tomohiro AKIYAMA[1], Masayoshi NAKAWO[2], Jumpei KUBOTA[2], Yutaka AGETA[1], Yuki KONAGAYA[3] ([1]Graduate School of Environmental Studies, Nagoya University, [2]Research Institute for Humanity and Nature, Kyoto, Japan, [3]National Museum of Ethnology, Osaka, Japan)

The objective of this study is to clarify the mechanism of groundwater recharge in an arid area, Heihe river basin, Gansu Province and Inner Mongolia, China. This river is typically an inland river in an arid area, which originates from glaciers in the headwaters and disappears in the lower reaches. The basin could be divided into three areas by the topography and the vegetation: the upper, the middle and the lower reaches. Field investigations mainly in the lower reaches were carried out in August to September 2001, January to February, and June 2002. Groundwater level was measured, and water samples, which are groundwater, river water, precipitation, and melt water of glacier, were collected. Stable isotopic compositions of oxygen and deuterium, and chemical compositions were analyzed for all samples. The results are summarized as follows. The depth of groundwater table in the desert area was shallower than that in the area along the river, whereas, altitude of groundwater table in the desert area was higher than that near the river. Therefore, it is suggested that groundwater in the desert area is never recharged by river water directly. There should be a boundary of aquifer at a depth of 60 to 100 m. The d-excess of deep groundwater, which is deeper than 100 m, was significantly lower than that of the meteoric water. So, it is drastically affected by evaporation. Nevertheless, estimated isotopic compositions of its origin were lower than that of melt water of glaciers in the basin. Consequently, it is considered that water, that originated from outer the basin, must contribute to the recharge of the deep groundwater. On the other hand, the origin of shallow groundwater, which is less than 60 m, can be separated corresponding to the surface condition. Groundwater near the river is originated from river water. Its chemical and isotopic compositions are concentrated due to evaporation as it infiltrates. Groundwater in the desert area is completely supplied by some of precipitations with high intensity, not low intensity or river water. It is hardly affected by evaporation as it infiltrates. Hence, its isotopic compositions are little concentrated, but chemical compositions are significantly concentrated due to elution of salt accumulation. Therefore, the mechanism of groundwater recharge in the desert area is as follows. Precipitation with high intensity must be divided into two parts. One is evaporated completely near the surface so that salt can be accumulated. The rest part for infiltration, not being affected by evaporation, will recharge the groundwater. Salt accumulation is eluted due to precipitation so that it becomes of high salinity. As it is percolating and recharging the groundwater, chemical composition of the groundwater becomes high. However, isotopic composition is not concentrated, because it is hardly affected by evaporation in the infiltration process.

DRY DEPOSITION OF GASEOUS AND PARTICULATE MATTERS IN A JAPANESE CYPRESS FOREST

Tomoko OBOTE, Nobuhito OHTE, Masanori KATSUYAMA, Makoto TANI (Graduate School of Agriculture, Kyoto University)

In the last decades, dry deposited gaseous and particulate matters has been recognized as a major process for input of anthropogenic or naturally originated chemical substances from atmosphere into terrestrial ecosystems. To evaluate the effects of dry deposited chemical substances on the nutrient cycle in a forest ecosystem, we observed ionic concentrations of inorganic constituents of incident precipitation, throghfall, stemflow (Na^+, NH_4^+, K^+, Ca^{2+}, Mg^{2+}, H^+, Cl^-, NO_3^-, SO_4^{2-}, HCO_3^-), some trace gases (SO_2, HNO_3, NH_3, HCl, NO_2) and ionic concentrations of water-soluble constituents of particulate matters (Na^+, NH_4^+, K^+, Ca^{2+}, Mg^{2+}, Cl^-, NO_3^-, SO_4^{2-}) from 1999 to 2001 in a Japanese cypress forest, in the Kiryu experimental watershed, located in the southern part of Shiga prefecture, Japan. To estimate dry deposited rates of inorganic ionic constituents of gaseous and particulate matters, we used two different methods. (1) TF (throughfall) method, which is based on the difference in wet deposition above and below the canopy, was used to estimate dry deposited rates of particulate matters. (2) A single-layer canopy model with a canopy conductance submodel was used to estimate dry deposited rates of gaseous matters. Canopy conductance for gaseous matters were estimated from that for water vapor which was determined based on the flux measurements by the eddy correlation method. Estimated annual dry deposition rates of inorganic ionic constituents were almost same as that of wet deposition, namely, the ratio of annual dry deposition rate versus that of wet deposition for Na^+ was 1.1, NH_4^+ was 0.9, K^+ was 1.0, Mg^{2+} was 1.1, Ca^{2+} was 1.1, H^+ was 1.9, Cl^- was 1.6, NO_3^- was 1.5, SO_4^{2-} was

0.6 and HCO_3^- was 1.0, respectively. And the percentage of each component of total atmospheric sulfate deposition was estimated, the deposits with incident precipitation (6.9-9.8 kg S ha^{-1} yr^{-1}) was about 60 %, particulate matter (1.4-2.1 kg S ha^{-1} yr^{-1}) was about 15 % and SO2 (3.0-3.2 kg S ha^{-1} yr^{-1}) was about 25 %, respectively.

CHANGING OF STRAMN WATER CHEMISTRY AFTER THE DISTURBANCE OF CLEAR-CUTTING

Naoko TOKUCHI[1], Keitaro FUKUSHIMA[1], Kouichi MOURI[1], Nobuhito OHTE[2] ([1]Department of Forest Science, Kyoto University, [2]Division of Environmental Science and Technology)

Introduction There are many studies about the relation between nutrient cycling and forest management (ex. Bormann and Likens 1979).These studies showed that forest managements, clear cutting, thinning and pruning, had the large influences on nutrient cycling. However, it is difficult to detect the controlling factor for the influences, because the forest does not have the same characteristics of geology, slope direction and plant species composition etc.. Furthermore, the response and/or recovery of the forest sometimes show very slow and it takes long monitoring. In our study site, plantation forest is rotationally managed about 80 years interval and the unit of rotation is one watershed. Namely, there are more than 30 watersheds adjacent each other and it is almost same geology, slope direction, and the different age. It is very useful to understand the influences of the disturbance of forest management. In this study we introduce the experimental site and show the stream water chemistry after the disturbance of clear-cutting. **Study site and methods** Study site is Nara prefecture, Japan. There are 33 watersheds adjacent each other. Each watershed is the different age after the clear-cutting. The minimum age of the forest was 0 year, just after clear-cutting and planted, the maximum forest age was 87 years. Stream water samples were collected from each watershed every 2 weeks in 1998 and 2002. Precipitation was collected every week. Solution samples were kept under 4 °C until the analysis. Ion concentrations (Na^+, K^+, NH_4^+, Ca^{2+}, Mg^{2+}, Cl^-, NO_3^-, SO_4^{2-}) and total concentration of Si, Al, Mn, and Fe and dissolved organic C and N concentrations were determined. **Results and discussion**After the disturbance of clear-cutting, stream water chemistry dramatically changed. Especially, NO_3^- concentration in stream water increased after the clear-cutting and reached to 0.05 meq L^{-1} of 3 years after clear-cutting. Then NO_3^- concentration in stream water decreased with the forest age. After 25 years NO_3^- concentration in stream water showed the similar range to the concentration of 87 year-old forest. However, the deviation of NO_3^- concentration in 25 year-old forest was larger than 87 year-old forest. These temporal changes of NO_3^- concentration in stream water after the clear-cutting were very similar between 1998 and 2002. It suggests that the changes of stream water chemistry after clear-cutting is mainly controlled the local climate and geology.

HYDROLOGICAL TRENDS AFTER SUB-DRAINAGE AT THE HOVI EXPERIMENTAL CATCHMENT, SOUTHERN FINLAND

Pertti Olavi SEUNA (Finnish Environment Institute)

In 1971 the drainage of the small agricultural catchment of Hovi was changed from open ditches to sub-drains. Due to that change the annual runoff increased by 15 %, spring maximum decreased by 9 % and summer maximum decreased by 36 % judging from the control basin study carried out. Total nitrogen and nitrate nitrogen concentrations increased strongly. During the 30-year period after the sub-drainage the percentage of surface runoff has increased considerably. Right after the sub-drainage the annual surface runoff was about 20 % of the total runoff, while in the late 90's this per- centage exceeded 60. The respective trend was recorded for the summer maximum runoff; the surface runoff percentage grew from about zero to about 50 % of the total maxima. In the runoff maxima obtained from snowmelt the trend was not so clear due to the strong dependence on the soil frost. For the comparison it can be stated that according to the isotopic flow separation (oxygen-18) the percentage of the event water amounted to about 70 % of the total runoff on the annual basis, although a part of this event water came through the sub-drains. The nitrogen concentrations dropped by 50-60 % during the 30 years after the drainage change. A part of this trend can be explained by the decrease in fertilization by about 20-25 %. In general, it can be concluded that the trend towards higher surface runoff percentages may contribute to increased flooding on old sub-drainage basins.

NUTRIENTS RUNOFF FROM AN ABANDONED ARTIFICIAL FOREST OF CAMAECYPARIS OBTUSA DURING STORM EVENTS

Junichiro IDE[1], Osamu NAGAFUCHI[2], Atsushi KUME[1], Kyoichi OTSUKI[1], Shigeru OGAWA[1] ([1]Research Institute of Kyushu University, Forest, [2]Fukuoka Institute of Health and Environmental Sciences)

Japanese archipelago is covered with forested hills about 67%. Recently, the commercial use of these forests nearly ceased, but public functions of forests (e.g. controlling rising water level, water purification) have been highly evaluated. These functions are thought to work well as long as forest management is conducted sufficiently. However, many of Japanese artificial forests are abandoned and forest management such as tree thinning is not sufficiently conducted. The artificial forests were about 44% of the total forested area. In the abandoned forests, the canopy becomes dense and thick, and the development of understory vegetation is disturbed. In such forests, soil erosion is easily occurred during storm events because of bare soil surfaces. In the abandoned artificial forest of Japanese cypress, *Camaecyparis Obtusa*, which is one of the most typical forested species in Japan, the forest floor is denuded because the litter leaves of the tree are decayed on the forest floor soon after defoliation. The increase in the abandoned may decrease the water purification functions and increase the soil runoff during storm events. In order to estimate the water purification function of abandoned artificial forests, hydrological and hydrochemical survey was conducted in the small watershed covered by an artificial forest of Japanese cypress, and the flux budgets for total nitrogen (T-N) and total phosphorus (T-P) were investigated. In both T-N and T-P budgets, stream-water outcomes were greater than precipitation incomes. The concentrations of both T-N and T-P in the stream water increased during storm events. The concentration of phosphorus rapidly increased in the early stage of storm events because high-level particulate phosphorus (PTP) was flushed out together with suspended sediment (SS). The runoff of high-level PTP may coincide with soil erosion. These results suggested that the function of water purification of this watershed became dysfunctional because of soil erosion. We expect that the increase in the abandoned artificial forests will affect harmfully the watershed system in Japan.

MONITORING STABLE ISOTOPE HYDROLOGY AT THE FU-SHAN FOREST RESEARCH CENTER, TAIWAN

Jeffrey S. OWEN[1], C.H. WANG[2], Y.J. HSIA[3], H.B. KING[1], L.J. WANG[4] ([1]Taiwan Forestry Research Institute, [2]Institute of Earth Sciences, Academia Sinica, [3]National Dong-Hwa University, [4]National Taiwan University)

At the Fu-shan LTER (Long-Term Ecological Research) site in northeastern Taiwan, we have analyzed the δD and $\delta^{18}O$ compositions of drainage waters from two study watersheds as part of a hydrological and ecological research program. Streamwater δD and $\delta^{18}O$ values changed seasonally and probably reflected seasonal changes in precipitation isotopic composition. We intend to use differences between calculated fractions of event and pre-event water between the two adjacent watersheds were used to estimate the amount of water that likely does not flow through the outlet weir at one of these watersheds because of differing installation methods used. The results from this study are the first of this kind to include within event sampling in Taiwan and we hope to expand this research approach in the future.

ANTHROPOGENIC CHANGE AND THE WATER CYCLE: OUR SEARCH FOR MAUNA LOA

Charles J. VOROSMARTY (University of New Hampshire)

A careful monitoring of rising concentrations of atmospheric CO2, such as at the famous Mauna Loa observatory, has provided an important impetus for continued study of greenhouse warming and the carbon cycle. From the standpoint of predicted impacts on nature and society the concern is not difficult to justify. And, as a result of a clear global signature of change and an allied theory on global warming, substantial financial and intellectual resources are devoted to this topic. A postulated acceleration of the water cycle places hydrology stage center in the climate change debate. Case studies and regional analysis have been widely employed to assess the hydrological impact of climate change. Such vignettes provide an important start, but the global nature of water cycle changes has yet to be fully clarified. Hydrological changes embody many other impacts besides climate change including those associated with land cover change, hydraulic engineering, and pollution of inland waterways. I present a heuristic exploration how a hydrologically-oriented 'Mauna Loa curveAEmight appear, describing its features and exploring how human activities distort the nature of continental runoff. I provide evidence that such changes are now globally significant. Seeking a hydrological Mauna Loa curve raises several scientific, technical, and political issues AEthe adequacy of our capacity to monitor such changes, the need to inventory and understand human modification of the water cycle, and mechanisms to focus resources on the study of the more direct human interventions in the global water cycle.

MASS TRANSPORT MODELING FOR ASSESSMENT OF GROUNDWATER POLLUTION IN BOLARAM INDUSTRIAL DEVELOPMENT AREA AND ENVIRONS, MEDAK DISTRICT, A.P

Gurunatha rao VVGS, Subrahmanyam KAMBHAMPATI (National Geophysical Research Institute)

Bolaram Industrial Development area has been established during 1977 on the outskirts of Hyderabad city in Medak district, Andhra Pradesh, India. Bulk drugs and pharmaceutical industries form the main industries and a common effluent treatment plant has been commissioned to treat the wastewater. The effluents are let out in the open channels and minor irrigation tanks, which ultimately reach the tank in Krishnareddypet village through Pamulavagu. The total dissolved solids (TDS) concentration of the effluent ranges from 2500 - 4500 mg/l. The TDS concentration of groundwater has reached concentrations of 1500 - 2000 mg/l along Pamulavagu stream and in the command area of the Krishnareddypet tank during 1997. Water level and water quality monitoring was carried out during 1997-98 and also aquifer parameters have been estimated by carrying out pumping tests. Groundwater flow and Mass transport models have been developed to assess the extent of groundwater contamination that has occurred over the last two decades. The mass transport model has been calibrated for the year 1997 and the same has further been used to predict the contaminant migration for 2017 for present loading conditions in the area.

PESTICIDE AND NUTRIENT LOADINGS IN THE RIANA RIVER WITHIN THE LAKE VICTORIA - DRAINAGE BASIN

George ONGWENYI, John M. NYANGAGA (Post-graduate programme in Hydrology, Faculty of Science, University of Nairobi)

The use of modern Agricultural methods i.e the use of various varieties of Pesticide to control diseases and pests and chemical fertilizer to control diseases and pests and chemical fertilizers is now a pre-requests of increasing agricultural productivity, world over. Despite the fact that this is a positive move, its has serious problems to water resource managers. After application, some of the pesticides and fertilizer residues get their way into surface and ground water bodies in various ways, i.e. through direct application to control aquatic pests, runoff from agricultural farmlands, soil erosion and sedimentation, which may lead to water pollution. The paper describes a 3 year period study on the effect of landuse on water quality and examines pesticide and nutrient (P&N) Loading And concentrations in Riana river catchment within the lake Victoria drainage basin. The common pesticides dicussed include, Diazinon, malathion. Ambush, Aldrex, Furadan, D.D.T. and Ridomil. The study incorporated a detailed porogramme of water quality and riverflow, monitoring, landuse surveys, soil surveys and stream ecological surveys. The study gives unveiling challenges to planners particularly those in the water and agricultural sector.

ASSESSMENT OF IRRIGATION IMPACT ON WATER RESOURCES OF PANGANI RIVER BASIN IN TANZANIA

Simon Hosea MKHANDI, George Venance LUGOMELA (Department of WRE, University of DSM)

Pangani river basin is the second most important river basin in Tanzaniain terms of water resources development. The major water users in the basinare for irrigation and hydropower generation. The effective management ofthe water resources of Pangani river basin is crucial to ensure sustainabledevelopment and elimination of conflicts between different water users.Usually, available water in a basin cannot satisfy all demands and consequently restrictions have to be imposed for the benefit of all the stakeholders.Since irrigation

transforms water into a form which makes it unavailable forother users, it is therefore important to quantify the amount of water requiredfor irrigation purposes at present and in the future for Pangani basin.This paper investigates the present and future impact of irrigation on waterresources of Pangani river basin in relation to the effect on the generation ofhydropower downstream of the river. Irrigation water requirement are estimatedusing the Penman Monteith method. This approach is incorporated in the F.A.Oprogram developed for irrigation management and planning known as CROPWAT.The paper gives the recommendations to reduce the strain in the competition foruse of water between irrigation and hydropower generation in Pangani riverbasin.

STUDIES ON THE EFFECT OF SOIL PROPERTIES ON RETENTION OF HAZARDOUS ORGANICS ON HAZARDOUS WASTE DUMPSITES

Zareen KHAN, Anjaneyulu Y. (Center for environment, Jawaharlal Nehru Technological University)

Laboratory experiments were carried out on the field samples to study the effect of soil properties in retention of hazardous organics like phenol, p-nitro phenol, 2,4-dichlorophenol and 4-chloro,2-nitrophenol which are released in the waste waters and solid wastes of several industries in Patancheru industrial area, Hyderabad,(India). The parameters like organic matter, clay and iron and aluminium oxides which are known to influence the soil adsorption capacity are studied in the present work. Several soil samples in the entire industrial area were collected and characterized and the adsorption-desorption studies were carried out.The results clearly indicated the decrease in the adsorption capacity by 67% when organic matter was removed from the soils when compared to untreated soils indicating that soil organic carbon content plays a major role in the adsorption process of hazardous organics. Adsorption isotherm data reveal that the Freundlich constant Kf and the distribution constant Kd are significantly correlated with organic carbon content of the soils and hydrophobicity of organics while the Koc, the soil water distribution coefficient, per unit organic content varied for different hazardous organics. The CBD (citrate-bicarbonate-dithionite) treated soils exhibited a reduction of up to 24.2% in adsorption indicating the significant contribution of free iron and aluminium oxides which are reduced to lower levels. The clay destructed soils also showed a reduction in adsorption capacity up to 53.8%. From these studies it can be concluded that soils having more organic matter, clay and oxides of iron and aluminium content help in retention of hazardous organics in the soil thereby preventing their leaching into groundwaters. Thus the disposal of industrial wastes containing these hazardous organics can be made on soils containing high percentage of these components and further treatment can be accomplished by adopting cost effective methods like bioremediation and phytoremediation on the site.

GROUNDWATER FLOW SYSTEM ESTIMATED BY WATER QUALITY

Yusaku TAGUCHI (Geological Survey of Japan, AIST)

It is well known that groundwater quality has been gradually changed by ion exchange and other reactions with soil granules with keeping long residence time going through the process of groundwater flow. Conversely, there is some possibility that groundwater flow in a basin can be traced using groundwater quality as a tracer. Especially, groundwater quality will be the most important tool for estimating the groundwater flow system in the basin where an area distribution of hydraulic potential could not be clarified.   The author proposed the method on how to estimate the groundwater flow system in the basin from the concept of evolution ratio of water quality, distance of groundwater flow, and pattern of groundwater quality. To verify this method, the author selected the Hayadegawa basin, located in Niigata Prefecture, Japan, where there is a lot of information on hydrogeology, as the area for this study. The result of groundwater flow system estimated by this method was harmonized with those known by previous hydrogeological studies. It means that this proposed method has a high possibility to be applicable for field surveys.

CRITICAL ANTHROPOGENIC LOAD AND TEMPORAL TRENDS OF HEAVY METALS IN SOIL - WATER SYSTEM

Tomas PACES[1], Milan SANKA, Radek KADLUBIES, Milan ZAPLETAL, Petr CHROUST ([1]Department of Geochemistry, Czech Geological Survey, [2]Centre for Environment and Land Assessment, EKOTOXA, Horni nam. 2, 74601 Opava, , Czech Republic)

Accumulation or depletion of heavy metals in soil and water is result of a mass balance between natural andanthropogenic inputs and outputs. The mass balance of heavy metals is expressed by a differential equationdP /dt = Fatm + Fagr + Fwth -Fup -Frun , where dP/dt is the temporal change in the pool of the metal, Fx isflux of the metal by a transport mechanism x; Fatm - atmospheric deposition, Fagr - application ofagrochemicals, Fwth - dissolution of bedrock minerals, Fup - biological uptake, Frun - runoff of water. Theintegral of the equation from an initial pool Po at the initial time to isP = (Finput /k) –[(Finput /k – Po) exp[(–k(t - to)], where Finput represents the sum of all inputs and k isthe first rate constant of all outputs (Foutput = k/ P). The critical load is calculated as a steady-state pool ofthe metal that is not yet harmful to the soil ecosystem (Pcritical) according to(Fatm + Fagr)critical = k. Pcritical - Fwea . The exceedance of the critical load, EX is the difference betweenthe real input from atmosphere and from agricultural chemicals and their critical values:EX = Fatm + Fagr - (Fatm + Fagr)critical. The future trends of the soil pool of the heavy metals are definedusing the difference between the present inputs and outputs d = Fatm+Fagr+Fwea-Fup-Frun,the ratio between present pool and critical pool of the metals r = Po/Pcritical and the critical time (tcritical) whenthe critical pool will be reached. Four regions were defined in the Czech Republic: (1) r $<$ 1, d $<$ 0, andtcritical $<$ 0: no environmental problem is expected, (2) r $<$ 1, d $>$ 0, and tcritical $>$ 0: environmental problem iseither not expected or it is expected that the critical limit will be reached in a distant time, (3) r $>$ 1, d $>$ 0, andtcritical $<$ 0: this is the worst case when the present soil pool is higher than its critical value and will still increase infuture. The negative time is not significant because the pool will be always above the critical limit, (4) r $>$ 1,d $<$ 0, and tcritical $>$ 0: the present concentration is above the critical limit. It will

decrease in future if the presentinputs prevail. The critical time indicates when the pool of the metal in soil reaches its critical level. The massbalance was calculated for various soils in the Czech Republic and maps of the critical loads of Pb, Cd andCu were constructed. Other maps represent the exceedance of the critical load by present atmospheric andagricultural inputs, projected temporal trends and critical times when the critical pool will be reached. The mapsand their environmental significance serve to decision-makers to locate regions where industrial emissions andagricultural inputs of heavy metals should be decreased in order to lower the dangerous contents of the metalsin soils.

CONSEQUENCES DU DRAINAGE AGRICOLE SUR LES ECOULEMENTS DE CRUE

Claude COSANDEY, Tatiana MUXART, Marie-Jos-PENVEN (C N R S, Lab de Géographie physique)

La question des conséquences du drainage agricole (par drains enterrés) sur l'ampleur des crues est une question largement controversée. Selon certains auteurs, le drainage agricole, obligeant l'eau a transiter par le sol, augmente le temps de transfert et modère donc les écoulements de crue. Pour d'autres pourtant, les processus de transferts résultent essentiellement de transmission de pression : lau qui tombe a la surface d'une parcelle drainée provoque rapidement une montée du niveau de la nappe ; cette montée rapide augmente la charge hydrostatique et entraû ⟨e une augmentation simultanée du débit des drains ; le temps que met l'eau a être évacuée de la parcelle n'est pas plus long que celui qui lui serait nécessaire par ruissellement dans une parcelle non drainée.L'étude des conséquences du drainage sur la formation des crues a ét menée dans les terres loessiques du Bassin Parisien a partir de trois unités hydrologiques emboûées : une parcelle drainée de 6.4 ha, un petit bassin agricole presque totalement drain de 52.4 ha, et enfin un petit bassin versant rural de 20 km². A l'échelle de l'événement pluvieux, le drainage se révèle parfaitement efficace pour assurer une apparition rapide de l'eau a l'exutoire de la parcelle (sans qu'il soit possible de savoir s'il s'agit de l'eau de pluie, ou d'eau préexistante, « chassée » par l'eau de pluie) ; de plus, le coefficient d'écoulement est proche de 100 % pour cette parcelle, alors qu'il est toujours sensiblement plus faible pour des territoires plus grands. Cette observation se retrouve pour l'ensemble de la période dite « de drainage intense » c'est a dire pendant la période d'hiver durant laquelle, la réserve hydrique étant reconstituée et les prélèvements de l'évaporation très faibles, l'essentiel des précipitations contribue au ruissellement. Dans ces conditions il semble bien que, au moins a l'echelle de la parcelle, le drainage agricole ne ralentisse ni la vitesse, ni le volume de l'eau qui rejoint le réseau hydrographique.Le drainage d'une région s'accompagne de travaux connexes que sont la remise en état de tout le réseau de collecteurs a ciel ouvert. C'est a ce niveau d'aménagement plus global que le drainage peut jouer un rôle positif sur les écoulements de crues, par la mise en action des processus dits de « ralentissement dynamique »

HW01/10A/C26-003   **0910**

APPROACH IN IDENTIFICATION HEAVY METAL POLLUTION SOURCES OF DNIESTER RIVER

Vera MUNTEANU (Aquatic Ecosystems National Institute of Ecology)

The Republic Moldova is a country located in the drainage basin of the Black Sea. Dniester River, a main water artery of the country, being a transboundary river with a total length of 1352km, is of great importance for a wide variety of uses, especially drinking water purpose for about 10 mln. population of Moldova and Ukraine. In the last decades, however development of economic interests conflicts more and more with the ecological functioning of the ecosystem. On the both sides of the Dubasari reservoir, total length 125km, total volume of 485 mln. m³, are located the Rezina-Rabnita industrial complex, consisting of 2 cement plants, with annual production of 4.4 mln.tonn/yeare and one metallurgical plant, 0.7 mln tonn/year, potential sources of heavy metal. Analysis of environmental parameters contamination requires a reliable, quantitative understanding of natural conditions. Seasons monitoring (2000-2002) have shown the highest concentration of mercury (Hg), cadmium (Cd), lead (Pb), copper (Cu) in river water (dissolved + suspended forms) and soils in the nearest zone of industrial complex, to compare with downstream part of the reservoir. For mercury and cadmium water contents are three times higher, for their contents in soils 8-11 times highest, respectively. Taking into account the erosion process (16 tonn/ha/year) from neighboring soils, the purpose of this study was to estimate the influence of heavy metal content from sediment on their contents in water, assessing that these parameters are in a linear interdependence. The mathematical processing of data demonstrated that metal content in dissolved form have a ration of $r=0.95 - 0.99$ with its content in sediment and suspended matter, respectively. The presence of an interaction structure between model parameters is a typical feature of the classification of model realizations. It is known that the complex models have a lot of causes, which reduce their importance, the ecological processes being very hard to be described in an adequate way. The simple models now are not only satisfactory, but usually are recommended. This simple model has been developed to assess short-term prognostication of heavy metal content both in sediment and dissolved form. In case of dry season the predicted values correspond satisfactory with whose measured and confirm the negative impact of industrial complex on heavy metal content in Dubasari aquatic ecosystem. The utilization of model for data interpretation in case of abundant atmospheric precipitations, decreases the errors between measured and calculated values and denote conclusive that the polluted soil from neighboring zone of industrial complex are the main source of heavy metal pollution of Dubasari aquatic ecosystem. Positive value of the parameter, describing the contribution of metal content from sediment on that in dissolved from indicates, for mercury and cadmium, transport direction downward-top, for all longitudinal reservoir direction, when for copper and lead, this process is observed only downstream, fact explained by low velocity of suspended particles sedimentation Aknowledgement This work was supported by the research Support Scheme of the Open Society Support Foundation, grant N246/2000.

IQUID ANALOG MODELLING OF RIVER POLLUTION PROBLEMS

Parzhang MONADJEMI (Civil Engineering Department, School of Engineering, Shiraz University)

The idea of an analog model is to create a small seale, easily managed system that behaves in critical ways in the same manner as its prototype. Many examples could be given of the successful application of analogs to engineering problems. The main requirement of such models is that it be governed by the same differential equations. Almost all of the analog models are of electronic type. An exception is an analog model which uses liquid flow in a thin slot between two smooth plates. This is the Hele-Shaw which is mathematically similar to the liquid flow in a two dimensional potential flow. It is the object of this paper to introduce and describe a novel and innovative liquid analog model of extremely simple construction which is able to model various problems of river pollution (A patent has been issued for this device). The model contains two basic elements: a reservoir unit (RU) and a linear friction unit (FU). There is also a terminal reservoir unit (TRU) which is a constant level overflow device. The following figure shows a liquid analog model which is capable of

modeling various river pollution problems. RU_1 & RU_2 are cylindrical shape with cross sectional area A. Initially all the valves in FU_1 & FU_2 are closed and the potential heads in RU_1 & RU_2 are respectively Lo and Do. At time $t = 0$ the valves are opened. At time t water levels in RU_1 & RU_2 are L & D and a mass balance in RU_1 & RU_2 with q_1 flowing through RU_1 and q_2 flowing through FU_2 results in: Which is exactly the differential equation defining the oxygen sag curve. Experiments with the above model has given very good results which will be fully discussed in the final paper. It has been demonstrated that the liquid analog model can be used for river pollution studies where there are more than one concentrated loads where there are distriluted loads along the river and where the deoxygenation rate K_1 and rearation rate K_2 are not constant and change along the stream. The model described above can also be used for situations where BOD reaction is not first order and for many other complex situations. Experimental results with excellent fit will be described in the final paper. There are many advantages of the liquid analog modeling of river pollution problems. The primary advantage is that the input signals and response signals c.e. the solution to the problem is readily observable by the maked eye. Therefore the solutions may be sensed and visualized and even predicted. The visualization & actual observation of the solutions assigns a great value to this model as an instrument for educational and instructional purposes. There are many other advantages which will be discussed in the final paper.

USING MAPS OF DOMINANT RUNOFF PROCESSES TO IDENTIFY AREAS THAT ARE SUSCEPTIBLE FOR PESTICIDE REMOVAL

Petra SCHMOCKER-FACKEL, Felix NAEF (Institute of Hydromechanics and Water Resources Management, Swiss Federal Institute of Technology Zurich)

Chemical compounds like pesticides, phosphorous, nitrate, etc. are applied to most agricultural fields in Switzerland. Considerable amounts of them do reach rivers and lakes and cause water quality problems. To be able to reduce these amounts, e.g. through change of land-use or change of farming practices, it is necessary to identify areas that are susceptible to compound removal. The percentage of a compound applied to a field that reaches a river depends on the chemical properties of the compound and the soil, as well as on the process of runoff formation on the field. In the following the process of runoff formation and its implication on pesticide transport will be discussedin more detail. Compounds like pesticides can be transported to a river by different runoff processes. One possibility is transport by surface runoff. Surface runoff results either because rainfall intensity exceeds the infiltration capacity of the soil (Hortonian overland flow, HOF) or because of saturation of the soil (saturated overland flow, SOF). In the first case, rainfall intensity and infiltration capacity are the critical parameters that determine time and amount of runoff, in the second one it is storage capacity of the soil and amount of rainfall. Another, less known runoff process that removes pesticides is fast preferential subsurface flow (subsurface flow, SSF). Here the density and capacity of preferential flow paths like macropores and tile drains are important parameters concerning runoff formation. Contrary to fast SSF, slow SSF in the soil matrix is not a relevant pesticide transport mechanism. Thus to understand and predict pesticide transport, the spatial distribution of the runoff processes in a catchment has to be known. A methodology was developed to map the dominant runoff process (DRP) using information about soil structure, geology, topography, land-use, etc. as well as from sprinkling and infiltration experiments. The dominant runoff processes were mapped in great detail for several small agricultural watersheds on the Swiss plateau, which react very differently to intense precipitation. The difference in hydrological reaction could be explained with the extend and distribution of the DRP in the catchments. Leu (2003) applied the pesticide atrazine plus a labelling substance to several corn fields in one of the catchments and measured their concentrations in runoff in high temporal resolution. The concentration curves of the pesticides were then compared with the estimated runoff from the respective fields. Fields with HOF or fast SOF as dominant runoff process contributed most to pesticide transport, followed by areas with retarded SOF and fast preferential SSF, while fields dominated by slow subsurface flow did not contribute at all. The delineation of areas that are hydrologically susceptible for pesticide removal is a pre-requisite for taking measures to reduce pesticide load in rivers. This requires a detailed evaluation of the spatial distribution of runoff processes as proposed in this paper. Leu, Ch. (2003): Input of corn herbicides and metabolites from small agricultural fields to surface waters: A study in four sub-catchments of lake Greifensee, PhD thesis, EAWAG.

AUTOMATIC STORM-TRIGGERED, CONTINUOUS AND DISCRETE HYDROCHEMICAL MONITORING ON A GRASSLAND CATCHMENT

Wayne MENARY, Jeff SHI, Phil JORDAN, Richard DOUGLAS, Brian RIPPEY (University of Ulster)

Sampling methodologies have to be developed which accurately qualify and quantify hydrochemical fluctuations. Sampling inaccuracies associated with discrete monitoring has led to the implementation of auto sampling. The advantage of such an approach is the ability to quantify whole storm loads and qualify the variations of chemicals and suspended sediment during and between storm events, thereby facilitating an examination of inter-storm patterns such as nutrient and sediment washout. We describe the application of automatic storm triggered hydrochemical monitoring on the Oona Water river catchment. Automatic and discrete sampling of phosphorus (P), suspended sediment (SS), volatile organic matter (VOM), ammonia (NH_4), nitrate (NO_3), iron (Fe), manganese (Mn), silica (Si), potassium (K), calcium (Ca) and sodium (Na) concentrations in the Oona Water river catchment began on 1 October, 2001 across 6 spatial scales ranging from 0.15km² to 88km². This places phosphorus and suspended sediment runoff into the context of wider catchment processes such as other nutrient losses, soil erosion and chemical transformations. Furthermore, a YSI 6920 multi-probe sonde was deployed at the 88km² site and continuously monitored pH, temperature, conductivity, dissolved oxygen and turbidity at a 15 minute resolution. This established total solids fluxes and the seasonal and diurnal effects of eutrophication. The turbidity data is highly correlated with suspended sediment concentration and had provided a high resolution series for sediment loads and associated nutrient loss. Data generated from the automatic samplers and discrete sampling programme show that SS varied from a minimum of -0.4 to a maximum of 342.7 mg/l, total P (from -0.072 to 1.468 mg/l), total soluble P (from -0.083 to 0.360 mg/l), soluble reactive P (from 0.008 to 0.200 mg/l), NH_4 (from -0.020 to 1.491 mg/l), NO_3 (from 0.0002 to 5.04 mg/l), Fe (from 0.162 to 2.935 mg/l), Mn (from 0.13 to 2.824 mg/l), VOM (from 6.25 to 96.55 %) across the 6 spatial scales. Sonde data reveals fluctuations for turbidity (from -1.6 to 1470.9 NTU), temperature (from 3.36 to 21.07 ºC), conductivity (from 0.001 to 14.75 ms/cm), pH (from 5.8 to 8.73), DO (from 0.21 to 14.75 mg/l). The sonde also highlights the close relationship between suspended sediment and turbidity fluxes ($r^2 = 0.91$). Deployment of the YSI 6920 multi-probe sonde facilitated monitoring of selected parameters on a resolution not feasible for routine monitoring programmes. Analysis of the results generated permits a qualified estimation of how monitoring programmes should be undertaken, which parameters should be analysed and when.

HW01/10A/C26-007   1110

CARBON BIOGEOCHEMISTRY IN A COOL-TEMPERATE FOREST WATERSHED IN NORTHERNMOST OF JAPAN

Hideaki SHIBATA[1], Kentaro TAKAGI[1], Mutsumi NOMURA[1], Kaichiro SASA[1], Fuyuki SATOH[1], Tatsuya FUKAZAWA[2], Masazumi KAYAMA[1], Karibu FUKUZAWA[3], Mineko KOHNO[4], Masami OHGI[5], Yasumi FUJINUMA[6] ([1]Field Science Center for Northern Biosphere, Hokkaido University, [2]Graduate School of Engineering, Hokkaido Univ., [3]Graduate School of Agriculture, Hokkaido Univ., [4]Faculty of Agriculture, Niigata Univ., [5]Faculty of Agriculture, Hokkaido Univ., [6]Center for Global Environmental Research, National Institute for Environmental Studies)

The quantitative understandings of biogeochemical processes of carbon in forest-soil-stream ecosystem are very important to assess the ability of terrestrial ecosystem to sequestrate the carbon from atmosphere locally, regionally and globally. Human activities (e.g. climate change, forest harvestings and nitrogen deposition) sometimes disturbed such carbon cycling and budgets in natural ecosystems, motivating us to study the effect of the anthropogenic disturbance on the carbon biogeochemistry and to compare the carbon dynamics between disturbed and undistudied conditions. We conducted the intensive monitoring of carbon cycling and budgets in a natural cool-temperate mixed-forest as a component of a comprehensive project (CC-LaG: Carbon Cycle and Larch Growth Experiment) to assess the effect of the clear-cut and following plantation on the carbon biogeochemistry in a forest watershed. We report the preliminary products related to the carbon cycles and budgets under the undisturbed condition before the clear-cut treatment. The study basin (1st order stream, 0.08 km2, 55-75 m.a.s.l) is located in Hokkaido University's Teshio Experimental Forest, northern Japan (45o 03´ N, 142o 08´E). The vegetation is a natural mixed forest, mainly dominated by Abies sachalinensis, Quercus crispula, Betula platyphylla var. japonica, Betula ermanii, Picea jezoensis, Kalopanax pictus and Acer mono. The understory vegetation is mainly dominated by dense Sasa senanensis. The dominant bedrock and soil is Cretaceous sedimentary rock and Pseudogley brown forest soils, respectively. Annual precipitation and annual mean temperature in this region was ca. 1000 mm and 5.7 °C, respectively. We observed net ecosystem exchange (NEE) of carbon between canopy and atmosphere using eddy covariance methods (at 30 m height tower), particulate and dissolved carbon leaching from soil to the stream using intensive monitoring of soil solution and stream chemistry on annual basis. Stand biomass, litterfall, bulk deposition, throughfall, litterfall and soil respiration were also measured in the study basin. We quantified these carbon fluxes separately and established the carbon budgets in this watershed. Our result suggested the leaching of dissolved organic carbon to the stream is relatively important component for the carbon balance in a whole watershed compared to other Japanese forest basins in previous studies.

HW01/10A/C26-008   1130

APPLICATION OF STABLE ISOTOPES TO IDENTIFY NITRATE CONTAMINATION SOURCES AND ALANYZE HYDROLOGIC TRANSPORT: A CASE STUDY IN A SHALLOW AQUIFER, KOREA

Seong-Chun JUN, Kang-Kun LEE (School of Earth and Environmental Sciences, Seoul National University)

This study applied a hydrogeological field survey and isotope investigation to identify source locations and delineate pathways of groundwater contamination by nitrogen compounds. The study site is covered largely with agricultural fields and partly with residential sectors. The infiltration and recharge processes were analyzed with groundwater-level fluctuation data and oxygen-hydrogen stable isotope data. The groundwater flow pattern was investigated through groundwater flow modeling and spatial and temporal variation of oxygen isotope data. Based on the flow analysis and nitrogen isotope data, source types of nitrate contamination in groundwater are identified. Groundwater recharge largely occurs in spring and summer due to precipitation or irrigation water in rice fields. Based on oxygen isotope data and cross-correlation between precipitation and groundwater level changes, groundwater recharge was found to be mainly caused by irrigation in spring and by precipitation at other times. The groundwater flow velocity calculated by a time series of spatial correlations, 231 m/yr, is in good accordance with the linear velocity estimated from hydrogeologic data. Nitrate contamination sources are natural and fertilized soils as non-point sources, and septic and animal wastes as point sources. Seasonal loading and spatial distribution of nitrate sources are estimated by using oxygen and nitrogen isotopic data.

HW01/10A/C26-009   1150

HYDROLOGICAL CONDITIONS AND ITS EFFECT ON NITROGEN DYNAMICS IN UNSATURATED LOAMY SOIL COVERING THE UPLAND SURFACE

Baku OHJI, Hirohumi IWAMI, Changyuan TANG (The Graduate School of Science and Technology, Chiba University, Yayoi 1-33, Inage-ku, Chiba 263-8522 JAPAN)

One of the most important problem need to be evaluated is the effect of the agriculture activities on the groundwater quality. Based on these needs, the relationship between hydrological condition and nitrogen dynamics in unsaturated loamy(volcanic ash) soil was studied at different types of land use (coniferous-forested and cultivated sites). The study area is located in Ochi experimental watershed, Chiba prefecture, Japan. Nitrate concentration in groundwater of the study area has been increased and detected above the accepted level for safe drinking-water. Although groundwater table in upland area is relatively deep (about 20m below the ground surface), loamy soil with high moisture content (about 70%) is widely distributed over sandy upland surface. As soil moisture content is one of the most important factors which can control the biogeochemical cycle, therefore, in such loamy soil, it is important to investigate the role of special hydrological conditions which affect to the nitrogen cycle. In this study, porous cup samplers were set at different 11 depths in both forested and cultivated areas. Soil water chemistry and in situ various processes controlling it in loamy soil were monitored to the depth of 4m (the thickness of loam layer is about 3-4m). In coniferous-forested site, with increasing the depth, nitrate concentrations in the soil water decrease till approximately 0mg/L. The mechanisms of nitrate debilitating with depth, however, were complex and different by the depths. Vertical changes in NH4+ concentration and NO3-/Cl- ratio suggest that there are three stages of processes controlling nitrate concentration: (1)uptake by plant and nitrification at depths of 0-1.0m below the ground surface. (2)nitrification and dilution caused by increase of soil moisture content at depths of 1.0-2.5m. (3)nitrate loss by the microbial reaction under anaerobic condition due to high soil moisture at depths of 2.5-4.0m. Nitrification is the main biochemical process at the most depths of loamy soil, in the cultivated site strongly affected by human activities such using the fertilizer, probably due to lower soil moisture content of the cultivated soil than that of the forested soil. These results suggest that although upland surface soil is generally considered as aerobic environment, loamy soil can make, in macro-scale level, anaerobic condition due to high soil moisture content under the forested sites. In this case aerobic/anaerobic zone boundary may exist at the depth of about 2.5m. In cultivated soil it was suggested that not only use of fertilizer but also soil moisture deficit caused by cultivation and/or vegetation can be one of the most important process as human impact to upland surface environment. Furthermore, the application of conceptual model

which had been proposed in previous studies on nitrogen cycling in near-stream environment to the upland surface soil was also examined.

HW01/10A/C26-010   1210

N2O EMISSION FROM TEMPERATE MONSOON FORESTS IN JAPAN AS CORRELATED WITH STREAM NO3- CONCENTRATION

Muneoki YOH[1], Yuji TAKESHIGE[2], Eiichi KONOHIRA[3] ([1]Faculty of Agriculture, Tokyo University of Agriculture and Technology, [2]Shimadzu Techno-Research, Co., Ltd., 604-8436, Japan, [3]Graduate School of Environmental Studies, Nagoya University, 464-8601, Japan)

Terrestrial ecosystems act as an important source of atmospheric N_2O, but uncertainties remain in not only their quantitative importance but the mechanics. The estimated emission from temperate forests has a wide range of 0.1-2.0 Tg yr-1. Actual effect of 'nitrogen saturation" on N_2O emission as presumed by Aber et al. (1989) has little been clarified. In addition, few data on forest N_2O emission are available for monsoon Asia that has charasteric climate and soil properties. Here, we present a correlation of annual N_2O emission rate with corresponding streamwater NO_3^-. N_2O emission was measured in 5 forested watersheds in Japan using a closed chamber set at 10-15 places per watershed. A specially intensive research was made for adeciduous forest near Tokyo, which has been demonstrated typically N-saturated (Yoh et al., 2001; Yoh, 2001). In this site, N_2O fluxes showed a clear seasonal variation, having an onset in spring, a maximum in summer, and a decline in late autumn. A significant correlation was observed between the flux and soil temperature, which has scarcely been observed in Europe and North America. This seasonality may be reasonable considering that microbial activities have little limitation all the year round by water in soil, thus probably representing a feature of humid monsoon climate. Consequently, the change in fluxes at a site was successfully described as a function of soil temperature. Taking advantage of it, we estimated annual N_2O fluxes in other less often studied forests, which are variable in region, altitude, or geological and ecological conditions. The results showed a large difference in N_2O fluxes ranging 20-fold from 0.04 to 0.9 kg N /ha/yr. However, we found a linear correlation between the magnitude of annual N_2O flux and stream NO_3^- concentration of the corresponding watershed. This relationship implies that: (1) the large variability of N_2O emission observed among watersheds is accounted for just by a factor reflected in stream water NO_3^-, little by any others. (2) nitrogen saturation may really accelerate N_2O emission from forest ecosystems as well as NO_3^- leaching, indicating an increasing source for atmospheric N_2O. (3) stream NO_3^- concentration could be a powerful parameter that enables an easy estimation of N_2O emission from a whole area of corresponding forested watershed. The emission factor of N_2O calculated from annual N_2O flux / annual NO_3^- flux by stream outflow is 3.1 %. Seasonal variation in stream NO_3^- concentration seems practically insignificant judging from its averaged CV as low as 25% through preceding seasonal observations on stream water chemistry (Yoh et al., 2001). Under similar climate condition at least, annual N_2O emission from a watershed could be calculated from a single measurement of stream NO_3^- concentration (**C**) from the following formula: N_2O (g N/ha/yr) = $0.031*10000$(m²/ha)*C (gN/m³)*$Discharge$ (m/yr).

IMPORTANCE OF COMPARATIVE CATCHMENT STUDIES FOR UNDERSTANDING BIOGEOCHEMICAL CYCLES IN FORESTED ECOSYSTEMS: SUGGESTIONS FROM HYDROLOGICAL CONTROLS ON NITROGEN DISCHARGE

Nobuhito OHTE, Naoko TOKUCHI (Graduate School of Agriculture, Kyoto University)

In studies of hydrological and biogeochemical cycles in forested ecosystems in humid regions, a key strategy is to define watersheds as ecosystem boundaries, because precipitation usually exceeds evapotranspiration in such regions, and many nutrients are transported by water flow through various pathways within a catchment. Therefore, the nutrient budget can be quantified directly by hydrologic observations coupled with chemical analyses, which means that nutrient cycling in a forest is an open system. For example, the quantity and quality of nitrogen in a forest ecosystem is controlled both by the within-system cycle among plants and soils, and by the exchange of nutrients between systems (catchments) via hydrological and meteorological transport. We emphasize the importance of catchment-scale studies focusing on the hydrological control of nutrient cycles for the following reason. Anthropogenic and chemical disturbances of forest ecosystems, such as the impact of acid rain, have been continuously investigated, beginning in the 1960s. Since the late 1980s, these studies have focused on the effects of heavy nitrogen deposition as one of the critical factors in nitrogen saturation in the forest ecosystems of the northeastern United States and northern Europe. In many cases of nitrogen saturation, high NO_3^- loads in stream and lake water have been reported. In order to elucidate the mechanisms causing these problems, it is very important to recognize that the major substances related to nitrogen dynamics are usually transported by water flow, and the related microbiological activities are controlled by hydrological and meteorological conditions, since the responses to such disturbances occur very transiently and are spatially heterogeneous within a watershed. This paper reviewed previous experimental results regarding the effects of hydrological processes on N-related biogeochemical reactions, such as mineralization, nitrification, and denitrification, and the seasonal pattern of nitrogen discharge via drainage system in Japanese humid temperate regions. In addition to these review, we compare the discharge characteristics of NO_3^- between watersheds in the northeastern United States and Japan, to evaluate differences in the status and process of nitrogen saturation, focusing on the hydrologic controls. From these geographical comparisons, following differences were pointed out. 1) High precipitation and runoff by Asian monsoon in warm summer caused higher NO_3^- discharge in Japanese cases than the northeastern United States, even though high nitrogen demand by plants removes inorganic nitrogen vigorously from soil solution in summer. 2) High NO_3^- discharge led to higher leaching of base cations to the drainage system instead of streamwater acidification, which was frequently found in the northeastern United States. These findings suggest that the comparative analysis on catchment biogeochemistry can obtain important information to approach a universal understanding of ecosystem response to environmental changes.

HW01/10P/C26-002   1420

GEOCHEMICAL MASS BALANCES FOR WATERSHEDS OF THE USGS WATER, ENERGY, AND BIOGEOCHEMICAL BUDGETS (WEBB) PROGRAM, 1992-97

Norman E. PETERS, James B. SHANLEY, Brent T. AULENBACH, Alex E. BLUM, Donald H.CAMPBELL, Robert F. STALLARD, Joseph W. TROESTER, John F. WALKER, Arthur F. WHITE (U.S. Geological Survey)

Geochemical mass balances for 1992-97 were evaluated for five relatively pristine watersheds of the WEBB Program to determine the primary regional factors controlling

yields of the major dissolved inorganic solutes. The sites, which vary markedly with respect to climate, geology, physiography, and ecology, are: Allequash Creek, Wisconsin (low-relief humid continental forest); Andrews Creek, Colorado (cold alpine, taiga/tundra, and subalpine boreal forest); Icacos River, Puerto Rico (lower montane, wet tropical forest); Panola Mountain, Georgia (humid subtropical piedmont forest); and Sleepers River, Vermont (humid northern hardwood forest). Average annual air temperature ranged from about 0°C in Colorado to 21°C in Puerto Rico. Likewise, hillslope gradients vary markedly among sites from extremely low slopes (average <1%) associated with the groundwater dominated system in Wisconsin to very steep slopes (average = 66%) in Colorado. For the WEBB sites, annual precipitation ranged from 950 to 5,340 mm at the Wisconsin and Puerto Rico sites, respectively, and the associated annual runoff ranged from >500 to >4,000 mm at these sites. Atmospheric deposition was calculated from volume and solute concentrations of weekly wet-only precipitation data, which were linearly scaled for the estimated watershed precipitation. Streamwater solute fluxes were computed by integrating the product of discharge and streamwater solute concentration, which was estimated from an objective function for each solute that includes streamflow and time. The annual wet-only constituent deposition was comparable among continental sites typically varying by less than a factor of 5, and was much less than in Puerto Rico, which has very high annual precipitation that is dominated by sea salt. Wet-only deposition is a dominant source of N, S, and Cl- in each watershed. Droplet deposition (fog and cloudwater) and dry deposition (gases and aerosols) probably contribute most of the remaining difference between outputs and inputs for these constituents, but were not measured at all sites. Bedrock type, residence time of water in the watershed, and temperature are important controls on the weathering contribution of other solutes to streamwater, as reflected by streamwater H_4SiO_4 and alkalinity among sites. The highest average streamwater H_4SiO_4 concentrations were in the warmest watersheds in Georgia and Puerto Rico and the lowest was in the coldest watershed in Colorado. The highest average alkalinity was at the groundwater-dominated site in Wisconsin and in the watershed in Vermont, which contains calcite in the bedrock.

HW01/10P/C26-003   **1440**

INTERSITE COMPARISON AS MEANS TO QUANTIFY THE PRIMARY PROCESSES CONTROLLING HYDROLOGICAL AND BIOGEOCHEMICAL CYCLING AT THE HILLSLOPE SCALE

Taro UCHIDA[1], Jeffrey J. MCDONNELL[2], Yuko ASANO[1] ([1]Graduate School of Agriculture, Kyoto University, [2]Department of Forest Engineering, Oregon State University)

Effects of land use and land use change on hillslope hydrology are usually made by quantification of the inter-site comparison of catchment response to rainfall or snowmelt. To date, most of these inter-comparison studies have dealt only with the timing and volume of stream flow. In the past several decades, tracer approaches and internal soil water and groundwater response observations have revealed complex runoff process behaviors. Nevertheless, the many different hillslope hydrological processes often seem to very similar hydrograph response. Here we compare stream flow response, tracer and internal pore pressure response data for two well studied sites; Maimai in New Zealand and Fudoji in Japan. These catchments share remarkably similar topography, soil depth, slope angles climate conditions. However, soil drainable porosities at Fudoji are much greater than that in Maimai. Maimai is also underlain by a firmly compacted poorly impermeable conglomerate, whereas Fudoji is underlain by permeable granite. Results show that baseflow recession curves in Fudoji hillslope discharge are significantly gentler than that of Maimai and mean residence time at Fudoji was > 200 % larger than Maimai. Mean residence time gradients at Fudoji increased vertically through the soil profile whereas mean residence time of soil water and transient groundwater increased in a predominantly downslope direction at Maimai. A examination of hydrograph shape and soil water potentials in medium size storms (total rainfall amounts ranges 20 to 60 mm) suggest that these sites are functionally similar. Nevertheless, event/pre-event water components for medium size storms at Fudoji were >3 times that of Maimai and the extension of subsurface saturation area at the Fudoji hillslope was significantly less than that of Maimai. While, during the heaviest storms (total rainfall amounts is greater than 60 mm), the quick flow rate in Fudoji was much greater than Maimai. We argue that a holist approach to compare and contrast processes among watersheds should include multiple data constraints, including flow, tracers and internal pore pressure and groundwater responses.

HW01/10P/C26-004   **1500**

REGIMES DE FLUX DES MATIERES SOLIDES EN SUSPENSION A L'ECHELLE DES PRINCIPAUX ECOSYSTEMES DU CAMEROUN : DIVERSITE CLIMATIQUE ET ACTIONS ANTHROPIQUES

Gaston LIENOU[1], Gil MAHÉ[2], Luc SIGHA-NKAMDJOU[3], Daniel SIGHOMNOU[3], Georges Emmanuel EKODECK[1], Felix TCHOUA[1] ([1]FacultAEdes sciences, UniversitAEde YaoundAEI, Cameroun, [2]IRD, 01 BP 182 Ouagadougou Burkina Faso, [3]Centre de Recherches Hydrologiques BP 4110 YaoundAE(Cameroun))

Situé en Afrique Centrale, le Cameroun couvre une superficie de 475 000 km², étirée entre le 2° et 13° nord. Le pays est alors soumis à deux grands ensembles climatiques : Le climat équatorial à quatre saisons dans la partie sud et le climat tropical à deux saisons au nord. Le relief du pays, marqué principalement par la mégastructure tectonique de l'Adamaoua, et son exposition aux flux de mousson atlantique associent aux deux principaux climats des nuances maritimes et montagnardes. Le couvert végétal se différencie aussi dans le sens sud au nord, de la forêt dense humide à la steppe à épineux, en passant par les savanes de moins en moins boisées. La population, estimée à 15 millions d'habitants en l'an 2000 est très inégalement repartie sur le territoire, la densité variant de moins de 8 hbts/km² à plus de 200 habts/km². C'est donc par la combinaison déléments complexes : configuration donnant l'avantage à la latitude, localisation au golfe de Guinée, relief trèsdifférencié, population inégalement répartie, que le Cameroun affirme sa diversité, faite de nombreuses interférences entre climats zonaux et azonaux, et modes d'occupation de l'espace. Les mesures des matières en suspension dans les fleuves et rivières du Cameroun sont faites depuis la fin de la décennie 1950. Ces mesures, pour une unité hydrologique, ont souvent été limitées dans le temps. Mais l'ensemble constitue un support privilégié pour une approche globale des régimes des transports solides en suspension dans les différentes rivières. On tente d'appréhender l'intensité de lérosion et d'en déterminer les principaux facteurs conditionnels à léchelle des principales unités climatiques. L'activité humaine est mise en évidence. Il ressort que les fortes pentes, la densité de la population, les cultures et lélevage en sont les facteurs primordiaux. La charge solide des rivières croû avec les latitudes de 20-40 g/m³ vers léquateur à 80-100 g/m³ dans les zones de transition et à 150-160 g/m³ en zone tropicale sec. Le choix de la taille du bassin versant pour la caractérisation du taux dérosion effectif est indispensable. En effet, à léchelle des grands (S > 5 10⁴ km²), il y une intégration des caractéristiques géomorphologiques, phytogéographiques, pédologiques et anthropiques hétérogènes en caractéristiques moyennes qui ne rendent plus compte de l'influence du milieu sur lérosion. Mots clés : érosion, action anthropique, diversité climatique

---

HW01/10P/C26-005   **1520**

SUBSURFACE HYDROLOGIC FLOWPATHS AND BIOGEOCHEMICAL CONTROLS OF NO3- TRANSPORT IN KAWAKAMI FORESTED HEADWATER CATCHMENT, CENTRAL JAPAN

Kasdi Subagyono --[1], Tadashi TANAKA[2] ([1]Center for Soil and Agroclimate Research and Development, Agency for Agricultural Research and Development, [2]Institute of Geoscience, University of Tsukuba, Tennoudai 1-1-1, Tsukuba, Ibaraki 305-8571 Japan)

NO_3^- is important nutrient in agricultural and forested lands, yet the assessment of its dynamic behavior under controls of hydrologic pathways and biogeochemical characteristics is still under considerable debate. NO_3 concentration, hydrometric and biogeochemical characteristics were measured during storm event on August 21-22, 2001 and monthly during the period of August 2000 to August 2001 to define NO_3 mobility in Kawakami Experimental Basin (KEB), Central Japan, a forested headwater catchment with various soil depths overlying late Neogene of volcanic bedrocks. pH, electrical conductivity (Ec), dissolved oxygen (DO), and oxygen reduction potential (ORP) were also measured. Flux of NO_3 was obtained using the convection-dispersion model and its residence time was estimated from its mass divided by its flux. Change in NO_3 concentration agreed well with magnitude and direction of flow. Its concentration in deep riparian groundwater zone increased during low flow, and decreased during high flow. At early onset rain during storm event, its concentrations in deep riparian groundwater was 4.62 mg/L, which significantly differed with that in near surface riparian (0.16 mg/L) and hillslope soil water (0.26 mg/L) due to difference of residence time. At peak storm, its concentrations decreased more than 50% suggesting an occurrence of flushing high concentration of NO_3^-. The NO_3 residence time (Tr) obey the following sequence: Tr (deep riparian groundwater) > Tr (near surface riparian) > Tr (hillslope soil water), which have positive correlation with its concentrations. The spatial distribution of NO_3 concentrations showed general patterns in which it increases away from the stream and decreases near the border between riparian and hillslope as well as at hillslope. Bevariate diagrams of stream chemistry show controls of Ca^{2+} and Mg^{2+} on the NO_3 transport to the stream channel. High concentration of NO_3 in permanent anaerobic deep riparian groundwater zone in some extend of considering an obvious downward flow and the flux of NO_3 (the flux ranges from 0.16 to 1.64 mg.cm-2.day-1) in this zone suggest that the rate of NO_3 accumulation is higher than that of transformation due to long residence time.

A PHOSPHORUS TRANSPORT MODEL FOR SCENARIO-BASED EUTROPHICATION ASSESSMENT IN CATCHMENTS

Jonas OLSSON, Lotta ANDERSSON, Berit ARHEIMER, Göran LINDSTRÖM, Charlotta PERS, Jörgen ROSBERG (Swedish Meteorological and Hydrological Institute)

Several possible measures are available to reduce diffuse (non-point source) nutrient load to surface water and thereby reduce eutrophication. Such measures include changed arable practices and constructions of wetlands and buffer zones in the landscape, as well as managing lake ecosystems. For some measures, there is an intense debate regarding their nutrient reducing capability. Further, the combined effect of several measures in a catchment is not necessarily equal to their sum. Finally, scale effects (e.g. between fields and catchments) may significantly influence loadings. It is therefore important to apply a holistic and integrated catchment approach when applying and evaluating different management strategies. To facilitate such catchment analyses, the Swedish research program on water quality management - VASTRA - focuses on the development of modeling tools addressing both phosphorus (P) and nitrogen (N) dynamics in catchments. The program is a multidisciplinary effort and in Phase II of the program (2002-) in particular three urgent problem areas are tackled: stakeholders´ participation and resolution of conflicts, modeling P transport for eutrophication control, and integrated tools for scenario analysis at the catchment scale. One sub-program aims at improving the description of nutrient flow in catchments by studies of three key landscape elements: (1) arable land - nutrient leakage under differing agricultural management practices will be assessed, (2) wetlands - crucial factors for nutrient reduction will be identified and a model for nutrient trapping in wetlands and buffer zones developed, and (3) lakes - operational scenario modeling including nutrient turnover routines of in-lake measures will be performed. Finally, the findings will be combined to build an integrated, predictive tool for catchment synthesis of nutrient fluxes. The current development of a P transport model builds on the successful decision support tools for N management in rivers and lakes, developed by the group within Phase I of the program. The N model is based on the conceptual, semi-distributed HBV hydrological model, equipped with routines for N transport and turnover. The HBV-N model has been used for estimation of natural retention and source apportionment of N in entire Sweden. Roughly, the P model is designed as an extension of the N approach, taking into account additional processes relevant for P transport such as P turnover in streams, streambank erosion, surface runoff, and sediment transport. The sub-routines for these processes are presently being tested in an experimental catchment in southern Sweden, where the effect of various reducing measures of diffuse nutrient release will later be demonstrated in scenario-based modeling. Further, extensive P transport data bases are being analyzed in order to optimize the sub-routines´ design. The presentation will introduce the VASTRA program in general, and in particular present recent results from data analyses and the ongoing P transport model development.

PREDICTING THE IMPACT OF AFFORESTATION OR DEFORESTATION ON RECHARGE USING ONLY TIME SERIES SOIL MOISTURE DATA

Joseph POLLACCO (School of Civil Engineering and Geosciences, University of Newcastle)

Modelling the impact of afforestation or deforestation on water resources is complex. Many factors need to be taken into account such as the microclimate, the soils, the underlying geology, the presence of macropores, the species and their age and density. Parameters used in modelling the different processes are traditionally determined individually from laborious and expensive measurements such as the evaluation of transpiration from branch bag; sap flow; eddy covariance method; the interception calculations of the precipitation differences next to and within the canopy. In this study a modelling approach is taken where the only input data required are time series precipitation and penman evapotranspiration. The SheLuc (System Hydrological Europeen Land Use Change) model uses parameters describing interception, evapotranspiration and soil parameters (van Genuchten parameters). The novel aspect of the SheLuc model is that the parameters are determined solely from normalised time series soil moisture profiles measured by neutron probes. Thus the SheLuc inverse problem for calibration uses a minimum of parameters to describe the different processes which renders SheLuc a valuable tool to predict scenarios of climate and

landuse change. SheLuc is the merger of two models, SHETRAN and Hyluc. The latter is a parsimonious parameter water balance model which predicts evaporation, interception, soil moisture deficit and recharge. Hyluc uses only the integrated soil moisture content within the upper 2m of soil and employs the concept of field capacity and has been used on its own and in many studies to predict recharge. The only component of SHETRAN employed in this model represents the Richards equation for 1-dimensional flow through unsaturated porous media. A finite difference solution to the equation is calibrated using all of the soil moisture data to a depth of 9m, and the method avoids the concept of the field capacity. SheLuc is being used as a Decision Support tool to estimate whether there will be an increase or decrease of recharge if the Midlands region of the UK is forested or deforested with pine or oak on current pasture grassland and heather landuse. SheLuc gives quantitative predictions that recharge would be greatest for pasture grass decreasing in the following order for Heather, Oak and then Pine.

HW01/10P/C26-008   1700

THE EFFECTS OF 3-YEAR OLD ROAD NETWORK ON BIOGEOCHEMICAL RESPONSES OF A SMALL TROPICAL HEADWATER CATCHMENT TO STORM EVENTS IN PENINSULAR MALAYSIA

Junjiro N. NEGISHI[1], Roy C. SIDLE[2], Shoji NOGUCHI[3], Robert STANFORTH[4], Abdul RahimNIK[5] ([1]Department of Geography, National University of Singapore, [2]Disaster Prevention Research Institute, Kyoto University, Japan, [3]Japan International Research Center for Agricultural Sciences, [4]Department of Chemical and Environmental Engineering, National University of Singapore, [5]Forest Research Institute Malaysia)

Tropical rainforests are generally characterized by being nutrient poor compared to temperate forests because the relatively high temperatures throughout the year and the large amounts of precipitation promote nutrient mobilization through higher decomposition rates of organic detritus as well as leaching from organic matter and inorganic minerals. However, continuous and efficient internal recycling of nutrients within tightly-coupled trophic levels enables exceedingly high productivity and biological diversity of tropical rainforests to be established. Construction of road networks for timber production is among the most devastation land uses ralated to nutrient cycling in forested catchments because it greatly alters the residence time and pathways of precipitation and runoff leading to the discontinuity of nutrient recycling. Compacted bare soil surfaces and intense rainfall promote occurence of infiltration-excess overland flow and surface erosion, particularly on roads. Formation of artificially extended surface runoff networks on the roads not only cause a quick delivery of precipitation water and eroded sediment into stream systems, but also promotes a net loss of nutrients associated with runoff and eroded sediment due to a shortened residence time and decreased chance to be utilized by vegetation. Although the effects of logging operations on flow regime, sediment and water yields are somewhat understood, most of the previous studies have been based on the monitoring at catchment outlets. Therefore, our process-based understanding of how road networks influence nutrient pathways and how such intra-catchment processes are reflected in the outlet measurements is limited.In this study, biogeochemical responses of road systems to precipitation events were examined by collecting water samples over several storm events along with hydrological measurements in a small headwater catchment (13ha) at Bukit Tarek Experimental Watershed, Peninsular Malaysia. The road networks were established within the catchment in 1999 when it was selevtively harvested. We employed an experimental design in which a subcatchment ($<$1ha) is nested within the 13ha catchment. Infiltration-excess overland flow generated on the road surface appeared to have consistently contained one of the highest concentration of dissolved organic carbon (DOC) and potassium (K) observed in the catchment. The concentrations of these elements did not significantly drop even during highly intense rainfall and also had a positive relationship with suspended sediment (SS) concentration. This observation suggest that these elements might originate from organic matter rich side cast materials that have been left on the road edges. At the catchment outlet, the trajectories of concentration level of DOC, K and SS appeared to be synchronized, suggesting their origin as the road surfaces. Our preliminary findings support our origical hypothesis that road surfaces are the major source of elements such as DOC and K even 3 year after the road construction.

HW01/10P/C26-009   1720

AQUATIC ECOSYSTEMS WITHIN THE CHERNOBYL NUCLEAR POWER PLANT EXCLUSION ZONE: 17 YEARS AFTER THE ACCIDENT

Dmitri I. GUDKOV[1], Valery V. DEREVETS[2], Mikhail I. KUZMENKO[1], Alexander B. NAZAROV[2] ([1]Department of Radioecology, Institute of Hydrobiology, [2]SSSPE Chernobyl Radioecological Centre)

The territories of the Chernobyl NPP exclusion zone are characterised bysignificant heterogeneity of radionuclide contamination, which is significantlyreflected by the radioactive substances contents in aquatic ecosystemcomponents. Primarily this is due to the composition and the dynamics ofradionuclide emissions into the environment as a result of accident in 1986, as wellas to the subsequent processes of radioactive substances transformation andbiogeochemical migration in the soils of catchment basin and bottom sediments ofreservoirs. Relatively low contents of radioactive substances are found in the riverecosystems. Due to high water change rate the river bottom sediments haveundergone decontamination processes (especially during floods and periods ofhigh water) and over the years that passed since the accident have ceased to playthe essential role as a secondary source of water contamination. The main sourcesof radionuclides in rivers are currently the washout from the catchment basin, theinflow from more contaminated water bodies, as well as the groundwater. On theother hand, the closed reservoirs, and in particular the lakes in the inner exclusionzone, have considerably higher levels of radioactive contamination caused bylimited water change and by relatively high concentration of radionuclidesdeposited in the bottom sediments. Therefore, for the majority of standing reservoirsthe level of radionuclide content is determined mainly by the rates of mobileradionuclide forms exchange between bottom sediment and water, as well as bythe external wash-out from the catchment basin.In this paper will be considered: (1) the latest data on content of the mostlybiohazard radionuclides (Sr-90, Cs-137, Pu-238, Pu-239+240 and Am-241) in water,seston, bottom sediments and hydrobionts of the different trophic levels andecological groups (higher aquatic plants, molluscs and fish); (2) the dynamics ofradionuclide distribution in components of aquatic ecosystems; (3) the impact ofhydrotechnical facilities within the Chernobyl NPP exclusion zone on hydrologicregime of flood-lands of the Pripyat River; the main water way of the exclusionzone; (4) the peculiarities of formation of vegetative communities from lakes withinembankment territory of Pripyat River flood-lands and its impact on radionuclideredistribution in aquatic ecosystems; (5) the major hydrochemical factors, whichdetermine the behaviour of radionuclides in the aquatic ecosystems; (6) thepossibility to use of hydrobionts of different trophic levels as biological indicators ofradioactive contamination of water objects; (7) the seasonal dynamics ofradionuclides content in macrophytes and the role of main aquatic plantassociations in processes of radionuclides distribution in biotic component ofbiohydrocenose; (8) some biological effects (somatic and citogenetic) of radiationexposure on hydrobionts living in water reservoirs with different levels of radioactivecontamination; (9) the level of ecological risk for aquatic organisms within theChernobyl NPP exclusion zone.

HW02/11A/C31-001   0835

SEASONAL VARIATION IN RIVER HEAT BUDGETS

Bruce W. WEBB, Yu ZHANG (School of Geography and Archaeology, University of Exeter)

The nature of the seasonal variation in the non-advective components of river heat budgets has beeninvestigated for four streams of different character in South-West England. These comprise an exposedupland tributary, a regulated water course, and tributaries shaded by deciduous and coniferous riparianwoodland. The contribution of radiation (including short-wave and long-wave components), sensible heat,evaporation, bed conduction and friction to the heat energy gain and losses of the study streams has beendetermined from on-site hydrometeorological measurements conducted over a complete annual cycle (May 1995-April 1996) and is reported as monthly mean values. The results highlight how the river heat energy budget changesthroughout the year, but also emphasise the effects of stream charcateristics in influencing the seasonal march of energybudget components.

HW02/11A/C31-002   0900

HEAT EXCHANGES AND TEMPERATURES WITHIN A SALMON SPAWNING STREAM IN THE CAIRNGORMS, SCOTLAND

David M. HANNAH[1], Iain A. MALCOLM[2], Chris SOULSBY[2], Alan F. YOUNGSON[3] ([1]School of Geography, Earth and Environmental Sciences, University of Birmingham, UK, [2]Department of Geography and Environment, University of Aberdeen, UK, [3]Fisheries Research Services (FRS) Freshwater Laboratory, Pitlochry, UK)

Stream bed gravels are important spawning areas for salmonid fish, which bury their eggs in a redd (nest) within river bed sediments to a depth of 0.30 m. The rate of development of salmonid eggs is largely dependent upon temperature and dissolved oxygen profiles. Stream temperatures are often used to predict salmonid embryo development; but there are very few medium-term studies of the heat exchanges determining water column and bed temperatures. Furthermore, no research exists on the energy balance for subarctic Scottish rivers. Hence, this paper reports the results of a hydrometeorological study of a salmon spawning stream in the Cairngorms that aims: (1) to characterise seasonal and sub-seasonal stream energy budget and thermal dynamics and; (2) to explain these variations in terms of meteorological and hydrological factors. Field data were collected within a study reach of Girnock burn (Aberdeenshire, northeast Scotland) from salmon spawning (late October 2001) until estimated egg hatch (mid-April 2002). Energy budgets for the air-water column and river bed interface were estimated based upon hydrometeorological observations made above the river (automatic weather station) and within both the channel and river bed. Bed thermal profiles were monitored to 0.4 m depth. River discharge was approximated from records at the outlet of Glen Girnock and stage (water depth) was recorded for the study reach. All field data were recorded at 15 min intervals. In terms of average river energy flux contributions, net bed radiation (35.6%), sensible heat (24.9%), bed heat flux (23.8%) and friction at the stream bed and banks (15.7%) are heat sources; while latent heat (73.1%) and net radiation (26.9%) are heat sinks. All energy losses and 24.9% of heat gains occur at the air-water interface; and 59.4% of energy gains (75.1% including friction) take place at the water-channel bed interface. Typically, temperatures increase (+1.97°C) and show dampening of thermal response from the water column to depth in the stream bed. The most salient findings include: (1) the stream bed (atmosphere) is the dominant energy source (sink) for heating (cooling) channel water, which may be attributed to inferred heat advection by groundwater up-welling into the bed of this upland stream; (2) sensible heat is the primary atmospheric energy source due to limited net radiation; (3) friction at the stream bed and banks is an important heat source. Energy budget terms and temperatures exhibit sub-seasonal changes (daily and diurnal) in response to meteorological and hydrological conditions. This research may inform models of salmonid embryo development through physical process understanding of energy fluxes driving stream temperature dynamics.

HW02/11A/C31-003   0925

STREAM TEMPERATURE AS AN INDICATOR OF HYDROLOGICAL CIRCULATION IN A STEEP FORESTED MOUNTAIN BASIN

Andrew C. WHITAKER, Hironobu SUGIYAMA (Graduate School of Science and Technology, Niigata University)

Seasonal and short-term flood event changes in stream temperature are examined for a steep forested basin in the Asahi Mountains of Niigata Prefecture on the Japan Sea coast. Average annual precipitation is 3000-4000mm with seasonal snow cover December-May, a rainy season June/July, summer typhoons, and a wet autumn season. Vegetation is mainly natural mixed beech with some planted cedar and larch. Stream temperature is monitored at three nested scales: (1) zero-order spring, (2) 1.32 km[2] second-order tributary, and (3) 19.45 km[2] third-order stream. Soil temperature is monitored to a depth of 1m close to the spring and beside the tributary/main stream channel. The dependence of stream temperature on ambient air temperature is observed, although during freezing winter periods the stream temperature is maintained well above zero by deep groundwater contributions, including very stable temperatures of about 10°C at the spring. Seasonal changes in stream temperature are driven by strong variations in the seasonal climate and the occurrence of heavy rainfall and snowmelt runoff. Short-term flood event stream temperature dynamics, which are unrelated to air temperature patterns, may be explained by changes in the dominant streamflow generation mechanisms. A drop in stream temperature can often identify peak snowmelt contributions. However, in two successive years a dramatic though short-lived drop in stream temperature occurred during the peak flood event of the warm rainy season, slightly delayed on the early falling limb. A corresponding drop in soil temperature occurring only at the zero-order site (especially 80-100cm layer) indicates rising water tables and a sudden increase in subsurface flow from these headwater hollows. In contrast, other summer rainstorms (intensities up to 50mm/h) caused only a rise in stream temperature due to the apparent dominance of surface or near-surface flow paths. Simple monitoring of stream, source spring, and soil temperature is shown to be useful in identifying dominant mechanisms of hydrological circulation, although cases of contradictory evidence are also presented.

HW02/11A/C31-004   0950

SPATIAL AND TEMPORAL STREAM TEMPERATURE DYNAMICS WITHIN AN ALPINE CATCHMENT: IMPLICATIONS FOR BENTHIC COMMUNITIES

Lee E. BROWN, David M. HANNAH, Alexander M. MILNER (School of Geography, Earth and Environmental Sciences, University of Birmingham, UK)

Stream temperature is one of the key physical habitat factors influencing the distribution and diversity of macroinvertebrate taxa in alpine catchments. However, a limited number of studies have been conducted to determine temperature variations in alpine streams other than those fed primarily by glacial meltwater. Furthermore, the thermal regime of the hyporheic zone (i.e. the active streambed layer where surface water and groundwater interact) in alpine streams has received very little attention. Hence, the aims of this paper are: (1) to characterise the nature and dynamics of water column and bed temperature patterns within alpine streams and (2) to determine the key physical factors influencing spatial and temporal variability in alpine stream thermal behaviour. Field data were collected over the 2002 summer melt-season in the Taillon-Gabiétous catchment, French Pyrénées. The catchment contains four distinct and highly dynamic hydrological stores: (1) two cirque glaciers (Taillon and Gabiétous), (2) seasonally variable snowpacks, (3) a karst groundwater system, and (4) hillslope/alluvial aquifers. Water column temperatures were recorded at 8 sites: (A) the Taillon stream near the glacier snout; (B) 1 km downstream on the main Taillon stream, upstream of the confluence with C; (C) a karst groundwater spring; (D) the Taillon stream downstream of the confluence with C, upstream of the confluence with E; (E) a predominantly groundwater fed tributary (Tourettes) with a small glacial input; (F) the Taillon stream downstream of the confluence with E; (G) a hillslope groundwater stream that is a tributary of E; and (H) a large upwelling fed by alluvial groundwater. At three sites (D, E and F), bed temperatures (0.05, 0.20 and 0.40 m depth) and stream discharge were monitored. An automatic weather station was installed over the stream at Site D. All data were recorded at 15 min intervals.   With the exception of streams fed directly by deep groundwater stores and at the Taillon Glacier snout, surface water temperatures were strongly influenced by air temperature, and inputs from tributaries. Bed temperatures in the Taillon (Tourettes) stream were on average, coldest (warmest) and most (least) variable. However, dynamic sub-seasonal contributions from different water stores resulted in short term deviations away from seasonal patterns. Hyporheic water temperatures were strongly influenced by the direction and extent of inferred groundwater-surface water interactions. In the Taillon stream, thermal regimes of surface and hyporheic waters were very similar with short lag times and limited vertical dampening of thermal response, indicating strong surface water downwelling. In the Tourettes stream, bed temperatures were colder than surface waters and hyporheic thermal responses to warming of surface waters were increasingly lagged and attenuated with depth, suggesting groundwater upwelling. In providing an insight into the controls upon water column and streambed temperatures, this research will inform ongoing hydroecological investigations in the Taillon-Gabiétous catchment and, more widely, the study of benthic communities in alpine catchments.

HW02/11A/C31-005   1045

WATER-AIR TEMPERATURE RELATIONSHIPS AND THE ROLE OF FLOW

Bruce W. WEBB, Paul D. CLACK, Des E. WALLING (School of Geography and Archaeology, University of Exeter)

The nature of the water-air temperature relationship, and its moderation by discharge, have been investigated for catchments ranging in size from 2.1 to 601 km² in the Exe Basin, Devon, UK and for data relating to hourly, daily and weekly time bases. The sensitivity and explanatory power of simple water-air temperature regression models based on hourly data were improved by incorporation of a lag, which increased with catchment size, while relationships became more sensitive and less scattered as the time base of data increased from hourly to weekly mean values. Significant departures from linearity in water-air temperature relationships were evident for hourly, but not for daily mean or weekly mean, data. A clear tendency for relationships between water and air temperatures to be stronger and more sensitive for flows below median levels was apparent, and multiple regression analysis also revealed water temperature to be inversely related to discharge for all catchments and timescales. However, discharge had a greater impact in accounting for water temperature variation at shorter timescales and in larger catchments.

HW02/11A/C31-006   1110

EFFECTS OF RIPARIAN MANAGEMENT ON STREAM TEMPERATURE IN HEADWATER STREAMS, COASTAL BRITISH COLUMBIA, CANADA

Takashi GOMI[1], R. Dan MOORE[1], Amod S. DHAKAL[2] ([1]Department of Geography, University of British Columbia, [2]Department of Forest Resources Management, University of British Columbia)

Stream temperature is arguably the "master variable" in stream ecosystems. Forest harvesting can influence stream temperature regimes, and the potentially deleterious impacts of higher temperatures on salmonids and other species have generated significant debate. One common approach to protecting streams is to leave a riparian buffer to provide shade. However, little information has been collected on the effectiveness of different buffer widths. We report the results of a 6-year field experiment to evaluate the effects of riparian buffer widths on stream and riparian ecosystems, including stream temperature response, in headwater streams in coastal British Columbia. The experiment included 12 streams, of which three were assigned to each of four treatments, including no harvesting (80 yr-old second growth conifer riparian forest), 10 m and 30 m riparian buffers, and clear-cut harvesting with no buffer (no riparian overstory vegetation). Regression analysis was used to calibrate the pre-harvest data for each treatment stream with one of the control streams, to provide a basis for estimating post-harvest treatment effects. Autoregressive and heteroskedastic errors were included in the regression model, because stream temperature exhibited serial correlation and the error variance increased with stream temperature. Water temperature in the streams with 10 and 30 m buffers did not exhibit significant warming. Summer temperature increases averaged only 2 to 3 °C in the streams in the no-buffer treatment, compared to increases of up to 7 to 10 °C, or greater, found in previous studies. Because the headwater channels are narrow (bankfull width 1-3 m), both over and under-story vegetation provided shade and reduced direct input of solar radiation. In addition, ongoing research suggests that hyporheic flow through step-pool features formed by pieces of large woody debris may have a strong role in moderating water temperature increases in these steep headwater streams.

HW02/11A/C31-007   1135

EVALUATION OF POTENTIAL ENERGY LOSS WITH DAM CONSTRUCTION

Koshi YOSHIDA, Hajime TANJI (Graduate School of Agricultural and Life Sciences,The University of Tokyo)

This paper attempts to propose an idea of dam assessment, which aims after potential energy of river water. It is easy way to estimate an impact of dam development by volume balance that many previous studies have employed for dam assessment. Generally dam for generating electricity has been regarded as non-consumptive water use in the past. Of cause, that does not consume river water volume, however potential energy must be consumed for generating hydroelectricity. In this study, authors estimated potential energy loss based on the following two conversion theories. 1) The potential energy of river water must be converted into heart energy on non-dam condition. The change of river water temperature by dam construction was estimated to evaluate an impact to the heart environment. 2) The potential energy of river water must be converted into friction stress to erode the riverbed on non-dam condition. The change of soil erosion by dam construction was estimated to evaluate an impact of soil supply to the downstream area. Needless to say, soil is important medium to transport nutritive salts and the amount of soil supply must be considered to assess an ecological system in downstream area. The proposed model was applied to Nam Theun dam in Laos. Laos is blessed with topographical condition for dam site of hydroelectric power and recently converted an economic policy by the exportation of forest resources into by the one of electric power. Therefore the results of this study will give one solution to the adjustment between the dam development and the environmental protection in this area

HW02/11A/C31-008   1200

TEMPERATURE-OXYGEN REGIMES OF SOME TROPICAL STREAMS IN SOUTH-WESTERN NIGERIA

Catherine Imhangulaya IKHILE[1], Stella Maris AKHIONBARE[2] ([1]Department of Geography and Regional Planning, [2]New Grass Technologies)

The temperature-oxygen variations in seven rivers (Orle, Edion, Ojo, Owan, Ule, Obvioti, Oruen) located in the tropical rainforest area of Edo State, Nigeria were studied in the periods 1987 and 1997. In 1987, air temperatures ranged from 29.5-37.0 °C and water temperatures ranged between 21.0-34.0 °C. Values were lower for air temperatures in the dry season (29.5-37.0 °C) than in the wet season (30.0-37.0 °C); and water temperatures were generally higher in the wet season (range: 25.0-33.0 °C) than in the dry season (range: 21.0-34.0 °C). In 1997, the temperatures of the rivers ranged from 20.0-29.0°C while air temperatures ranged from 26.0-34.0 °C; being generally higher in the dry season than in the wet season. Dissolved Oxygen (DO) in 1987 was generally low (ranging from 2.1-36.8 mg/l), being lower in the dry than in the wet season while in 1997, DO for the rivers rangd between 0.30-2.20 mg/l and were generally low especially during the dry periods of the year. Various factors were attributed to the regimes of temperature and dissolved oxygen namely; (i) Effect of sunlight and cold harmattan winds that lower temperatures of air and water to different extents (ii) Effect of mixing and turbulence in the river flow of the dissolved oxygen as observed for River.

WATER TEMPERATURE VARIATION IN AUSTRIAN RIVERS DURING THE TWENTIETH CENTURY

Bruce W. WEBB[1], Franz NOBILIS[2] ([1]School of Geography and Archaeology, University of Exeter, [2]Hydrographisches Zentralbuero, Budesministerium fuer Land- und Forstwirtschaft, Vienna)

Trends in water temperature during the twentieth century have been investigated for 10 rivers in Austria, whichrange from small upstream tributaries strongly influenced by glacial and snow meltwater, to downstream locationson the River Danube, affected by regulation for H.E.P. generation. Monthly mean values for the period 1901 - 2000 have been investigated using LOWESS smoothing techniques to identify trends in annual and seasonal water temperatures, and tohighlight different patterns of variation in catchments of different character. Variation in water temperature has also beenexamined in relation to the North Atlantic Oscillation Index as an indicator of climatic conditions during the twentiethcentury.

HW02/11A/D-002   Poster   0830-134

EXPOSED RIVERINE SEDIMENT PATCHES: ENERGY FLUXES AND THERMAL PROFILES

David M. HANNAH (School of Geography, Earth and Environmental Sciences, University of Birmingham, UK)

Exposed riverine sediments (ERS) represent important habitats along both natural and highly modified rivers. Furthermore, ERS have long been associated with rare and scarce invertebrates in the UK. Some ecologists have suggested faunal communities in these 'harsh' environments are influenced by abiotic factors. Heat transfer within ERS is a key determinant of physical habitat quality between disturbance (inundation) events. However, there is currently no information about ERS surface and subsurface microclimate (specifically vertical energy fluxes and thermal profiles) during these 'drying-out' periods. Hence, the primary aim of this paper is to determine the nature and dynamics of energy (heat) fluxes within ERS and, thus, to elucidate the key factors that control variations in surface and subsurface physical habitat in space and over time. Field observations were made during summer 1999 and 2001 on the Fiume (River) Tagliamento, Italy. Two study sites were instrumented to provide both alpine (upstream) and Mediterranean (downstream) hydroclimatic conditions and a complete range in ERS calibre from fine sand to coarse gravel. At each site, an area (e.g. gravel bar) of varied ERS patches was identified. An automatic weather station was set-up in the middle of each area to collect meteorological time-series at 15 min intervals from which the surface energy balance was estimated. Thermal profiles (0.05-0.3 m depth) were monitored for patches of different sediment calibre using synchronised miniature temperature dataloggers. Spot measurements of surface albedo and surface sediment calibre and mineralogy were determined for each patch. The results show net radiation (Q*) is dissipated by latent (Qe), sensible (Qh) and ground (Qg) heat fluxes in descending order. Qe is dominant because of freely available water but as sediments dry-out Qh becomes more important. Typically, net daily Qg is a small heat gain (warming sediments) but under overcast conditions Qg supplies energy to the atmosphere (cooling sediments). Diurnal temperature cycles are attenuated and lagged with depth. Finer calibre sediments produce stronger near surface thermal response. Moist sediments exhibit a larger amplitude response at depth, although sub-surface temperatures are lower than adjacent dry patches due to channelling of Q* into evaporation (Qe). Together, diurnal

fluctuations in energy fluxes and spatially variable sediment characteristics (i.e. size and mineralogy which control surface albedo and thermal conductivity) interact to govern the dynamic and heterogeneous physical habitat conditions found within areas of ERS.

QUALITY ASSURANCE IN ENVIRONMENTAL MODELS AND DATA: SCIENTIFIC AND ORGANIZATIONAL ASPECTS

Jacques JANSEN[1], Harm HOUWELING[2], Jûnt HALBERTSMA[1], Michiel JANSEN[3], Hans HEESTERBEEK[4] ([1]Alterra Green World Research, Wageningen University & Research Centre, [2]Nature Policy Assessment Office, Wageningen Branch, [3]Biometris, Wageningen University & Research Centre, [4]Faculty of Veterinary Medicine, Utrecht University)

The Nature Policy Assessment Office Wageningen branch is an integrated part of The Environmental and Nature Policy Assessment Agency (MNP), a collaboration between the National Institute of Public Health and the Environment (RIVM) and Wageningen University and Research Centre. This organization acts as a centre of expertise for the national government in the development, monitoring and assessment of policies for the the quality of environment and nature. Models and databases on various environmental disciplines and topics are important instruments in the MNP-toolbox. Quality assurance is crucial to provide policy makers, parliament and the public in general with reliable information. The paper presents and discusses the results of a recently finished research project by Wageningen University and Research Centre aiming at: 1) quality assessment of 27 individual models or databases and 2) development of a policy and organizational framework for quality assurance of models and data. The quality aspects examined in the individual audits are: a) scientific soundness of the model concepts, b) translation of these concepts into mathematical formula's and numerical procedures, c) statistical aspects including the treatment of uncertainties, in particular when models and databases are linked into chains, d) quality assurance of the procedures followed in building and using a model or database and e) communication of the results to policy makers and the public. The audits were designed and conducted on the basic principle that the quality of a model or database cannot be described as such but only in terms of fitness for a specific use, in this case the design and assessment of national environmental and nature policies. The central themes in the development of a methodology and organization for quality assurance of models and data are: a) roles and responsibilities in the process of quality assurance of models and data, b) development of sets of quality criteria and standards, c) integration of procedures for quality assurance and management (development, maintenance and operational use) of models and databases, d) incorporation in ISO-9001 procedures of the institutions involved and e) interaction with the MNP as the client for the assessment studies. Especially the conclusions and recommendations of this second part of the study, the development of a methodology and organizational framework for quality assurance, are relevant for other types of models and databases, other applications and other organizations.

HW03/11A/C30-002 — 0850

QUALITY ASSURANCE IN CATCHMENT AND RIVER BASIN MODELLING USING KNOWLEDGE ENGINEERING TECHNIQUES

Huub SCHOLTEN[1], Jens Christian REFSGAARD[2], George ZOMPANAKIS[3], Ayalew KASSAHUN[1], Costas GAVARDINAS[3], Hans Jørgen HENRIKSEN[2], Bill HARRAR[2] ([1]Wageningen University, the Netherlands, [2]Geological Survey of Denmark and Greenland, Denmark, [3]National Technical University of Athens, Greece)

Mathematical models have been applied forseveral decades in solving problems in many domains of water management. In thelast decade a strong need for Quality Assurance has emerged among professionalsin this field. A summary of reasons for this growing interest in QualityAssurance includes: a lack of mutual understanding between key-players(modellers, clients, auditors and the general public), malpractice (careless handling of input data, insufficientcalibration/validation and model use outside of its scope), overselling ofmodel capabilities, confusion on terminology and uncertainty on how to usemodel results in decision making. Theaim of the HarmoniQuA project is to provide Quality Assurance support tokey-players in model based water management. The complex process of modellingis decomposed into tasks that are defined at levels consistent with theconceptual understanding and action repertoire of the associated key-player.The body of knowledge describing these tasks has been compiled by expertswithin various domains of water management, discussed until consensus wasreached and stored in a Knowledge Base (KB) with an ontology-based structure.The KB also contains a glossary of terms and concepts used in model based watermanagement and is designed to allow easy maintenance and upgrading of theknowledge structure and content. In order to facilitate the ease of use of the KB, a toolbox has been developed that facilitates the use of theknowledge in the KB by key-players, who may be inexperienced in knowledgeengineering. A *guideline tool* provides help for each task pertinent to specific key-players by defining tasksand offering information on methods and activities to solve these tasks. A *monitoring tool* stores the activities ofeach key-player in a model journal, the data structure of which is based on thesame ontology as the KB. Other components of the HarmoniQuA tools suite offer auser demand driven *reporting tool* andan *advisor tool*, which enables modellers to use expertise accumulatedduring previous model studies and available through a model archive consistingof a set of model journals. A prototype of the KB and the toolbox are tested using two series of tencommercial case studies. These tests represent common model applications invarious domains of model based water management throughout Europe. Theprototypes are revised and improved after each test series. What´s new? Existing guidelines for model based water management are generally writtenfor modellers interested in a single domain. The static nature of thesedocuments hinders their application, upgrading and consistency evaluation.HarmoniQuA provides the required knowledge and tools to support the wholemodelling process for integrated studies applied in combinations of sevendomains in water management. The HarmoniQuA tools suite enables universalaccess to modelling knowledge, documentation of modelling activities, includingclient-modeller interaction, model development and review of the model studyrendering the quality of modelling explicit.

HW03/11A/C30-003 — 0910

UNCERTAINTY ANALYSIS AND MULTI-CRITERIAL VALIDATION OF REGIONAL-SCALE ECOHYDROLOGICAL MODELS

Valentina KRYSANOVA, Fred HATTERMANN (Global Change and Natural Systems Dept., Potsdam Institute for Climate Impact Research)

The need for powerful validation techniques for distributed hydrological and ecohydrological models has often been pointed out. The validation has to be multi-scale, multi-site and multi-criterial, if the model has to be further used for regionalisation or global change impact assessment. While the primary idea of distributed hydrological modelling is to reproduce water fluxes in sub-basins and hydrotopes along with river discharge, the models are often validated using only observed river discharge, and multi- scale validation is rather exceptional. This is especially true for macro-scale basins. The river discharge is an integral characteristics of hydrological processes in the basin, but its correct representation by the model does not guarantee adequacy in spatial and temporal dynamics of all water components in the basin. The presentation will demonstrate a method to perform the multi-criterial and multi-scale validation of a regional-scale ecohydrological model based on uncertainty analysis performed in advance. The method enables to reproduce local hydrological processes like water table dynamics in sub- basins, using contour maps of the water table and observed groundwater level data. The study was carried out with the ecohydrological model SWIM (Soil and Water Integrated Model). The model integrates hydrological processes, vegetation/crop growth, erosion and nutrient dynamics at the basin and regional scale, and was developed for climate and land use change impact assessment in meso- to macro-scale river basins and at the regional scale. The study area is the German part of the Elbe River basin (about 100.000 km ^{2}). It is representative for semi-humid landscapes in Europe, where water availability during the summer season is the limiting factor for plant growth and crop yield.

HW03/11A/C30-004 — 0930

THE IMPROVEMENT OF A DISTRIBUTED HYDROLOGICAL MODEL BY USING CIP METHOD

Yasuhiro ISHIMINE, Yasuhisa KUZUHA, Tokuo KISHII, Tomonori MATSUURA (Disaster Prevention Research Group, National Research Institute for Earth Science and Disaster Prevention)

The improvements in a computer performance and the advances of geographic information systems (GIS) make numerical studies in hydrology more and more important.In particular, numerical simulations based on a distributed hydrological model are expected to provide useful information about flow characteristics.However, many of conventional distributed hydrological models have to be used with the optimization of the parameters to fit the calculation results with observed data.This implies that we need to make a further effort to improve these models.A key of hydrological process is the horizontal transport of water along the topography, and thus, it should be precisely calculated in distributed hydrological models.Nevertheless, some models bring unreliable results, such that the directions of flows are affected by the configuration of computational cells, because the calculation of the horizontal transport is not appropriate.The finer the computational cells we use, the more significant the effect of this drawback becomes.Thus, it is desirable to calculate the horizontal transport by a numerical scheme in which the configuration of computational cells little affect the flow directions.For the purpose, we have adopted the CIP method and developed a new distributed hydrological model.The CIP method is a kind of high-order upwind differencing schemes and has received much attention in the field of computational fluid dynamics since it proposed about twenty years ago.This method can obtain a fine structure of flows with a relatively small number of computational cells.In addition, the flows calculated by this method are little affected by the configuration of computational cells, despite that the CIP method is a finite differencing method using uniform rectangular computational cells.We have improved the original CIP method so as to conserve the total volume of water and applied to the distributed hydrological model.The calculation results of example problems with simple topography are satisfactory good.As is expected, the flow pattern obtained from the new model is little affected by the configuration of computational cells.In particular, the calculation of the flow spreading concentrically over the ground surface clearly shows the superiority of the new model.

HW03/11A/C30-005 — 0950

VALIDATION OF THE MODEL HBV TAKING INTO ACCOUNT THE UNCERTAINTY DUE TO THE SPATIAL INTERPOLATION OF THE RAINFALL

Radhia MCHIRGUI, Zoubeida BARGAOUI, Andreas BARDOSSY (Department of civil engineering,school of engineering of TUNIS)

The use of a hydrologic model for the simulation of the rainfall-runoff transformation is submitted to many uncertainties related to (i) accuracy of hydrometric , climatic and pluviometric data, (ii) to the model structure, and (iii) to the parameter estimation method.The scope of this study is to evaluate the effect of the uncertainties due to spatial interpolation of the rainfall data on the identification of the conceptual hydrologic model HBV.For simplification, only three parameters were identified during the calibration procedure, the other parameters being fixed. They have been selected because they are related to the soil function of the model .As entry to the model , we have considered pluviometric fields simulated with the turning bands method. The application of the Turning Bands Method implies that we know the covariance function of the rainfall field.The application concerns the basin of TESSA ,located in the North of Tunisia , having a total area of about 1950Km² and limited by the hydrometric station TESSA SIDI MEDIEN(coordinates). Available obeservtions are used for the years 1974 to 1977:the maximum daily runoff registred in this period is of 528m3/s. Respectively 11, 7 and 3 rainfall-runoff events with a point rainfall exceeding 30mm have been observed each year (from 1975 to 1977).Two events were changed among calibration input sets. They are the most important from the chronolgy regarding the maximum runoff registred and the rainfall .The event of the 25/03/1975 is caracterized by a maximum rainfall observed=40mm,a mean rainfall=9mm over a network of 23 stations in service with 9 zero observed values, which show a high intermittency of the rainfall field. The 17/11/76 event is has a less intermittent field: one zero observed value among 12 rainfall stations in service, while its maximal rainfall=69mm, its mean rainfall=31mm; In both cases the maximal distance between two stations is of 86. 5Km. In order to describe the covariance structure of the rainfall field, we have modellised the experimental variograms of the two events with spherical models:25/03/1975 (Landing=120mm², range=30Km, Nuggeteffect=0); 17/11/1976 (landing=300mm², Range=30Km, Nugget effect=0).This spatial structure is preserved during the simulations.We have achieved the kriging of the rainfall over a network of 2Km of side.Twenty fields have been then simulated for each event (Randomseed=3, number of generating lines=16) and introduced as a part of the model inputs.Model calibration was performed for each input serie . For the verification of adequation between observed and calculated runoff ,we have used Nash criterion and the correlation coefficient between calculated and observed runoff during the events of 25/03/75 and 17/11/76 over a period of three days.For each simulation , we also compared the hydrographs of the observed and calculated discharges over the period 1975-1977.The optimal values are

H

respectively 400mm,130mm and 0.67. We have then obtained the probability distributions for each parameter in addition to the joined distributions of these parameters.Key-words :Uncertainty ;calibrating ;conditionalsimulation,parameter,spatial interpolation.

HW03/11A/C30-006   1030

WHY IS QUALITY ASSURANCE IN RAINFALL RUNOFF MODELLING SO DIFFICULT?

Feli Robert NAEF (Institute of Hydomechanics, Swiss Federal Institute of Technology, Zurich)

In the last decades, countless procedures and models to simulate parts of the hydrologic cycle have been developed. However, the benefits or superiority of these different approaches could not be assessed, mainly because a generally agreed scale how to measure quality was missing. In addition, the highly exaggerated expectations on the accuracies that could be reached with model simulations prevented a meaningful comparison. It probably started with the publication of the simulations of the Stanford Watershed Model in the sixties, which were already in a nearly perfect agreement with the observed hydrographs. Authors of later models felt obliged to present simulations that were at least as good or even better. The main thrust was therefore put to attain an optimal fit between the observed and simulated hydrographs. It can be shown, however, that an optimal fit does not guarantee an adequate representation of the catchment's response by a model. On the contrary, the errors from different independent sources should be reflected in the results of a suitable model. Basically, the errors from the different sources are independent. If an optimal fit is sought, they become interdependent and the model parameters are misadjusted in such a way, that the different errors compensate each other. To assess any research progress, it should at first be evaluated which results can be reached with the present day knowledge for each of the following areas. Any progress should then be measured against this background. Precipitation: The transformation of point measurements into an adequate representation of the time variant rainfall field is not yet solved satisfactorily and even larger gaps exist in determining rainfall fields with defined return periods. The error of the precipitation input using the methods available today can easily surpass 20 to 30%. Runoff production: Infiltration and retention capacity of the soil varies enormously throughout a catchment. Progress has been made in upscaling process knowledge from the plot to the catchment scale and to define infiltration parameters from field measurements. However, the uncertainty of these parameters is still considerable.Discharge measurements: Detailed evaluation of numerous stream gages showed that measurements during floods often contain large errors, putting in question results of studies that used these data without corrections. Extreme Floods: Hydrological research is often aimed to estimate floods with return periods of 100 years and more. As series of rainfall and discharge measurements hardly ever exceed 100 years, the magnitude of such floods is not well known.

HW03/11A/C30-007   1050

APPLICATION OF FUZZY MULTI-OBJECTIVE FUNCTION ON HYDROLOGICAL MODEL CALIBRATION

Tao-Chang YANG, Pao-Shan YU, Chen-Min KUO (Department of Hydraulics & Ocean Engineering ,National Cheng Kung University)

Storm event rainfall-runoff models are essential tools to simulate peak flows or design floods for many purposes in water resource projects. As the application of rainfall-runoff models is important for water resource projects, attention to further improve performances of rainfall-runoff models is increased. Successfully modeling the rainfall-runoff relationship depends on many factors, ranging form model input data (rainfall, geographic data, and runoff etc.), model structure, optimization technique to the selection of an objective function. This study proposed a fuzzy multi-objective function to improve model calibration, which has the capability of combining various objectives of features in storm hydrograph (such as time to peak, peak of discharge, total runoff volume, etc.). A grid-based distributed rainfall-runoff model was applied to simulate hydrological processes over each grid. Watershed boundaries, river network and geographic characteristics were determined by using the GIS technique based on the Digital Terrain Model (DTM). The images of the SPOT satellites were utilized for land use classification. The rainfall-runoff model was then calibrated by using the shuffled complex evolution global optimization method, in which the fuzzy multi-objective function proposed in this work was compared with a conventional single objective function. The basin of Pa-Chang Creek is located in southern Taiwan and has a drainage area of 475 km^2 and the main stream length of 87.1 km, in which seven bigger storm events were collected as the data set in which five of them were arbitrarily chosen for model calibration and the other two were used for model verification. The study results conclude that the fuzzy multi-objective function can calibrate the model more reasonably than the single objective function and have better hydrograph simulations.

HW03/11A/C30-008   1110

IDENTIFICATION OF THE HYDROLOGICAL PARAMETERS AS AN ILLUSTRATION WAY OF THE SEMI-EMPIRICAL MODEL DEVELOPMENT

Valentina A. KHAYDAROVA[1], Natalia V. PENKOVA[2], Evgenia L. PAK[1] ([1]Institute of Water Problems, Uzbek Academy of Sciences, [2]INENCO Centre of Russian Academy of Sciences, 14 Kutuzova Embankment, 191187 Saint-Petersburg, Russia)

In the hydrological cycle models a modeling subject is the water balance dynamic. Up today a lot of the heat and water balance models for description of the lands hydrological regime are suggested. The main difficulties of its application are connected with necessity for identification of a number of the combined empirical parameters, which are totally taking into account of the surface peculiarities (including vegetation) on evapotranspiration. Last years authors were conducting investigations on development of new modification of the Heat and Water Balances Model (HWBM) and its adaptation to arid and semi-arid regions in the framework of the INCO-COPERNICUS project ″Adaptation of Efficient Water Use Criteria in Marginal Regions of Europe and Middle Asia with Scarce Sources Subject to Environmental Control, Climate Change and Socio-Economic Development″. The obtained results show that the observation data from the complex network give wide possibilities of describing the combined parameters features and allows to extend knowledge about the heat and water balances components. The diagrams obtained by the using of the observation data from the complex network reflect all hypothetical possible combinations of factors affecting on the combined parameters. Therefore they must be considered as combinations of possibilities for the plants functioning. The non-linear multi-dimensional relationships between the heat and water balances components and characteristics of the plant growth conditions can broaden the possibilities of investigations of the limiting factors of plant´s life under different (including extreme) conditions. The major feature of the semi-empirical submodels obtained for the heat and water balances of agricultural lands is that they are described by curves with saturation, i.e. reflecting the fundamental characteristics of the biogeocenoses functioning: appearance of the ″negative″ feedback to achieve the equilibrium state minimizing the external forcing effects on ecosystems. Taking into account features of the system of measurements of evapotranspiration and precipitation it is necessary to consider their values not as components of water balance, but as their indices. Systematic errors can be taken

into account by means of construction of empirical relations between elements of water exchange at stressing the most authentic characteristics. In this case such characteristic can serve the soil water content measured by a thermostat method. At such approach the non-accounted elements of water balance are considered as components of a total systematic error of measurement of basic elements. Researches cover the analysis of parameterized imitation models for heat and water regimes of regional and local ecosystems.

ALEAS DU RESEAU PLUVIOMETRIQUE DU BASSIN VERSANT DU TESSAETUDE DE LA VARIABILITE DU CHAMP PLUVIOMETRIQUE PAR KRIGEAGE ET VALIDATION CROISEE PLUIE-DEBIT

Radhia MCHIRGUI, Zoubeida BARGAOUI, Andreas BARDOSSY (Department of civil engineering,school of engineering of TUNIS)

Le bassin versant du TESSA situ au nord de la Tunisie et ayant une superficie avoisinant 1950Km^2 limit la station hydrométrique TESSA SIDI MEDIEN, présente une structure pluviométrique très particulière. Notre étude porte sur les années 1984 - 1992 et a pour objectif d'analyser les évènements pluvieux de cette période afin de valider les observations dans le réseau pluviométrique constitu de 27 stations.Les évènements sont choisis tels que la pluie est supérieure ou égale 30mm en l'une quelconque des stations , on a ainsi déduit 51 évènements.Pour ce faire , nous avons établi d'abord les variogrammes spécifiques chaque événement pluvieux : la majorit de ces variogrammes est sphérique et a une portée variant entre 25 et 40km , avec un palier compris entre 300 et 4500mm^2.Afin de dégager les singularités des observations pluviométriques , nous avons procéd par le krigeage par validation croisée , qui nous a permis de simuler l'effet du choix du voisinage dans l'incertitude des résultats.Nous avons alors calcul pour chaque événement les erreurs relatives de krigeage après élimination des stations une une , puis compar les lames brutes et écoulées.Cette comparaison nous a permis de dégager les évènements du 01/08/90, du 11/07/89 et du 15/10/90 , comme évènements douteux.Puis , nous avons procéd par une validation pluie observée-pluie krigée , pluie-débit maximal , intensit de pluie-débit maximal, intensit de pluie-écart-type , intensit de pluie-lame écoulée.Toutes ces analyses nous ont permis d'avoir une critique bien fondée de la qualit des données de pluie et de conclure quant la variabilit spatio-temporelle de la pluie dans la région.Mots-clés : Incertitude ; Variogramme ; Krigeage ; validation croisée ; variabilit.

HW03/11A/C30-010   1150

ANALOGOUS SIMULATION THE ANNUAL RUNOFF OF HEIHE RIVER (CHINA,QILIANSHAN)

Vladimir G. KONOVALOV[1], Masayoshi NAKAWO[2] ([1]Institute of Geography, Russian Academy of Sciences, [2]Institute for Humanity and Nature, Kyoto, Japan)

In order to solve the entitled problem the criteria of river basinssimilarity are defined based on the conditions of runoff formation andits intra-annual distribution. Characteristic features of intra-annualdistributions of climatic factors of runoff (precipitation and airtemperature) were revealed for the Heihe river basin by data ofmeteorological stations. Calculated set of morphometry parameters of the Heihe river watershed includes: area of the basin, its averageweighted altitude, function of the basin area distribution in relationwith elevation above sea level, glaciers area and its average weightedaltitude. Role of mean weighted elevation of a watershed was shown ascharacteristic level to determine precipitation, air temperature oranother meteorological variable equaled to their average values forthe whole given area of a river basin. Thus calculation of the climatefactors at the mean weighted elevation of a watershed allows using thewater balance method for the simulation the annual runoff within the Heihe and its analogy river basins. After selecting analysis, the Naryn river basin was adopted as basin-analogy for the Heihewatershed. Empirical formulae of good quality were obtained tocalculate the annual sum of precipitation and average summer airtemperature at the mean weighted elevation of the Heihe river and itsbasin-analogy. These variables were applied in the multiply regressionequation obtained to compute the annual runoff coefficient for the Naryn river basin. Precipitation and air temperature were transformedto their normalized form in order to eliminate influence of differentnorms of climate factors within Naryn and Heihe river basins. The long-term range of Heihe river annual runoff for 1957-1993 was simulated asthe results of applying the water balance method and the equation forcalculating the annual runoff coefficient, obtained by means of thebasin-analogy. Quality assurance of the computed runoff range wasbased on three different estimations: a) Comparison of calculated andmeasured long-term ranges of Naryn river runoff and their statisticalparameters which demonstrates a rather acceptable quality of thesimulation results based on water balance equation; b) Preparation ofa diagram of temporal course for computed annual runoff within Heiheriver and its neighboring basin (measured one). Its analysis showedsynchronism of low and high water years for the compared watersheds.c) Calculation of input and output components of water balance for theHeihe river basin. Annual evapotranspiration was estimated for thisbasin. After solving the equation of water balance, we found, that thedifference was only 6 % between input (precipitation) and output (runoff + evapo-transpiration) parts of this equation.

PROBABILITY-STATISTICAL ANALYSIS DYNAMICS OF POLLUTION THE BELAYA RIVER

Tatyana FASHCHEVSKAYA, Natalya KRASNOGORSKA (Department of Ecology, Ufa State Aircraft University)

The Belaya river is situated in limitations of South Ural and is one of main tributary of the Volga River with area catchment is 142 000 km^2. The volume of average annual flow is 29,2 km^3 in the year. The quality water doesn´t remain as in time as in space that essentially is connected with disposition on the river banks the large industrial ecologically dangerous objects exert influence to the quality water. The basic loading to the river exerts the oil-refining, chemical and oil-chemical industry. These plants are concentrated in cities Ufa, Salavat, Sterlitamak, Meleuz etc. The main pollutants of wastewaters of the plants are oil-products, phenols, nitrogen of nitrite and nitrate, ammonia, phosphorus, copper, zinc, nickel

and suspended matters. Their mean yearly concentration in the river water is more than 5-10 maximum admissible concentration (MAC). We made probability-statistical analysis of dynamics of pollution in the Belaya River water using perennial data observations. The comparison of empirical and theoretical (asymmetrical binomial Pirson III type) frequency curves demonstrated possibility of their using for the investigation. The parametres of probability curves (norm, Cv, Cs) and scale of quality significance (frequency range: 10, 25, 50, 75 and 95%) were calculated through using perennial data series observations. For taking into account the water availability under analysis of water quality is used not concentration of pollutants in water river (in mg/l) but recalculated values of mass pollutants in tons per year. The calculated data made by probability-statistical analysis perennial observations gives information about water quality not only during the moment of sample but in long-term period. Besides, they taking into account processes which are in a concrete water environment: migration, transformation and bioaccumulation of pollutants and ability of a concrete water body to be selfpurificated and assimilated. We considered the annual water quality change in the Belaya River during different seasons. We found out that non-point pollution (spring snowmelt flood surface washing off) put in pollution process a very big share. It is obtained links entering of pollutants to river between volumes for year and for period of the spring snowmelt, which could be used for forecasting of entering pollutants. For the long-term period contributions of the main industrial centers into pollution of the Belaya River are computed. So, Ufa gives over 64% oil-products, 56% phenols etc. These data could be used for compiling ecological passports of different regions, development of plans of ecological situation improving and reducing of discharges of wastewater into water bodies.

MONITORING THE GARONA RIVER WATER TABLE BY MICROGRAVIMETRY AND GPS

Jean-Pierre BARRIOT, Michel SARRAILH, Thierry FAYARD (UMR5562/CNES/BGI)

We show the first results of the monitoring of the superficial water table associated with the Garona river near Toulouse, in the south of France. We use two kinds of gravity meters: a Lacoste and Romberg model D and a SCINTREX CG-3, as well as two operators, and two different close sites, to avoid systematic effects (microgal level). The soil motion is separated by doing a simultaneous GPS surveying of the site altitudes at the mm level. The equation of state of the water table is written with respect to inputs and outputs of water, and expected and computed gravity signatures are compared.

HW03/11P/C30-001   1400
QUALITY ASSURANCE IN HYDROLOGICAL DATA

Takeo KINOSITA (The Representative of Suimon Kankyo)

Background: In order to discuss about quality assurance in hydrological research, basic attention should be paid to quality assurance in original data. On the way to quality assurance, various kinds of unknown hydrological phenomena will be found in and around observation sites. Quality assurance is called researches by itself. In this report, several experiences obtained in Japan will be discussed for further development of quality assurance in hydrological community. A rating curve is commonly applied to calculate hourly discharge from hourly water stage. The author points out two major topics, field check and check of a rating curve. Field check: Field works at the gauging site are the most essential in quality assurance. Is the bench mark installed at clear place near the water gauge? Is the staff gauge set at the base line? The zero point must be levelled from the bench mark. Is the recording gauge operating? Is its sensor fixed deep enough to measure the lowest water. The observed value by the recording gauge must coincide with the staff gauge. The current meter site must be adequately selected. Distribution of measuring point must be correct. Is the current meter calibrated once a year? Drift rods must be properly used. Submerging length must be corresponding to the depth. Is there any unusual flow of a drift rod? Rating Curve: A rating curve, called an H-Q curve in Japan, is drawn by the least square method as Q=a(H+b)^2, where H is the water stage on the ordinate, Q is the discharge on the abscissa, a and b are empirical constants. When the H-Q curve makes a clockwise loop, some event, for instance a tide, is coming upstream. When it makes a counterclockwise loop, it means a flood. If not, careful inspection should be given to basic data, especially the stage velocity relation. When the rating curve makes a counterclockwise loop in the flood period, the surface gradient is useful to adjust the curve to a single-valued function. The adjusted discharge is written by Qa=Qo SQRT (Ia/Io) where Qo and Io are observed discharge and surface gradient and Ia is an average gradient. The surface gradient must be calculated at two gauging sites separated each other several kilometer. A steady flow H-Q curve is proposed to check the observed H-Q curve and to extrapolate the curve slightly. Two parameters in a H-Q curve, a and b, are determined by   a=v (1+p))^2*B)^2/4A   b=2R/(1+p)-H where v is the mean velocity, p is the power of steady flow formula, B is the river width, A is the cross section, R is the hydraulic radius and they are all observed values. Conclusion: The author presents several experiences to assure hydrological data. All procedures have been developed at the operational work in water managements.

HW03/11P/C30-002   1420
INFERRING HIGH AND LOW TRANSMISSIVE ZONES AS WELL AS DISCONTINUITIES IN AN AQUIFER USING SPATIAL CORRELATION OF WATER LEVELS

Tanvi ARORA, Shakeel AHMED (INDO-FRENCH CENTRE FOR GROUNDWATER RESEARCH)

Water levels if measured accurately, reveal the most information about the dynamics of the aquifer system. The water levels, measured at some points/well are often used in drawing iso-lines with suitable interpolation and extrapolation. The gradients of water level then provide the knowledge of zonal transmissivity. However, several time data could not be used simultaneously as well as this procedure assumes inherent continuity in the aquifer system. The availability of the water level data from 51 observation wells for about 24 months period has allowed to carry our statistical studies and inferring high and low

---

transmissive zones in the Srikakulam district of Andhra Pradesh, India. The study area with an extent of 5837 sq. kms consists of khondalites, granite gneiss and charnolites. The normal annual rainfall is 1085.6 mm. The periodic changes in groundwater regime are monitored through measurement of water levels regularly in the monitoring dug wells distributed over the area. These wells are monitored 6 times in a year. Well depth varies from 6.3 m to 12.90 m. An effort was made to analyze the spatial correlation of the water table for a span of 11 years (time for which maximum data is available). Large number of correlation coefficient were calculated between two wells water level and the correlation matrix was prepared. The correlation coefficient varies from AE.001 to 0.91. From the study 21 wells show good correlation among each other and 10 wells shows intermediate to poor correlation. The correlation coefficients were plotted on the area map to demarcate the areas with high, moderate and poor correlation. With comparatively high rainfall and assuming a uniform rainfall recharge, the areas with high correlation coefficients were demarcated as having high transmissivity and with low correlation coefficient as low transmissivity or aquifer with possible discontinuity or geological barrier. The present method using a set of large time data provide more reliable estimates than the water level contours of individual time period.

HW03/11P/C30-003   1440
ANALYSIS OF NON-LINEARITY BETWEEN THE DESIRED ACCURACY AND THE DATA NETWORK DENSITY

Shakeel AHMED, Dewashish KUMAR (INDO FRENCH CENTRE FOR GROUNDWATER RESEARCH, N.G.R.I.)

A water level monitoring network in a small watershed of about 60 km[2] in a crystalline fractured aquifer under semi-confined condition has been optimized. Initially a network of about 56 wells fairly distributed in the area and based on the drainage system was selected. The monthly water-level measurement has been analyzed geostatistically. The standard deviations of the measured water levels have been on average 12 meters. There have been a number of constraints on measuring the water levels in the shortest period of time and it was decided to reduce the number of wells in the network without loosing the benefit of measurements. Thus a monitoring network to have only 40 wells and providing a maximum standard deviation of the estimation error (σ_e) of 8 meters was designed. In this paper, it has been studied that if the σ_e varied from the value of 8 meters what could be the effect on various norms of optimization and the final number of measurement points to make the network optimal. It has been found that for the same change in σ_e when σ_e has lower value the number of measurement points are much more compared to the same change in σ_e for the greater value of σ_e. The variation of other norms of optimization has also been studied with different values of σ_e and a non-linear relation was always found. Such an exercise provides the estimated water levels for example to calibrate an aquifer model in an unbiased way.

HW03/11P/C30-004   1500
ABOUT ASSURANCE TO THE QUALITATIVE PARAMETERS OF WATER RESOURCES IN RIVERS AND LAKES

Boris FASHCHEVSKY (International Sakharov Environmental University)

In this paper the qualitative parameters of water resources (physical, chemical, microbiological) are considered, with goal estimation of their reliability and trustworthy. It is determined that the main factors for achievement of these goals are: representativeness of disposition points of observation on locality, representativeness of sampling in points of cross-sections of rivers and lakes, in width and in depth, taking into account the frequency of sampling, taking into account the development of plants and animals into rivers and lakes and so ice phenomena, storm weathers and snowmelt and rainfall floods. It is necessary to notice that on the whole a statistical treatment of observed data with using probability (frequency) curves for estimation all diapason fluctuations of the qualitative characteristics of water resources is needed. One of the main factors for assurance of qualitative parameters of water resources in water bodies is rational disposition network of points of observations, taking into account sources of discharges of waste waters and development processes of selfpurification in locality. The second important factor is representativeness of sampling in the cross-section of river (mean as a channel as a floodplain) or in lake, taking of a shallow zone and deep-water zone. In case a stratification of water column in epilimnion, metalimnion and hypolimnion depending on the frequency of this phenomenon. The field experiments on the Zapadnaya Dvina River have shown that for getting a real average estimation it is necessary to sample as minimum in three verticals across the water surface and two points (0.8H and 0.2H). The third factor is a time course. The presence practice of sampling (one-two samples in month) especially in small rivers leads to that enterprises discharge waste waters in the interval between measures. Such a bright example is the Svisloch River, flowing through city Minsk when of night many big plants discharge waste waters and ever rubbish. The forth factor, disturbing the accuracy definition of a real quality of water, serves the development of plants and animals in water bodies, when in certain period all these organisms are dead, causing sharp worsening of ecological conditions. The fifth factor is the development of ice phenomena, including ice cover, ice drift, frazil drift, ice-jam and frazil-jam, etc.For rivers and lakes with developed floodplain, that is flooded for a long time it is necessary to samples from floodplain. The special attention would be attracted to disposition of sections for sampling upper and below of waste water discharge in order to estimate the influence of these discharges on water quality.However, only taking into account the above-mentioned factors the task of assurance of the qualitative parameters of water resources is not solve to the end. For the objective assessment ofassurance on the whole we need the estimation of all diapason fluctuations of qualitative indices. For decision of this task it is necessary to use the probability-statistical methods of analysis. The application of probability or frequency curves allows to get an objective picture of the water body state.

HW03/11P/C30-005   1520
SPATIAL VARIABILITY OF VERTICAL PERMEABILITY OF THE SOIL COVER DETERMINED USING DOUBLE RING INFILTROMETER IN MAHESHWARAM WATERSHED IN A GRANITIC SEMI-ARID REGION

Dewashish KUMAR, Shakeel AHMED (INDO FRENCH CENTRE FOR GROUNDWATER RESEARCH.,N.G.R.I.)

Ring infiltrometers are commonly used for in situ measurement of soil hydraulic properties. The infiltration test was carried out specially to know the rate of percolation or rate of vertical flow from the surface to few ten´s of centimeter below the ground. As the hard rock region is extremely heterogeneous system so as to understand the unsaturated zone specially the top layer, this infiltration test was very useful to have idea of vertical flow of fluid. The objective of the infiltration test has been understand the characteristics of the top layer zone and the vertical flow rate as well as characterize soil types, infiltration property of the tank beds and the behavior in the dug wells. In the present study infiltration test was carried out at 38 sites in a small watershed of about 60 km[2] in a crystalline hard rock terrain. Out of 38 sites; 16 tritium injection sites comprising different type of soils, 17 tank beds, 4 bottom of the dug

H

wells and 1 near the hydro-meteorological station. The infiltration test performed by double ring infiltrometer with a diameter of 30 and 60 cm respectively were placed on the surface of the ground and were firmly fixed few centimeters below the ground so as to avoid direct passage of water from the sides of the ring. A height of 5 cm was marked on the inner and outside of the inner ring. Water was added in both the rings simultaneously up to the mark and the level was maintained throughout the test period. Known amount of water was added to the inner ring subsequent to the fall of water level below the marked position. Throughout the test the level of water in the outer ring was also maintained up to the marked position so as to prevent the lateral flow of water into the ground from the inner ring. The result shows significant variation of the infiltration rate in different soil types, tank beds and dug wells. Different soil types shows different rate of infiltration at some place where the soil colour is light red, the infiltrate rate was found to be high. Some of sites do not show any percolation showing a thick siltation in the area. The infiltration rates vary from 848.8 to 1.7mm/hr, such a wide variation in rate again confirms the heterogeneity although it also depends on the initial soil moisture content. This infiltration results could be used for the correlation of the recharge measured with tritium injection and also these results has provided spatial variability of rainfall recharge an important input to the groundwater flow model.

HW03/11P/C30-006 — 1600

A NEW GEOSTATISTICAL APPROACH TO ANALYZE SPATIO-TEMPORAL VARIATION OF FLUORIDE IN GROUNDWATER AND OPTIMIZATION OF ITS MONITORING NETWORK

Shakeel AHMED (Indo-French Centre for Groundwater Research, NGRI, Hyderabad, India)

A small watershed in the granitic aquifer has shown increase in Fluoride content beyond the permissible limit of 1.5 mg/L. In the present study A simple and new method has been developed using the cross-validation technique of Geostatistics to analyse and optimize an existing network for monitoring Fluoride in Maheshwaram watershed, RR Dist. of Andhra Pradesh, India. Water samples from 60 wells fairly distributed in 60 Sq. km area of the watershed are available. They are analyzed for water chemistry and Fluoride. Using the result of the cross-validation of the variogram particularly jack-knifing, it has been possible to assign a priority index to all these measurement points and depending on the constraints such as financial and logistic, a network could be reduced without loosing the outcome. A number of monitoring networks with less number of wells have been prepared and compared. A number of network with reduced size have been analyzed from the given measurements. The change in the mean value is not much. However, with the close observation, it is found that the mean is slowly reducing when the network is reduced from 60 until 50 or 45 but the difference is considerable when we further reduce the network. Iso-lines of fluoride were drawn based on the 60 and 30 measurements respectively coming from the network decided on the basis of the priority index. The two contours show more or less similar distribution and the regionalized picture is almost identical. Although, slow but fluoride is a time varying parameter, an optimal network will make the sample collection easy and in the shortest possible time. This optimal network will also be cost-effective and the priority index will be helpful to vary the network size depending upon the financial and logistic constraints. However, one should remember that a network of (say for example) 30 measurement points would obviously provide high variance of the estimation error at the remaining parts of the study area.

HW03/11P/C30-007 — 1620

HYDROECOLOGICAL MAPS OF BELARUS

Boris FASHCHEVSKY[1], Anatoliy SHARIKOV[2] ([1]International Sakharov Environmental University, [2]Laboratory of Hydroecology, Central Research Institute for Water Resources Management)

It is considered principles of hydroecological maps compilation for the territory of Belarus. Assessment reliability of initial data for compilation of maps is done. In the basis of selection indices for compilation of hydroecological maps the following principles are put: -presence of the spatial-temporary series of observation for qualitative and quantitative characteristic for the long period; -degree of influence of the qualitative and quantitative changes of water resources on the natural background regime; -revealing of the most changing indices; -presence of discharges of pollutants in composition of wastewater´s. In the result of carefully analysis the following indices have been chosen: the main ions (Cl, Mg, HCO3, Ca, SO4) and general mineralization, O2, BOD5 and COD, phenols, surfactants, oil products, the main biogenic-phosphorus and nitrogen, salts of heavy metals (copper, lead, zinc, etc), temperature of water and suspended loads and as well annual, ecological and free flows, minimum and maximum flows. Dissolved substances and suspended loads are presented in a view of modules flow-kilograms and tons from square kilometer of catchment. Oxygen, BOD and Cod are presented in a view of mg/l. Mapping of dissolved substances were timed to the water availability of 75 % frequency. Modulus of suspended loads and temperatures were taken for the average year of water availability. Comparative analysis of the observed data with the data of discharges from point sources are greatly differed especially as for such indices as oil products, phenols, copper, nitrate and nitrite. If take into account a phenomenon of selfpurification then the real discharges of wastewater are reduced on average in 2 times. The experimental material shows that the share of surface inflow into rivers from urban and agricultural territories don´t exceed more than 20-30 % of the whole pollution of water bodies. Hence, 70-80 % pollutants are discharged by enterprises without any control. The analysis distribution all above mentioned characteristics on the territory of Belarus is done.

HW03/11P/C30-008 — 1640

FRACTIONAL GOVERNING EQUATION OF GROUNDWATER FLOW: A NUMERICAL ANDEXPERIMENTAL STUDY

Kenta OKADA, Yuko HATANO (Institute of Engineering Mechanics & Systems, University of Tsukuba)

In the present study, we experimentally show the efficacy of a new governing equation of transport in the groundwater. Instead of the widely-used advection-dispersion equation (ADE), we use an equation with ˝fractional˝ derivatives. It is first introduced by Benson et al. (1998) and gradually gaining recognition (e.g. Sokolov et al., 2002). The new equation utilizes the fractional derivatives (1.5th or 2.1th derivatives) in the diffusion term, such as $\partial C/\partial t = D \partial_\alpha C/\partial x\alpha$ This equation has an advantage over the classical ADE, since it does not depend on scales of heterogeneity of geologic media. In the presentation, firstly, we show the numerical solution of the fractional governing equation, calculated by the finite difference method, and discuss the profiles. Specifically, the concentration profiles show clearly different behavior from the classical ADE. The difference at the long-term or at the location distant from the source indicates that the evaluation with the classical ADE would result in underestimate for the risk assessment. The present numerical result could reproduce the concentration profiles with ˝tailing behavior˝, which the classical ADE didn't. We used the data of a column experiment, and found that the order of derivative is about 1.5. Secondly, we show the efficacy of the governing equation with experimental data. Since we still do not have the knowledge how we can determine the value of the index of derivative, α, we do a

series of experiments in a sandbox, with different degree of heterogeneity. The experiment system is built based on Berkowitz et al., (2000). The container is filled with Tohoku keisa (1000mm x 710mm x 120mm; with a channel switching machine, amplifier, and PC). Two tanks are installed at the both end of the test section, whose water heads are kept constant. We use a marriott tank for the inlet container. The solution of tracer (NaCl 3%) flows horizontally with the head difference between the inlet- and the outlet-tank. With the breakthrough curve of the experimental result, we discuss the value of the index of the fractional governing equation. In conclusions, we show that the new fractional governing equation can describe the phenomena called ˝subdiffusion˝ in geologic media.

HW03/11P/C30-009 — 1700

GEOSTATISTICAL ANALYSIS OF GROUNDWATER CONTAMINATION IN PAGERU RIVER BASIN AND TESTING THE ADEQUACY OF THE MONITORING NETWORK

P.D. SREEDEVI, Shakeel AHMED (Indo-French Centre for Groundwater Research, NGRI, Hyderabad, India)

Pageru river basin lies in the drought prone areas of the south India as the aquifers are usually over exploited. The studied watershed covers an area of 480 Km2 and forms the part of the Pageru river basin which is an ephemeral river. The groundwater resources are exploited through a large number of dug-wellsand some bore-wells. About 99 dug wells fairly distributed in the area have been systematically monitored for water quality during pre and post monsoon seasons of 1996-97. The variographic analysis through calculation and modeling of experimental variograms as well as cross validation test show a large variation in the variability of chemical properties of the groundwater concluding the strong influence of anthropogenic activities such as use of fertilizers and pesticides on groundwater quality. The geostatistical analysis testing the adequacy of the monitoring network shows that with the variance of the data as the cut-off for monitoring network precision, the network remains adequate and rather dense. However, when the cut-off value is reduced to half of the respective variances, the network becomes inadequate and sparse for most of the parameters except pH.

RISK ANALYSIS FOR WATER RESOURCE SYSTEM BY USING SYSTEM DYNAMICS: CASE STUDY IN YELLOW RIVER BASIN

Zongxue XU, Kuniyoshi TAKEUCHI, Hiroshi ISHIDAIRA, Zhifeng YANG (Institute of Materials and Environmental Technology, Graduate School of Engineering of Engineering, Yamanashi Universiy)

Sustainable development issue has been received wide attention by scientists, politicians, and publics during the past decade. Sustainable water supply is particular a key problem in this century. With the development of economics and urbanization, this issue has become one of the greatest challenges both central and local government in China faces. Streamflow cessation and water curtailment, occurred in Yellow River several years ago, further aggravated the tension state of water supply in the study area. As the 'cradle of Chinese civilization" and one source of humankind's civilization, the water resources issue in Yellow River basin has received great attention everywhere in the world. Water authorities in Yellow River basin has and will continue to face great challenges in meeting both in-stream flow and ecological requirements, and providing more water for the growing populations, industry and agriculture. On the purpose to evaluate the risk of the water resource system in Yellow River basin, a system dynamics model for water resources planning is developed to analyze the risk of water resources in Yellow River basin to climate change, population growth, and industrial development in the future. The objective of the model remains on simulating the water resources system and capturing the dynamic characteristics of the system. The existing and potential water supplies from surface water, aquifers and treated wastewater are estimated, and potential water demands for domestic, industrial and agricultural uses are projected. The model has been developed using STELLA Research 6.0, and may be used to identify preferred solutions to satisfy a variety of requirements relating to the development, environmental concerns and ecological needs of the water resources in the study area. It is an interactive, computer-based tool with friendly user interface, allowing users to explore how various water-supply objectives can be met for future scenarios. Water supply risk is then estimated with the combination of the observed streamflow data. From this result, the regions with high risk in shortage of water have been identified. It has shown that although the downstream of the Yellow River previously had the greatest risk in shortage of water, the risk in this region has been considerably decreased due to the construction and rational operation of the Xiaolangdi reservoir with an effective storage of 5.05 billion m3. It also shows that the river segment from Lanzhou to Hekouzhen will take great risk if the present way of flooding irrigation can not be improved with more efficient irrigation techniques such as spray and drip approaches. The result provided in this study is helpful for the regionalization of the water supply. This also makes it possible to evaluate the impacts of large projects such as 'South-to-north water transfer' on water resources in the Yellow River basin.

HW04/09A/C31-002 — 0920

SYSTEM DYNAMICS APPLOACHE FOR REGIONAL WATER RESOURCES

Toshiharu KOJIRI, Nobuchika TAMURA (Disaster Prevention Research Institute, Kyoto University)

Recently, climate change and environmental issues have been the important problems in water resources development. However, hydrological process of precipitation and evapotranspiration due to climate change has so much relationship with regional development and economical activities. System Dynamics (SD) is the great power to represent this water behavior including the related factors. On the other hand, recently the distributed runoff model has been developed using the digital geographical data and land use data.The main purpose of this research is to develop an understanding of 1) the influence of water resources distribution on agriculture yield, economic activity, population change and so on, and 2) the influence of change in those distributions on nation's water resources demands. We are focusing on the closed region such as main island of Japan in

order to the regional water circulation, water utilization, population change and economic dynamics. Moreover, the proposed system will be connected with runoff model showing the detail water utilization processes.SD simulation is performed to model the changing circumstances in the area's water resources distribution. The proposed regional SD divided into ten regions; namely Tohoku-northwest, Tohoku-southeast, Kanto, Shinetsu, Hokuriku, Tokai, Chubu, Kinki, Sanin, and Sanyo and consists of ten sectors; namely population, land use, agriculture, industry, information technology, pollution, water quality evaluation, water quality treatment, climate and water balance. Through investigation of the environmental factors contributing to changes in the hydrological circulation, such as regional deforestation and heat island phenomenon, and through simulation of the effects of climate change and realization of social policies, a research tool capable of providing meaningful information, and aiding in reaching consensus regarding policies for the development and allocation of domestic water resources will be achieved.

HW04/09A/C31-003   0940
WATER RESOURCES DYNAMICS MODEL CONSIDERING REGIONAL INTERDEPENDENCIES

Tomoharu HORI, Michiharu SHIIBA, Toshiharu KOJIRI (Faculty of Global Envronmental Studies, Kyoto University)

In recent years, water problems are getting one of the major issues of earth's human life in various levels of policy making: international, national, regional, municipal, etc. Water resources development and distribution to meet the predicted demand in a basin have been major issues in such decision levels for a long time since they requires a lot of time and money. People, however, are now getting aware that it is also important to take regional interdependencies about water resources in terns of transportation of various products. In highly networked environment, a water-related problem in a certain place or basin will affect social life in other regions through economic activities. Water resources assessment based on the dynamical environment would have a great importance for making water policy. One of the difficulties in water resources assessment in such a networked and dynamic circumstances is the complexity of water resources systems. They include various sectors such as consumers and providers: consumers comprise of agricultural, industrial and municipal sectors. System Dynamics approach is one of the powerful methodologies to model those complex systems. SD modeling was mainly applied to water demand prediction in Japan but its inherent flexibility to express the complex system structure will be good in modeling various water-related component and their interdependencies. In this study, we design a regional water dynamics model to analyze stability of water supply-consumption systems not only in a single city or basin but also in the interdependencies among regions. First, water users are categorized into agricultural, industrial and municipal sectors. In agricultural sectors, water demand is modeled by the use of depletion depth in paddy fields. In industrial and municipal sectors, water demand is expressed in terms of multiple regression models through the past industrial and water use statistics data in Japan. Next, water consumption sectors are connected to population sectors and regional water flow sectors. Emigration sectors are introduced to explain the movement of products in one region to others. Finally by putting all the sectors into one system dynamics model, the behavior of the water resources systems in Kinki-region in Japan is analyzed under the possible future scenarios.

HW04/09A/C31-004   1000
MODELING HYDROSYSTEM DYNAMICS OF MAE KLONG RIVER BASIN, THAILAND

Ekasit KOSITSAKULCHAI[1], Pierre CHEVALLIER[2] ([1]Department of Irrigation Engineering, Faculty of Engineering, Kasetsart University, Nakhon Pathom, Thailand, [2]Institut Languedocien de Recherche sur l'Eau et l'Environnement, Maison des Sciences de l'Eau, Monpellier, France)

Modeling of integrated water resources management of Mae Klong river basin (31,000 sq.km.) is based on the system approach. The variability of water resource and the increasing competition of water uses (irrigation, hydropower, urban water supply, seawater intrusion protection, and recreation) entail a cautious water management in highly developed hydrosystems. In order to tackle such a complex dynamical situation, simulation models that take into consideration the existing management rules play a crucial role. The system thinking coupling with System Dynamics modeling tool, Vensim®, offer double advantages in helping to learn and to represent complex systems. Firstly, a lumped rainfall-runoff model was developed in order to represent unregulated stream flows at various control points in the basin. Moreover, a water management decision model was elaborated. The latter model incorporates technical aspects of multi-purpose multi-reservoir operation, governing rules, and economic evaluation. This model can be considered as a tool supporting decision in water management processes. The diverse questions related to water management in the Mae Klong river basin can be clarified as a result of the applications of model.

HW04/09A/C31-005   1020
SOLVING URBAN REGIONAL WATER HOUSEHOLD AND QUALITY PROBLEMS UNDER GLOBAL CHANGE

Volker WENZEL (Potsdam-Institute for Climate Impact Research)

Subject of investigations is the future optimization of water household and water quality conditions within the urban region of Greater Berlin driven by global change.The hierarchy of scales to be considered together with appropriate problem-oriented bridging strategies from global dynamics down to the water-related problems of Berlin is as follows: 1. Exogenous drivings of global change, 2. Elbe river basin: From divided Germany to globalization, 3. Landscape-specific upstream-downstream conflicts in the tributary Spree region, 4. Urban agglomeration and capital Berlin.Climate change and the new economic conditions caused by globalization are the components of global change considered in this context. The IPCC scenarios A1 and B2 serve as an orientation.The drastic structural changes since 1990 concerning values, administration and economy led also to a considerable restriction of the intensity of open-cast lignite mining in the upper Spree area.As a consequence, it has been stopped to pump into Spree river the ground water out of the mining holes of the abandoned mining places. At the opposite, all this holes need a lot of water for a rather demanding restoration process.Thus, we have a genuine water scarcity conflict and distribution problem, because downstream follows the Spreewald area with biotope quality to be protected. This is necessary even by economic reasons, taking into account the tourism and the specific agricultural production of this region. And further downstream follows Berlin where, in addition, the water quantity problems are causing serious water quality problems.10 alternative strategies for water management in Berlin with options from 6 fields of activity including rain water management, additional water purification efforts, biotope protection measures etc. are defined under participation of about 10 interest groups or their stakeholders. The model fund for impact analyses comprises climate, sealing and runoff models, hydraulic and long range water management models, water quality and aquatic ecosystem models. For the realization of a specific epistemic aggregation, the manifold of single indicators delivered by those models, in analogy to the prenatal human ontogenesis process of the formation of organs and the potential realization of their functions, are then

combined to few relevant index variables and evaluation criteria, integrating ecological, economic, social and normative aspects. Finally, the results of corresponding multicriteria and equity analyses may be used for planning and decision support.

HW04/09A/C31-006   1100
THE THEORETICAL MODEL OF OPTIMAL DIVISION OF WATER RECOURSES BETWEEN DIFFERENT COUNTRIES OF CENTRAL ASIA

Andrei V. KHRISTOFOROV (Department of Hydrology, University of Moscow)

For the countries of Central Asia (Khazakhstan, Kirghizstan, Tajhikistan, Turkmenistan and Uzbekistan) the problem of the division of water recourses is very actual and difficult and many political, economical and social problems of this region are connected with it. For the scientific substantiation of political solution of this problem the theoretical model of optimal division of water recourses between different countries of Central Asia is offered. The model is based on the principles of the market economy, which are rather new for these postsoviet republics. The main instrument of the model is a total economical effect of water recourse utilization as a function of quantity and quality of water, which is used during a calculation period. Such functions must be determined not only for every country, but for their regions and districts too. The general type of these functions is offered. Every country, region or district is considered to be a participant of the market and can buy or sell some part of quote for the water utilization and pollution. The model determines the optimum strategy and gives the possibility to reach maximum profit. The model can be used for the scientific substantiation of quotes and expenses for the ecological monitoring and protection. The successful realization of this model can give an opportunity for the normalization of the political situation and for economically effective and ecologically safe utilization of water recourses in Central Asia and other regions of the world.

HW04/09A/C31-007   1120
MODELING IRRIGATION WATER REQUIREMENT USING FUZZY LOGIC

Yutthana PANKAMOLSIN, Ekasit KOSITSAKULCHAI (Department of Irrigation Engineering, Faculty of Engineering, Kasetsart University, Nakhon Pathom, Thailand)

This paper proposes the fuzzy approach for representing the irrigation water requirement under the conditions of imprecise human decision and uncertain environment. The irrigation water requirement is the results of various processes at the field level, including crop evapotranspiration, changes in soil moisture storage and variations of irrigation supply. The input parameters of the model, based on daily time step, consist of temperature, crop development stages, sunshine duration and rainfall. The first three parameters are applied in the model for estimating the crop evapotranspiration. In order to assess the soil moisture states, the model takes into an account the rainfall data and the feedback information of irrigation supply in the previous days. The relationships between input and output variables were defined by fuzzy rules. These rules are established according to human reasoning and decision. The calibration and validation of model were performed by comparing the simulated results with the conventional method of soil water balance, and the recorded field data. The results of fuzzy model are highly correlated with those of soil water balance. Furthermore, the model is capable to estimate daily water requirement from monthly or annual mean data sets. The results of estimation are as reasonable as those of daily input data.

HW04/09A/C31-008   1140
CONTINENTAL SCALE MODELING OF WATER BALANCE IN EAST EURASIA FOR EVALUATING AGRO-WATER RESOURCES

Yasushi ISHIGOOKA, Hitoshi TORITANI, Tsuneo KUWAGATA, Shinkichi GOTO, Hiroyuki OHNO (Department of Global Resources, National Institute for Agro-Environmental Sciences)

In evaluating climatic agricultural productivity, it is important to recognize renewable water resources. In this regard, we should attend not only to the effective precipitation but also to the supply of water by irrigation systems. In order to estimate the potential available water for irrigation, it is necessary to comprehend water dynamics on a global or continental scale, with river discharges being one of its most important components. In this study, we attempted to construct a simple water balance model to estimate the discharges of the main river basins and to evaluate the agricultural water requirement as irrigation for cropland throughout East Eurasia. Our model is based on the aggregation of small drainage basins instead of rectangular grids, in order to eliminate the geographical disagreements between actual drainage basins and those defined by grids. The model consists of runoff model and river flow model; the former estimates the amount of runoff from basin according to the hydrological process, and the latter represents lateral movement of water through the network of river-channels. In runoff model, calculation was performed independently for every 6 type of land cover, and each hydraulic characteristics of soil and phenology of vegetation which expressed by seasonal variation of NDVI were used as the boundary conditions. Evapotranspiration was calculated as the sum of the evaporation and the transpiration, both of which were calculated by using FAO-56 method. In this process, the crop water requirement was estimated as the deficit of the actual transpiration against the transpiration without water-stress. In river flow model, the discharge of each stream was calculated by accumulating the runoff from the current contributing drainage basin and the flow from the upper streams. The model were implemented using published monthly climate data obtained from Climatic Research Unit (CRU), in which global historical various climatic data are constructed with 0.5 degree resolution from 1901 to 1995, as forcing data, and then the annual discharge of each stream was estimated. Observed discharge data from 118 selected gauging stations on several main rivers, which were obtained from GRDC and IHP/UNESCO, were used for the validation of the simulated discharges. In many cases, it was found that this model tended to underestimate the discharge in comparison with the observations. This tendency seemed to be more obviously at the area with sparse vegetation, which indicate that the model tend to overestimate the evaporation from bare soil.

HW04/09A/C31-009   1200
ASSESSING THE SIGNIFICANCE OF GLOBAL SCALE WATER STRESS INDICATORS

Martina FLOERKE, Petra DOELL (Center for Environmental Systems Research, University of Kassel)

Indicators are used for a clear illustration of complex results, for example those obtained with global models. We present two indicators of water stress that are based on water availability, water withdrawals, water consumption, and 90% reliable monthly discharge. All these quantities have been computed with the global water model WaterGAP (Water Global Assessment Prognosis), which has been described among others in Alcamo et al. (2002) and Döll et al. (2003).The first indicator is the commonly used withdrawals-to-availability ratio (w.t.a.), which is obtained by dividing the long-term average (30 years period) annual

withdrawals for the four main water use sectors (domestic, industry, irrigation, and livestock) by the long-term average annual availability on a drainage basin level (Alcamo & Henrichs, 2002). A drainage basin is assumed to be under medium water stress if $0.2 <$ w.t.a. 0.4 and under severe water stress if w.t.a. > 0.4.The second indicator introduced here is the consumption-to-90% reliable monthly discharge ratio (C/Q90). Here the long-term average annual water consumption is divided by the long-term average 90% reliable monthly discharge on the drainage basin level. Under water consumption we understand the fraction of the withdrawn water that is lost by evaporation or evapotranspiration during its use. The 90% reliable monthly discharge Q90 is the discharge that is exceeded in 9 out of 10 months for the period under consideration, and can considered as a typical design flow for surface water supply. The C/Q90 indicator considers not only the variability of the discharge but also the reduction of natural discharge by upstream consumptive use. With this indicator, we assume that a drainage basin suffers from severe water stress if C/Q90 1. For $0.5 <$ C/Q90 < 1 the basin is under medium stress. It should be kept in mind that this indicator, as calculated here, does not take into consideration the storage of water (neither surface water nor groundwater).Both indicators are computed for current conditions (1995) as well as for scenarios of the future. Due to the uncertainties in the calculation of the future precipitation, both indicators are computed using two different global climate models, HadCM3 (Hadley Center, UK) and ECHAM4-OPYC3 (MPI, Germany), to better assess the impact of climate change. Additionally, results for the SRES scenarios A2 and B2 (IPCC, 2001) in 2075 are included to analyse the influence of technological and structural changes on these indicators. The water stress results obtained using the two different indicators withdrawal-to-availability ratio and consumption-to-90% reliable monthly discharge ratio point out that there is no best indicator. Both indicators are complementary and illustrate different aspects of water stress. Each of them has its own advantages and disadvantages related to its significance and uncertainty.

HW04/09A/C31-010 **1220**

STATISTICAL THE ASSESSMENT OF THE WATER RESOURCES ON METEOROLOGICAL EVIDENCE. FORECAST OF ANNUAL RUNOFF FOR DIFFERENT CLIMATIC SCENARIO

Natalie LOBODA (Department of Hydrology & Water Resources, Odessa State Environmental University (OSEU))

The water-management transformation of runoff and prospective change of a global climate calls for the necessity of studying the climatic factors contribution to the runoff formation process. In present paper we consider and try to solve the problem of the ″climate-runoff″ interaction with the use of mathematical and computer modelling on the basis of the empirical orthogonal functions (EOF) and water-heat balance methods. The approach is illustrated by studying the north-west Black Sea region, where data about a runoff in a natural condition is not available and, therefore, it is necessary to develop methods of its account on basis of meteorological information. For modelling of natural annual runoff series the results of analysis of annual precipitation and maximally possible evaporation fields with the empirical orthogonal functions method are used. Spatial distribution of the first four weight expansion coefficients for annual flow can be considered as a result of the interaction between the climatic factors in the meso- and macroscale. For an evaluation natural (not infringed the economic activity) runoff in conditions of defect of the hydrological observations data there have been proposed the modification of method of water-heat balance, in which the meteorological data are used (Loboda, 1998b, 1999). Basis of water-heat balance method is joint solving of the equations of water and heat balances of an earthly surface, which contain a common component - total evaporation. The empirical orthogonal functions analysis of the annual precipitation, maximum possible evaporation and runoff data showed that the fields of main climatic factors (annual precipitation and maximum possible evaporation) and annual flow are formed under influence of the common physical processes, which can be reflected by the first components of the fields expansion on the empirical orthogonal functions. Spatial distribution of the first four weight expansion coefficients for the annual runoff can be considered as a result of the interaction between the climatic factors in the meso- and macroscale. For river, where there are no measurements of runoff, this coefficients can be calculated as linear functions of norms of annual precipitation and maximally possible evaporation by maps of isolines. The water-management transformation of annual runoff is excluded by fulfilling the filtration of initial data on the basis of the first components. Approach proposed opens the new perspective possibilities for the natural rivers runoff (runoff non-transformed by the economic activity) restoring problem solution. For regions where the meteorological studying is better than hydrological one, the average arithmetical values and average quadratic deviation of a natural runoff series (necessary for modelling within the empirical orthogonal functions formalism) can be determined by using the regional generalization of the climatic flow characteristics, calculated on the basis of meteorological information.

MODIFICATION OF RESERVOIR OPERATION RULES BASED ON MATHMATICAL SIMULATION AND OPTIMISATION APPROACHES

Manfred Walter OSTROWSKI (Department of Civil Engineering, Darmstadt University of Technology)

Reservoirs have substantial effects on society and the environment. While the construction of new reservoirs is still in progress, the functioning of existing reservoirs has to be re-evaluated for several reasons. Many of them are approaching their expected lifetime and it has to be decided whether and to what extent they should be maintained or re-constructed or even de-commissioned. Other reservoirs have to be operated under changing boundary conditions such as climate and to account for changing objectives such as satisfying new uses as well as meeting new ecological and socio-economic criteria. Existing reservoir operation rules often resulted from heuristic optimisation of purely economic objectives; only in a few cases mathematical optimisation was applied. At present, reservoir owners and operators tend to maintain the actual release rule as the development of modified rules is expected to be most complex, controversial and thus time consuming. To account for new objectives a different decision making approach is necessary to include the interests of a wider stakeholder community. This requires the use of decision support systems (DSS) to analyse multiple scenarios and to present these in an adequate form to decision makers and stakeholders. A gap can be observed between analysts, using advanced simulation and optimisation approaches and decision makers. The key problem is the translation of technical results into information to be evaluated and decided on by non technical people. The presentation includes a brief description of a simulation/optimisation package (TALSIM) as part of a DSS which has been applied to ten reservoir systems in Germany, Spain and East-Africa. Some of the case studies will be presented to make the problem transparent and to identify requirements for an improved interface between technology and decision maker/stakeholder. The simulation/optimisation package is a generic tool being solely controlled by input data, which does not need any sources code modifications. Case studies

URBAN HYDROLOGY AND RECLAMATION POTENTIAL OF URBAN STORMWATER

Parviz MONADJEMI, N. VASSELI (Civil Engineering Department, School of Engineering, Shiraz University)

Urbanization increases the volume of stormwater runoff, greatly amplifies its peak, and modifies its quality. The use of ponds detention of urban stormwater began to gain broad recognition only in the early 1970s. Nowadays stormwater detention ponds are being used in many countries, e.g., the United States, Australia, Sweden, Canada, etc. The purpose of such detention ponds in urban areas has been the mitigation of urban floods downstream and reduction of pollution. In these chemes the ultimate arm is stormwater disposal and not stormwater conservation. However a new and innovative approach to urban stormwater management is beginning to take shape. Many arid urban areas are looking to stormwater as a potentially valuable resource. Urban stormwater is being stored in detention ponds for immediate irrigation or is being transferred to appropriate places to be stored underground for later use. In this paper conservation and reclamation potential of urban stormwater is investigated. A systematic analysis is introduced using a detention ponds and diversion facilities to transfer stormwater for reclamation. Bander Abbas, a rapidly urbanizing & arid region located in the southern part of Iran was chosen for this study. The amount of stormwater reclaimed is a function of rainfall/ runoff, characteristics of urban watershed and the size of detention ponds and diversion or reclamation facilities. The basic elements of detention and diversion of stormwater are shown below. Runoff is temporarily stored behind a small dam with height H. At the same time the water is diverted by gravity through outlet facilities e.g. a rcctagular weir with width of W. Ten years of 10 - minute interval rainfall data and 14 years of daily rainfall data were disaggregated into 1 - hr data. All the rainfall data, basin data, loss rate data function, unit hydrograph data, river & reservoir routing data and diversion data blocks were prepared as input data file. HECI model was chosen to handle these data. In order to determine the reclaimed or diverted fraction of runoff for the chosen basin, the curve number CN, lag time, slope, roughness, flood plain geometry, main channel geometry and reservoir geometry were treated as fixed. A 20 meter long overflow dam was used. The total areas, of watershed was 22 km². A Matlab based computer package was developed. 129 rainfall events, 11 values for the height of the dam and 4 values for the width of diversion cabal were used to determine the amount of reclaimed stormwater. The results shown in the following figure. Stormwater reclamation potential for a 22 km² urban watershed in Bandar Abbas with an average annual rainfall of 179 mm could be as high as 1.4 million m³ per year. This is a substantial amount and is highly desired for arid areas. Reclamation of stormwater in urbanized regions especially in arid climates e.g. Western China, Western United stated, North Africa, Middle East, etc, is technically and economically feasible and environmentally desireable.

HW04/09P/C31-003 **1440**

STORM LOSS STUDIES FOR THE BREMER RIVER CATCHMENT IN AUSTRALIA

Mahbub ILAHEE, Rahman ATAUR (School of civil engineering, QUT)

The rainfall based design flood estimation techniques are commonly adopted in hydrological design, which require a number of inputs including storm loss characteristics. Storm loss or simply loss is the part of rainfall that does not appear to the stream during or immediately after the rainfall event. A conceptual loss model known as the 'iinitial loss-continuing loss modelAEis the most commonly used method in Australia. The loss that occurs in the beginning of the rainfall event, prior to the commencement of surface runoff is called initial loss. After initial loss is satisfied the continuing loss is the average rate of loss throughout the remainder of the storm. The current Australian design flood estimation technique is known as the Design Event Approach in that it is assumed that the design rainfall frequency can be preserved in the final design flood estimate by considering representative values of other model inputs such as rainfall temporal pattern and loss. In practical situations, losses show a wide variability and it is more logical to consider loss as a probability-distributed variable in design flood estimation This paper examines losses for the Bremer River catchment located in southeast Queensland which has a catchment area of 130 km2. The study uses one pluviograph and one daily rainfall station having 33 and 80 years of data respectively to compute catchment average rainfall. The continuous streamflow record length at the Bremer River is 32 years The paper focuses on continuing losses. Continuing loss estimates obtained from selected observed rainfall and streamflow events include errors arising from factors such as inadequacies of input design rainfall, flow rating and separation of baseflow from total streamflow. It has been found that continuing loss shows a wide variability and it is unreasonable to adopt a representative value (either mean or median) of continuing loss in design flood estimation. The paper examines the potential of adopting probability-distributed continuing loss in design flood estimation using a joint probability approach. It has been found that probability-distributed continuing loss can offer significant improvement in design flood estimation. Keywords: rainfall runoff modelling, flood estimation, probability-distributed losses.

HW04/09P/C31-004 **1500**

A REMOVED DYNAMICAL MODEL OF A GEYSER INDUCED BY INFLOW OF GAS

Hiroyuki KAGAMI (Wakkanai Hokusei Gakuen College)

Though some models of a geyser induced by inflow of gas has been proposed for a long time, a comparison between the model and observational data has not been made enough and as a result the mechanism of it, especially the dynamical one, has not been solved enough yet. Lately, model experiments of the geyser were tried to do (Katase et al. (1999)) based on observation of Hirogawara geyser (Yamagata) (Ishii et al. (1999)). These experiments showed that periods of spouting depend on various parameters height of a spout from the bottom, volume of a cave (under the ground), a supply rate of gas and so on. Then a mathematical model of the experiments was proposed by Kagami et al. (2000). The model qualitatively explained results of the experiments dependence of a period of spouting on each parameter, but the dynamics of spouting was not dealt with in this model. Then a dynamical model of a geyser induced by inflow of gas was proposed by Kagami (2001). The model assumes that structure of a natural geyser is essentially as same as that of the model experimental system. From the result of simulation using this dynamical model, it was found that the model reproduced characteristics of observational data of a natural geyser just before spouting the water level under a spout oscillates with it rising. In this meeting, we will introduce an improved dynamical model of the geyser and report minute results of simulation using the model dependence of a rate of spouting and a period of the water level?s oscillation just before spouting on each parameter (height of a spout from the bottom, a diameter of a spout, volume of a cave under the ground, a supply rate of gas and so on. In the dynamical model, dynamical equations after the event that balance of power affecting a lump of water is lost, when pressure of gas under the ground becomes larger than the sum of power surface tension, gravitation and so on holding a position of the lump of water stable, are led. In the improved dynamical model, both effects of complex structure of the paths of

---

water under the ground and friction working between the wall's surface along the edge of the paths of water and water are taken into account. Through simulation, we will evaluate minutely above 2 new effects of the improved model comparing with results of the first model.

HW04/09P/C31-005   1520

NEURAL NETWORKS & FRACTAL MODELLING THE FRUSTRATED AQUIFER SYSTEMS: ANNUAL RUNOFF ANALYSIS

Natalie LOBODA (Department of Hydrology & Water Resources, Odessa State Environmental University (OSEU))

A new approach to the neural networks and multi-fractal modelling the frustrated hydrological systems (calculation of the river runoff fractal spectrum is developed and numerically realized. It is well known that hydrological (etc.) systems (and the dynamics of their key characteristics fluctuations) can be described as a mechanical dissipative multi-body systems, which are fundamentally non-linear (Davis, 1991; Kothyari and Singh, 1999; Loboda, 1998;). General non-linear parameter dependent dynamical dissipative systems very often have parameter ranges, in which the dynamics is chaotic. Chaotic behaviour in the sense of a fully deterministic evolution of the systems in time bounded in phase space with sensitive dependence on initial conditions, might therefore be expected to occur in above cited systems. Dissipative non-linear systems typically have a long-term behaviour, which is described by an attractor in phase space. At the same the chaotic dynamics in details is often unknown. It is well known that an attractor is called strange attractor if its dimension is non-integer, i.e. fractal. Non-linear systems of fractal objects like interfaces or time-series is their scaling property related to invariance under magnification. For uniform fractals the scaling is uniquely described by one-fractal exponents, the so-called fractal dimension. In last years studying the fractal properties of dynamical systems is of a great interest. In this paper we consider an effective method for treating the non-linear complex systems, based on the 'neural networks' and multi-fractal modelling (Glushkov *et al.*, 2001; Loboda, 1998; Loboda, 2001). Approach developed allows getting a possibility of forecasting the evaluation dynamics, including the extreme phenomena in non-linear complex systems. We apply these models to treating the chaotic dynamics and fluctuations of the annual run off for natural rivers. As example, we present the time-series of the annual runoff fluctuations for the Pripyate, Southern Bug rivers (Ukraine; catchment squire 26.4·10^3 km^2), received by us on the basis of processing the experimental data and calculating within the neural networks stochastic model. Non-uniform and multi-fractal objects can be more completely characterized by spectrum of $D(q)$ fractal exponents, where q is a real number, the so-called generalized dimension, where the fractal dimension is equal to $D(0)$ and the function $D(q)$ is generally referred to as multifractal spectrum. We carried out numeral modelling of chaotic dynamics for studied systems and our analysis (annual runoff fluctuations) shows that the average fractal dimensionality is 1.3-1.9. The knowing of the multi-fractal spectra allows to reconstruct the natural annual runoff with reasonable degree of accuracy.

RELATIONSHIP ANALYSIS BETWEEN MULTI-YEAR SOIL MOISTURE AND CLMATE CHANGE OF NORTHWEST OF CHINA

Mingguo MA (CAREERI,CAS)

Based on the SMM/I data, a set of skin soil moisture data were estimated for Northwest China from 1987 to 2001. The vegetation condition was calculated from AVHRR data during 1987 to 2001. The temperature data and precipitation data were also collected for our work. In this paper the relationship between soil moisture change and the above factors was analyzed.

PRESENT SITUATION AND ISSUES OF GROUNDWATER USE FOR EMERGENCY IN JAPAN

Norio TASE[1], Yoshizumi HOSONO[2] ([1]Institute of Geoscience, University of Tsukuba, [2]Department of Geography, Nara University)

There are two approaches to cope with groundwater issues for emergency situations. One is to use groundwater as supplementary sources when water supply systems are destroyed by disasters such as earthquakes and can not supply enough water. The other is to measure against destruction of natural groundwater systems by disasters when groundwater is used for water supply source. The former is common but the latter may be seldom considered. This paper introduces present conditions and issues on groundwater resources for emergency in Japan. Although groundwater accounts only for 30% of water use in Japan at present, it is recognized as important water resources for emergency situations, especially after the Great Hansin-Awaji Earthquake(GHAE) in 1995, which revealed essentials of waters for extinguishing fires and domestic uses. Roles of groundwater for extinguishing fires have been decreased to 1.2% in 1995 because groundwater wells cannot always supply enough water for fire fighting. While, in Japan, many local municipalities are storing water in ground and underground tanks, installing emergency wells, or designating private wells as emergency ones. For example, Nerima Ward in Tokyo, with 675,000 population in area of 48.16 km2, has 22 deep wells with generators for potable water, and 103 shallow wells in public schools and more than 500 private shallow wells for domestic uses except drinking. Under other emergency situations such as droughts, floods, and volcanic eruptions, groundwater resources are also affected in various ways. Drastic changes of groundwater in quantity and quality due to earthquakes and volcanic activities have been reported in many cases such as GHAE and Mt. Miyake. Deterioration or destruction of groundwater resource systems due to disasters and its effects on water supply systems may not be evaluated yet. During droughts, groundwater has been used as a supplementary source mainly for irrigation, which brought drastic water decline and occasionally land-subsidence. Under very extreme droughts such in 1939, we do not know well what happens.

HW05/10A/C31-002   0850

EVALUATION OF GROUNDWATER DAM SITES FOR EMERGENCY WATER SUPPLY

Sang-il LEE, Byeong-Chan KIM (Dongguk University)

Global climate change accounts for frequent drought and flood occurrences in many regions over the world. The Far East including the Korean Peninsula is also experiencing ever-increasing extreme events, and Korea has seen eight years of drought during the last decade. About thirty cities and counties located in southern and eastern parts of the country suffer from chronic water shortage. In addition to the climate change, steady increase in population and economic development have yielded imprudent expansion of urban areas, sometimes resulting urban floods which, in turn, lead to emergency situations such as suspension of water supply in some regions. These circumstances have increased the overall hazard potential due to either natural phenomena such as flood and drought or side effects of excessive development. The resultant hazard might cause not only tremendous amount of costs but social instability. While the construction of dams are delayed or challenged on account of environmental concerns, groundwater having annual recharge of about 13 billion cubic meters can be a reliable source of water supply for emergency situations in some regions of Korea. The hydrogeologic conditions of most regions of the country, however, make the major development of groundwater infeasible. Thus environmentally friendly small-size groundwater dams are being considered as a solution for emergency situations as well as for sustainable water supply source. In this study twenty-one candidate groundwater dam sites, selected based on preliminary studies, are evaluated in terms of their suitability. Systematic quantification of the suitability as a reliable source of water supply in emergency situations is the goal of the evaluation. The process of evaluation involves various factors: they include hydrogeologic, environmental, social, and economic attributes. The possibility of groundwater use in conjunction with available surface water is one of the important assessment criteria. Since the evaluation incorporates both qualitative and quantitative aspects of the complex decision-making problem, AHP (Analytic Hierarchy Process) was adopted as an analysis tool. Various influence factors of the candidate locations were identified and weighted. Suitability index was defined as a function of weighted influence factors. As a result, candidate locations were ranked and categorized into three groups based on the quantified suitability index. The evaluation results showed some discrepancies in suitability and priority from the preliminary study in which only some parts of factors such as water shortage and hydrogeology were considered for qualitative judgment. We believe that the suitability index approach based on AHP could be used as a guideline for decisions such as prioritization of further site characterization or of investment for groundwater dams. Acknowledgement: This research was supported by a grant (code 3-4-1) from Sustainable Water Resources Research Center of 21st Century Frontier Research Program.

HW05/10A/C31-003   0905

CONJUNCTIVE USE OF GROUNDWATER AND SURFACE WATER FOR DRINKING WATER SUPPLY BY USING IRRIGATION RESERVOIRS

Takeshi HATA (Faculty of Agriculture, Kobe University)

There are lots of small-scale irrigation reservoirs in Japan, especially in Kinki, Chugoku and Shikoku districts, southwestern part of Japan. For example, their number is around 50,000 in Hyogo Prefecture in Kinki district. In the drought season irrigation reservoirs, which are close to the supplying system to a water purification plant, are to be used for drinking water by installing shallow or deep well to pump up groundwater. These systems are for the emergency and are used for municipal use as well as agricultural use. The conjunctive use of small-scale irrigation reservoirs and the large volume of groundwater resources will raise security of drinking water. The reservoirs especially in the urban areas became evacuation places where people hit by the great earthquake in Kobe and the surrounding areas in 1995 lived in sheltered tents for some period of time with getting necessary water there. Many of the reservoirs are now in the difficult situation in their maintenance and management, because of severe decrease in the number of farmers. Besides the irrigation water, these reservoirs have some important roles of recharging groundwater storage, flood mitigation, valuable biotope areas for the species of plant and animals with scarcity and so on. Especially paddy fields contribute so much to the recharge of groundwater throughout the wide areas of paddies. In these areas lots of irrigation reservoirs have been constructed since 5th century in Japan. These 40 years many of the local areas have been developed and changed their land use from paddies to residential zones, and many plant factories have been constructed. Introducing the drinking water use to an irrigation reservoir will contribute to the maintenance of reservoirs under the support by the residents of urban areas and also to maintain the paddies as the source area of groundwater recharge. These days the source of drinking water has been changed from groundwater to surface water by constructing dams. However, the construction of new dams and large-scale reservoirs has become difficult mainly by reason of its severe affects to the natural ecosystem. Therefore the broad use of irrigation reservoirs is to be more important. Detailed system of the conjunctive water use including its social support system is discussed in the paper, i.e. how the storage water in a reservoir is allocated to the multi-objective use, how to support the maintenance of a reservoir by the participatory approach. Concerning the relationship between groundwater and surface water, water logging and leaching water are important issues for the agricultural water use in the world. These issues also should be considered in the application of the system to the arid zone like in Africa.

HW05/10A/C31-004   0920

CONJUNCTIVE USE OF SURFACE AND GROUNDWATER RESOURCES FOR WATER SUPPLY OF NUCLEAR POWER PLANTS DURING EXTREME LOW FLOW PERIODS

Mikhail V. BOLGOV (Water Problems Institute, Russian National Committee for IAHS)

Using the one Nuclear Power Station (NPS) in Russia as an example, the complex of hydrological and water management problems arising when designing system of industrial water supply for such station was considered. A variant of joint use of surface water and groundwater was suggested. It consists in the intermittent exploitation of aquifers within the system of industrial water supply in the years with a water deficit. A method was developed that permits one to assess the degree of reliability of water supply for the nuclear power station under the condition of the preservation of aquatic ecosystems. The imitation model for investigation was created. Next conclusions were received. 1. Natural regulation of the runoff of lakes and strongly waterlogged rivers used for the water supply of NPS results in the tendency of low-water years toward grouping. Under such conditions, the reliable satisfaction of demands on water can be provided only if the proportion of utilised water resources is small. For a great proportion of utilised runoff, the system of water supply should comprise either several surface sources with asynchronous fluctuations of runoff or aquifers. 2. When using internal reservoirs and the rivers flowing out of them for the water supply of the nuclear power station, one should take into account the requirements for environmental preservation. 3. Presently, no unified method for the estimation of admissible disturbances of the hydrological regime of rivers exists. Thus, the restrictions on transformation of the natural hydrological regime should be substantiated individually in each

H

case. 4. When making water management calculation, one should correct water loss for additional evaporation (at the expense of heated wastewaters discharged into the lake). In addition, changes in the dates of freeze-up (later freezing and earlier break-up) should also be taken into account. 5. The calculations showed that the beginning of operation of the NPS based on the current system of water supply will be followed by violating the ecological requirements and serious failures in the operation of NPS. On average, the units of the nuclear power station should be stopped once every five years. 6. The system of water supply of NPS should be connected to additional ground water sources. For effective operation of this system, it is necessary to develop special rules.

HW05/10A/C31-005   0935

SIGNIFICANCE OF GROUNDWATER EXPLORATION AND ITS DEVELOPMENT IN NORTH WEST INDIAN HIMALAYAS: IMPLICATIONS FOR FINDING EMERGENCY AND SUSTAINABLE SOLUTIONS

Ritesh ARYA (Aqua Associates)

This paper emphasise the significance of groundwater exploration and its development to solve drinking water problem in the high altitude($>$3000 meters above mean sea level), cold mountain (in winters,temperatures drop to -30*centigrade), deserts of northwest Indian Himalayas of Ladakh. Present findings are based on studying data from more than 500 boreholes drilled in the last 5 years in different hydrostratigraphic zones, identified by Arya(1996) along and across the Indian Himalayas. Prior to this study, entire system of water distribution and its management was based on surface water as the main source. Water was tapped from rivers/streams and distributed by water tankers to various places of habitation. Main problem with these water supply schemes was that in summers, due to snow melt ablation there was flashflooding. As a result water remained turbid,when it was most needed. Whereas in winters the surface water in rivers /streams freeze and sub surface temperatures drop down to +1*centigrade. Results from our present study shows that even in winters, when outside temperatures drop down to -30*centigrade,groundwater from the borehole always enjoys temperature difference of +4* centigrade over surface/sub surface waters. Therefore groundwater harvesting not only provides drinking water solutions on sustainable basis but also helps in finding emergency solutions to solve drinking water problem, arising due to extreme hydrological conditions (due to freezing of source in winters and turbidity due to flash flooding in summers) in the Ladakh,Indian Himalayas.

HW05/10A/C31-006   0950

MEASURES, TAKEN FOR PREPARING UNDERGROUND WATER SOURCES TO BE USED IN CASE OF EMERGENCY

Inom Sherovich NORMATOV (Institute of Water Problems, Hydroenergetics and Ecology, Academy of Sciences, Republic of Tajikistan)

In case of emergency (during earthquakes, floods), the problem of providing people with lodging, food, and clean potable water is becoming actual and requires immediate solving. In such cases the water supply will be submitted mainly from underground sources. Therefore one of urgent tasks is preliminary monitoring of underground waters, especially in the suburbs of densely populated cities and villages, industrial and agricultural sites. This is first of all the completing of measures to define: - the depth of underground water level; - the lithological contents and the capacity of water carrying horizons, water stress; - the feeding and unloading conditions of underground waters; - mineralization and chemical contents of underground waters; - contents of technogen pollutants and supposed polluting sources; - the underground waters regime and its defining factors; - the observing chinks on the site. According to above-mentioned characteristics there must be created GIS for every underground water source supposed to be used in case of emergency. Alongside, cartographic materials must illustrate the characteristics of underground waters. While constructing the underground water sources providing people with drinking water, the special attention should be paid to establishing the areas of sanitary security of water-intakes, their working ability in case of emergency, stability and lasting ability of constructions and auxiliary units.

HW05/10A/C31-007   1005

MANAGEMENT OF DROUGHT EVENTS IN A SMALL ISOLATED ISLAND

Manta Devi NOWBUTH[1], Teeluck BHOWRUTH[2], Farook MOWLABACCUS[2] ([1]Department of Civil Engineering, Faculty of Engineering, University of Mauritius, [2]Water Resources Unit, Ministry of Public Utilities)

Water is an inexhaustible and replenishable natural resource, which circulates through the hydrologic cycle. It is essential to meet several requirements of man starting from food to recreation. When demands exceed supply, there is naturally a scarcity of water in space and time, and this is generally referred to as ´drought´. Drought events can have impacts on both the social and economic sectors of a country. However, the impact of drought in isolated islands, is very critical, given that options to cater for deficits in water supply are not readily and economically available. This present study considers the management of water resources for Mauritius both during the normal and during a severe drought conditions. It places emphasis on the effectiveness of the short term measures taken to management water resources as well as the long term though expensive measures which had to be considered given the situation. The response of the public with regards to the campaign of the water authorities is analysed. The effectiveness of statistical analysis currently being used by the water authorities and the possibility of using other analytical methods that could provide sound basis to help in improving the management of severe drought events were compared. The results of the study indicated though there may be a number of measures that can be taken to manage water resources during drought events the actual measures which work efficiently is largely dependent on the understanding and sense of responsibility of the public. The local water authorities have over time develop a relatively quick and effective way of predicting drought events. However, with new development in the field of statistical methods such as the low flow frequency method, the run-sum analysis and the moving-average method, for drought predictions, can provide sound basis for decision making. It was found that the Run-Sum method of analysis is the most flexible approach for our region. It is advantageous, as both daily data for short droughts and annual data for multi-year droughts can be analysed. The use of a variety of different thresholds allows it to be applied over the whole range of flow regimes found in the region. For Mauritius, the Normal Flow or the Mean Flow can be used as threshold.

HW05/10A/C31-008   1020

THE IMPACT OF REFUGEES ON GROUNDWATER RESOURCES IN KENYA

Francis Mwaura MWANGI (Department of Geography)

Kenya receives an average annual rainfall of 567 mm which converts to approximately 322.8 billion cubic metres of water. The country is considered to be a water scarce area because it has an annual freshwater per capita of about 700 m3 compared to the world benchmark of 1000 m3. The country supports and maintains a large number of refugees from the war-torn countries of Somalia, Sudan and Ethiopia. The settlement of a large number of refugees can cause a wide range of environmental transformations including high consumption of natural resources including water. An Assessment of groundwater extraction in a dryland area of northern Kenya which supports a large number of refugees was undertaken for the last one-decade. The overall objective was to determine the effects of groundwater withdrawal on water levels and quality. A total of 13 boreholes were considered in the assessment.Six boreholes operating in Liboi Refugee Camp were found to have average yields in the range of 9-12 cubic metres per hour. The estimated daily discharge was approximately 660 cubic metres in a network of boreholes within an area covering 4 km2. Elsewhere, a total of six boreholes in the Ifo Refugee Camp were analyzed and found to produce upto 6 cubic metres per hour within a small area of about 6 km2. The Merti Aquifer which underlies about 35 000 km2 of Northern Kenya was estimated to supply approximately 880 000 cubic meters per year to the refugee camps alone. The assessment of 4 boreholes in the Hagadera Refugee Camp indicated an average monthly water consumption of 25 621 cubic metres and 65% increase in production since the early 1990s. The analysis of groundwater levels did not show any tremendous variability in the water table. However, the analysis of water quality trends indicated that the chemical characteristics of water in the Merti Aquifer have been changing most likely as a result of increased withdrawal. A consistent increase in electrical conductivity was observed. The results indicated a need for close aquifer monitoring to capture the variability in terms of groundwater quality and quantity. There is also need for greater efforts towards water conservation and new alternative sources including the use of rainwater harvesting for the artificial recharge of groundwater aquifers.

HW05/10A/C31-009   1055

GROUNDWATER RECHARGE BY LEAKING WATER SUPPLY NETWORK IN LARGE CITIES, JAPAN

Masaya YASUHARA (Geological Survey of Japan)

Unconfined groundwater (phreatic water) in urban areas, whose importance had been disregarded due to its deteriorated quality, is now attracting a great deal of attention again as a potential source of water after catastrophic events like large earthquakes, when the water supply system can be broke down for a long period of time. The study was carried out for a better understanding of origin of unconfined groundwater in large urban cities. As well as reducing recharge by precipitation, urbanization creates new sources of groundwater recharge, including leaking water mains. It is widely recognized that most, if not all, of pipe networks leak and a large part or all of leakage flows vertically downward and recharge groundwater. The leakage and its interconnections with groundwater have rarely been quantified in Japan. The water supply data of 1995, published by the Japan Water Works Association, were examined mainly for 47 high-density prefectural capitals with large imported water supplies. The total water supply across the country was 16 x 10^9 m^3/yr and 9.7% of supply, that is 1.6 x 10^9 m^3/yr, was lost through leakage. For respective capitals, leakage rate (% of total water supply) ranges from 2% in Niigata to 22% in Gifu. A simplifying assumption was made that all leakage became recharge, and dividing the leakage quantity by the areal extent of water supply for each capital gave recharge flux as 8 mm/yr (Niigata) -214 mm/yr (Osaka). This recharge flux was compared with net precipitation, which was obtained by subtracting annual evapotranspiration based on the Thornthwaite method from annual precipitation. The ratio of recharge flux to net precipitation is found to be low, being below 5% for 43 out of 47 capitals due mainly to high precipitation (900-2,600 mm/yr) under the monsoon climate and relatively low leakage rate. However, the ratio is exceptionally as high as 16.1% for Osaka and 10.5% for Tokyo, the third largest and the largest city in Japan, respectively. For these highly urbanized cities with impermeable-surface ratio of 0.8 or more, net groundwater recharge by precipitation, calculated by multiplying net precipitation by permeable-surface ratio, becomes less than one-fifth of the net precipitation. Therefore, despite high precipitation and low leakage rate, in Tokyo and Osaka, leakage must be comparable in size with recharge by precipitation or already be a predominant source of groundwater recharge. With the decreased infiltration accompanying further progress of urbanization, it is highly probable that leakage comes to play a predominant role in recharge and preservation of unconfined groundwater even in other cities such as Kyoto and Kofu, where impermeable-surface ratio is still relatively low at present.

3D SOLID MODEL FOR GROUNDWATER AQUIFERS NORTH-EAST MOSUL

Abdulghani A. HASAN (Saddam Research Center for Dams and Water Resources, University of Mosul)

The fact is producing a 3D solid model for Aquifer characteristics is very complicated and may produce inaccurate model, but with using a good finite elements numerical modeling technique and depending on a good lethological data for wells and data from electrical investigations a good model for representing geological aquifer dimensions could be produced. In this paper the data for the region north-east Mosul have been used to build a 3D solid model with an area about 1750 square kilometer and to depth about 250 m and the numbers of artesian wells are 87 and the numbers of electrical data points are 46. All geological layers have been connected with 3D finite elements to produce the final 3D solid model for aquifers in this region. After completing this model a horizontal and vertical sections are produced to declare the types and the shapes of different layers. The main objective from producing this model is to seek for a good isolated aquifer that could be used as a ground water basin in case of emergency.

HW05/10A/C31-011   1125

EVALUATING THE GROUNDWATER VULNERABILITY DUE TO OVER EXPLOITATION IN WALAWE BASIN, SRI LANKA

Ranjan Priyantha SARUKKALIGE[1], Ashim Das GUPTA[2], So KAZAMA[1] ([1]Department of Civil Engineering, Tohoku University, [2]School of Civil Engineering, Asian Institute of Technology, Thailand)

Walawe river basin is located in the southern part of Sri Lanka and major part of it is located in the dry zone, which is frequently face the water scarcity problems and droughts. The availability of surface water becomes limited in the area and the reserve of groundwater becomes an important source of water supply in drought periods. The over exploitation of groundwater resource will enhance its adverse effect like depletion of resources and degradation of groundwater quality. The increasing trend of anthropogenic stresses on groundwater resource has made it vulnerable. Adequately assessing the vulnerability of groundwater systems is important, since it is very costly to restore the resource once it reaches certain deterioration thresholds. One of the fundamental problems with the groundwater resources unlike surface water is that, the resource is not physically visible. Groundwater indicators therefore should provide a means to appraise the groundwater situation. Among the potential variables to be considered in evaluating vulnerability of

groundwater with respect to groundwater exploitation, groundwater level decline was used to indicate how various factors influence the susceptibility of the aquifer and cause future problems occur in Walawe river basin.Adams and MacDonalds (1995) produced a set of diagnostics, involving hydro-geological criteria, which could be used to indicate aquifer susceptibility and vulnerability. With regard to this diagnostic approach, a relative simple technique was developed to determine the susceptibility of aquifers to water level decline. According to the available data only the selected factors, hydraulic diffusitivity, lateral heterogeneity and annual recharge were considered to determine the susceptibility of the aquifers in the study area. The technique was based on assigning numerical values for contributing factors and then summing to give an overall grade of susceptibility. Three grades were possible for each factor: high, moderate and low. These grades were estimated for each aquifer parameter with respect to the available data. Once the grades have been determined, the tables were used to determine the attribute numbers for each parameter, and then summed to get an overall score. This score was finally used to give a general indication of the vulnerability of the area with respect to groundwater quantity. Results of vulnerability assessment were portrayed on a map showing various homogeneous areas, which have different levels of vulnerability. The ultimate goal of the vulnerability map was a subdivision of an area into several units showing the differential potential for a specified purpose and use. It shows that the groundwater resource is highly susceptible for the excess use in lower part of the basin and it is less susceptible in the upper- west part of the basin. The groundwater exploitation in lower part of the basin is more susceptible than other areas. This methodology can be taken to prevent the decline of groundwater resource due to over exploitation, support decision making and making long term commitments to achieve sustainable groundwater usage.

HW05/10A/C31-012   1140

ESTIMATION OF GROUNDWATER RESOURCES IN PAGERU RIVER BASIN, INDIA

P.D. SREEDEVI, Shakeel AHMED (Indo-French Centre for Groundwater Research, NGRI)

Groundwater is the main source of supply for domestic and irrigation purposes in Pageru River Basin, India in the absence of even meager surface water resources. Thus a perceive groundwater balance and resource estimation is extremely important in the drought prone areas. Groundwater estimation has been made quantitatively by using hydraulic budget method in the study area. It is a quantitative measure of the balance between the total water gains and losses of the basin for a particular period of time. The hydrograph analysis clearly reveals the fluctuations in the water levels have direct relationship with the intensity and amount of rainfall in the catchment area. Groundwater balance studies are carried out by taking in to consideration aspects such as rainfall, runoff, percolation, evapotranspiration, groundwater recharge, discharge, change in soil moisture and changes in groundwater storage and by following the norms recommended. The total area of the basin is 480 km2. The basin area lies between latitudes 14o29'04" and 14o39'51" N and longitudes 78o19'12" and 78o41'32" E. The Pageru River Basin receives an average annual rainfall of 581mm with significant seasonal variations usually the region receives its first spell of rainfall from pre-monsoonal convectional showers in the month of May. But its occurrence is erratic. The intensity and amount of rainfall is unpredictable during the Southwest monsoon period (June to September). In fact, highest rainfall occurs in the basin during the Northeast monsoon period (October and November). The period between January and May is the main dry seasons and receives some rainfall due to convections or winter cyclonic disturbances. The hydrograph analysis clearly reveals the fluctuations in the water levels have direct relationship with the intensity and amount of rainfall in the catchment area. It is also noticed that the water table levels rises in the wells to a maximum in the months of November and December and starts declining from January to June. The total quantity of groundwater recharge per annum is estimated as 5434.5 ha.m, where as draft accounts for 4649.5ha.m with a net groundwater balance of 785 ha.m in the catchment area.

UNDERGROUND WATER STUDIES IN THE CRYSTALLINE BASEMENT AQUIFERS OF SOUTHERN NIGERIA

Omeimen E. UJUANBI, Collins OSE INEGBEDION (AMBROSE ALLI UNIVERSITY, EKPOMA.)

Increases in population and industrial activities during the past decade have increased the demand for water in the northern part of Edo State Nigeria. This study area is situated within the crystallie precambrian rocks, collectively known as the basement complex of Southern Nigeria.The survey is part of regional exploration programme at delineating the presence of diastrophic features like fractures within the study area.It was observed that the ground water flow pattern follows the fracture lines and the fracture lines in turn allign themselves in the direction of the major foliations within the rocks.

HW05/10P/D-002   Poster   1400-156

OCCURENCE OF GROUNDWATER IN HARD ROCK TERRAIN

Faisal Kamal ZAIDI, Dewashish KUMAR (INDO FRENCH CENTRE FOR GROUNDWATER RESEARCH, N.G.R.I.)

Ground water is a distinguished component of the hydrologic cycle, however the uncertainty about the occurrence distribution and quality aspect of ground water and the energy required for its withdrawal impose certain restrictions on its exploitation. Fractured igneous, metamorphic and consolidated sedimentary rocks are distributed abundantly both in time and space. They occur principally in large areas called shields and smaller massifs and partly in cores of major mountain ranges. The extension of shield rock outcrop built usually by igneous and metamorphic rocks is estimated to be 20% of the present land surface. India is a vast country having diversified geological setting. Variation exhibited in the rock formation ranging from the Archean crystalline to the recent alluvia are as great as the hydro meteorological conditions. Almost the entire of south and central India is occupied by a variety of hard rocks with hard sediments in the intercratonic and river basins. The hard rock terrains, river valleys and abandoned channels, wherever having adequate thickness of porous material act as potential areas for groundwater storage and development, but the lack of primary porosity restricts the movement and storage of ground water in these hard

rock aquifers. Thus the ground water availability is dependant upon the development of secondary porosity caused by the weathering and fracturing of the rock matrix. The weathering reactions of granitoid rocks are affected by a number of factors but permeability to weathering solution and mineral composition appear to be the most important. The density of joints control permeability at the macro and meso scale. The extent of macro and micro fracturing depends directly on the thermal and stress history of rocks concerned. Rocks, which contain high proportion of quartz and potassium feldspars, are generally more resistant to weathering than rocks, which contain substantial amount of calcic plagioclase, biotite and other mafic minerals. One of the most important properties of hard rock aquifer is that the aquifer parameters like Storativity (S) and Transmissivity (T) often show erratic variation within short distances. Increasing amount of hydro geologic data due to increasing demand for water and improved drilling technology have simulated efforts to regionalize and generalize results from different fractured environments. Data on rock transmissivity, ground water resources and quality obtained from different methodological approaches offer excellent possibilities of correlative hydro geologic studies. Thus new important results have enabled better understanding of hydro geological studies of hard rocks both in local and regional scales and improvement of methodological approaches to be used there.

WATER BALANCE STUDY AND ESTIMATION OF NATURAL RECHARGE IN THE BARIND AQUIFER OF BANGLADESH

Md. Monirul ISLAM[1], Pintu KANUNGOE[2] ([1]Associate Specialist, Coastal Hydraulics Division, Institute of Water Modelling, H # 476, R # 32, New DOHS, Mohakhali, Dhaka-1206, Bangladesh, E-mail: mnr@iwmbd.org, [2]Senior Scientific Officer, Hydraulic Research Directorate, River Research Institute, Faridpur, Bangladesh, E-mail: rri@bttb.net.bd)

In this paper, for the planning purpose, results of the study for preliminary estimation of the recharge rate as well as sustainable yield will be presented for the semi arid Barind Tract of Bangladesh. It is found from detailed water balance study for the area that natural recharge rate in the Barind Tract vary widely year to year. And for the same time period different method gives different result. In managing a groundwater basin efficiently and effectively, evaluation of the maximum annual groundwater yield of the basin that can be withdrawn and used without producing any undesirable effect is one of the most important issues. In investigating such recharge rate, introduction of certain terms, such as sustainable yield, safe yield, and perennial yield has been accompanied. Basically there is no significant difference between them. They are almost synonymous (Kashef,1987).The Barind tract in North-West region of Bangladesh is characteristically dry (Semi arid region) and of elevated land feature covered with a thick clay layer althrough upto a depth of 30m in some places and underlying a sand layer which serve as the aquifer. Natural recharge in this region is quite uncertain because of the thick clay layer and the aquifer may be treated as the confined one (Ahmed and Burgess, 1993). Development of this area is closely related with the intensive use of vast land, which is now under utilization. Utilization of this land is possible only under ensured irrigation. The Government has a plan to develop the irrigation facilities by optimum utilization of available ground and surface water (BWDB, 1989). The available surface water for irrigation purpose is very low in comparison with the demand. In this context under groundwater utilization programme, installations of huge amount of deep tube wells have been proposed (2000 in 1st phase and 3000 in 2nd phase). Installation of deep tube wells of the 1st phase was completed by June 1988 and 3000 deep tube wells of the 2nd phase have also been installed. The sustainability of this large-scale abstraction programme has been questioned by environmental scientists (Ahmed et al., 1995). The present rate of extraction for irrigation is 1.2*109 m3/year, which may lead to exhaustion of the aquifer in nearly 53 years time (Khan & Sattar, 1995). The rivers around Barind Tract have an effluent character, which gain water from the aquifers throughout the year. The groundwater table is lowering rapidly and whole region is in the acute state of deforestation. Indiscriminate groundwater development may accelerate deforestation trend (Khan & Sattar, 1995). In this context estimation of actual natural recharge rate to the Barind aquifer will unquestionably assist in proper management and planning of environmentally viable abstraction schemes.

ESTIMATING GROUNDWATER RECHARGE IN A VOLCANIC BASALTIC AQUIFER

Manta Devi NOWBUTH[1], Satyajay Prayagsingh MOHUNGOO[2] ([1]Faculty of Engineering, Civil Engineering Department, University of Mauritius; [2]Faculty of Engineering, Civil Engineering Department, University of Mauritius)

Reliable estimates of recharge rates to an aquifer are often a pre-requisite to the development of efficient plans for the management of groundwater resource (Raper & Sharma, 1989). There are several methods commonly in use for estimating groundwater recharge and these methods vary in degree of complexity and their adaptability to a particular geological conditions. Review of relevant published literature revealed that for regional studies of highly complex geological formations, the common practice is to use simplified methods for estimating groundwater recharge. In the present study, a simple water balance method was used to estimate groundwater recharge in a complex geological formation, a volcanic basaltic aquifer. This method has been reported to perform reasonably well in similar geological formations. Results showed that about 23% total rainfall is annually converted to recharge in that particular area. This value correlated well with the predicted percentage recharge but was lower than those values used for past local studies in estimating potential of groundwater basins. The results therefore emphasised not only on the need for good recharge estimates but also on the consequences of water resources management locally.

HYDROLOGIC CYCLE USING RADON CONCENTRATION AS AN INDICATOR OF GROUNDWATER IN THE SMALL CATCHMENT OF THE TOHTSURU MARSHLAND, EASTERN HOKKAIDO, JAPAN

Takeo TSUCHIHARA[1], Satoshi NIHIRA[2], Satoshi ISHIDA[1], Masayuki IMAIZUMI[1] ([1]National Institute for Rural Engineering, [2]Hokkaido Development Agency)

A lot of wetlands have disappeared due to human activities such as drainage, reclamation and deforestation for cultivating agricultural land. Although the importance of wetlands has been widely recognized, the basic components of wetlands are not sufficiently understood. The hydrology of a wetland system is fundamentally involved with their formation and persistence. Nevertheless, the hydrology of wetland systems is complicated by geographical conditions. In particular, the groundwater input to a wetland is generally considered one of the most difficult components to quantify. The estimation of water balance in wetland hydrologic cycles has been requested strongly in order to take effective countermeasures for preservation of wetlands. In this study, investigation and analysis for hydrologic cycle using radon concentration as an indicator of groundwater revealed a hydrologic system with a 1.58 km2 catchment area in Tohtsuru marshland, eastern Hokkaido. The hydrologic system consists of a swamp of 0.5km2 surface area, 3 small recharge rivers and Uenbetsu

discharge river. Water flows between the Uenbetsu River and the swamp is interchanged due to difference between river and swamp levels. Radon-222 is a radioactive gas that is soluble in water. The concentration of radon dissolving in groundwater is extremely more than that in surface water because radium-224, which is the source of radon, is ubiquitously included in the material of aquifers such as soil and rock. This difference of solubility enables radon concentration to be an indicator to evaluate the contribution of groundwater in a hydrologic cycle. The measurement of radon concentration at survey points of a 100-m grid system in the swamp and every 100 m along small recharge rivers revealed the distribution of a spring in the marshland. Marshland basin model with a radon mass-balance equation is introduced to quantify the groundwater input to the swamp. The ratio of groundwater to the total recharge volume of the river was calculated at 73.7%. The water balance model with a three-layered tank model to calculate recharge from the 3 small rivers and an exchange model to calculate interchange of water between the Uenbetsu River and the swamp was constructed to confirm the results of the marshland basin model. The results of simulation show that the ratio of groundwater volume to this river volume was 74.7%. This good agreement between the results from the marshland basin model and the water balance model confirms the effectiveness of the investigation and analysis using radon concentration.

HW05/10P/D-006 Poster 1400-160

MODELING GROUNDWATER REMEDIATION

Khaled Ismail HAMZA (Department of Civil, The Hashemite University)

Assessment of contaminant migration and remedial options are crucial due to theincreased environmental problems related with long term groundwater pollution. Groundwater flow simulation models are commonly used to simulate hydraulic conditions in an aquifer. They are also useful in the design of aquifer remediation system where the remediation technology used is pump and treat. To that end a two-dimensional vertical cross-sectional model is developed taking into account reference density concept. Governing equations are combined into two nonlinear coupled partial differential equations in only two variables namely, the concentration and the equivalent freshwater. Dispersion coefficient are taken to be scale and velocity dependent which increases the nonlinearly of the problem. The concept of variable-density fluid flow, in which the fluid density is affected by the presence of pollutant, is considered. Numerical integration is carried out using the Gauss method. The dispersion tensor is dependent on the velocity and is updated after each iteration. The model is able to simulate groundwater's aquifer cleanup using pump-and-treat method. It is capable to construct equi-concentration lines and equi-potential lines with different conditions under transient and steady state conditions. Polluted zone is clearly described.

HW05/10P/D-007 Poster 1400-161

CAUSES AND EFFECTS OF ARSENIC CONTAMINATION IN DRINKING WATER IN WEST BENGAL: A PUBLIC HEALTH ISSUE

Debashis CHATTERJEE, Joydev JANA, Sudip Jyoti SAHU, Rupa BHATTACHARYYA, Bibhas NATH, Sudipto CHAKRABORTY (Department of Chemistry, University of Kalyani, Kalyani, India)

High arsenic groundwater is widely reported in the Holocene sedimentary aquifers of the Bengal Delta Plain, BDP (West Bengal, India and Bangladesh) causing serious threat to the supply of safe drinking water. Manifestations of skin lesions, cancer and other toxic exposures are envisaged among the affected population. The arsenic content (>50 µgL^{-1}) of the contaminated aquifers are far above the recommended Indian and Bangladesh drinking water standards (50 µgL^{-1}) as well as the WHO guidelines (10 µgL^{-1}). The scale of the problem is therefore serious and unprecedented. Groundwater chemistry demonstrates that the water is generally fresh exhibiting Ca-Mg-HCO$_3$$^{-1}$ nature predominantly and the acid – base equilibrium of the system is well controlled. The nitrate and sulphate content is generally low to very low indicating the anoxic environment. High alkalinity of the groundwater in the contaminated wells is by and large associated with relatively high DOC reflecting the microbial degradation of organic matter in the sediment. Absence of dissolved oxygen and low to very low Eh further confirms the prevalent anoxic conditions in the system. This facilitates the anaerobic microbial processes favored by the relatively high groundwater temperature of the BDP. Arsenic and iron seldom shows a unique relationship. The vast majority of the arsenic contaminated water on regional basis exhibits positive correlation with high iron concentration. On the contrary, high iron enriched water does not necessarily contain high arsenic. Dissolved Fe(II) and As concentration show positive correlation with DOC. Therefore, arsenic may be derived as a consequence of desorption and dissolution of oxy iron hydroxides, originally precipitated as weathered product during land formation. The release of the sorbed arsenic into the groundwater occurs during iron reduction. The process is driven by microbial metabolism of sedimentary organic matter and locally developed reducing conditions. Arsenic is introduced into the alluvial aquifers in the soluble state during sediment transportation from upper catchment and subsequently deposited(mostly oxidized form) on secondary iron/aluminium/manganese phases in the deltaic plain. Grain size of the aquifer sediments, concentration and allocation of microbial activity as well as the role of terminal electron acceptors across the fluid interface of the mineral grains assist in the micro scale control and release of arsenic, the redox sensitive species. The microbial cycling of redox sensitive species (FeII / MnII) is the key player for such environmental processes.

HW05/10P/D-008 Poster 1400-162

GEOELECTRIC STUDY ON THE FACTORSCONTROLLING THE GROUNDWATER OCCURENCESIN THE AREA NORTH OF NEKHL, CENTRAL SINAI, EGYPT

Nasser Mohamed HASSAN[1], Talaat A. ABDELLATIF[2], Mohamed Abbas MABRUK[2], Abdallah El-Abasery ABDELRAHMAN[2] ([1]GEOPHYSICS DEPT.,FAC.OF SC.,AIN SHAMS UNIV., [2]GEOPHYSICAL EXPLORATION DEPARTMENT, DESERT RESEARCH CENTER, CAIRO, EGYPT.)

Exploration for groundwater in anisotropic aquifers, such as carbonates, requires accurate identification of the lithologic changes and delineation of the structural elements with the associated features. According to borehole data, groundwater exists within the carbonate rocks that dominate the area lying to the north of Nekhl,Central Sinai. The present geoelectrical sounding survey was carried out in two selected sites (Abu Hamth and El Bruk areas) lying to the north of Nekhlwith the purpose of delineating the lithological and structural factors that contribute to the groundwater flow and accumulation in that area. A total of 58 vertical electric resistivity soundings (VES) were distributed along the selected sites. The resistivity sounding data has been qualitatively and quantitatively interpreted. The qualitative interpretation gave information about the number and continuity of the layers throughout the area. The data of the existing boreholes was used to construct the initial model for the quantitative interpretation. Electrical resistivity mapping was carried out at EL Hassana area with the purpose of verifying and delineating some marked features. Two-dimensional resistivity imaging profile (electrical tomography) was measured at EL Hassana area in NNW-SSE direction along a distance 246m.in order to investigate the shallow structural elements that contribute to the groundwater occurrence in the study area.

HW05/10P/D-009 Poster 1400-163

THE CONTRIBUTION OF SHALLOW GEOHYSICAL INVESTIGATIONS IN DELINEATING THE HYDROGEOLOGICAL MODEL FOR THE SHALLOW AQUIFER IN WADI EL NATRUN AREA,WESTERN DESERT,EGYPT

Nasser Mohamed HASSAN[1], Ahmed Ragab ALLAM[2], Ahmed Moustafa ABDEL GAWAD[1], Abdallah Ibrahim AMMAR[2] ([1]GEOPHYSICS DEPT.,FAC.OF SC.,AIN SHAMS UNIV., [2]RESEARCH INSTITUTE FOR GROUNDWATER,MINSTRY OF IRRIGATION AND WATER RESOURCES,EGYPT.)

Wadi El Natrun area is located at the western part of the Nile Delta,about 86 km northwest of Cairo city,parallel to Cairo-Alexandria desert road.This area belongs to thearid zones,where the groundwater is considered the main water source. The present work deals with the building of the hydrogeological model of the study areabased on the available hydrogeological data and the obtained geophysical results. Forty three vertical sounding stations were measured throughout the study area. Quantitative interpretations were done through the analysis of the field curves in terms of electric layers of specified thicknesses and resistivities,then constructing the geoelectric cross sections along the layout of the electrical profiles.The quantitative interpretations revealed the presence of five geoelectric layers forming the shallow section of the study area.The well log data of fifteen wells selected in Wadi El Natrun area were used for the evaluation of the encountered rock units; lithology,shale content,porosity and water saturation.Results were represented in different isoparametric maps for the encountered geoelectric layers. These maps were used for integrated subsurface geologic and hydrogeologic evaluation. Among the encountered five geoelectric layers,the second,third and fourth layers reflect the main water unconfined aquifer in the study area.The constructed hydrogeological model for the second layer,which is the best layer with the highest groundwater potentiality,revealed that the flow direction of groundwater is from the NE(high velocity) and from the SW(low velocity) toward the central part of the study area.Also the area will be dry gradually from the southwestern to the northeastern directions and its expected limitations will be from the southeastern and eastern directions. Recommendations were made for future production wells and pumping rates to avoid fast depletion of the shallow aquifer of Wadi El Natrun area.

THE EVOLUTION CHARACTERISTICS OF GROUNDWATER IN SHULE RIVER BASIN AND THEIR EFFECT ON ECO-ENVIRONMENT

hanzhang BAO, tandong YAO, shiyin LIU, anxin LU (Laboratory of Ice Core and Cold Regions Environment,CAREERI,CAS)

Shule River Project, which supported by loan of World Bank, is an integrated project for agricultural development and immigrant allocation in Hexi Corridor, west of China. The whole construction will be built up in 2005a. In view of global climatic changes and the executing of the project, the change of water resources of the basin in space—time distribution and the interaction between surface water and ground water are more intensive. Based on the long-term hydrological, climate and regular groundwater observation data, the evolution characteristics of groundwater are studied by using water budget model and groundwater flow model in this paper. The results illustrate that groundwater system of the basin now is in a period of great variation. In the basin, hinge project of Changma reservoir and long-distance canals have been finished. The artificial hydraulic irrigating project took place of natural river system. Yield of groundwater heavily increases with the expanding of immigrant allocating areas and land reclamation. All these above lead to the recharge and discharge condition of groundwater changed obviously, and the process of circulation and conversion between surface water and groundwater are much faster than ever. So the quality and quantity of groundwater, dynamic characteristics of groundwater varied correspondingly. Furthermore, along with the adjustment of groundwater system, groundwater change has led to structural failure of region eco-environment. The main environmental problems in the basin, such as everglade atrophy, plant degradation and land desertification, which are all getting more and more serious, are also studied in this paper.

GENETIC ALGORITHM BASED DESIGN FOR DRAINAGE WELL ARRANGEMENT

Takeshi SATO[1], Takao SUZUKI[2] ([1]Dept. of Civil Engineering, Gifu University, [2]Dept. of Civil Engineering, Gifu National College of Technology)

Genetic algorithm was applied to determining arrangement and number of deep wells for groundwater drainage from excavation area of an underground parking station construction. The site locates in central area of a downtown of which groundwater level stands near the surface. Environmental assessment required suitable drainage to minimize the impact of deep well technique for withdrawal of groundwater and decrease of the level. This is a case study of genetic algorithm application to engineering practices in decision making from some alternatives of arrangement and number of deep wells.

HW05/10P/D-012 Poster 1400-166

GROUNDWATER POLLUTION VULNERABILITY AND GROUNDWATER PROTECTION STRATEGY FOR THE OWERRI AREA, SOUTHEASTERN NIGERIA

Ibe Kasimir MADUABUCHI, G. I. NWANKWOR, S. O. ONYEKURU (Head, Department of Geology, Federal University of Technology)

The vulnerability to pollution of the Owerri regional water-supply in, Nigeria, was assessed as the basis for proposing an appropriate strategy for protecting the groundwater resources. The vulnerability assessment was accomplished using the LeGrand, GOD, SIGA, and DRASTIC computer models. Techniques of the models generally involve parameter-rating and point-count systems, based on the evaluation of various hydrogeologic parameters in relation to their capacity to influence the flow of contaminants in the groundwater system. The Owerri study area is generally flat and the amount of groundwater recharge is relatively high. The area is underlain by predominantly sandy strata in the north, which grade into gravelly sequences toward the southwest. The southeastern part of the area is underlain in part by a thick clayey facies that thins and interfingers into the gravelly strata. Effective hydraulic conductivity ranges from 5.6 x 10-9 - 1.44 x 10-3 m/s, the higher value being in the coarse sand and gravel units. The depth to the water table is about 60 m in the north and decreases southward, to less than 20 m; the hydraulic-head gradient is 9-22%. The southwestern part of the Owerri area including the Owerri metropolis have a high vulnerability, togroundwater pollution and therefore are areas where waste disposal site should not be located. The northern and southeastern have moderate and low vulnerabilities, respectively, and carefully parts, selected and engineered sites within those area could be considered for future waste disposal.   Policies should be instituted to facilitate the closing of pollution sources in area of high vulnerability suchas open disposal pits, leaking petrol stations, discharge of effluents from industries, and use of pit latrines and to locate future disposal site in areas of lower vulnerability.

the saturated and unsaturated zone influence the results of hillslope and watershed scale investigations. We also show how these controls combine with the history of different rainfall signatures to produce observed hillslope and catchment mixing. We argue that this virtual isotope hydrograph separation experimental approach may provide a well-founded basis for defining the limitations of spatially invariant end member hydrograph separation and under what circumstances it may be best applied.

HW06/07A/C31-004   1030
A NEW TRANSFER FUNCTION BASED HYDROGRAPH SEPARATION MODEL

Kevin James MCGUIRE[1], Markus WEILER[1], Brian MCGLYNN[2], Jeff MCDONNELL[1] ([1]Department of Forest Engineering, Oregon State University, [2]Department of Land Resources & Environmental Sciences, Montana State University)

Isotope based hydrograph separation has been an important tool for defining water source components in headwater catchments. One major limitation to the further development of these techniques has been the often observed large temporal variations in rainfall isotope composition through the event. Here we present a new hydrograph separation approach (TRANSEP) that uses the temporal variability of the rainfall isotopic composition to more accurately determine hydrograph components and to provide transfer functions for both the tracer and runoff responses separately. TRANSEP overcomes many limitations of traditional two-component hydrograph separations (e.g. tracer travel time) by integrating the instantaneous unit hydrograph and isotope hydrograph separation techniques. Separate functions that describe the lumped transfer of runoff, event water, and pre-event water to the stream were derived and used to interpret hydrograph components. We argue that TRANSEP provides a new and better method for extraction of runoff generation information.

HW06/07A/C31-005   1110
STABLE ISOTOPIC COMPOSITIONS OF SUBSURFACE WATER AND WATER VAPOR IN THE ATMOSPHERE AT FORESTED REGIONS

Maki TSUJIMURA, Yuichi ONDA, Risa SASAKI, Tadashi TANAKA (Institute of Geoscience, University of Tsukuba)

The data on stable isotope in subsurface water and water vapor in the atmosphere from the field has not been enough for modeling of the water cycle and isotope processes at the local to regional scales. We have performed tensiometric observation and isotopic study of subsurface water in the slope to clarify the formation process of stable isotopic ratio profile of subsurface water in forested catchments. Isotopic analysis of deuterium and oxygen-18 for subsurface water in the slope revealed systematic trend in a vertical profile direction in catchments where vertical subsurface flow is dominant in hillslopes. The monthly observed isotopic ratios of subsurface water showed a large variation in response to the rainfall and evapotranspiration above the depth of 50 to 70 cm, and the isotopic ratio was homogenized and the temporal variation of observed data were dampened below the depth of 70 cm. Also, the average stable isotope ratios in subsurface water was a little higher than the volume weighted mean of rainfall because of evaporation from the soil surface, though the evaporation rate itself was low in the forested area. The stable isotope in water vapor in the atmosphere and soil water was monitored synchronously to investigate the stable isotope profile throughout the soil and atmosphere. Stable isotopic compositions in the water vapor at the height of 5 cm above the soil surface were affected much by the evaporation from the soil water. The contribution ratio of evaporated water vapor from soil surface to the atmosphere was estimated to be from 16 % to 55 % based on the observed stable isotopic ratio of water vapor and soil water under a humid condition in winter season. More data should be necessary for modeling the formation process of stable isotopic compositions in water near the soil surface in the forested regions.

HW06/07A/C31-006   1130
CONTINUOUS SOIL WATER ISOTOPE OBSERVATIONS AND MODELING APPROACHES AT A FOREST METEOROLOGIAL EXPERIMENTAL SITE IN GERMANY

Paul KOENIGER[1], Lutz JAEGER[2], Helmut MAYER[2], Christian LEIBUNDGUT[1] ([1]Institute of Hydrology, Albert-Ludwigs University Freiburg, Germany, [2]Meteorological Institute, Albert-Ludwigs University Freiburg, Germany)

At the forest meteorological experimental site Hartheim (Pinus sylvestris) in southwestern Germany, soil water isotope concentrations (deuterium and oxygen-18) were measured biweekly over a three-year period to investigate unsaturated water flow and recharge mechanisms. The study site is characterized by small amounts of rainfall and relatively high evapotranspiration. A human-influenced lowering of the groundwater level has led to the classification of the area as almost semi arid. The soil layer is characterized by a low water storage capacity and a high permeability. The root depth is about 40 cm. A distance of 7 m to the groundwater table suggests that capillary rise and groundwater uptake are negligible. Water extraction for isotope analyses was carried out using the toluene distillation method and soil water contents were analyzed gravimetrically. An estimation of isotope concentrations in rainfall and groundwater together with micrometeorological observations allow a qualitative and quantitative description of hydro-meteorological frame conditions. In order to complete the study and evaluate the influence of evapotranspiration on water movement, actual evapotranspiration was calculated using the Bowen Ratio Energy Balance method. Continuous isotopic observations at 2, 20 and 40 cm depth in the soil layer indicate a sharp decrease of seasonality with depth, allowing an estimation of the depth of dampening of the isotope signature, to a value of 1% by 200 cm. Flow velocities calculated using a sine curve fit resulted in values of 1-2 cm per day. These values indicate a rather slow matrix flow but correspond with investigations summarized by other authors. In contrast to the monitoring, two deeper profiles (150 cm) that were taken in August and November 1999 showed that the isotopic signal changed significantly. This leads to the conclusion that additional rapid water movement through macro pores was occurring to the entire depth of the profiles. An interpretation of the observed field data using a lumped parameter approach and sine wave fitting allows an discussion of flow velocities and transport processes. The results enlighten mechanisms that are usually not considered in regional and macro scale modeling approaches.

HOW TO ESTIMATE THE MEAN RESIDENCE TIME OF WATER IN A CATCHMENT? RESULTS FROM A MODEL COMPARISON AND THE SIGNIFICANCE OF ISOTOPE RECORDS

Stefan UHLENBROOK, Falk SCISSEK (Institute of Hydrology, University of Freiburg)

The mean residence of the water is a crucial parameter to characterize a hydrological system. In a previous study, the spatial and temporal (event and seasonal time scale) variability of major runoff components and residence times in the mountainous Brugga basin (40 km2, Black Forest, Germany) were examined. For this purpose, time series of the tracers 18O, 3H, CFCs, dissolved silica and major anions and cations were analyzed over the period 1995-1998 (Uhlenbrook et al. 2002, WRR). Residence times were estimated using classical lumped-parameter approaches. It was found that the shallow groundwater is the predominant system and originates from the upper drift and debris cover. For this paper longer isotope records (1995-2002) could be analyzed and the following questions are examined: (i) What is the potential benefit of longer records to estimate the residence-time distribution and the mean residence time? (ii) What is the influence of the modeling time step (monthly vs. bi-weekly), generation of the isotope-input data, and different infiltration/recharge modeling approaches for the residence-time estimation? (iii) How good is the performance of simple estimation techniques, as for instance the amplitude-dampening method? (iv) What are the main reasons for the uncertainty of the residence-time estimation, and how could these be reduced?Using different lumped-parameter models, it was found that the analyses of the longer isotope records resulted in about the same residence-time estimations for the whole Brugga catchment (26 months) and the shallow groundwater (3 years). Thus, previous results could be confirmed. Using the longer records did not reduce the uncertainty interval of approximately ±6 months. The influence of shorter modeling time steps was negligible. It is interesting to note that the simple amplitude-dampening method resulted in only slightly different estimations of the mean residence times. This method is 'like the used lumped-parameter model' based on an exponential distribution of residence times. In addition, the significance of the infiltration/recharge modeling became obvious. In consideration of this fact, some shortcomings of the lumped-parameter approach were investigated, and the importance of a correct isotope input into the investigated hydrological systems was highlighted. For the study area, in particular, the problematic estimation of the spatially and temporally variable snowmelt input and soil-water movement caused uncertainties. Finally, new modeling strategies for isotope modeling that contain an improved process-realistic description of water movement in the investigated system are discussed.

HW06/07A/C31-002   0930
EXAMINATION OF MRT MODELING CONCEPT THROUGH A FIELD MEASUREMENT OF SPATIAL VALIABILITY IN GRODUNWATER SEEPAGE ISOTPIC COMPOTIONS

Taro UCHIDA[1], Shyusuke MIYATA[1], Yuko ASANO[1], Yuichi ONDA[2], Takahisa MIZUYAMA[1] ([1]Graduate School of Agriculture, Kyoto University, [2]Institute of Geoscience, University of Tsukuba)

Mean residence time (MRT) modeling is a useful tool for characterization of catchment behavior. Kirchner et al. (2000, Nature, 403) showed that the residence time distribution of stream water had very long and fractal tail, suggesting that the stream water consists of diverse residence time water. This result suggests two possibilities; (1) there is underground large well-mixed reservoir in hillslopes and (2) diverse flowpaths contribute to rainfall-runoff process in hillslopes. However, the processes, which produced these residence time distributions, are poorly understood. While spatial aspects of flowpath dynamics have been examined, the classifications of flowpaths in hillslopes have been simple (i.e., a shallow soil flowpath, flow along the soil-bedrock interface and flowpath in the bedrock). Thus, most of previous studies have not paid attention to the diversity and the distribution of flowpaths in the hillslope that ultimately control residence time distribution. Here we measured the spatial and temporal variability of flow rate, dissolved silica concentration, temperature, and isotopic composition of groundwater seepage in a small first-order catchment in central Japan. Our measurements showed that there are large spatial variations in the recession curve of hydrograph, standard deviation of dD and amplitude of temperature in groundwater seepage. The spatial distribution of mean dissolved silica concentration ranged from 6 to 14 mg/L, although the seasonal variation of dissolved silica concentration at each groundwater seepage was relatively small ($<$2.5 mg/L). The recession curve of hydrograph, the standard deviation of dD and the amplitude of temperature decreased with increasing with the mean silica concentration, indicating that the longer mean residence time of the groundwater seepage had a deeper source. These results imply that there are diverse and discrete flowpaths in the hillslope, an that these flowpaths are not well mixed before entering the stream channel. We also measured the first-order streamflow hydrograph at five adjacent catchments. A examination of hydrograph shape would there was very small spatial variation of streamflow response, suggesting that would suggest that these catchments were functionally similar, suggesting that diverse and discrete flowpath systems may commonly control the stream flow response in this region. According to these results, it concluded that the very long and fractal tail of residence time distribution was produced by diverse and discrete flowpath.

HW06/07A/C31-003   0950
EXAMINATION OF THE ASSUMPTIONS IN ISOTOPE-BASED HYDROGRAPH SEPARATION: A VIRTUAL EXPERIMENT APPROACH

Jeffrey J. MCDONNELL, Markus WEILER (Dept. of Forest Engineering)

The assumptions for hydrograph separation associated with spatially invariant end members are well known. Unfortunately, due to expense and difficulty of collecting the large amounts of data necessary to understand the limitations of the approach, the assumptions are rarely examined in detail in experimental studies. We present a new set of ´virtual´ hydrograph separations where isotope tracing is performed within a physically-based hydrologic model. The spatial and temporal variability of water components are examined in terms of how these result in mixing internal to the catchment. We define virtual experiments as numerical experiments with a model driven by collective field intelligence stemming from field-based isotope tracing experiments. We analyse how the depth distributions of saturated hydraulic conductivity and drainable porosity, soil depth variability, as well as mass exchange between

production limitation by phosphorus or inorganic carbon. These lakes are mainly fed by groundwater inflow. Due to their distinct hydrological regime, mining lakes differ considerably from natural lakes with consequences for mixis, hydrochemistry and biology. The aim of the study was to quantify the groundwater inflow for the assessment of water balance calculations by the use of isotope tracers and to estimate the influence of the groundwater on lake water chemistry. Both are of fundamental importance for the ecosystem. With a groundwater model and the results of seepage meter measurements, the groundwater inflow was calculated directly and compared with the results of the hydrological water balance from direct in- and outflow measurements. These results were verified using the environmental isotopes $\delta 18O$ and $\delta 2H$ by employing an autonomous water balance. Through separate sampling of the individual components, groundwater inflow and -outflow, surface in- and outflow and precipitation, the quantitative distribution of ground- and surface water in the lake was possible. It could be shown that the groundwater model and the environmental isotope water balance method lead to comparable results. The seepage meter data showed strong heterogeneity. The water balance results indicate that the direct groundwater inflow is about 60% of the total inflow to the lake. The groundwater outflow is around zero, which was also verified by the groundwater model. This represents the influence of the groundwater on the lake water chemistry.

HW06/07A/C31-008	1210

BLACK-BOX MODELS FOR THE INTERPRETATION OF ISOTOPE DATA IN DIFFERENT GROUND WATER SYSTEMS (MONO- AND BI-POROUS) TO DETERMINE SOME HYDROLOGICAL PARAMETERS

Piotr MALOSZEWSKI (GSF-Institute of Hydrology, D-85764 Neuherberg, GERMANY)

The paper presents different types of black-box models which are applicable for the interpretation of environmental tracer data in different ground water systems (mono- and bi-porous). Black-box models have found relatively wide application in isotope hydrology, mainly due to their simplicity and reduced number of fitting parameters. The use of these models requires the environmental tracer concentrations measured, in most cases as a functions of time, in the input (recharge zone, infiltration area) and in the output (i.e. springs, streams, pumping/observation wells, etc.) of the system. Generally, only limited hydrological and geological information about area under investigation is needed. However, this knowledge has to be sufficient to construct a conceptual model of water flow through the system and in turn, to decide which type of black-box model (or their combination) should be used. Each model is defined by its own transit time distribution function, $g(t')$. The function $g(t')$ describes the whole spectrum of transit times of single tracer particle (t') on the pathway between input and output. Most frequently used are the models, which were developed for mono-porous mediums (fully saturated, include only mobile water). These models were constructed assuming piston-flow (PFM), exponential (EM), combined exponential-piston flow (PFM) or dispersive (DM) types of transit time distributions. When the isotope technique is used in so called bi-porous mediums then completely different models has to be applied. Bi-porous medium exists when the water flows through the unsaturated zone (mobile water in capillaries or channels and quasi stagnant water in the matrix), in fissured aquifers (mobile water in fissures and immobile in micro-porous matrix) and by water flow through aquifer (mobile water) surrounded by aquitard (immobile water). Near advection and/or dispersion in the mobile phase, the diffusive transfer of tracer mass between mobile and immobile water and diffusion process in immobile water have to be taken into account. The paper presents three black-box models which can be used in such a cases: Parallel Fissure Dispersion (PFDM), Single-Fissure Dispersion (SFDM) and Single-Fissure Piston Flow (SFPFM) model. Their parameters, limitations and applicability are discussed. The main parameter of all models is the mean transit time of water through the system. Other, additional, parameters, depend from the type of model used. All model parameters are determined by fitting the theoretical output concentrations (calculated for known input function) to the tracer concentration measured. By applying the model some additional practical information such a water velocity, volume of water in the system, portion of water flowing through macro-pores (channels) can also be found. The practical applications of a new models for the interpretation of isotope data obtained: (i) in lysimeter experiments within the unsaturated zone under natural flow conditions, and (ii) in the water flowing through the aquifer situated within the aquitard, are additionally shown.

HW06/07P/C31-001	1400

A FORMATION PROCESS OF STABLE ISOTOPIC COMPOSITIONS OF OXYGEN AND HYDROGEN IN SOIL WATER AND ESTIMATION OF AVERAGE RECHARGE IN THE UNSATURATED ZONE OF THE KANTO LOAM,JAPAN

Shiho YABUSAKI[1], Norio TASE[2], Maki TSUJIMURA[2], Atsuko SUGIMOTO[3] ([1]Doctoral Program of Geoscience,University of Tsukuba, [2]Institute of Geoscience,University of Tsukuba, [3]Center for Ecological Research,Kyoto University)

In recent years, it has become important to make clear the soil water movement for preventing the groundwater pollution and establishing sustainable water use. Using the stable isotopic compositions of oxygen and hydrogen has been pointed out as one of the effective methods to estimate the soil water movement. The soil water in the loamy soil were sampled at University of Tsukuba, Japan, eleven times from April to November in 2001, and groundwater and event precipitation are also collected. The $\delta^{18}O$ and δD were analyzed for all samples, and the tritium analysis is carried out for samples of precipitation and groundwater. In the vertical profiles of isotopic compositions in soil water, the variations of isotopic composition near the soil surface are very large, because soil water is affected by the evaporation and precipitation. The variation, however, decreases gradually as the soil depth. Isotopic compositions become almost constant near the water table. Furthermore, some cyclic variations are observed in the vertical profiles of isotopic compositions of soil water. The time series variations of isotopic composition in soil water and precipitation suggest that the isotopically heavy peak of soil water was formed in summer period, and it moved downward during fall season when intensive rainfall happened. It is also indicated that the piston flow is dominant in this study site. Using the results of migration length of isotopic composition in soil water, average recharge is about 658 mm, which is close to other places of the loamy soil in Japan. The result from Displacement Flow Model explains the observed results well, and quantitative estimation of the groundwater recharge could be possible by the model. The data of isopleth indicate that groundwater recharge occur under the condition that rainfall amount exceeds 50 mm per event, which is agree with the result of δ diagram of different size event precipitation and groundwater. The isotopic composition in soil water can be used for estimation of the soil water movement in these places such as depositing of loamy soil mainly in Japan.

HW06/07P/C31-002	1420

SUSTAINABLE GROUNDWATER ABSTRACTION BASED ON THE CALIBRATION OF NUMERICAL MODELS USING RESULTS OF AN ENVIRONMENTAL ISOTOPE MONITORING

Klaus-Peter SEILER (Gsf-National Research Centre)

Safe groundwater abstraction is mostly based on management strategies elaborated by means of validated and calibrated mathematical models; to verify this mathematical prediction, as a rule this step is followed by a water quality monitoring, because calibration does not cover all necessary extrapolation stages. This procedure leads to three challenges: 1. Mathematical modeling has to face hydraulic and geologic uncertainties, which are often difficult to assess, and may lead to non-adapted decisions; 2. The monitoring results often lead to a passive assessment, because whenever the contaminant the exploitation site, it is too late for respective changes in the management strategies;3. Traditional predictions often disregard the transient hydraulic behavior of many subsurface systems. All three challenges can be faced by an additional monitoring of environmental isotopes and by using the analytic results on environmental isotopes to recalibrate iteratively the existing mathematical model. This procedure was applied to elaborate an early warning system for bank-filtration and to better survey the sustainable abstraction of groundwater from the passive recharge zone, which is often transient over decades.To use this tool it is important to select the appropriate observation wells and the most sensitive environmental isotopes. In the case of deep groundwater abstraction, downstream areas proved to be more sensitive than upstream areas; with increasing observation depth, 3H, 39Ar and than 14C in turn become the most sensitive parameter. In the case of bank-filtration, stable environmental isotopes can be used to calibrate the behavior of non-reactive and reactive contaminants as well and to set up base lines of contaminant concentration in the river to avoid groundwater contamination exceeding international health standards.

HW06/07P/C31-003	1440

CHARACTERISATION OF AQUIFERS IN KARSTIC TERRAIN USING STABLE ENVIRONMENTAL ISOTOPES

Ninad BODHANKAR[1], K.M. KULKARNI[2] ([1]School of Studies In Geology & WRM, Pt. Ravishankar Shukla University, Raipur 492010 INDIA, [2]Isotope Hydrology Section, International Atomic Energy Agency, Vienna AUSTRIA)

Hydrogeological investigations were carried out to study the groundwater condition and groundwater interconnections in karst terrain around Raipur. The ground elevation varies from 270 meters to 300 meters above mean sea level, and the average mean annual rainfall is about 1200 mm. The Chandi limestone of Raipur Group of Chhattisgarh Supergroup forms the major geological unit in the study area. Laterite/ shale cover, at places, overlies the limestone. Apart from conventional hydrogeological investigations, thirty-six water samples were collected from different sources like, dugwells (10), tubewells (21) and surface water bodies (05). The samples were analysed for major chemistry. Stable environmental isotope measurements for delta 18O and delta D were also carried out. The Piper trilinear plot reveals Ca-Mg-HCO3 facies, which is characteristic of limestone aquifer. The delta 18O values vary from -3.14 to -0.98 for dugwells, from -3.75 to -0.7 for tubewells and from -3.2 to 0.68 for surface water bodies. The delta D values vary from -18.5 to -7.7 for dugwells, from -25.1 to -5.8 for tubewells and from -18.9 to -3.5 for surface water bodies. The coalesce of hydrogeological information, environmental isotope measurement along with chemistry data has helped to deduce a conceptual model of the hydrodynamic system as follows: (a) the soil cover over limestone, which varies from laterite to black soil, forms the shallow aquifer catering to the needs of dugwell. It extends up to a depth of 10 meters and at places is intercalated with yellow shale. The yellow shale is impervious thus forms an aquiclude, as deduced from the depleted delta 18O and delta D values for dugwell water, (b) weathered limestone zone, 2 meters thick, and (c) compact limestone at the bottom, which forms the major aquifer supplying to the tubewells. At places, the enriched delta 18O and delta D values for tubewell water is indicative of rapid recharge to the aquifer due to karstification. Thus, development of secondary porosity in limestone makes the hydrological situation more complex to understand and model the groundwater hydrodynamics.

HW06/07P/C31-004	1500

USING THE TRITIUM/HELIUM AGE DATING METHOD TO CHARACTERISE TWO RIVER RECHARGED AQUIFER SYSTEMS IN GERMANY

Massmann GUDRUN[1], Juergen SUELTENFUSS[2], Andrea KNAPPE[1], Asaf PEKDEGER[1] ([1]Free University of Berlin, [2]University of Bremen)

The T-He age dating method uses the ratio of the concentration of radioactive tritium (3H) derived from atmospheric nuclear bomb testing and its decay product Helium (3He) in the groundwater to determine a groundwater age, i.e. the time passed since the water had its last contact with the atmosphere. At the Free University of Berlin, hydraulic and hydrochemical processes accompanying bank-filtration are currently examined at two very different locations: In metropolitan Berlin and the rural Oderbruch polder region. The city of Berlin enhances bank-filtration through well galleries located adjacent to the surface water system. The spatial and temporal development of the bank filtrate is studied in cooperation with the Berlin Waterworks and the Berlin Centre of Competence for Water at several exemplary piezometer transects. The system generally behaves highly transient due to continuously changing pumping regimes. At the gallery Lake Wannsee, the well filter screens are pumping water from 3 different glacial sand layers separated by aquitards. The well water is a mixture of very old deeper groundwater, medium old water from the middle layer and very young bank-filtered water. The Oderbruch is located north-east of Berlin aside the river Oder. Intensive melioration activities in the past 250 years converted the former swamp into a fertile, agricultural region and lead to the permanent infiltration of river water into the shallow, confined aquifer. Compared to Berlin, the infiltration is a long-term, very stable process. The groundwater is getting older with increasing distance and travel-time from the river. The concentration of ˝stable˝ tritium (sum of 3H and tritiogenic 3He) increase from the river inland reflecting the decrease of 3He in the atmosphere from the early 60´s onwards. Peak concentrations are encountered in 2.1 km river distance whereas further inland (3.4 km river distance) old water which infiltrated prior to the nuclear bombing peak is encountered. In addition, the groundwater has a high radiogenic 4Heterr concentration which also indicates that the groundwater is more than a few decades old. Even further inland, in the central polder areas, the groundwater is unconfined and continuously recharged to some extend by percolating water infiltrating through shrinkage fissures in the overlying dried alluvial loam. The water is a mixture of young seepage water and very old bank filtrate, the resulting ˝mixed˝ T-He age is getting younger again. The T-He method was successfully applied to support estimated groundwater ages derived from tracer analysis (e.g. 2H, 18O, EDTA, Gd) at both locations. In the Oderbruch, the T-He ages were used to calibrate a flow model. The method also proved to be a very good indicator for the identification of mixing processes.

HW06/07P/C31-005 — 1520

REGIONAL MODELLING OF ISOTOPE EXCHANGE DURING EVAPORATION

John J. GIBSON[1], S. Jean BIRKS[2] ([1]Water & Climate Impacts Research Centre, National Water Research Institute, P.O. Box 3050, University of Victoria, Victoria BC V8W 3P5 Canada, [2]Department of Earth Sciences, University of Waterloo, Waterloo ON Canada)

Tracking and modelling the stable isotope content of water as it passes through the continental water cycle requires use of algorithms to account for the well-known isotope enrichment effects that accompany open water and soil evaporation. While the primary forcings on the isotope enrichment processes have been well documented (Craig and Gordon 1965; Allison et al. 1983), model application at the continental scale has largely been limited by availability of regional isotopic datasets. This study demonstrates use of the Global Network of Isotopes in Precipitation database in combination with global climatological fields to obtain a first approximation of atmospheric conditions that control the isotope enrichment process and their global variability. This new conceptual model (Gibson 2002) predicts changes in the slope of the Local Evaporation Lines that are consistent with regional observations from north America and northern Eurasia. Although a simplified approach, the model helps to understand broad trends and systematic variability in evaporative enrichment using monthly potential evaporation, temperature, humidity, oxygen-18 and deuterium composition of precipitation. Results suggest that seasonality is a strong control on the slope of local evaporation lines in ^{2}H-^{18}O space, which is particularly important for explaining differences in enrichment behaviour in lakes across the polar regions. Allison, G.B., Barnes, C.J. and Hughes, M.W., 1983. The distribution of deuterium and ^{18}O in dry soils. J. Hydrol., Vol. 64, pp. 377-397. Craig, H. and Gordon, L.I., 1965. Deuterium and oxygen 18 variations in the ocean and marine atmosphere, Stable Isotopes in Oceanographic Studies and Paleotemperatures, E. Tongiorgi (Editor), Lab. Geologia Nucleare, Pisa, pp. 9-130. Gibson, J.J., 2002. A new conceptual model for predicting isotope enrichment of lakes in seasonal climates. IGBP PAGES News 10 (2): 10-11.

HW06/07P/C31-006 — 1540

ISOTOPIC SIGNATURES OF SOURCE WATER AND RAIN FORMATIONMECHANISM IN INDIAN MONSOON PRECIPITATION

Sourendra Kumar BHATTACHARYA, Pradeep Kumar AGGARWAL, Kshitij M. KULKARNI (Isotope Hydrology Section, International Atomic Energy Agency, Vienna)

The stable isotopic composition in precipitation reflects the composition of the moisture source and the fractionation associated with the mechanism of precipitation formation. Often these factors are too intricately linked to decipherthe moisture source and identify the causes of seasonal and inter-annualvariations in isotopic composition. In this context, isotopic data of New Delhi and Bombay rains (from GNIP database of IAEA) from the Asian monsoon region are investigatedhere to identify the signatures of moisture source and meteorological processes. In Bombay, rains occur mainly from June to September whereas New Delhi has precipitation throughout the year with peak rainfalls during July to September. The seasonal variation of Bombay rains show that isotopic ratios (in per mill) are heavier from December to May (-1 to +1) but decrease smoothly from June to September. The decrease in isotope ratio is initially associated with increase in precipitationsuggesting an amount effect but later on, delta variation pattern deviatesfrom the amount effect prediction. Co-variation plots of monthly rainfalls in New Delhi and corresponding d-18O values show that the two variables are poorly correlated. In contrast, the data for Bombay show quite different features. Though the September rainfall is much lower than July rainfall the mean monthly delta values from July to September are close to each other (~ -1.3). Interestingly, the delta values are quite low (-4.5 to -5.5) in October and November when precipitation is small. Above analysis shows that the mean isotopic compositions of monthly precipitation samples from New Delhi and Bombay do not correlate with the rainfall. Though both the stations belong to a region under the influence of the Asian Monsoon the rain forming mechanisms in these places are significantly different. The rainfall at New Delhi is controlled by north-west moving depressions with diverse routes and variable transit times over the land subsequent to their formation at the head of Bay of Bengal. The mean life-time of these stormy depressions seems to determine the rain isotopic composition through a Rayleigh mechanism. In contrast, the Bombay rains are caused by cyclonic vortices on the west coast of India with constant supply of oceanic moisture resulting in small isotopic variation over the rainy months. Analysis of the data reveals a dominant role of meteorological factors in controlling the rain isotopic composition and only a minor dependence on the amount of rain.

HW06/07P/C31-007 — 1600

OBSERVATION ON RECYCLING OF WATER IN EAST SIBERIAN TAIGA

Atsuko SUGIMOTO[1], Daisuke NAITO[1], Kimpei ICHIYANAGI[2], Naoyuki KURITA[2], Yoshiyuki ISHII[3], Tetsuo OHATA[3] ([1]Center for Ecological Research, Kyoto University, [2]Frontier Observation Research System for Global Change, [3]Institute of Low Temperature Science, Hokkaido University)

East Siberian taiga is a unique ecosystem, which is established on permafrost. Climate there is extremely dry (about 250mm of annual precipitation). Oxygen and hydrogen isotope ratios of precipitation, soil water, sap water of plants, river, surface water, and atmospheric water vapor were observed in deciduous boreal forest near Yakutsk, Russia, to investigate the water cycle in the ecosystem. Large inter-annual variation was observed in soil moisture and its stable isotopic composition, depending on summer rainfall. As we already reported, isotope signature of water in plants shows that snow melt water is essential for plants in early summer: the highest activities of plants soon after leaf unfolding in June are supported by the snow meltwater. In late summer, plants use summer rainwater when the amount of rainfall is enough, while, ice meltwater from permafrost is used as a direct water source for plants during drought. Namely, function of soil for water storage stabilizes transpiration, and it is very important for water cycle in this region. Discrepancy of the period of transpiration by plants (maximum in June) and soil thaw may also cause another time-lag for hydrologic cycle (Sugimoto et al., 2002, Ecol. Res., 17; Sugimoto et al., in press, Hydrological Processes).Water used by plants for transpiration returns to the atmosphere. This ˝recycled water˝ may be very important as atmospheric water vapor. Since eastern Siberia is extremely far from the source area of water vapor, the isotopic composition of atmospheric water vapor is expected to show great variability depending on precipitation in the upstream area and recycling of water from the surface. Actually, the observed isotopic composition of water vapor varied largely. Oxygen isotope ratio was varied from -39 to -19 permil in delta value against SMOW, during the period from May to September in 2000. The value of d-excess of water vapor also varied: extremely high d-excess was observed during May in 2000. Isotopic variation of water vapor may reflect on the condition of surface and the isotopic composition of evaporated and transpired water vapor. Trend of oxygen isotope variation of water vapor was similar to that of transpired water by plants and precipitation. This result indicates that water in this area is on a recycling mode during summer. Isotopic composition of precipitation was also observed at Tiksi which locates near arctic ocean. Variation of the oxygen isotope ratio and d-excess in precipitation at Tiksi was also indicative of the difference in isotopic composition of water vapor. Isotopic composition of precipitation formed in the air from southwest (from inland area) was clearly different from that derived in

the airmass from northeast (from arctic ocean).

APPORTS DES TECHNIQUES ISOTOPIQUES A LA CONNAISSANCE DE LA DYNAMIQUE DES EAUX SOUTERRAINES DANS UN BASSIN TRANSFRONTALIER (BASSIN DE TAOUDENNI)

Denis DAKOURE[1], Ghislain (de) MARSILY[1], Mustapha BESBES[2], Henri SALVAYRE[3], Martial DRAY[1] ([1]UNIVERSITE PIERRE ET MARIE CURIE, [2]ECOLE NATIONALE INGENIEUR DE TUNIS (ENIT) TUNISIE, [3]MAS SARRAGOSSE)

La région sud-ouest du Burkina Faso partage avec le sud du Mali, un système d´aquifères sédimentaires transfrontalier, celui de la bordure sud-est de Taoudéni. L´extension ainsi que le fonctionnement de ces aquifères àforte potentialité´exploitation demeurent imprécis, notamment en ce qui concerne l´origine, l´intensitéde leur recharge et leur taux de renouvellement. A cette échelle (180.000 km² environ) la connaissance des écoulements se heurte àl´absence de piézométrie fine indispensable pour une meilleure exploitation et gestion des eaux souterraines. Cette absence est d´autant vraie qu´il existe peu ou presque pas de nivellement topographique adapté Les circuits hydrogéologiques sont souvent longs, complexes et quelquefois profonds. La connaissance détaillée de ces circuits et de leur fonctionnement est indispensable pour en assurer une gestion optimale. Une bonne connaissance du circuit nécessite de répondre aux interrogations sur l´origine de l´eau (où), et sur la durée du circuit (quand). Les méthodes isotopiques se prêtent remarquablement àce genre d´études. Une approche multicritère combinant entre autres techniques, la géochimie isotopique et l´hydrodynamique couplée àun essai de modélisation est utilisée pour comprendre le fonctionnement hydrogéologique de ce vaste bassin sédimentaire. Les études chimiques et isotopiques donnent une homogénéitéde faciès qui ne dégage pas d´éléments convaincants pour envisager d´une circulation souterraine individualisée entre les différentes formations géologiques. Le bassin sud-est de Taoudenni dans sa grande partie contient des eaux qui se renouvellent lentement. Cette faiblesse de recharge est confirmée par l´esquisse de modélisation hydrogéologique. Cela hypothèque pour l´avenir le dèveloppement socio-économique de la région.

ISOTOPE METHODS AND THEIR ROLE IN ANALYZING THE ALLOCATION OF WATER RESOURCES

Inom Sherovich NORMATOV (Institute of Water Problems, Hydroenergetics and Ecology, Academy of Sciences, Republic of Tajikistan)

In the conditions of hydrological situation and lack of hydrometric observations the isotope methods open wide perspectives to define more precisely the allocation of water resources. The applying of correlation of even uranium isotopes(γ=U^{234}/ U^{238}) and its general contents (C) in waters is perspective for defining more precisely the water balance characteristics of mountainous rivers. The waters formed or running in different hydrogeological conditions are distinguished by γ and C values. Having defined with the help of isotope dilution equations, the γ and C values in 2 merging flows before and after dislocating them, it is easy to evaluate the relative flowing part of every flow. During isotope surveying in different seasons (transition period), it is possible to evaluate the average annual flowing rate and to foresee the resources even for those rivers, which were not hydrometrically measured. We checked the advantages of uranium isotope method, having defined the forming of Panj River flowing.

HW06/07P/D-003 — Poster — 1400-187

SEASONAL CHANGES IN STABLE ISOTOPE CONTENTS OF STREAM WATER IN A SMALL TUNDRA WATERSHED, EASTERN SIBERIA

Yoshiyuki ISHII[1], Atsuko SUGIMOTO[2] ([1]Institute of Low Temperature Science, Hokkaido University, [2]Center for Ecological Research, Kyoto University)

As a part of the GAME-Siberia project, meteorological and hydrological observations concerning the basin water balance were carried out in the Siberian tundra region near Tiksi, in eastern Siberia, during the summer seasons in 1998 and 1999. To clarify how the snow meltwater and the ground-ice meltwater contribute to the hydrologic cycle in the arctic tundra basin, lateral inflow rate of the surface and subsurface water to the stream was evaluated by the hydrograph separation technique using the stable isotope contents (oxygen-18 and deuterium) and the major ion concentrations. Stream and rain waters were collected every morning around the base station, and snowpack, soil water, lake water, spring water, puddle water were also sampled at one or two times during the summer. Lake water was collected every evening in 1999 only. The oxygen-18 versus deuterium diagram of all sampled water shows that not only rainwater but also all other waters are distributed on the global meteoric water line (MWL) and d-values of those are nearly 15 per mill. This means that the isotope fractionation effect due to the phase change is small. The oxygen-18 content of rainwater shows high fluctuation with every storm event, ranging between -10 per mill and -25 per mill with an average of -16.6 per mill. These values are not depending on the intensity and the total amount of rainfall. Whereas, the oxygen-18 content of snowpack collected just prior to snowmelt season has a large minus value remarkably, ranging between -33.7 per mill and -35.5 per mill with an average of -34.4 per mill, and there is clear contrast between winter and summer precipitation. In the beginning of snowmelt season, stream water has a large minus value of the oxygen-18 content due to the extensive mixing of snowmelt water that has a larger minus value. As the season progresses, its minus value decreases due to the increase of mixing of summer precipitation, which has a small minus value. After the totally 10 to 20 mm storm event in the middle of August in both year, oxygen-18 content of stream water does not change during the storm event and it approaches to the value of soil water. According to the simple two-component model for hydrograph separation, summer rainwater occupied 40 to 45% of the total stream water in the typical storm event.

STABLE ISOTOPE SIGNATURE OF SUMMER AND WINTER MONSOON RAINSIN SHALLOW GROUNDWATERS FROM INDIA

Sourendra Kumar BHATTACHARYA, R.D. DESHPANDE, R.A. JANI, S.K. GUPTA (Planetary Geosciences Division, Physical Research Laboratory)

Isotopic character of groundwater can, in principle, be used to determine the relative influence of different vapour sources contributing to the local precipitation if post-precipitation modifications during groundwater recharge are small or can be quantified. In case of south India, the dominant vapour sources for the two rainy seasons, namely, Southwest Monsoon and Northeast Monsoon are respectively the north Indian ocean/the Arabian Sea and the Asian continental sources supplemented by moisture from the Bay of Bengal. Oxygen and hydrogen isotope ratios of groundwater and river water samples from the south Indian peninsula were measured to look for the influence of these two vapour sources in the rains. Our studies show that the groundwater oxygen isotopic ratios (in per mill) in the west coast of India are fairly uniform at a value of around -2 which is only slightly depleted compared to the mean rainwater ratio of about -1.5 based on the GNIP data set of Bombay rains. In contrast, the areas adjoining the east coast of India are characterized by depleted ratios ranging from -3 to -5 signifying sizeable contribution from depleted surface water of the Bay of Bengal and winter precipitation bringing Asian continental moisture. The distribution of the isotope ratios also signify the influence of the Western Ghat hills in shielding a large part of the southern peninsula from the Arabian Sea moisture. Assuming groundwater ratios as representative of rain water ratios and the fact that the isotope contours do not match the rainfall contours the role of the amount effect seems to be marginal. Rather, the isotopic distribution indicates strong influence of vapour sources, the orography and local re-evaporation component in some cases. Our earlier work on north Indian groundwaters, in contrast, showed influence of continental effect and contribution of evapotranspiration component. Rains in north India are caused by northwestward moving storms and depressions starting from the northern Bay of Bengal. As these systems move inland progressive rainout depletes the heavy isotopes. However, a good amount of the rainfall is returned back as evapotranspiration. Based on a simple box model incorporating the fluxes of moisture and isotopic changes during condensation using Rayleigh fractionation we estimated that about 30% of moisture is derived from evapotranspiration in this region. Monthly isotope monitoring stations in a few key locations in north and southIndia are required to confirm the above conclusions.

DIVERSITY OF SR ISOTOPIC COMPOSITIONS OF HOT SPRING AND VOLCANIC WATERS FROM ZAO VOLCANIC AREA, JAPAN

Hiromasa ISHIKAWA, Hirokazu FUJIMAKI (Institute of Mineralogy, Petrology and Economic Geology, Graduate school of Science, Tohoku University)

$^{87}Sr / ^{86}Sr$ isotopic analyses were carried out for hot spring water, volcanic lake water, and some rocks in Zao volcanic area to investigate the origin of Sr and water—rock interaction. Based on Sr isotopic and major chemical compositions, various hot spring water and volcanic lake water in this area are divided into three types. Type I is characterized by high Mg•Ca—SO4•Cl abundances, and their $^{87}Sr / ^{86}Sr$ ratios are around 0.7053. Zao hot spring water belongs to this type. Type II is characterized by high Ca—SO4 concentrations, and their $^{87}Sr / ^{86}Sr$ ratios range from 0.7039 to 0.7043. Waters from the volcanic lake and Shinfunkiko hot spring belong to this type. Type III is characterized by high Na•Ca—HCO3•SO4 contents, and their $^{87}Sr / ^{86}Sr$ compositional range is 0.7070—0.7073. Waters from Gaga, Aone, and Togatta hot spring belong to this type. The $^{87}Sr / ^{86}Sr$ ratio of basement pre—Tertiary granite is 0.7068, and the value of plagioclase separated from the granite is 0.7064. Whereas Tertiary sedimentary rocks show such a wide range of $^{87}Sr/^{86}Sr$ ratio as 0.7054—0.7202. The $^{87}Sr / ^{86}Sr$ ratios of the Quaternary volcanic rocks range from 0.7038 to 0.7044. The $^{87}Sr / ^{86}Sr$ ratio of Type I is similar to the average value of the pre—Tertiary granite and the Quaternary volcanic rocks. Therefore soluble Sr in Type I might have been derived from both the pre—Tertiary granite and Quaternary volcanic rocks. Sr in Type II might have been derived from the Quaternary volcanic rocks because the $^{87}Sr / ^{86}Sr$ ratios of Type II are similar to these of the Quaternary volcanic rocks. The $^{87}Sr / ^{86}Sr$ ratio of Type III is higher and it is within the range of Tertiary sedimentary rocks; they should be the source of the Sr of TypeII. SO_4 / Cl ratio of Type I is lower than Type II. Judging from the chemical characteristic and geological structure of this area, Type I might be the residual liquid phase derived from hot water boiled in a reservoir. High SO_4 / Cl ratio of Type II can be explained by low Cl. Because Cl can be strongly partitioned into liquid phase while boiling.

HW06/07P/D-006   Poster   1400-190

TEMPORAL VARIATION OF STABLE ISOTOPES IN PRECIPITATION AT THAILAND OBSERVED IN 2001

Kimpei ICHIYANAGI[1], Manabu D. YAMANAKA[2] ([1]Frontier Observational Research System for Global Change, [2]Kobe Univ.)

Spatial and temporal variability of the stable isotope composition of precipitation in the Asia Pacific region was discussed based on the monthly dataset, and regional climatology and atmospheric circulation patterns were shown in Araguaas-Araguaas et al. (1998). However, the relationship between isotope signature of precipitation and climate in Tropics is not well understood, because the daily isotopic data in precipitation is limited. The purpose of this study is to understand the temporal variation of stable isotopes in precipitation at Thailand based on the daily observation.Stable isotopes (Oxygen-18, Deuterium) in precipitation and meteorological data were observed at Bangkok, Phuket and ChaingMai from August to December in 2001.Temporal variations of stable isotopes in precipitation were almost same features among three stations, ranged from -15 permil to 0 permil.Considering relationships between Oxygen isotopes and precipitation amount, there were positive correlations in three stations by the monthly basis.However, there was no correlation between them by the daily basis.In general, isotopic compositions are heavy in low precipitation and light in high precipitation caused by the amount effect.Conversely, observed isotopic compositions were opposite change at Bangkok in October 2001.In this study, this strange phenomenon will be considered with meteorological data.

THE CONTRIBUTION OF WATER RECYCLING TO THE ISOTOPIC COMPOSITION OF RAINFALL OVER CENTRAL EURASIA

Naoyuki KURITA[1], Kooiti MASUDA[2], Koji YAMAZAKI[3], Naohiro YOSHIDA[4] ([1]Frontier Observational Research System for Global Change, [2]Frontier Research System for Global Change, [3]Gladuate School of Environmental Earth Science, Hokkaido University, [4]Frontier Collaborative Research Center, Tokyo Institute of Technology)

The response of the isotopic ratio of summer precipitation over centralEurasia to recycled

water from land surface is estimated by examination ofstable isotopic ratios in the summer precipitation and by evaluatedcontinental precipitation recycling ratio.The isotopic composition of precipitation are collected at thirteenmonitoring stations across Russia between 1996 and 2000, and determinedthe spatial and temporal isotopic variation. The result showsremarkable isotopic tendency more negative isotopic content fartherinland, i.e., ``continental effect´´ and these largely varied in timeand space. The comparison with continental moisture recycling ratio andobserved isotopic data shows that both temperature and moisturerecycling explains more than half of the variabilityof spatial isotopic feature, however the anomalies of summer isotopiccomponent in each stations are explained by neither temperature normoisture recycling. The atmospheric moisture balance model is applied to air massesforming observed precipitation along trajectories and used to evaluatethe factors that control the observed temporal variation of isotopeswhich is not explained by recycling ratio. The model extends Rayleighdescriptions of isotopes in precipitation by including effects ofrecharge to air masses by evapotranspiration from land surface. The waterfluxes used in this model are based on National Center for EnvironmentalPrediction (NCEP) reanalysis. The isotopic composition of recycledmoisture is adopted as an input parameter in model calculation ofobserved isotopes in precipitation at each stations. At inland stationswhere recycled moisture largely contributes to precipitation, totalamount of precipitation and evaporation during air mass traveling acrosscontinent is balanced in each air masses, thus the evaluated temporalisotopic variation of precipitation primarily depends on the isotopes inrecycled moisture. This suggests that the temporal isotopic variabilityof summer precipitation is controlled by the variation of isotopiccomponent from moisture source. Because the evapotranspiration isassumed to transfer soil water into atmosphere without isotopefractionation, the variability of soil moisture may result in isotopicvariation of recycled moisture. Furthermore, in Siberia region, the factthat the isotopes in thaw water are lighter than other season´sprecipitation suggests that estimation of the contribution ofthaw water to summer precipitation may be possible using isotopes.

SULFUR ISOTOPE CONSTRAINT ON THE PROVENANCE OF SALINITY IN CONFINED AQUIFER SYSTEM.A CASE STUDY IN ESTUARINE AREA OF KISO RIVER, CENTRAL JAPAN

Masaru YAMANAKA, Yoshihiro KUMAGAI, Hiroki TAKAMURA (Faculty of Geo-environmental Science, RISSHO University)

This study aims to comprehend the provenance of salinity in confined aquifer system in estuarine area of Kiso River, central Japan, by using water quality and sulfur isotopic ratios ($\delta^{34}S$) as indicators. Groundwater samples were collected in July or August in 2002 from 29 wells which have single screen around 50m depth, and were used for chemical and sulfur isotopic analyses. High Cl content groundwater ($>1000mg/L$) is distributed in tongue-shape along Kiso River (where three rivers: Kiso, Ibi and Nagara Rivers flow into sea) and has fairly low SO_4/Cl ratios and high $\delta^{34}S$ values (~79 permil) than those of present seawater. Assuming that present seawater induces the salinization of confined groundwater, intruded SO_4 with Cl is expected to be reduced in confined aquifer where is in anaerobic condition. The $\delta^{34}S$ values of the saline groundwater would be well explained by following Rayleigh distillation model, in which initial SO_4 has $\delta^{34}S = 21$ permil of the seawater (Longinelli, 1989): $\delta^{34}S = 21 + \epsilon \ln f$ (1) where ϵ is the isotopic enrichment factor and f is the fraction of initial SO_4 remaining in groundwater. Based on previous field studies of sulfate reduction, -20 permil can be adopted as ϵ for the model. The f is calculated by following equation using SO_4/Cl content ratio of present seawater: $f = SO_4 / (Cl \times 2700/19000)$ (2) A part of the saline groundwater along the Ibi-Nagara Rivers can be well explained by this Rayleigh model, in which volume contribution of present seawater in the groundwater is 10.7% as a maximum, whereas most of the saline groundwater plotted on smaller f field than theoretical line of the model on $f - \delta^{34}S$ diagram. This is caused by overestimation of initial SO_4 contents ($Cl \times 2700/19000$) on Equation (2), strongly indicating another Cl source without SO_4 besides present seawater. Fossil seawater trapped in aquiclude layer for hundreds years is the most plausible candidate for the Cl source, since SO_4 can be completely reduced in anaerobic stagnant conditions. Based on Equations (1) and (2), it is estimated that the volume contributions of present and fossil seawaters are 10.1% and 9.4% respectively, and the lost SO_4 content through sulfate reduction process is 350mg/L as maximums.

CHARACTERIZING THE HYDROLOGY OF HEADWATER SYSTEMS USING RESIDENCE TIME DISTRIBUTIONS

Kevin James MCGUIRE[1], Jeff MCDONNELL[1], Carol KENDALL[2] ([1]Department of Forest Engineering, Oregon State University, [2]US Geological Survey, Menlo Park, CA)

The relationship between streamwater residence time and landscape character is poorly understood. Residence time distributions can be used to gain a better understanding of landscape organization, storage, and subsurface flow routing mechanisms. Few studies have yet examined explicit residence time relations at multiple nested watershed scales. We present new data for the H.J. Andrews Experimental Forest where we examine the relationship between rainfall and streamflow 18O for weekly data over the period October 2000 through February 2003 to estimate watershed residence time. Residence time distributions from hillslope (~0.3 ha) to watershed scales of 10, 100, 500, and 6,000 ha with varying degrees of geomorphic complexity are explored to clarify landscape unit (i.e. hillslopes and riparian zones) influence on runoff generation processes.

IMPLEMENTATION AND TESTING OF WATER ISOTOPES INTO THE WEATHER RESEARCH AND FORECAST (WRF) MODEL

Norman L. MILLER, Prudence N. FOSTER, Donald J. DEPAOLO (Earth Sciences Division, Lawrence Berkeley National Laboratory)

To date, atmospheric water isotope modeling has been performed on a global scale. The development of a stable water isotope scheme in a mesoscale model will lead to a simulated spatial distribution that will improve our understanding of present day climate variability, as well as historical climate patterns. The purpose of this study was to add water isotope tracers to the regional atmospheric model WRF (NOAA´s Weather and Research Forecast model) in order to link existing global and basin-scale isotope models, and to work toward an improved understanding of the water budget at the ARM/CART site.In order to include isotopic processes in WRF, eight new prognostic variables were added to the model´s dynamical core. These are the isotopic mixing ratios for water vapor, cloud liquid water, cloud ice, and rain for the stable isotopes O18 and deuterium. The isotopes are treated in a manner similar to the natural water vapor, cloud liquid water, etc. in terms of diffusion, advection, nudging, and filtering. Isotope fractionation and diffusion are handled using the approach of Gedzelman and Arnold (1994). Processes handled in this model are fractionation during deposition of water vapor onto cloud ice and condensation of water vapor onto cloud water, and also diffusive exchange of isotopes between vapor and falling rain drops. The bulk flux model of Hoffman et al. (1998) is used here as a first order

approximation for isotopic evaporative processes. For the runs to be discussed here, lateral boundary conditions were generated by the Melbourne University General Circulation Model. This GCM runs at a resolution of R21, and predicts values of the O18 and deuterium mixing ratios at each grid point. Results of preliminary model runs will be discussed.

CHANGE OF THE ISOTOPIC PARAMETERS OF RIVER WATER ALONG THE RIVER COURSE:- TO WHAT EXTENT CAN ONE USE IT AS A MEASURE OF THE WATER BALANCE IN THE RIVER BASIN?

Joel Robert GAT[1] ([1]Environmental Science and Energy Res., Weizmann Institute of Science, [2]Center for Dryland Water Resources Research, Ben-Gurion University of the Negev)

The isotopic composition of an undisturbed flowing river represents the amount-weighted summation of the composition of its tributaries. Evaporative water losses along its course, be it from through-flow lakes, reservoirs or from overflow wetlands along the river banks, result in the enrichment of the heavy isotopes of both hydrogen and oxygen in the residual waters in addition to the increase of the salinity. In particular, the decrease of the d-excess value is a tell-tale indicator of such a process. In contrast, the extraction of water by means of the transpiration of water plants does not affect the isotope composition but adds to the accumulation of salinity in the residual waters whereas, obviously, the loss by outflow or pumping of the riverwater does not fractionate at all between the components of the system. These different attributes of these three processes form the basis for using the isotopic and salinity parameters for quantifying the river's water balance. The Isotopic River Continuum model (IRCM), developed within the framework of the Coordinated Research Program of the IAEA on " Isotope Studies in Large River Basins", provides both the conceptual and mathematical tools for quantifying the water balance along the river course. It follows the isotopic composition from the input by precipitation through the watershed and along the river course, accounting foremost for the seasonally changing input (including the effect of snow-melt), the "catchment effect" on the isotopic composition of the runoff to the river, the effect of holdup in lakes or reservoirs both in terms of water loss and mixing and, finally, the recycling of the river water following its use either in agricultural or urban activities. Due to the non-linear degree of the isotopic enrichment as a function of the fractional amounts of water lost by evaporation relative to the total amount of water, it is necessary to follow the evolution of both flow and isotopic parameters along the different sections of a river. The IRCM can then provide the monitoring scheme required for the purpose of both the water balance evaluation under steady state conditions, as well as in order to detect changes, climatic or anthropogenic in origin, in a river's water balance.

REGIONAL ATMOSPHERIC WATER ISOTOPE MODELLING

Kristof STURM[1], Georg HOFFMANN[2], Bärbel LANGMANN[1], Hans GRAF[1] ([1]Max-Planck-Institute for Meteorology, [2]Laboratoire des Sciences du Climat et de l'Environnement)

We introduce a new module handling the water isotope tracers $H_2{}^{18}O$ and HDO in the atmospheric *REgional circulation MOdel* REMO, based on previous work with the ECHAM (*EC*mwf inspirated, in *HAM*burg enhanced climatemodel) atmospheric global circulation model. Preliminary results over Europe (from Moroccan coast to the Barents Sea and from the Egyptian coast to South-East Greenland) are analysed, with particular emphasis on the comparison with a regional isotopic precipitation climatology compiled from station measurements. The atmospheric models ECHAM-4 and REMO-5 use the same physics scheme, referred to as EC4-physics. An isotopic module was elaborated for ECHAM, accounting for isotope fractionating processes in stratiform and convective clouds, vertical diffusion, and evapo-transpiration from the surface with regard to sub-surface reservoirs ; a centennial experiment was run in the T30 spectral truncature, corresponding to a horizontal resolution of 3.75°, i.e. ca. 450 km. This isotopic module was adapted for REMO, with a standard resolution increased to 0.5°, i.e. ca. 50 km over Western and Central Europe. A rotated grid was applied, providing an equal grid cell area over the entire study domain, with its longitudes and latitudes comprised in [50°E;70°W] and [30°N; 75°N] respectively. The main aim of this study is an improved representation of the atmospheric processes, especially the hydrological cycle, contributing thanks to the increased model resolution to a better understanding of the measured isotopic signal. Preliminary results of REMOiso are compared to monthly means of meteoric isotopic measurements from the Global Network for Isotopes in Precipitation (GNIP) over the study area. We focus on case studies in mountain areas during the BALTEX experiment , discussing the need of further downscaling of precipitation and related isotopic processes. Further investigations will test the model output against events measurements at several study sites in Germany monitored by the GSF, based at Neuherberg, Germany.

HW06/08A/C31-003   1120
APPLICATION OF STABLE ISOTOPES IN LARGE SCALE HYDROLOGICAL STUDIES

Balazs M. FEKETE[1], Pradeep AGGARWAL[3], John J. GIBSON[2], Charles J. VOROSMARTY[1] ([1]Water Systems Analysis Group, Complex Systems Research Center, Institute for Earth, Oceans, and Space, University of New Hampshire, NH 03824 USA, [2]Water & Climate Impacts Research Centre, National Water Research Institute, P.O. Box 3050, University of Victoria BC V8W 3P5 Canada, [3]International Atomic Energy Agency)

Isotope tracers offer complimentary tools for hydrologists to study hydrological processes. Traditionally, application of isotope tracers has been limited to small scale hydrological studies due to the lack of isotope data in large catchments. New efforts initiated by the International Atomic Energy Agency (IAEA) and the World Meteorological Organization (WMO) pave the way for large-scale hydrological research by establishing complimentary networks for monitoring stable isotopes globally both in precipitation and large rivers. This effort has already resulted in valuable preliminary datasets such as Global Network for Isotopes in Precipitation (GNIP) and Global Network for Isotopes in Rivers (GNIR). The primary focus of current research and monitoring efforts is on 2H and 18O, which are naturally present in trace quantities within water, and systematically vary in components of

the water cycle due to fractionations that accompany phase changes and diffusion. These differences result in marked regional differences in the isotopic composition of precipitation and runoff. The new global data sets offer new opportunities for the testing of analysis tools and for assessing the applicability of stable isotopes in large scale hydrological studies. The present paper demonstrates the use of the newly emerging data sets representing the isotopic composition of precipitation and runoff in the context of a high resolution (6´ longitude x latitude) gridded network. Simple GIS analyses were performed to assess the consistency between the isotopic composition of the precipitation and runoff. Further tests were carried out applying a modified version of the water balance and water transport modeling framework (WBM/WTM) developed at UNH. This modified version of WBM/WTM incorporated additional processes to track the migration of isotopes through the evapotranspiration and water transport processes. This modeling environment allowed the simulation of the key processes affecting the changes in the isotopic composition of the runoff at large scale. The modified WBM/WTM was tested using climatological climate forcings (e.g. air temperature, precipitation, vapor pressure, solar radiation, wind speed) at monthly time step. The results from the GIS analysis and the modeling excercise are presented demonstrating the potential of using isotopes as additional constraints in large scale hydrological modeling. The paper highlights the regional variations in isotopic composition of runoff and evaluates the representation of hydrological processes in the modified WBM/WTM with respect to the capturing changes in the isotopic composition of the runoff.

HW06/08A/C31-004   1140
SIMULATING SHORT-TERM 18O VARIABILITY WITH A RAYLEIGH-TYPE ISOTOPE CIRCULATION MODEL

Kei YOSHIMURA[1], Taikan OKI[2], Nobuhito OHTE[3], Shinjiro KANAE[1] ([1]Institute of Industrial Science, University of Tokyo, [2]Research Institute of Humanity and Nature, [3]The Graduate School of Agriculture, Kyoto University)

Large spatial and temporal variability of stable water isotopes (D and 18O) in precipitation are widely used to trace the global hydrologic cycle. Rayleigh-type models have first explained the spatial and temporal variability. Subsequently, studies that incorporate the isotopic physics into atmospheric general circulation models (AGCM) have examined the isotopic variability at monthly or annual scales. The causes of short-term (1-10 days) variability in precipitation isotopes, however, remain unclear. This study seeks to explain isotope variability quantitatively at such scale. Thus, a new water isotope circulation model on a global scale that includes a Rayleigh equation and the use of external meteorological forcings is developed. Transport and mixing processes of water masses and isotopes that have been neglected in earlier Rayleigh models are included in the new model. A control simulation of 18O for 1998 is forced with data from the GAME (GEWEX Asian Monsoon Experiment) reanalysis. The results are validated by GNIP (Global Network of Isotopes in Precipitation) monthly observations with correlation R=0.76 and a significance level >99%. The short-term isotopic variability is well reproduced comparing with daily observations at three sites in Thailand with similar correlation and significance. The present study also confirms that the impact of the amount of precipitation at the site, i.e., ´amount effect,´ is insufficient to explain the short-term isotopic variability. The causes of short-term variability are quantitatively revealed for the first time in this study. Among three factors that cause isotopic variability, i.e., precipitation, evaporation, and moisture flux, the contribution of moisture flux is the largest, accounting for 37% at Chiangmai, and 46% in the global average. This highlights the importance of transport and mixing of airmasses with different isotopic concentrations. Furthermore, sensitivity experiments reveal required temporal and spatial resolutions of each variable and enable to use different datasets. The more accurate GPCP (Global Precipitation Climatology Project) precipitation dataset yields improved model results at all three observation sites in Thailand. For example at Chiangmai, Thailand, the correlation increases to 0.80 from 0.76, and the root mean square error decreases to 2.9 per mill from 4.2 per mill comparing with the control simulation. In addition, data from the NCEP/NCAR (the National Centers for Environmental Prediction and National Center for Atmospheric Research) reanalysis allow the simulation to cover two years, reproducing reasonable interannual isotopic variability. In particular, the model reproduces the downward arch in seasonality over Thailand in 1998, and the upward arch in seasonality in 1999. The improved results from GPCP and the reasonable interannual reproduction from NCEP/NCAR support that the study appropriately models isotope circulation in an area influenced by the Asian Monsoon.

SCIENCE AND IMPLEMENTATION PLAN OF IAHS PUB: HERALDING EXCITING FUTURE FOR HYDROLOGIC SCIENCE AND PRACTICE

Murugesu SIVAPALAN (Centre for Water Research, University of Western Australia)

The IAHS Predictions in Ungauged Basins (PUB) initiative was launched at a workshop held in Brazil in November 2002. The central cross-cutting themes of PUB will be heterogeneity and its effect on uncertainty of hydrologic predictions. PUB is geared towards developing methodologies for assessing the uncertainty in hydrologic predictions arising from the heterogeneity in landscape properties and climate inputs, the uncertainty in the choice of model structure and methods of information transfer from gauged to ungauged catchments, and towards developing targeted methods to constrain and reduce these uncertainties. This talk will present for discussion the latest outlines of the science and implementation plan for PUB prepared by the Scientific Steering Group appointed by the IAHS to lead the PUB initiative. The PUB Science and Implementation Plan will be organized around the following thematic objectives: 1) Explore ways to characterize heterogeneity of landscape properties and climatic inputs; 2) Develop general model framework for heterogeneity and predictive uncertainty; 3) Carry out model inter-comparisons in selected gauged basins (PUB-HELP basins) to investigate the uncertainties due to choice of model structure; 4) Explore methods for the efficient assimilation of gauged and/or remotely sensed data in order to constrain predictive uncertainty; 5) Promote process studies and field experiments to advance process understanding and conceptualizations with a view to reducing predictive uncertainty; 6) Advance our understanding and predictions of the effects of hydro-climatological variability and change; and 7) transform the available global research products into the hydrological information useful for local and regional water resources management.

HW07/10A/C25-002   Invited   1000

PUB FOR TRANSFORMING GLOBAL HYDRO-METEOROLOGICAL PRODUCTS INTO LOCAL WATER RESOURCES INFORMATION

Kuniyoshi TAKEUCHI (Yamanashi University)

There are an abundant number of global research programs and their products in various institutes at freely accessible web sites encouraging a wide use. They are precipitation, cloud cover, temperature, radiation, soil wetness etc. It is, however, little, if not at all, heard about the examples used in local water resources planning and management. This is because the information is too crude and unreliable. While the reliability is essential and is the major scientific agenda, the downscaling/disaggregation of large scale information to local scale is another important subject. Even if the information is only a qualitative and with high uncertainty, if it is translated into the local condition, it is of great value for local water management, especially in ungaged basins. There are a number of downscaling/disaggregation techniques such as statistical methods and physical dynamic equation methods. In any case, the local topographic, land cover features and local land/water use are the main elements that determine the local variation. In the presentation, the experiences in the Mekong and the Yellow River basins studies will be reported.

HW07/10A/C25-003   1045

A METHODOLOGY FOR THE DYNAMICAL RECONSTRUCTION OF HISTORICAL TIME-SPACE PRECIPITATION DATA OVER UNGAGED WATERSHEDS: APPLICATION/VALIDATION OVER TOKYO AREA

M.L. KAVVAS[1], Z.Q. CHEN[1], M.L. ANDERSON[1], J.Y. YOON[1], J. YOSHITANI[2], T. MATSUURA[2], H. OKUMURA[2] ([1]Hydrologic Research Laboratory, Dept. of Civil & Envr. Engineering, University of California, Davis, [2]Hydraulics Engineering Research Group, Public Works Research Institute, 1-6 Minamihara, Tsukuba, 305-8516 JAPAN)

Water resources studies require precipitation input to hydrologic models. However, there are many ungaged watersheds around the world where precipitation data are completely lacking. There are also many watersheds where precipitation data are available at a few ground locations, yielding an unsatisfactory quantification of the spatial distribution of precipitation over such watersheds. Therefore, it is necessary to reconstruct historical precipitation data at fine spatial (~ 6km grids) and time (~1 hour intervals) resolutions over ungaged and sparsely gaged watersheds around the world. A methodology for dynamically downscaling the 1948 – 2002 historical atmospheric data of U.S. National Center for Environmental Prediction (NCEP) and U.S. National Center for Atmospheric Research (NCAR) at 2.5° latitude x 2.5° longitude spatial grid resolution over the whole globe at 6 hr time intervals, to any specified watershed at 6 km spatial grid resolution and 1 hr time intervals has been developed and successfully tested over the Tone and Arakawa river basins, draining to the Tokyo Area. This methodology consists of sequentially nesting the Integrated Regional Scale Hydrologic-Atmospheric Model (IRSHAM) first over a continental domain (in this study, the Eastern Asia continent) at 54 km grid resolution within the global domain of NCEP/NCAR atmospheric data, and then nesting IRSHAM over a country domain (in this study, the Japan Islands) at 18 km grid resolution within the continental domain IRSHAM. Then these nested models are run by means of initial and boundary conditions, provided first from the NCEP/NCAR atmospheric data (for the continental domain simulations), and then from the continental (Eastern Asia) domain IRSHAM to country (Japan) domain IRSHAM. Finally, for the reconstruction of precipitation data at 6 km grid resolution and 1 hr time intervals over a specified watershed (in this study, Tone and Arakawa watersheds), the MM5 non-hydrostatic regional atmospheric model of NCAR which is set up over that watershed, is nested into the country domain IRSHAM. Then the historical atmospheric simulations of country domain IRSHAM provide the initial and boundary conditions for the watershed domain MM5 model simulations of the historical precipitation data over the specified watershed. This methodology was applied to Tone and Arakawa watersheds that drain into the Tokyo Area. Over this region historical precipitation data were constructed for the 1994 – 2000 period at 6 km spatial resolution and 1 hr time intervals by means of the above methodology without using any of the available precipitation data over this region. Then the reconstructed historical precipitation data were compared against corresponding precipitation observations at daily and monthly intervals and for the historical extreme storm events. The comparison results are quite promising.

HW07/10A/C25-004   1100

USE OF SATELLITE REMOTE SENSING IN PREDICTION OF UNGAGED BASINS

Venkat LAKSHMI (University of South Carolina)

Ungaged basins pose a challenge to hydrological studies as they lack both calibration and validation data for the use of land surface models. Therefore, one has to use the satellite data that is available which describes the aspects/attributes of the basin from a hydrological perspective. Soil moisture is routinely mapped by the Advanced Microwave Scanning Radiometer (AMSR). Vegetation is characterized by MODIS (Moderate Resolution Imaging Spectroradiometer) and surface temperature is estimated using AIRS (Advanced Infra-Red Sounder) as well as MODIS. Precipitation is measured (in the tropical regions) from the TRMM (Tropical Rainfall Measuring Mission) Microwave Imager (TMI) with the Global Precipitation Mission (GPM) due to be launched in a few years. The synergistic use of these data sets along with hydrological models would help us to (a) input precipitation and vegetation information into a hydrological model and calculate the soil moisture and surface temperature using the water and energy balance equations (b) the measured soil moisture and surface temperature can be used in two ways (i) to calibrate certain model parameters (ii) to verify the output of the model through validation. The overland runoff from the hydrological model would be routed in the stream channel network (obtained from the Digital Elevation Data) to obtain the streamflow at the catchment outlet. This would help in estimation of the water resources for the catchment.

HW07/10A/C25-005   1115

ON THE COMBINED USE OF SURFACE AND AIRBORNE MEASUREMENTS FOR BASIN SCALE ASSESSMENT

Yoram N. RUBIN[1], Yoram N. RUBIN[1], Katharine GROTE[1], Susan HUBBARD[2] ([1]U.C. Berkeley, [2]Lawrence Berkeley National Laboratory)

Large scale monitoring of soil moisture dynamics is important for agricultural applications, for investigating the dynamics of ecosystems, and for basin-scale water resources budgeting. The current state-of-the –art in remote-sensing techniques is still unsatisfactory due to the limitations of low-resolution and the limited depth penetration. In this talk we propose to combine remote-sensing techniques with ground-based measurements in a way which allows to bypass these difficulties. Specifically, we propose to use geophysical techniques such as Ground-Penetrating-Radar (GPR) for measuring the soil moisture profile at the shallow subsurface and to correlate these measurements with remotely-sensed information.

GPR allows substantial depth penetration for a wide range of soil types, and accurate measurements of soil moisture over the rooting depth. Where depth-penetration is limited, such as in clay-rich soils, ground wave techniques can be used, augmented by physically-based mathematical models. These techniques allow to measure rapidly soil moisture over large areas, in a non-invasive manner, and over short periods of time. By correlating these measurements with airborne data, a correlation function can be developed which will allow us to conduct rapid and accurate interpretation of airborne surveys. This talk will report the principles and concepts of our approach, as well as applications to field sites.

HW07/10A/C25-006   1130

MULTISENSOR OBSERVATIONAL NETWORK OF RAINFALL FOR FIELD EXPERIMENTS ON THE PUB PROBLEM

Witold F. KRAJEWSKI, Anton KRUGER (IIHR-Hydroscience & Engineering, University of Iowa)

Experimental studies aimed at addressing prediction from ungauged basins require quantitative knowledge of space-time rainfall fields. These could be provided by specially designed observational systems. There are several requirements that such systems should fulfill. First, they have to be able to provide high space and time resolution rainfall estimates over a substantial area to enable scaling studies of rainfall. Second, they should be able to provide highly accurate estimates of ground rainfall with known measures of the associated uncertainty. Third, they should be relatively inexpensive in deployment and operation. Forth, they should be robust and redundant. The authors justify and elaborate on these requirements and demonstrate gaps in state-of-the-art of such systems. In particular they discuss rain gauge network design in terms of the network configuration, the sensor requirements, and the engineering design of the observational platforms. They also discuss issues of design and deployment of a network of small inexpensive X-band polarimetric radars. In particular, they discuss the issues of signal attenuation at X-band and development of rainfall estimation algorithms based on polarimetric radar data.

HW07/10A/C25-007   1145

MULTIFRACTAL SIMULATIONS OF RAIN, TIPPING BUCKET GAUGE NETWORKS AND RADAR REFLECTIVITIES

Shaun M. LOVEJOY[1], Daniel SCHERTZER[2] ([1]Physics, MCgill University, [2]LMM, U. P. et M. Curie)

Measuring, modeling and predicting rain is essential for the success of PUB. Rain is a typical PUB variable: it displays extreme variability over huge ranges of space-time scales, yet it has the advantage that it is in some ways easier to measure and can thus be used as an exemplar for measurements of other fields.This is not to say that rain is at the present time reliably measured. There are currently no direct ways to measure the areal distribution of rain fields: gauges make measures at (nearly) spatial points, radars measure effective reflectivity factors which are non trivially related to the rain rate. Indeed, in order to interpret these measurements detailed assumptions are necessary about the structure of rain and (typically sparse) measuring networks; these are usually implicit, the usual one being some form of space-time homogeneity assumption. For example, classical geostatistics (e.g. Krieging) implicitly assume both the regularity of the network as well as of the other relevant measures with respect to the standard (Lebesgue) measure. This effectively rules out sparse fractal networks as well as all but the most trivial scaling behaviours in rain. At the same time, the standard interpretation of the fluctuating radar echo assumes a statistical homogeneous (Poisson) distribution of rain drops.During the last twenty years, the quality and quantity of rain data has improved, and systematic scaling analysis techniques have been developed and applied to rain and related fields. These have shown that - as predicted by cascade models - the statistics are multifractal implying systematic resolution dependence of rain.In this talk we show how to analyze and model these multifractal rain fields, carefully taking into account the strong stratification in the vertical as well as in space-time. We then show how these multifractal models can be used to simulate space-time rainfields, sparse gauge networks, tipping bucket gauge response to rain, and biases in the standard radar rain rates.

HW07/10A/C25-008   1200

PROPOSAL FOR AN INTERNATIONAL NETWORK OF MESOSCALE CATCHMENTS IN SUPPORT OF PREDICTION IN UNGAUGED BASINS (PUB)

Patrick Enda O'CONNELL[1], R.B. GRAYSON[2] ([1]School of Civil Engineering and Geosciences, University of Newcastle upon Tyne, UK, [2]Department of Civil and Environmental Engineering, University of Melbourne)

The vast majority of catchment experiments have been conducted at the small scale ($<$ 10km2), and it has not generally been possible to transfer the understanding gained from these experiments to larger scales. However, it is at larger scales that predictions are required, and so the PUB (Prediction in Ungauged Basins) initiative has focussed on the problem of making reliable predictions in ungauged basins. However, to enhance the reliability of such predictions, a better understanding is needed of how the hydrological functioning of catchments changes with increasing scale across a wide spectrum of physiographic settings, and under different land use and climate change scenarios. Mesoscale catchments (100-1000km2) play an important role in determining the responses of larger catchments, and are frequently major sources of runoff and flooding. However, a major challenge in instrumenting such catchments is the difficulty of sampling the hetereogeity in hydrological response associated with the spatial variability in climate, topography, soils, vegetation, geology, and geomorphology encountered with increasing scale. Dealing with heterogeneity is a central theme of PUB.Mesoscale catchment experiments are now being undertaken in several countries, notably Australia, Brazil, New Zealand, the UK and the US, and some valuable understanding and experience has already been gained. To promote a coordinated approach to catchment experimentation within PUB, it is proposed to establish an international network of mesoscale catchment experiments involving a coherent experimental design approach, the networking of researchers, and the sharing of people, expertise, data and facilities. This would provide a major contribution towards achieving the scientific goals of PUB.

HW07/10A/C25-009   1215

AN AUSTRALIAN COLLABORATIVE NETWORK FOR LONG-TERM HYDROLOGICAL AND ECOLOGICAL MONITORING

Richard P. SILBERSTEIN (IAHS)

Australian hydrology is in need of an injection of vitality and long-term vision. Continuing scientific input is essential to keep water management and natural resource management (NRM) at a high standard, and we have not kept pace with international developments. The ability to predict hydrological behaviour in ungauged basins depends absolutely on good data in basins that are gauged. While the goal is to make predictions with minimal data, we need data to test this ability. Since 1960 there has been a major review of hydrological

monitoring in Australia at least twice every 10 years. Each has concluded that long-term monitoring is essential, but needs focus and coordinated analysis to ensure its value. There is widespread recognition within Australian State and Federal agencies that long-term monitoring is essential for good NRM, and general recognition that the timing is good for renewed activity, partly because of frustration in the hydrological science community. In this paper I call for a significant improvement in the state of hydrological gauging and ecological monitoring networks, data processing, quality control and data sharing. Existing networks should be expanded to include ecological indicators. I seek new opportunities for funding and renewed collaboration between agencies on analysis of the data and hydrological and ecological research. We need to expand beyond our one link in the International Long-term Ecological Research Network, to establish catchments around the country that satisfy the criteria, and can contribute to international efforts in understanding the global bio-geo-chemical and hydrological cycles. A national workshop is proposed to establish: a) minimum levels of monitoring activity; b) common interests; c) collaboration between agencies; d) a reinvigoration of hydrology in Australia. It is aimed to generate a collaboration to establish links between data collection agencies, Universities, CSIRO, and other research agencies, industry, schools and the community, all participating at some level in the hydrological science activity through data collection, analysis, and reporting. Such an activity would have irreplaceable value to the Australian community if adequate monitoring is undertaken and well-designed. A model for this is the highly successful Australian Collaborative Land Evaluation Programme (ACLEP). Key threats to the project are insufficient funding for the basic science to maintain the enthusiasm of the key protagonists, complexity of the bureaucracy in funding and coordinating data collection and collation, and communication linkages. A major threat is the perception that computer models are now sophisticated enough to replace the need for data. This is very dangerous. It is the **science** (that is, understanding observations) in hydrology that generates new knowledge, and leads to better engineering and better land management.The Australian Commonwealth Government has launched a National Action Plan on Salinity and Water Quality that offers both opportunities and threats to this activity. There are potentially competing demands on the resources, with many monitoring sites chosen for their convenience of location and focussed on filling a regulatory requirement, rather than their scientific value. This project´s mission could be to coalesce the regulatory requirements with scientific goals.

Thursday, July 10 PM

HW07/10P/C25-001   Invited   1400

A PILOT STUDY FOR FLOODS IN THE WHITE-WATER RIVER BASIN, KANSAS USING A SCALING FRAMEWORK

Vijay K. GUPTA (DEPT. OF CIVIL ENG. AND CIRES)

Our objective is to design a pilot study for floods in the White Water sub basin of Walnut River basin, KS, USA using the scaling framework. Special emphasis will be given to the role of scaling in space-time variable rainfall and spatially variable channel network structure in determining the scaling parameters of peak flows. We are first testing the scaling framework for peak flows using existing observations from the semi-arid Walnut Gulch basin, AZ, and for both peak- and low flows using existing observations from the humid Goodwin Creek basin, MS. Tests of physical hypotheses are being carried out using a GIS-based numerical simulation laboratory for these two basins. In addition, we will simulate peak flows in the White Water sub basin. From the simulation results, we will design a pilot study for strategically gauging the basin to test peak flow scaling. The scaling framework unifies spatial flood statistics with its physics, and thereby addresses a longstanding fundamental problem in hydrologic sciences and engineering. The body of new knowledge under scaling provides the scientific foundations for solving the long-standing global problem of prediction of floods and low flows from ungauged and poorly gauged basins. This is a cooperative interdisciplinary project involving scientists and engineers from the University of Colorado, Boulder, the U.S. Geological Survey and the University of Iowa. The proposed pilot study is also a first step to conduct large-scale cooperative field experiments in the future in the Walnut River basin, KS, which has been the site for cooperative atmospheric surface exchange studies (CASES) for nearly a decade. Recently, White Water sub basin is being used for the Department of Energy (DOE) Water Cycle Pilot Study involving five DOE laboratories. These on-going activities are complementary to our long-term goal of conducting large-scale cooperative field experiments.

HW07/10P/C25-002   1430

SCALING ISSUES IN PUB

Daniel J.M. SCHERTZER[1], Shaun LOVEJOY[2] ([1]Meteo-France and LMM, U. P. M. Curie, [2]Physics dept., McGill U.)

PUB problem is still unsolved because some fundamental questions have prevented its solution. Nonlinearity is at the core of the question of prediction and hydrological fields indeed display an extreme variability over a wide hierarchy of space-time scales . This variability is beyond the scope of classical mathematical and modeling methods which are forced to introduce scale truncations and ad-hoc parameterizations. These ad hoc procedures nevertheless lead to complex numerical codes: they are difficult to transfer from one basin to another one, or even to verify with data at a different scale. Tuning the model parameters is hazardous: predictions are often reduced to fitting existing observations. In contrast, in recent scaling approaches heterogeneity and uncertainties at all scales are no longer obstacles. It is viewed as a consequence of a scale symmetry which must first be analyzed and then exploited: small scale homogeneity assumptions are replaced by small scale heterogeneity assumptions that are verified from data covering a wide hierarchy of scale. PUB provides an unprecedented opportunity not only to test scaling concepts and techniques, but also to develop them further. The latter cross-cut PUB, since they are indispensable to evaluate: the information requirement, e.g.: which space and time scales are sensitive for a given prediction, what are the scaling regimes, the experimental requirement, e.g.: space and time resolution, outer/inner scale ratio, new data acquisition and processing methodologies to deal with wide range of space-time scales, strong variability, sparse networks, measurements at different scales and of different dimensionalities , implement a new modeling framework to incorporate the natural heterogeneity over a wide hierarch of scales, use the latter to explore the heterogeneity and uncertainty in hydrologic predictions, maximise the yield of available hard and soft data by overcoming their mutual scale incompatibilities We will illustrate the current state of the art on these questions and discuss their implementation in IAHS PUB initiative.

HW07/10P/C25-003   1445

MULTIFRACTAL METHODS OF FLOOD PREDICTIONS IN THE UNGAUGED BASINS

Ioulia TCHIGUIRINSKAIA[1], Pierre HUBERT[2], Daniel SCHERTZER[3], Hocine BENDJOUDI[1], Shaun LOVEJOY[4] ([1]UMR Sisyphe, LGA, University P. et M. Curie, [2]UMR Sisyphe, CIG, Ecole des Mines, Paris, [3]Meteo-France & LMM, University Paris VI, [4]Physics Department, McGill University, Montreal)

River runoff phenomena reflect many complex interactions between diverse basin factors as well as meteorological and climatic fluctuations that strongly modify the precipitation input. Therefore the river runoff forecasting is a rather unresolved issue in hydrology. The question is even more puzzling for the areas where no actual flow measurements are available. Deterministic models based on various physical and/or statistical approaches are still face difficulties in capturing the phenomena of extreme precipitation and floods. It is well known that one of the main difficulties for the description of hydro-meteorological extremes is the colossal variability of their intensities over a wide range of space-time scales. To contribute to the PUB initiative, we use the multifractal framework not only to explain the power-law fall-off of probability distributions for hydrological-meteorological extremes, but also to explore a connection of the observed variability with the physics.We analyze space-time distributions of precipitation and discharges over different hydrological regions. A multifractal data performed in the space-time domain produces - amongst other things - a physically-based tool for the clear distinction and multifractal description of flash-floods. We illustrate these methods on two recent flooding events in France: the Abbeville phreatic floods in 2001 and the flash floods in Gard in 2002.

HW07/10P/C25-004   1500

APPLICATION OF A RANDOM CASCADE MODEL TO TEMPORAL AND SPATIAL PRECIPITATION DATA IN JAPAN

Kunio TOMOSUGI[1], Yasuhisa KUZUHA[2], Tokuo KISHII[2] ([1]DPRI, Kyoto University, [2]National Research Institute for Earth Science and Disaster Prevention, and the Cooperative Graduate School, University of Tsukuba)

The theory of random cascades is useful for prediction of ungauged basins (PUBs) in the following contexts: 1) Multiscaling, which is one of the scale invariance properties resulting from spatial variability of precipitation, which can be reproduced by the theory of random cascades [e.g. Gupta, 1996], and the notion of scale invariance is very important for scaling, which is a powerful tool for PUBs in flood prediction. 2) The random cascade model is expected to be used as a tool for downscaling outputs from GCMs or radar data of precipitation and such downscaled data will be used as precipitation data of ungauged basins. Over and Gupta [1994] applied beta model to a meso-scale rain field and subsequently many researchers have investigated the theory of discrete random cascades. We applied the model whose generator is a beta model to temporal and spatial precipitation data in Japan. We applied the model to a long term's (8192 days) daily precipitation time series. Although the beta model is not adequate to reproduce the time series, we believe that a parameter p (see Over and Gupta,1994), which governs the rate at which no-precipitation periods (pixels) appear in the time series, is meaningful in analyzing characteristics of the time series. Using the parameter, the meteorological observation sites are classified into two groups. One is along the Pacific and the other is along the Japan Sea. Time series of the former is relatively intermittent and the latter is less intermittent. Moreover, although both groups exhibit multifractal properties through convex function $\tau(q)$, the former exhibits a stronger multifractal property than the latter. Concerning spatial analyzing, we applied the beta model to many more scans than Over and Gupta. Because a rain field is affected by topography, we compared the data on 'land region' with those on 'sea region'. In respect to $\log[\lambda_n]$ versus $\log[f(\lambda_n)]$, there is a difference between a land region and a sea region; for a land region, both positive and negative intercepts appear equally, but the positive intercept dominates in summer for a sea region. This results from the large spatial scale of a rain field. However, in respect to the correlation coefficient between $\log[\lambda_n]$ and $\log[M_n(q)]$, both land and sea regions exhibit scale invariance in the range of 5 – 100 km, and random cascades can be applied to a land region as well as a sea region. We extracted some storms from the whole dataset and looked for a one-to-one relation between the spatial average of precipitation and parameter p. We concluded that the relation is a one-to-one function if we extract each 'individual' rain event, and the equation proposed by Over and Gupta [1994] is more appropriate than Over and Gupta [1996] for data in Japan. Gupta et al.(1996): J. Hydrology, 187, 81-104, Over and Gupta (1994): JAM, 33, 1526-1542. Over and Gupta (1996): JGR, 101, D21, 26,319-326,331.

HW07/10P/C25-005   1515

PREDICTION IN UNGAUGED BASINS - DEVELOPMENT OF A COUPLED LAND SURFACE - CLIMATOLOGICAL MODEL FOR NEW SOUTH WALES

Stewart William FRANKS (School of Engineering)

It is well known that Eastern Australia and New South Wales in particular experience one of the most variable climates at a range of timescales. Marked predictability of seasonal to interannual variability is governed by the occurrence of individual El Nino/Southern Oscillation (ENSO) events. In addition, recent research has also revealed multi-decadal modulation of both the magnitude and frequency of ENSO events, governed by a low frequency mode in midlatitude Pacific Ocean sea surface temperature (SST) anomalies. Given simple indices of ENSO and multi-decadal variability, a simple conceptual model of climate variability is shown to provide good explanation of the historic occurrence of every major drought and flood event across NSW, and may be used to anticipate future climate variability from seasonal to multidecadal timescales. With these insights, it is proposed that a coupled landsurface-climatology model is developed across NSW. The aim of such a model scheme is to provide prediction of a range of key hydrological variables under different multidecadal ENSO climate states. The utility of such a modelling scheme lies in its applicability to a range of users. This naturally necessitates a multi-objective conditioning approach (for instance, soil moisture, surface water, evaporative demand). To achieve a state-wide coupled model, regionalisation of both the climate and landsurface hydrological models is required. In this presentation, novel regionalisation methodologies to provide prediction in ungauged catchments are proposed. These include (a) conditioning a distributed rainfall model, (b) regional landsurface model structure assessment and identification and (c) the robust quantification of uncertainty.

HW07/10P/C25-006   1545

GLOBAL ANALYSES OF SIMULATED HYDROLOGICAL BUDGET SENSITIVITY TO TEMPORAL CHARACTERISTICS OF PRECIPITATION

Yukiko HIRABAYASHI[1], Shinjiro KANAE[1], Taikan OKI[2], Katumi MUSIAKE[1] ([1]Institute of Industrial Science, University of Tokyo, [2]Research Institute for Humanity and Nature)

Global numerical runoff simulation driven with global atmospheric datasuch as satellite estimation and output of atmospheric generalcirculation model (AGCM), is practical for providing probable runoffperspectives in ungauged basins.Since global atmospheric forcing which is indispensable for globalhydrological simulation is limited in temporal resolution, severaldownscaling methods are proposed to obtain temporal characteristicsof precipitation input, which has a large impact for hydrologicalbudget estimation.In order to examine when and where the hydrological budgetestimated in the Land Surface Model (LSM) is sensitive to the temporalcharacteristics of precipitation input,two sets of off-line experiments are investigated.The first set of the experiments is global 1 x 1 degreesimulation in 1987, which is driven by the same atmospheric forcing butdifferent precipitation input, varying in temporal

scale from high(6-hourly) to low(deca-day or monthly).Low temporal precipitation is obtained by averaging original 6-hourlyprecipitation. Original 6-hourly and obtained deca-day averaged ormonthly averaged precipitation forcing are provided to the model and theresults are compared at each grid pixel.The results show that increases in surface runoff are obtained at mostof the grids with the low temporal precipitation, due to large increasein canopy interception.At the place where monthly LAI value is large and monthly precipitationis around 100 mm/month, the effects of the temporal scale of precipitationtend to be the largest.Another set of experiments is also 1 x 1 degree off-line simulation atone grid pixel using the accumulation of the observed precipitation.Three downscaling schemes for retrieving daily precipitation from the monthlyvalue are compared in terms of water balance calculated in the LSM.Both the number of days and intensity are shown to be important for thehydrological estimation in LSM.Thereby the water balance calculated in the experiment with a gammadistribution method shows fairly well accorded with the experiment usingobserved daily precipitation, and shows the applicability of the schemefor downscaling of daily precipitation from monthly data.

HW07/10P/C25-007   1600

GLOBAL WETNESS PROJECT 2 AND PUB

Taikan OKI[1], Paul A. DIRMEYER[3] ([1]Reseach Institute for Humanity and Nature, [2]Institute of Industrial Science, University of Tokyo, [3]Center for Ocean-Land-Atmosphere Studies)

The Second Global Soil Wetness Project (GSWP-2) is the principalelement of the large-scale uncoupled land surface modeling actionin the Global Land-Atmosphere System Study (GLASS; Polcher et al. 2000)and a major element of the International Satellite Land-SurfaceClimatology Project (ISLSCP), both contributing projects of GEWEX.The overarching goal of GSWP is to produce as a community effortthe best model estimates of the global land-surface water and energycycles. This will entail an evaluation of the uncertainties linkedto the land surface schemes (LSSs), their parameters, the forcingvariables which drive them, and the spatial and temporal scalesto run the numerical simulations. The original pilot phase of GSWP covered the two-year period of theISLSCP initiative I data set (1987-1988), and proved the utility ofmodel comparison and sensitivity studies of the land surface at theglobal scale (Dirmeyer et al. 1999).GSWP-2 will take advantage of the 10-year (1986-1995) ISLSCPInitiative II data set (http://islscp2.sesda.com/) and LSS simulationswill be conducted at a spatial resolution of 1degree, sans Antarctica. LSSs calculate runoff and it can be comparedwith river dischargewith applying runoff routing models. Therefore GSWP can be consideredas PUB on global scales. Regional scales should be more focusedin PUB as hydrological science, nevertheless studies on globalscale is also relevant since there are many places in the worldwhere global datasets of precipitation, landuse, soil types, etc.,are the only sources available for simulation and prediction ofriver runoff. Numerical experiments under GSWP2 is well designedto examine the uncertainties associated with the global offlinesimulations, and the outcomes should contribute for PUB studiesvery much. GSWP2 in PUB is also expected to identifyto what extent of temporal and spatial resolution predictingriver runoff can be estimated from global approach. Even though the major project under GSWP2 is the global approach,GSWP consists a few regional offline simulation, as well.Rhone-AGG experiment was carried out in the Rhone river basinwith gridded forcing data over Rhone river basin, and theeffect of the spatial resolution of the forcing data, suchas precipitation, radiation, on the energy balance estimationespecially river runoff by land surface models were evaluated.The scaling issues in land surface models particularly in termsof snow process and topography were addressed, and such anapproach can be expected to contribute for the PUB scaling issues.An intercomparison of regional offline simulations in the Chao Phrayariver basin in Thailand is planned under GSWP frame work,and it should also fit to be a suitable candidate for PUB basin.

HW07/10P/C25-008   1615

IMPROVED MODELING OF CATCHMENT SCALE HYDROLOGICAL PROCESSES: BRIDGING THE GAP BETWEEN LOCAL KNOWLEDGE AND THE GLOBAL PROBLEM OF UNGAUGED CATCHMENTS

Peter A. TROCH (Department of Environmental Sciences, Wageningen University)

Society is facing growing water resource needs (e.g. hazard mitigation) in a changing global environment. The postulated acceleration of the water cycle places hydrological science at the centre stage in the climate change debate. In IPCC reports, climate change predictions are more reliable for temperature as compared to precipitation, river flows and aquifer levels. This is due to the poor performance of hydrologic predictions at larger scales. Most hydrologic understanding is based at the point scale, whilst our needs for predictive modeling are at catchment scales. There is an urgent need for improved hydrologic predictions at that scale. Solving this spatial scaling problem requires a new approach along two lines of research. First, understanding the interaction between catchment characteristics and flow processes is of crucial importance. Recently, Troch et al. (2002a,b) developed storage-based dynamic equations able to capture the flow processes of complex landscapes by simple scaling laws pertaining to hillslope length, slope and form. Such a description will form the basis of a new generation of distributed catchment models that capture the essential behavior of the natural system but are low-dimensional and computationally efficient. Second, the complexity of the groundwater-surface runoff interaction forms a major challenge in catchment modeling. Due to the fact that the hydrologic system is heterogeneous and distributed, its identification is ill-posed. In this situation progress can be made by supplementing in-situ observation with remotely sensed soil moisture and evapotranspiration observations. By concentrating on the assimilation of remote sensing data in its broadest interpretation with the new strategy in catchment-scale hydrological modeling, this research aims at resolving the longstanding ungauged catchment problem.

HW07/10P/C25-009   1630

MODELLING UNGAUGED CATCHMENTS USING THE REW APPROACH: DERIVATION OF REGIONAL SCALE CLOSURE RELATIONS USING HIGLY RESOLVED, PHYSICALLY BASED SIMULATIONS

Erwin ZEHE[1], Murugesu SIVAPALAN[2] ([1]Institute of Hydraulic Engineering, University of Stuttgart, 70550 Stuttgart, Germany, [2]Department of Environmental Engineering, Centre for Water Research, The University of Western Australia, Crawley WA 6009, Australia)

Predicting the water balance of ungauged catchments is one of the most challenging tasks in hydrology. The Representative Elementary Watershed approach (REW) is a promising theoretical framework for that purpose. An REW is an abstract spatial object that shall be used as characteristic elementary unit to represent real world catchments in a model. Consequently it posses the most important properties of real catchments such as a saturated and unsaturated zone, saturated areas, a river net and a topography. The mass, energy and momentum balances in the individual zones of an REW are modelled using a set of coupled ordinary differential equations, that are derived from first principles using the second law of thermodynamics. The application of the REW approach to real catchments requires of course suitable parameterisations of the exchange terms of mass, energy and momentum across the boundaries between the different zones. The water and heat exchange between

the soil and atmosphere or between the unsaturated and saturated zone is determined by the subsurface thermal and hydraulic properties and their variability, due to the presence of macropores or strata in the soil or the aquifer. Appropriate closure relations have therefore to parametrise the main effects of the dominating subscale subsurface heterogeneity on the exchange of mass, energy and momentum. Thus, the concrete soil, geological and morphological properties of the region of interest come into play. A physically based model of catchment water and heat dynamics may explicitly account for the heterogeneity of hydraulic and thermal properties and therefore generate a suitable data base for deriving appropriate closure relations to parametrise the influences of subscale heterogeneity in the REW approach. Of course these relations are unique in the sense that the very details of the catchment properties are determined by unique details of a place. On the other hand catchments in the same landscape exhibit often similar geological, morphological and soil characteristics, which in turn affect the hydrological cycle in a way that is typical for that landscape. Due to this generality of places, the objective of our joint research is to derive closure relations for two typical regions in Australia and Germany, that reflect the typical subscale influences on the exchange of water and heat. To this end the water and heat dynamics of several typical catchments in each of the regions are simulated using a highly resolved, physically based model. Closure relations are derived, using appropriate measures for average quantities and their variation, and verified in a cross validation approach. By relating the closure terms to typical catchment characteristics, we hope to end at typical landscape specific closure relations. This would be significant progress towards the prediction of ungauged basins using the REW approach.

HW07/10P/C25-010   1645

THE ROLE OF 'TOP-DOWN' MODELLING FOR PREDICTION IN UNGAUGED RIVER BASINS

Ian Geoffrey LITTLEWOOD[1], Murugesu SIVAPALAN[2], Tony JAKEMAN[3], Barry CROKE[3] ([1]Centre for Ecology and Hydrology, [2]Centre for Water Research, The University of Western Australia, Crawley WA 6009, Australia, [3]Integrated Catchment Assessment and Management Centre (iCAM), Australian National University, Canberra ACT 0200, Australia)

Following the 2002 Kick-off Meeting to mark the start of the Decade on Prediction in Ungauged Basins (PUB), an initiative of the International Association of Hydrological Sciences, various groups were commissioned to prepare position notes as contributions towards the development of Science Plan and Implementation Plan documents for PUB. In the context of the role of 'top-down' modelling in PUB, this paper is an extension of the notes prepared on that topic for that purpose. Top-down modelling is described and placed within the broad spectrum of modelling approaches that will be adopted for PUB. The merits of top-down modelling in hydrology, and its applications for assisting with prediction in ungauged basins, are discussed through relevant examples.

HW07/10P/C25-011   1700

INVESTIGATION OF APPLICABILITY OF A PHYSICALLY BASED MODEL OF SNOWMELT RUNOFF GENERATION TO POORLY GAUGED BASINS

Lev S. KUCHMENT (Water Problems Institute of RAS)

A physically based distributed model of runoff generation, including the description of snow processes, soil freezing and thawing, formation of runoff losses and infiltration, evaporation, overland and subsurface flow, water movement in the river channel system, has been applied to investigate capability of assigning a priori values of the model parameters for snowmelt flood modelling. The measured or calibrated parameters which had been obtained for the models of runoff generation for two experimental river basins (the Kontaktny Creek basin with the catchment area 21 sq. km. and the Devitzca River basin with the catchment area 103 sq. km.), have been also used for modelling runoff generation in two large basins with similar physiographic conditions (the Kolyma River basin with the catchment area 100,000 sq. km. and the Seim River basin with the catchment area is 7500 sq. km., respectively). It has been shown that only 2-3 of the most important parameters should be recalibrated against runoff data for 2-3 years, whereas the values of the rest 10-12 parameters can be regionalized. Numerical experiments have been carried out to test ability of using different relationships between the most important parameters of the models under consideration and the measured basin characteristics for runoff modelling at absence of runoff measurements.

ACCURACY AND SENSITIVITY OF PHYSICS-BASED DISTRIBUTED MODELING USING FIRST-GUESS PARAMETER CHOICES DERIVED FROM GEOSPATIAL DATA

Baxter Ernest VIEUX, Jean E. VIEUX, Eddie KOEHLER (School of Civil Engineering and Environmental Sci., University of Oklahoma)

Hydrologic predictions in ungauged basins can be approached by using a physics-based distributed hydrologic modeling framework. The objective of distributed hydrologic modeling is to better represent the spatial heterogeneity of a watershed and thereby increase the prediction accuracy. Accomplishing this by representing the spatial pattern of important parameters requires assembly of geospatial data from a variety of sources including geographic information system maps and remotely sensed data (GIS/RS). Models that make use of these worldwide geospatial datasets offer important prediction capabilities where limited data exists. For example, digital elevation models (DEM) of terrain are available worldwide at 1-km resolution, and locally at even higher resolution. Prediction accuracy related to resolution and data accuracy of the DEM, as well as other data, can limit the ability to model certain basin scales or processes. Other sources of prediction errors stem from precipitation inputs, land cover/vegetation, and soils. Together, the data and associated uncertainties affect model accuracy for predicting various components of the hydrologic cycle. Rainfall-runoff is particularly important for a variety of applications such as water supply, flood prediction, and hydropower. Modeling event-scale runoff provides important decision support for water quality and quantity management. While calibration of conceptual models depends on historical archives of flow rates and precipitation inputs; physics-base models can be applied with fewer or even no historical data. Physics-based models that rely on conservation equations have the advantage of having physically significant parameter values that can be estimated from physical watershed characteristics, some of which are derived from GIS/RS geospatial data. Within such a modeling framework, an important question remains: How accurately can hydrographs be simulated using first-guess parameter choices? Several case studies using a fully distributed physics-based rainfall-runoff model, called Vflo™ will be presented that demonstrate the first-guess accuracy within this framework. The accuracy that can be expected and the sensitivity to geospatial data resolution, accuracy, and ancillary channel hydraulics will be examined. Understanding model limitations and sensitivities in these cases provides guidance for application in ungauged basins. Case studies are derived from model applications for basins in Romania, Taiwan, and the US that demonstrate model accuracy for river basins on the order of 100-10000 km². **Submitted under (iii) Methodological (Modelling) Frameworks**

HW07/10P/C25-013   1730

EXPLORING THE POTENTIALITY OF PREDICTION IN UNGAUGED BASINS OF A PHYSICALLY BASED HYDROLOGIC MODEL

Mario L.V. MARTINA[1], Ezio TODINI[1], Zhiyu LIU[2] ([1]Department of Earth Science, University of Bologna, [2]Hydrology Bureau, Ministry of Water Resources of P.R. China)

This work explores the potentiality of prediction in ungauged mesoscale basins of a physically based distributed rainfall-runoff model using some globally available data sets. The rainfall-runoff model TOPKAPI is characterized by a simple parameterization linked to the Digital Elevation Model, the soil type and land use maps of the catchment. The availability of these data at global scale makes possible to take advantages of information and results from gauged catchments for geomorphological and topological similar ungauged ones. The estimations of meteorological inputs from remote sensing campaigns are used either at their original scale or downscaled by means of a disaggregation technique which takes into account local variability (orographic effects). An application is presented for two morphological similar gauged catchments, one treated as ungauged.

HW07/10P/C25-014   1745

A HYDROLOGICAL MODEL FOR UNGAUGED BASINS USING THE KINEMATIC WAVE APPROACH

Amithirigala W. JAYAWARDENA, Pat J.-F. YEH (Department of Civil Engineering, The University of Hong Kong)

A physics-based distributed hydrological model that can be used for ungauged basins is proposed in this study. It can be thought of as a spin-off from an earlier study in which a catchment has been subdivided into strips of variable widths and the kinematic wave approximation used as the governing equation. With the availability of GIS techniques and digital elevations maps, the catchment topographical features can now be represented to a much higher degree of accuracy. The geometrical framework for the model would consist of a series of overland flow strips which will join the river network. Runoff would be simulated by assuming two layers of flow, one overland, and the other sub-surface, representing interflow, parallel to each other. The governing equations would be the kinematic wave equation for the overland flow, and the continuity equation coupled with Darcy's law for the sub-surface flow. The latter can also be expressed as a form of kinematic wave equation. Because of the kinematic wave assumption, this approach will be limited to steep catchments where hillslope hydrology dominates. The governing equations will have parameters that can be physically identified and therefore measurable at least in theory. Spatial variations can be accommodated to account for catchment heterogeneity. It is proposed to solve the governing equations within the distributed catchment framework using a numerical procedure based on the Finite Element Method. The Finite Element Method has the flexibility to accommodate uneven boundaries. The proposed technique will be applied to a small catchment in Southern China.

NESTED CATCHMENT EXPERIMENTS: CONSTRAINING THE HYDROLOGIC UNCERTAINTY IN THE PREDICTION OF UNGAUGED BASINS

Eduardo M. MENDIONDO (Escola de Engenharia de Sao Carlos, University of Sao Paulo, Brazil)

A central theme of the IAHS´ PUB initiative (Prediction in Ungauged Basins) is to constrain the predictive uncertainty through improved ways to study the effects of heterogeneity, process understanding and through access to new data resources. This is a task in the IAHSAEPUB Science Steering Group (http://www.cig.ensmp.fr/~iahs/), concerning experiences gained, lessons learned and perspectives on hydrologic uncertainty.Scientific questions are to be more developed in the forthcoming decade to constrain the predictive uncertainty in terms of the role of theory, basins, field experiments, process understanding and new data base required. Research pathways feasibly advanced on hydrologic uncertainty are here depicted, in order that regionalization thresholds could be grasped by practical methods of gauging. For instance, the Nested Catchment Experiment (NCE) sets up observational layouts of gauging catchments in nested spatial scales, i.e. from headwaters to lowlands. The NCE's focus is on multiple spatial gauges as well as on measurement of hydrologic parameters needed for modelling. By using NCE in representative basins is it better understood how space-time hydrologic variabilities occur and are related to basin heterogeneity of a specific world biome. Experiences gained with different NCE layouts sited in Brazil are presented, in terms of observational hydrology, modeling requirements and how they will be integrated into the entire PUB programme. Special attention of NCE layouts is outlined on the feedback from field hydrologists and water practitioners who are highly aware of the prior uncertainties in gauging station networks and experiments. NCE envisages new win-to-win opportunities in providing scientific underpinnings with UNESCO programmes like HELP and WWAP, as well with WMO. Summarized discussions look for lessons learned in those Brazilian NCE layouts showing what helpful yardsticks could collaborate with the IAHS´ PUB Decade, assisting new kind of experiments to the constrain of predictive uncertainty in world biomes.

HW07/11A/C25-002   0900

LESSONS LEARNT FROM TRACER AND CATCHMENT MODELLING STUDIES IN MESO-SCALE BASINS

Stefan UHLENBROOK, Nils TILCH, Jens DIDSZUN, Bettina OTT (Institute of Hydrology, University of Freiburg)

Beside the prediction of water quantities the PUB initiative focuses also on the prediction of water quality, erosion, sediment etc. In addition, predictions for future conditions under changed circumstances (i.e. altered land use, changed climate) or extreme conditions are wanted. Therefore, processes-based approaches are required since extrapolations are not feasible using purely empirical approaches. Since 3 years comparative field and modeling studies are carried out in four meso-scale mountainous basins in Germany and the Austrian Alps. The catchment sizes vary between 1.5 and 258 km2. Land use and other physiographic characteristics (climate, geology, soils, topography etc.) are different in each basin. Within this research initiative, the authors carried out tracer studies in each basin and applied the process-oriented catchment model TACD to several (sub-)basins. The tracer aided catchment model (TACD, D = distributed) is a raster-based conceptual catchment model that works on an hourly base. This paper summarizes some fundamental results and lessons learnt from it. Specifically it addresses the following questions: (i) How can a meso-scale catchment be discretizised from a process-based point of view into a set of response units? (ii) How can a better understanding of runoff generation mechanisms (incl. its heterogeneity and variability) at smaller scales be translated to an improved catchment modeling at larger scales? (iii) How can we use process knowledge and further hydrometric

measurements (tracers, snow cover, soil moisture, groundwater levels etc.) for model application and validation? (iv) What is the value of such data to reduce the predictive uncertainty in ungauged basins?

HW07/11A/C25-003   0915

NEEDS AND CONSTRAINTS FOR HYDROLOGICAL BEHAVIOUR OF UNGAUGED BASINS: AN EXPERIENCE IN SWISS AND LUXEMBOURG CATCHMENTS

Andre MUSY, Benoit HINGRAY, Markus NIGGLI (IAHS - CHy)

To provide operational methodological frameworks to institutions in charge of the sustainable management of water resources, various key issues have to be investigated and solved previously by the scientific community. Appropriated tools have to be identified for the various hydrological, climatic and physiographic contexts that are to be observed throughout the world. Hydrological models may be for example very different according to the scale of the catchment and to the dominant processes that govern the rainfall-runoff transformation. One challenging issue for the future decades is 1) to identify from the already available set of gauged catchments an exhaustive panel of the different kinds of possible hydrological behaviours, 2) to identify the dominant physical catchment and climatic characteristics that explain such behaviours and 3) to develop different criteria to identify for any ungauged catchment the catchment class it belongs to. The transposability of methodological tools that may be valid for a class of catchments has also to be explored. Dense experimental catchment networks are here of major interest as for these catchments the climatic context can be considered as homogeneous and as the hydrological behaviour variability observed between the different gauged catchments can be a priori explained by the variability of a small number of physiographic factors. The regional relationships that may be derived between the parameters of hydrological models and relevant physiographic features can be used afterwards for ungauged catchments. For the characterisation of some hydrological characteristics (floods, lows flows, seasonality) of the ungauged catchments located in the 'swiss plateau'region (approximatively 6000 km², with homogeneous climatic and physiographic context), the Laboratory of Hydrology and Land Improvement (HYDRAM) tested a continuous hydrological model on 30 gauged catchments belonging to the region. The good performance of the modelling approach obtained for the 30 studied catchments as well as the reasoned and robust multisignal calibration procedure developed for the calibration of the model parameters permitted the development of the model regionalisation. For the homogeneous climatic context of the studied region, the variability of the model parameters could be actually explained, as expected, from the variability of relevant physical catchment characteristics such as the catchment slope and surface area, the nature of the soil and underground material, To improve the transposability of the model, this regionalisation procedure is also performed for other climatic and physiographic contexts: this regionalisation was successfully applied for example to the very dense discharge measurement network of the Alzette catchment, Luxembourg, and is being carried out for different mountainous catchments located in the upper Rhone catchment (swiss alps). These works especially permit to highlight other relevant physiographic variables for the explanation of the model parameters variability.The development of appropriated tools for ungauged catchments could thus benefit from the experiences derived from very dense networks as the ones already available in some regions of the world. Such experiences could actually provide afterwards relevant basis for extension to other regions with lower instrumental potential but high interest in efficient methodological tools for water resources management.

HW07/11A/C25-004   0930

A SCIENTIFIC FRAMEWORK FOR MODEL EVALUATION WITHIN PUB

Thorsten WAGENER, Hoshin V. GUPTA, Soroosh SOROOSHIAN (Department of Hydrology and Water Resources, The University of Arizona, USA)

A large number of modeling approaches is available for predictions in gauged and ungauged basins. Modelling approaches differ, for example, in the degree of detail described, the manner in which processes are conceptualized, requirements for input and output data, and possible spatial and temporal resolution. However, there exists little scientific guidance to what modeling approach might be suitable for what circumstances. The result is that a range of modeling approaches often appear equally likely for a specific study, and the selection process amounts to a subjective decision by the modeler. What kind of approach is suitable for what case is one of the challenges we face within PUB. Progress in this area can only be made through the combined efforts of a large number of scientists with different expertise. Here, we suggest a scientific framework for this task. The main (scientific) criteria for the selection of a particular modeling approach are the modeling purpose (e.g. simple vs. complex), the basin characteristics (e.g. arid vs. humid) and the available data (e.g. sparse vs. abundant). These three dimensions of the classification problem have to be split into cases representative for realworld situations. Recent advances in model evaluation techniques, such as multi-objective and adaptive approaches, could then be utilized as far as possibleto classify modelling approaches. We outline the details of such a scientific framework for model evaluation and classification, including potential evaluation techniques to be used and open questions to be anserwed. Partial application examples for such a framework will be given.This effort can be an integrating element within PUB since it requires the contribution of scientists working on any element that contributes to hydrological predictions. The implementation of such an evaluation effort would mean significant progress in hydrological modeling and would also form a very valuable link between PUB and other existing initiatives such as MOPEX.

HW07/11A/C25-005   0945

MOPEX'S LINK TO PUB

John SCHAAKE, Qingyun DUAN (Hydrology Laboratory, NOAA/NWS/OHD)

The goal of the Prediction for Ungaged Basins (PUB) initiative is to gain scientific knowledge, acquire experimental data and routine observations, and develop application techniques to produce hydrologic predictions for basins where hydro-meteorological data are scarce or non-existent. Intercomparison of existing hydrological models, in a wide range of basins around the world, is identified as a key activity to achieve PUB goal. Model Parameter Estimation Experiment (MOPEX), an ongoing international project to develop a priori parameter estimation techniques for ungaged basins, can contribute the PUB initiative in several ways. First, MOPEX can contribute to PUB science as MOPEX leads to improved understanding of how model parameters reflects basin climatic and geophysiological properties and heterogeneities. Second, MOPEX has assembled a large number of basins worldwide that can facilitate the PUB model intercomparison study. Third MOPEX provides vehicles to transfer knowledge from gaged basins to ungaged basins.

HW07/11A/C25-006   1000

ON ENVIRONMENTAL MODELS OF EVERYWHERE AS A TEMPLATE FOR PUB

Keith J. BEVEN (Lancaster University, UK)

The PUB initiative will span the period during which , at least in the developed world, integrated environmental models will be developed of whole countries. Initiatives in this direction have already been taken for hydrological purposes in Denmark, the Netherlands, France and elsewhere. These will, in the future, be developed to include other environmental processes that are the subject of legislation for sustainable development. The computer power already exists to do this and it will become cheaper to implement and maintain in future. The interesting question of such systems is, of course, that nearly all the landscape that will be modelled is, to some greater or lesser extent, ˝ungauged˝. Thus, however such models are implemented - whether as fully distributed discretisations or overlapping scale-dependent lumped landscape units - initial representations of every ungauged units will be required. A viable PUB extrapolation methodology, from gauged sites to ungauged sites, is therefore initially essential. After that, however, the game will change to a process of learning about local places and, in particular, about local places where the initial representation turns out to be wrong. There will be places where that may not be important and uncertainty is acceptable, there will be other places where it is essential to have accurate predictions and uncertainty will need to be constrained. The really interesting question within the context of PUB is then how best to use sparse resources to constrain uncertainty at local places with their own unique characteristics.

HW07/11A/C25-007   1015

ANALYSIS OF UNCERTAINTY IN FLOW PREDICTION FOR UNGAGED CATCHMENTS

Manfred Walter OSTROWSKI (Civil Engineering, Darmstadt University of Technolgy)

Both, simulated river flows in gaged and ungaged basins contain considerable uncertainty, however, uncertainty of estimated flows in ungaged basins is considered definitely higher. To identify and possibly quantify these uncertainties, they have to be catagorised and analysed separately. Possible catagories could be uncertainties of data (random and systematic errors), models (structural and application errors) and parameter estimation (methodological and application). Data errors include input data (geographic, geometric and meteorological) and data being used for parameter estimation and verification such as measured flows. At times, uncertainty of stage discharge relationships used to derive flows from water levels is known to be as uncertain as no flow data at all. Model errors include e.g. errors related to deviations between physically defined and conceptual approaches, application errors cover inadequate application of model, e.g. through limited knowledge of user. Parameter estimation errors can relate to inadequate application of an estimation method or to weaknesse of the method itself. With such a differentiation it is possible to isolate and quantify the effects of e.g. missing flow data for parameter estimation. It clarifies the probably non linear superposition of single uncertainties, which provides much more information than simply applying a model with and without measured flow data. The paper will present the background of the problem, and demonstrate a possible approach for a separated analysis of single categories. The approach is based on the estimation of error distribution functions from which values are drawn randomly for Monte Carlo Simulation. A case study will be presented when errors involved in erosion process analysis were investigated.The paper is meant to contribute to the discussion rather than presenting new results.

HW07/11A/C25-008   1045

COLD REGIONS HYDROLOGY, UNCERTAINTY AND PREDICTION WITH MINIMAL INFORMATION

John W. POMEROY[1], Lev S. KUCHMENT[2], Alexander N. GELFAN[2], Raoul J. GRANGER[3], Donald M.GRAY[4], Newell R. HEDSTROM[3] ([1]Institute of Geography & Earth Science, University of Wales, Aberystwyth, [2]Water Problems Institute, Russian Academy of Sciences, Moscow, Russia, [3]National Water Research Institute, Environment Canada, Saskatoon, Canada, [4]Division of Hydrology, University of Saskatchewan, Saskatoon, Canada)

The IAHS 'Decade for Prediction of Ungauged Basins´ issues of predicting water resources in areas with poor or sparse observations have particular relevance to those interested in cold regions hydrology. The major hydrological events in cold regions are related to storage in and melt of snow, ice and frozen ground. However, observational networks of snowfall, snow depth, frozen ground, ice extent, and streamflow have never been particularly dense in cold regions, and recently have declined dramatically. The difficulties of measuring snow accumulation, interception, redistribution, frozen soil moisture content, and streamflow under ice have long meant that even routinely-gauged basins represent areas of high uncertainty in hydrological calibration and estimation. The transferability of regionally-developed modelling methods and parameters is of interest to improved water resource prediction in data sparse regions. Because of a long-standing problem of data availability in cold regions, there are several methods for applying physically-based models based on hydrological processes; the physical basis of these approaches may have relevance to improving more temperate hydrological applications as well as in the cold regions. Initial experiences suggest that physically-based snow process representations with parameters bounded by physical laws, field or analytical experiments rather than calibration show promise for inter-continental transferability of models, parameters and applications. Transferrability is most successful within similar biome types such as steppes, boreal forest, taiga and arctic tundra.

HW07/11A/C25-009   1100

WATER-QUALITY PREDICTION IN UNGAUGED BASINS

Norman E. PETERS (U.S. Geological Survey)

To date (January 2003), the focus of the International Association of Hydrological Science's decadal initiative on the Prediction in Ungauged Basins (PUB) has been on water quantity (storage and fluxes). A primary interest of hydrologists and water resource managers, however, is water quality, particularly as affected by human activities, i.e., growing and pervasive water-quality degradation. The quality of freshwater at any point on the landscape reflects the combined effects of natural and anthropogenic processes along hydrologic pathways, for which the process relations may be cyclical (interdependent and/or periodic) and cascading. Local, regional, and global differences in human activities (e.g., mining, industry, agriculture, waste treatment and disposal), climate, and streamflow are considerable, and, in turn, cause varying effects on water quality and quantity. This paper explores answers to several questions about a water quality component of PUB. What do we know about the water quality of ungauged basins? What confidence do we have to predict parameter or constituent concentrations and loads (averages, medians and ranges)? What information is required to reduce the uncertainty in water-quality predictions? How can information from well-studied areas be used for predictions in poorly studied areas?

HW07/11A/C25-010   Invited   1115

THE IMPERATIVE OF THE PUB APPROACH FOR SUSTAINABLE WATER MANAGEMENT IN WEST AFRICA

Lekan OYEBANDE, Olusegun ADEAGA (University of Lagos)

Rational water resources planning and development is being hampered by the problem of inadequate data and information in developing countries such as those of West Africa including Nigeria. An understanding of the spatial and temporal variation of hydrological phenomena and processes is crucial for sustainable water resources planning. Although great efforts have being made in the past at the national, regional and international levels in respect of hydrological monitoring and data bank creation as well as data dissemination. The status of gauging of the various basins is far from satisfactory and in many cases, worse that it was a decade ago. The hydrometeorological networks of the 1980s have fallen apart and there are doubts as to how many stations are actually functioning. Indeed the proportion of the established hydrometric gauging stations that may be functioning in the nine countries of the Niger basin represents as low as 45% in Niger and Nigeria to 50% in Mali and Burkina Faso. Only countries such as Benin, Cameroon and Cote d'Ivoire, which operated only 5-15 stations, have been able to keep those stations in operation. Efforts made to improve hydrological assessment of basins and their water resources in West Africa include those of the World Bank Sub-Saharan Hydrological Assessment, the HydroNiger a project consisting of 65 data collection platforms (DCPs) in the whole of the Niger basin with the technical assistance of WMO, OPEC Fund, EEC, and UNDP. The current and latest initiative is the West and Central African HYCOS being developed by WMO. It has inherited the DCPs used by the Niger Basin Authority's HydroNiger project and the WMO OCP/ONCHO. HYCOS involves 23 countries in West and Central Africa in its pilot phase launched in Dec 1999. In this study, the causes of the seeming failure of the past efforts and present status of hydrological monitoring and data base management task and data dissemination in West Africa are addressed. The imperative of adopting PUB as a complimentary tool for a better understanding of drainage basin dynamics and their aggravation by man's activities in these poorly gauged / ungauged basins is stressed. Ironically it is in such basins as the Niger that intensive and reliable data sets are more needed in order to understand the complexity of the basin hydrological systems. PUB is necessary if a policy-relevant science is to be adopted in this era of ever-reducing ground based conventional observation networks and wide spread ungauged basins. The paper examines the value that could be added by PUB through digital terrain modelling for a dynamic, if not near real time operational hydrological practice in the data-scarce basins of the Niger basin and West Africa.

HW07/11A/C25-011   1145

THEORETICAL EXPLORATION OF CLIMATIC AND LANDSCAPE CONTROLS ON INTER-ANNUAL VARIABILITY OF RUNOFF AND FLOW DURATION CURVES

Murugesu SIVAPALAN[1], Yoshiyuki YOKOO[2] ([1]Centre for Water Research, University of Western Australia, [2]Institute of Industrial Science, University of Tokyo)

The chief cause of the PUB problem is our inability to deal with the heterogeneity of climatic inputs and landscape properties, and their impacts on the space-time variability of streamflows. The main aim of this paper is therefore to present a theoretical framework with which to investigate space-time variability of runoff fields, with a view to eventually enabling us to interpret the space-time patterns in the variability of observed streamflows in terms of the underlying climate-soil-topography interactions. It is expected that the resulting understanding of the causes of observed variabilities will enable us to make improved predictions in ungauged catchments. In particular, the paper focuses its attention on two distinct signatures of such variability, namely the inter-annual (between years) and intra-annual (within year) variabilities of runoff. In this case we use a physically-based formulation of water balance developed that has been developed from first principles, directly at the scale of a representative elementary watershed (Reggiani et al., 2000), for an idealised catchment, and capable of including the effects of climate, soils and topography. The model is driven by synthetic realisations of precipitation events which are generated through a stochastic rainfall model but reflecting realistic conditions. The model simulations of catchment response are used to characterize the probability distribution functions of antecedent soil moisture content and storage, and within-year and inter-annual variabilities of runoff for various combinations of climate (including seasonality), and soil and topographic properties, and these will be interpreted in terms of key dimensionless similarity indices the climate, soils and topography (a dryness index, a storage index and a drainability index). Reggiani, P., M. Sivapalan and S. M. Hassanizadeh (2000). Conservation equations governing hillslope responses: Exploring the physical basis of water balance. *Water Resources Research*, Vol. 36, No. 7, pp. 1845-1864.

HW07/11A/C25-012   1200

ESTIMATION OF ANNUAL RUNOFF STATISTICS IN UNGAUGED BASINS WITH PARSIMONIOUS EVALUATION OF CLIMATIC INDICES

Pierluigi CLAPS[1], Giovanni LAGUARDIA[2] ([1]DITIC - Politecnico di Torino, [2]DIFA - University of Basilicata)

Relations between climatic parameters and hydrological variables at the basin and the regional scale are investigated, using climatic classifications as synthetic indices representing the average annual water budget. Precipitation, temperature and net radiation are the climatic variables required for evaluating the climatic indices in the formulations proposed by Thornthwaite, Emberger and Budyko. The spatial distribution of these variables has been studied in the 10,000 km^2 territory of the Basilicata region (southern Italy), to evaluate the possibility of their indirect estimation. Precipitation and temperature data was available for several stations within the region, while only measures of global radiation were available for few stations in a reasonable number of years. Simple, yet robust, literature methods for estimation of net radiation were adopted, to limit the ground data requirement to temperature, and relative heliophany. Temperature was, in turn, related to elevation and latitude in a statistical analysis performed earlier in a much larger area. Consequently, all of the climatic indices considered can have an approximate evaluation using only data of precipitation, elevation, latitude and relative heliophany. The above-mentioned climatic indices were evaluated after estimation of the mentioned variables over a grid of resolution of about 1 km. Satellite data of cloudiness were used in place of the relative heliophany. Lumped climatic indices computed on the gauged basins available in Basilicata were found to be clearly related to mean and variance of the measured annual runoff series. The Budyko index was the best in terms of symmetry of the frequency distribution, sensitivity to aridity and quality of the correlation with the moments of the annual runoff. To further substantiate the potential of synthetic climatic information to support a regional hydrologic studies, additional satellite data have been used, retrieved by NOAA-AVHRR. In particular, the normalized difference vegetation index (NDVI), obtained with the maximum value composite technique, has been compared to the above estimates of climatic indices. Dependency of the vegetation phenology from the available water and, as such, from the average water budget, support the connections found between NDVI and the estimated climatic indices. These initial results indicates that there are good premises in the task of reducing the

dependence of climatic mapping in a region from ground data, with special reference to the measure of precipitation.

HW07/11A/C25-013   1215

SOME PERSPECTIVES ON REGIONALISED MODELS FOR WATER RESOURCES ASSESSMENT: FROM FLOW STATISTICS TO TIME-SERIES

Andy R. YOUNG, Matt G.R. HOLMES, Alan GUSTARD, H.Gwyn REES (Centre for Ecology and Hydrology - Wallingford)

The estimation of river flows is a central component of water resources management, however management decisions are frequently required within catchments for which there are little or no gauged flow data. Since the 1970s this has led to many international examples of the development of regionalised hydrological models. Commonly these have been based on the development of empirical relationships between statistics of river flow and catchment characteristics. More recently, advances have been made in the science of regionalising parsimonious rainfall runoff models. From a regulatory perspective these recent advances have been primarily driven by the requirement for linking hydrological determinations with ecological assessments. Other drivers have been to improve the representation in land surface interactions within climate models and to improve our understanding of the scaling of hydrological processes. This paper will review the development of the science of regionalisation for water resources purposes within the United Kingdom from flow statistics to time series of river flows. The paper will discuss the drivers, the methods, data and will seek to identify some of the limiting factors and challenges that this area of research is faced by, using the UK as an example. The paper will conclude with a example of how similar principles have been used within the relatively data-sparse region of Nepal and the northern Indian state of Himachal Pradesh to elucidate relationships between river recession characteristics and basin characteristics.

Friday, July 11 PM

HW07/11P/C25-001   1400

THE NEED FOR A NEW LOOK AT REGIONALIZATION BY REGRESSION ANALYSIS

Robin Thomas CLARKE (IPH-UFRGS)

Regression analysis has long been used for the transfer of information from gauged to ungauged drainage basins. It is used not only for estimating (a) flow characteristics, such as mean annual flow, but also (b) extreme flows with given return period, and (c) estimates of parameters of rainfall-runoff models fitted to the hydrological data in gauged basins. As commonly used, the logarithm of the variable of interest (here termed Q) is expressed as a linear multiple regression in terms of the logarithms of explanatory variables which include basin area (A), together with other variables (S, P,..) describing basin topography, climate, vegetation, geology and lake storage. Until better procedures are developed, regression-type relations will continue to be used in the future for imputing the hydrological behaviour of ungauged basins. However, statistical methods and computing software have developed rapidly over the last quarter century, and there are now many alternatives to expressing $\ln Q$ linearly in terms of $\ln A$, $\ln S$, $\ln P$,... . This paper argues that there is a need to utilise existing data from gauged basins to explore the usefulness of the many alternatives to simple multiple regression, so as to (a) incorporate information on the spatial configuration of the gauged basins: namely, their degrees of spatial separation and orientation; (b) allow for the facts that the explanatory variables A, S, P... are known to be subject to error, which can often be estimated; (c) explore the use of possibly more appropriate functions of Q, A, S, P... than their simple logarithms; (d) allow for the correlation between different response variables Q_1, Q_2,.. where these are each to be estimated for an ungauged basin; (e) explore the use of robust regression procedures that are less susceptible to outliers in data than least-squares regression. Better empirical relations would not only be useful in their own right, but would also increase the value of prior information, where this is to be combined with limited data from an ungauged basin by Bayesian methods.

HW07/11P/C25-002   1415

SIMPLE METHODS OF HYDROLOGICAL DATA PROVISION FOR UNGAUGED CATCHMENTS IN DEVELOPING COUNTRIES

Vladimir SMAKHTIN (Hydrology and Eco-Hydrology, International Water Management Institute)

International Water Management Institute carries out a number of research projects in Asia and Africa, which are related to efficient water use in agriculture, food and environmental security. The quantification of hydrological processes under natural and modified conditions in study river basins, is a constant need, but often complicated by a decline of measuring networks in developing countries, limited quantity and poor quality of available data, and institutional barriers to data acquisition. These often necessitate the development and application of parsimonious methods of hydrological data provision. The paper will describe one group of such techniques, which are based on Flow Duration Curve (FDC). This methodology of pragmatic hydrological time series modeling includes: i) technique by which to establish FDCs at ungauged sites (primarily by means of hydrological regionalisation) and ii) techniques by which to convert the established FDCs into actual continuous hydrograph. The latter is a non-linear spatial interpolation technique based on the assumption that flows occurring simultaneously at sites in close proximity to each other correspond to similar percentage points on their respective FDCs. The technique is designed to work with either available flow or rainfall data from gauges in a catchment. Pragmatic hydrological modeling focuses exclusively on the generation of hydrological time series, has a limited number of parameters and unambiguous reasons for success or failure. It is simple to use, time efficient, not regionally restricted and is applicable for generation of both daily and monthly flow data. The paper presents examples of application of pragmatic time series modelling concept in several developing countries including South Africa, Sri Lanka and Nepal.

HW07/11P/C25-003   1430

EXTREME-EVENT MODELING IN UNGAUGED BASINS BY REGIONAL ESTIMATION

Taha B.M.J. OUARDA[1], Alin A. CÂRSTEANU[2], Hugo GINGRAS[1], Bernard BOBÉE[1] ([1]Institut national de la recherche scientifique - Eau, terre et environnement, [2]Cinvestav del IPN)

Regional estimation involves the identification of groups of hydrologically homogeneous catchments, as well as the regional estimation method used for information transfer from the homogeneous region to the ungauged site. We present, by means of a multi-method original software, the advantages of using neighborhoods in canonical correlation space, rather than geographically contiguous regions, for homogeneous-region identification purposes. The methods of index flood and multiple regression are used for regional estimation. A discussion is offered on the implications of scaling probability distributions of events, for these methods.

HW07/11P/C25-004   1445

ON DEFINING WATERSHED SIMILARITY FOR REGIONAL ESTIMATION OF FLOODS AT UNGAGED SITES

Van-Thanh-Van NGUYEN[1], Nelly PEYRON[1], Ganesh R. PANDEY[2] ([1]McGill University, Department of Civil Engineering and Applied Mechanics, [2]State of California, Department of Water Resources, Division of Planning and Local Asistance)

Accurate estimation of flood flows from a watershed is essential for the design of many hydraulic structures (e.g., dams, culverts, bridges). However, flow records that are needed for this estimation are either limited or unavailable at the site of interest. In such cases, regional estimation methods, which use hydrological information from many sites, have been proved to be able to improve the accuracy and reliability of the flood estimates. However, the success of these procedures lies upon the appropriate identification of hydrologically similar basins (or homogeneous regions). While several methods of delineating homogeneous regions, such as index-flood procedure, cluster analysis, discriminant analysis, or region of influence approach, have been proposed in the literature, the criteria used in these procedures for determining regional homogeneity involve still a great deal of subjectivity and may not be suitable for the estimation of floods at ungaged locations. Therefore, the main objective of the present study is to propose an objective approach to delineation of homogeneous regions for improving the accuracy of flood estimation at locations with limited or without data. The proposed method is based on the scaling of statistical properties of floods with basin characteristics. More specifically, the analysis of the physiographic and hydrologic data for over 200 watersheds of different sizes (ranging from 100 km2 to 90,000 km2) in Canada has indicated the scaling behaviour of the non-central moments of flood series with the basin areas. Based on this empirical evidence, a new definition of regional homogeneity of watersheds has been formulated. It was found that the grouping of homogeneous basins as proposed in this study formed well-defined geographical regions with distinct climatic characteristics. Further, it was recommended that the selection of regional probability distribution for the estimation of flood quantiles and the corresponding parameter estimation method should be made such that the scaling properties of the flood series were preserved. Finally, it has been demonstrated that, based on the proposed definition of regional homogeneity, the estimates of floods for ungaged sites could be more consistent and more accurate than those provided by existing methods.

HW07/11P/C25-005   1500

ANALYSIS BY THEORETICAL AND DISTRIBUTED MODELS ON FLOOD FREQUENCY AND PROBABILITY DISTRIBUTION OF RUNOFF SOURCE AREAS

Salvatore MANFREDA[1], Vito IACOBELLIS[2], Mauro FIORENTINO[1] ([1]Dipartimento di Ingegneria e Fisica dell'Ambiente, Universita' della Basilicata, [2]Dipartimento di Ingegneria delle Acque e Chimica, Politecnico di Bari)

Flood generation mechanisms depend on basin features as: soil type (soil water storage capacity and permeability), vegetation (surface coverage) and climate. These variables are spatially distributed, and we try to interpret their effects by using a distributed model. Such a model is physically based and capable to evaluate the runoff generation considering the influences of soil characteristics and local soil moisture conditions. The focus of this study is to identify the contributing areas to the peak flow and to underline the existing relations between the probability distribution of floods parameters, the physical characteristics of the watershed, and the contributing areas. By using the rainfall-runoff model Wetspa it is possible to evaluate the real contributing area to the peak flow. Synthetic rainfall series, generated by IRP model, were combined with the rainfall-runoff model, obtaining time series of discharge. Finally the annual maximum floods and the corrisponding contributing area have been extracted from the discharge series and their frequency distribution has been analyzed to interpret and support on physical bases the theoretically distribution of floods recently proposed by Fiorentino and Iacobellis (2000). Such a theoretical model for analytical derivation of the flood frequency distribution is based on a simple rainfall-runoff model in which the peak flow QP is treated as a stochastic variable function of two other mutually dependent stochastic variables, namely the mean areal rainfall intensity ia,t and the peak runoff contributing area a. The results validate the hypothesis of gamma distribution and show a strong correlation between the variable a, calculated by Wetspa, and the climatic and geomorphologic characteristics of the basin.

HW07/11P/C25-006   1515

PREDICTING FLOWS USING CLIMATE AND LAND USE DATA FOR UNGAUGED CATCHMENTS IN THE MURRAY-DARLING BASIN, AUSTRALIA

Barry FW CROKE (Centre for Resource and Environmental Studies, and the Integrated Catchment Assessment and Management Centre, The Australian National University)

Predicting flows in ungauged catchments using calibrated rainfall-runoff models requires determination of regional relationships between parameters and catchment attributes. This approach is only possible with parsimonious models (fewer than ~7 parameters). Even with such models, the uncertainties in the data used to determine the relationships between measurable catchment attributes and non-measurable parameter values generally results in poor predictive power. This paper presents three top-down approaches to improve the estimation of parameter values through regionalisation of three observable quantities: the runoff coefficient; shape of the flow duration curve; and the unit hydrograph. These approaches can be used separately or in combination to constrain model parameters depending on data availability and output requirements. Post et al (1999) found that constraining the parameter values using estimates of the runoff coefficient from similar neighbouring catchments improved the predictive power of this approach. This concept has been extended through development of a broad scale regionalisation of the runoff coefficient for the Murray-Darling Basin in Australia. The approach applied here is to estimate evapotranspiration (ET) using relationships developed by Zhang et al (2001), empirically corrected for variations in the potential evapotranspiration across the basin using gauged sites in the Goulburn-Broken and Upper Condamine catchments. The runoff coefficient is then derived assuming that the only significant terms in the water balance are rainfall, streamflow and ET. The performance of the model has been tested using gauged sites in the Upper Murrumbidgee and Wingecarribee catchments. A method of extending this to determine the relationship between catchment attributes and the shape of the flow duration curve is being developed. This method uses the linear form of the log-normal transformed flow duration curve, with the slope of the transformed FDC related to attributes such as land use, rainfall and potential evaporation. The third approach is to relate the shape of the unit hydrograph to catchment attributes. This is based on a technique to derive the unit hydrograph response curve directly from observed streamflow (Croke, 2003). These approaches constrain the model parameters and potentially increase the predictive power of the regionalisation approach. This work is part of the IHACRES component of PUB proposed by Littlewood et al. (2002) in Brasilia.

TOWARDS A SCIENCE PROGRAM FOR PREDICTION IN UNGAUGED BASINS (ALL IAHS COMMISSIONS)
Location: Site D

Friday, July 11 PM

HW07/11P/D-001   Poster   1400-137

TOWARDS THE PREDICTION IN UNGAUGED BASINS -- DATABASE DEVELOPMENT FOR A MESOSCALE RIVER BASIN IN TROPIC CLIMATIC ZONE

Taichi TEBAKARI[1], Chanchai SUVANPIMOL[2], Sukit SUANKUASAKOOL[2], Tianqi AO[1], Kazuhiko FUKAMI[1], Junichi YOSHITANI[1] ([1]Public Works Research Institute of Japan, [2]Royal Irrigation Department of Thailand)

In general, a hydrological model applicable for PUB (Prediction in Ungauged Basins) should be capable of identifying model parameters directly on the base of basin features, and model performance is desired to be free from uncertainty resulted from scale problem. To develop and validate such models and carry out their inter-comparisons, particularly in establishing the relationship between model parameters and basin features, hydrological databases of various well-gauged study/experimental basins are essential. For a selected study basin, the accuracy of collected hydrological data has the same importance as model itself. It is desired that the stream flow discharge is not disturbed by human activities, the intensity of hydro-climatic gauge station is not too low and long-term hydro-climatic records are available. Also, corresponding to physically based distributed hydrological models, data of land use/cover, soil type, soil water content and geology are desired to be available. Moreover, such database is desired to be prepared for such representative river basins that locate in different climatic zones and have different hydrological response characteristics.For the Southeast Asia, selecting a well-gauged representative study basin for PUB is necessary, because in this area there exist many unguaged basins and their hydrological predictions are becoming more and more important to overcome the water crisis in the 21st century. In this study, prepared was the database of a mesoscale river basin that locates in tropic climatic zone, the Khlong Luang River basin of Thailand.This basin locates in the southeast of Thailand, 100 km far from Bangkok, has a drainage area of 433 km2 and a mainstream of about 30 km. Its elevation is between 30-100 m and its topography is comparatively flat. There is not large dam and large city in the basin and no significant human made interruption to the natural stream flow. Its major land use is for agriculture; about 70% of the area is arable. Its surface soil is dominantly loam and clay. From 1965 to present, the Royal Irrigation Department of Thailand (RID) has been measuring water level, discharge, rainfall, and evaporation for the Khlong Luang River basin. The Public Works Research Institute of Japan (PWRI) and RID have carried out cooperative observation for soil moisture during 1994 to 1995. For the period of 1965-2001, the observed annual average rainfall is 1229.94 mm, the maximum and minimum are 1644.7 mm and 869.8 mm, respectively; annual runoff is 663.6-48.2 mm, and the annual runoff rate is between 43% and 5.5%. For the Khlong Luang River basin, the prepared hydrological database contains observed rainfall, stream discharge/water level, evaporation, land use, soil type, soil water content and geology. This database will open to PUB researchers who plan to apply watershed and rainfall data to a physically based distributed hydrological model and to verify the model with observed discharge data. The authors will report the analytical results using the BTOPMC (Block-wise use of TOPMODEL with Muskingum-Cunge method), for relating model parameters with physical features of the Khlong Luang River basin.

HW07/11P/D-002   Poster   1400-138

EXPERIMENTAL STUDIES ON RUNOFF AND SOIL EROSION OF BHETAGAD WATERSHED IN CENTRAL HIMALAYAS

Umesh Chandra KOTHYARI (Department of Civil Engineering)

Soil, water and nutrient conservation practices are increasingly being designed and adopted in almost every part of the world for enhancing the water availability and fertility of land surfaces as well as for curbing non-point source pollution from agricultural and other land usages. Therefore, in recent years there has been increasing demand for the need to include both water and sediment control strategies within the watershed management plans. The runoff and sediment discharge from a watershed is controlled by a complex functions of meteorological, ecological , climatic and geo-morphological processes. Compared to other parts of the world, the degree of controls affected by each of these factors is much different in the watersheds located in the region bounded by the Hindu-Kush Himalayan Region. The Himalaya is a fragile land and one of the greatest mountain systems of the world. Inspite of the fact that Himalayas play the role of a water tower for the entire Indo-Gangatic planes in Indian subcontinent, the availability of water is a big problem for the Himalayan inhabitants themselves. Also millions of tons of eroded fertile soil generated through erosion in watershed areas in upper parts is transported to the downstream plain area every year by the mighty rivers like Ganga, Yamuna, Brahmaputra and the others.In the above context, it becomes absolutely necessary to have better understanding of the natural processes causing runoff and sediment generation and also in identifying the influence of human activity on the watershed in these areas. Using such knowledge one can more accurately estimate the upper bound capacity of the earth in these areas to sustain the burden due to population. To fully understand the system and the involved processes there is only little reliable data available within the region mentioned above and most of the river systems are ungauged. Therefore, long-term data is needed for the understanding of the dominent nautural processes, resource assessment, possible changes and impacts.An extensive study on monsoon fed Bhetagad sub watershed in Hindu-Kush Himalayan area of the Garur Ganga, (tributary to river Gomti in the Ganga river system) watershed was started by the authors in the years 1997 for meeting above stated objective. Experiments both on plot scale and the watershed scale are being performed for investigating the rainfall – runoff – soil erosion processes in the study area, which lies in the Central Himalayan region having tropical climate. There are further plans for near future for gauging such macro size watersheds in the monsoon fed Shiwalik ranges of the Himalayas. These plans and the results obtained through earlier studies shall be presented in this paper.

HW07/11P/D-003   Poster   1400-139

THE DEVELOPMENT OF THE DETAILED CLIMATIC SCENARIOS FOR CENTRAL ASIA REGION

Inom Sherovich NORMATOV (Institute of Water Problems, Hydroenergetics and Ecology, Academy of Sciences, Republic of Tajikistan)

The Central Asia is a particularly bordered region. Almost all the climatic zones and high altitudes from the level of Caspian Sea to the highest peaks of Central Asia are located here.

The Aral Sea basin can be considered a closed one, as it has not any links with the World Ocean and borders with mountain chains of Tian Shan, Pamirs and Kopetdag on the south and the east. The only exterior factor, which influences the climate of this region is the atmosphere. In these conditions the most important of the main factors influencing the ecological situation in this region is the population increase and activation of human industrial activity, which intensifies ecological misbalance. In Tajikistan Republic over 10% of the territory is the zone of everlasting snow and glaciers. This territory requires strategic defense, as global anthropogenic increasing of temperature more perceptibly tells upon the regime of forming the river flow and activation of ice disintegration. Intense glaciers melting causes not only decreasing of the fresh water supply for Central Asia but also the formation of glacial lakes. Therefore there appears the danger of destructive mountain flows, which caused the human victims and land degradation not once. Under modern climatic conditions the area of the Pamirs and Alai's glaciers is decreasing annually by 1.2 sq. km. The observing network in Tajikistan Republic has a unique peculiarity, which differs it from similar networks in other countries. It is situated at the altitudes of 300 to 4,169 m, i.e. in the troposphere. All those stations were included into the world observing network. In Tajikistan numerous scientific works require proper processing. Today it is necessary to make systematization and scientific analysis of hydrometeological data, accumulated for the last hundred years. Only the analysis of long observations data, obtained from the stations in mountains will allow to reveal the changing trends of climatic hydrometeological parameters and to develop the prognosis method for the future perspective. This research work may contribute to fundamental international research on the program of global climatic changes. The foundation of the stations of the local and global monitoring of the greenhouse gases opens the wide perspective to establish the changing dynamics of green concentration according to the altitudes. It establishes the dependence of the snow and glaciers melting process and the formation of the river flows on the greenhouse gases concentration at the different heights, as well as the influence of the greenhouse gases on the flora and fauna. The results of conducted measurements, observations of the greenhouse gases influencing the environment will generate the research and practical works in developing modern technologies, which provide the essential decrease in the greenhouse gases emission and the wide use of untraditional energy carriers instead of organic fuels.

HW07/11P/D-004   Poster   1400-140

DATA AVAILABILITY PROBLEMS IN UNGAUGED BASINS OF DEVELOPING COUNTRIES - A TEST CASE

Syed Muhammad Saeed SHAH[1], Hazael Firoton GABRIEL[1], Iftikhar AHMAD[2] ([1]Centre of Excellence in Water Resources Engineering, University of Engg. & Tech., Lahore, Pakistan, [2]Department of Mining & Geology, University of Engg. & Tech., Lahore, Pakistan)

For the prediction and design of hydrologic phenomena, long term hydrological data is needed in most of the cases. In this paper the main data issues and problems those are concerned with the hydrologic prediction and design in ungauged basins are investigated with special reference to developing countries. As a test case, Pakistan one of the developing countries is chosen for the study. The ungauged basins of the country are selected and problems and main issues are determined. The whole region has been divided into three areas, arid, semi-arid and humid differentiated on the basis of occurrence of precipitation. In arid areas the rivers remain dry in most of the time of a year and rainfall is scanty. The problems found to be different as compared to other two regions. In semi-arid parts, the ungauged basins have different problems and issues. In humid areas the rivers are perennial and have appreciable water potential. Due to this reason the water funding agencies have more inclination towards these areas. There problems are different as compared to the other two areas.In developing countries, due to little available funds, the basins are poorly gauged. This problem is more critical if the area lies in arid to semiarid regions. These have little or no gauging stations due to less water resources. The water authorities in Pakistan, perhaps have no plan for the installation of new gauging stations. The information regarding precipitation, land surface processes, stream flow, ground water flow, snow and ice, sediments and water quality is limited.Data availability in these basins is discussed in detail. The shortcomings in data collection, storing the field data and analysis are also discussed. Although the population is increasing rapidly, and need of water resources is increasing but the density of hydrologic gauging is towards decreasing side. These issues have been discussed, some new suggestions are proposed

HW07/11P/D-005   Poster   1400-141

REPRODUCTION OF DISTRIBUTED RAINFALL INTENSITY USING NUMERICAL MODEL AND SATELLITE DATA

Satoru OISHI[1], Makoto AKAIKE[2], Kengo SUNADA[1], Kuniyoshi TAKEUCHI[1] ([1]Department of Civil and Environmental Engineering, University of Yamanashi, [2]Graduate School of Engineering, University of Yamanashi)

Introduction In order to prediction of ungauged basins, we will reproduce the distributed rainfall intensity in the Mekong river basin. The reason for the Mekong river basin is that the Mekong river is important international river without gauging the rainfall distribution. The Mekong river is important not only in hydrological aspect but in political and economical aspect. In order to investigate the hydrological process in the Mekong river basin, the distribution of rainfall is strongly required. Moreover, it is also required for flood disaster prevention. Therefore, we try to reproduce the distributed rainfall intensity by using a numerical weather forecasting model and satellite data. This research is basic investigation for nowcasting the real time rainfall distribution in the future. Method The target of this research is 1hr and 20km grid rainfall intensity data. For the reproduction, we use the MRI/NPD NHM as a numerical weather forecasting model and TRMM-PR as satellite data. MRI/NPD NHM is the Non-Hydrostatic numerical weather forecasting Model made by Meteorological Research Institute and Numerical Prediction Division both in Japan Meteorological Agency. MRI/NPD NHM can calculate the detailed meteorological situation including rainfall intensity by using the global assimilation data and nesting method. However, it is difficult to calculate the correct distribution of rainfall intensity by using numerical weather forecasting model. It is required to compare the result of numerical model and observed data. Moreover, the reproduced rainfall intensity data has to be modified by using satellite data. In the ungauged basins, the distributed rainfall intensity is obtained only from the satellite data. We use the TRMM-PR data as rainfall distribution data. TRMM-PR is Precipitation Radar onboard the Tropical Rainfall Measuring Mission satellite. Data from TRMM-PR is three dimensionally distributed rainfall data having good spatial resolution (horizontally 4.3km grid, vertically 250m grid). However, the temporal resolution of TRMM-PR is coarse (about twice a day). Therefore, it is necessary to interpolate the TRMM-PR data temporally by using the numerical weather forecasting model. The method of reproduction of distributed rainfall intensity data is summarized in the following sentences: 1) to calculate the meteorological situation by using MRI-NPD NHM, 2) to compare and modify the distributed rainfall intensity of the result of calculation by using TRMM-PR data, 3) re-calculating the modified rainfall intensity data by using MRI-NPD NHM, the result has the rainfall intensity of 1hr and 20km grid.

HW07/11P/D-006 Poster 1400-142

SIMULATION OF HISTORICAL RAINFALL OVER INDOCHINA PENINSULA

Hiroshi OKUMURA, Taichi TEBAKARI, Tianqi AO, Junichi YOSHITANI (Public Works Research Institute)

An opportunity for PUB (Prediction in Ungauged Basins) exists in the assessment of causes of flood risk increase over the South-East Asia such as the lower Mekong river. The lower Mekong experienced massive deaths and serious damages by six floods in 1991, 1994, 1995, 1996, 2000 and 2001 in the last decade, while it experienced only once in 1984 in 1980's. The increased flood damage may be caused by increased frequency of floods due to climate variation, landuse/landcover change, or artificial control of water, or by other human activities such as urbanization. Scientific assessment of causes of increased flood damage is the basic knowledge for decision-making, but poor data has prevented assessment. PUB will be the breakthrough technology for providing the knowledge base. PUB comprises rainfall prediction as the first step and flow prediction as the second step. Public Works Research Institute of Japan and the University of California at Davis jointly developed a downscaling model named IRSHAM (Integrated Regional-Scale Hydrologic Atmospheric Model) to reconstruct historic rainfall over ungauged basins. Downscaling requires a sophisticated integrated hydro-meteorological model that requires no parameter fitting, and it is one of the key technologies in PUB (IAHS PUB initiative web site). The downscaling approach has the advantages of (1) the applicability to any basins in the world, because all necessary input data can be obtained from world available database, (2) the availability of reanalysis data; and (3) the applicability to completely-ungauged basins, while remote sensing always requires a few ground rainfall data. This reconstruction technology is now being applied to reconstruct rainfall over the South-East Asia and to scientifically assess frequent-occurring flooding in the past years. In this research, the authors carried out a numerical simulation to reconstruct historical rainfall over the South-East Asia on the 0.1-degree mesh. In this simulation, a non-hydrostatic numerical model has been improved and developed based on IRSHAM. From the standpoint of numerical simulation, a highly accurate non-hydrostatic numerical model is required in the reconstruction technology at the scale of 0.1-degree (mesoscale). To verify the simulated rainfall data, ground-based observed rainfall at about 800 points in the ChaoPhraya river basin (162,800km2) of Thailand will be used.

HW07/11P/D-007 Poster 1400-143

HYDROLOGICAL ASPECTS OF THE RAINFALL VARIABILITY OVER KENYA: TREND AND PERIODICITY

Balla Paul MAGGERO (Kenya Meteorological Services)

Trends and periodicities in the seasonal rainfall of highlands and coastal climatic units are studied using 80 years database from a network of 25 stations. Standardized regional mean seasonal rainfall is determined in order to derive mean normalized anormaly index for each of the rain season eventually. Slight increasing tendencies are observed for the whole country during the long rains and over the Kenya high grounds areas during short rains. Slight decreasing tendencies are seen during the short rains in the whole region and the coastal. The Kenya high grounds and the coastal do not show any significant Trend. A general and statistically spectra can be seen. Peaks with a wavelength of about 3 to 4 years are prevalent in the Kenya series, Kenya high grounds and the coastal; this implicates a moderate variance. Peaks of about 4.5 to 5 periodicities are also conclusive, and they match the ElNino/Southern Oscillation (ENSO) phenomena. Both solar and the QBO are not exhibited from the analysis.

HW07/11P/D-008 Poster 1400-144

PUB AS HYDROLOGICAL PARADIGM, FOOD SECURITY AND POVERTY REDUCTION IN HIMALAYAN RIVER BASINS

R.B. SINGH (Department of Geography, University of Delhi)

The Prediction in Ungauged basins (PUB) has emerged as important hydrological paradigms. The monitoring and prediction of ungauged basins open up vast possibilities in order to achieve food security and poverty reduction in India. Geographers can, and should make a variety of contributions to the important international hydrological project form both natural science and socio-economic perspectives. The study of ungauged basin is very appropriate for India due to severe paucity of hydrological data e.g., quality, quantity, stream-flow, sediments, snow-melt, pollution, etc, through space and time. A good number of medium and minor river basins are still ungauged. Whereas, the major ones are poorly gauged with respect to one or the other hydrological variables. Considering above issues, the following two types of river basins are important: 1. Poorly Gauged Basins: Many of the major river basins and a few medium river basins which have flood-data but lacks adequate data about other hydrological variables. These include mostly peninsular river of India. 2. Ungauged Basins: Most of the Himalayan rivers and rivers of North-East comes under this category. Besides minor river basins, a good number of medium river basins are also ungauged basins. To coordinate the comparative PUB study, detailed case studies at different settings provide the bases of understanding environmental changes in the ungauged basins of the Himalayan India. Emphasis has been done not only on recent data, but also on historical materials. Technical issues related to remote sensing data, such as classification and scale are also considered to be important. The basins of India, specially ungauged ones are facing a multitude of hydrological challenges including: 1) reliability of water supply (quantity) i.e., seasonality of river basins, 2) water quality i.e., concentrations of contaminants; nutrients, heavy metals, etc.; 3) space-time variability of the hydrological variables 4) problems of extreme events such flood and drought, etc., 5) differences in the attributes e.g., soil, vegetation, topography, climate, demography, etc., 6) lack of information infrastructure both in quality and quantity e.g., remote sensing, GIS, ground observation and gauging network, etc. The hydrologic response to be predicted depends on the nature of the problems including prediction of floods of a given return period, extent and frequency of floods, mean annual water yield reliability of water supply, crop fields, irrigation scheduling and water quality (concentrations of contaminants; nutrents, heavy metals). In general, the predicted hydrologic response can be a continuous time series of the quantity and quality of interest (e.g., storm hydrograph) or statistical measures of its variability in space or time (e.g., mean, variance, annual total), including extremes (e.g., annual maximum floods, droughts etc.). Thus PUB must take into consideration the identification and measurements of hydrological data/information in spatiotemporal variability of a Indo-Ganga Brahmputra basins which are densely populated agricultural regions of India. Finally, the paper highlights water as driving force for food security and poverty alleviation in India.

HW07/11P/D-009 Poster 1400-145

PROBLEMS OF UNGAUGED BASINS IN PAKISTAN(WITH REFERENCE TO HYDROLOGIC STUDIES)

Syed Muhammad Saeed SHAH[1], Hazael Firoton GABRIEL[1], Iftikhar AHMAD[2] ([1]Centre of Excellence in Water Resources Engineering, University of Engg. & Tech., Lahore, Pakistan, [2]Department of Mining & Geology, University of Engg. & Tech., Lahore, Pakistan)

Why this presentation? Although the problems of ungauged basins with reference to different hydrologic studies are worldwide, but the specific problems of a developing country like Pakistan, where most of the basins are ungauged, rarely highlighted in detail in any international forum. Due to socio-economic and political reasons the problems of developing countries are much more than developed countries therefore this kick-off workshop on PUBs is the right forum to listen and discuss the real life problems based on the experience of different hydrologic studies from the hydrologists of a developing country.**Problem** Most of the techniques developed for ungauged basins, based on data from the watershed of developed countries, are not applicable in true sense even after certain modifications/calibrations.**Possible Reasons**- Not all but in most of the cases hydrologists of developing countries got higher education from the Universities of the developed countries therefore in most of cases their basic training is not helping much to solve the problems. - Infra-structure and required funds, for further developments, are not available to those who gained little experience on the local problems.- Research outcome (published in different journals), in most of the cases, unfortunately, is not covering and highlighting the real issues to be investigated, in detail, due to reasons.- Aliens try to give solutions to the problems, in most of the cases, within their own point of views.**Issues to discuss** In this presentation, because of time limitation, selected problems would be highlighted under the following topics:- Flood estimation for ungauged watersheds- Rational Method• discussion regarding Runoff Coefficient (C)- Empirical Method• discussion regarding Regression formulae and Envelope Curves- Application of Regional - Frequency Curves to ungauged basins - discussion about transposition of floods- Typical problems associated with- SCS Method- Multiple Regression- Physically based Catchment Models

HW07/11P/D-010 Poster 1400-146

THE PROBLEM OF UNGAUGED CATCHMENTS IN THE SUBHUMID TROPICS OF WEST AFRICA (BENIN)

Helge BORMANN, Bernd DIEKKRUEGER (Department of Geography, University of Bonn)

While predicting the hydrological behaviour of regional scale ungauged catchments in the future one is faced with diverse uncertainties. In addition to often non existing river gauge data one has to get by with coarse spatial data sets, sparse rainfall and climatic data and uncertain predictions of the expected future environmental changes. Before tackling the ungauged catchment problem, the standard data availability of ungauged catchments has to be defined: discharge data, climate and rainfall data and spatial data concerning soils, geology, and land use. Normally the data availability is dependent on the given scale as well as on the region. In the worst case one has to use globally available data sets (FAO soil map 1:5.000.000, USGS global ecosystems / Corine land cover data set for Europe, global digital elevation model of the USGS, HYDRO1k dataset; climate data from national services and remote sensing). Based on these data sets model predictions of many existing model approaches fail. Especially physically based models cannot be parameterised sufficiently. As calibration is precluded only those conceptual, but process based models remain applicable which represent the dominant water fluxes and consider the controlling land surface properties. As the predictive tools contributing to the PUB initiative focus on the support of management operations, the question has to be posed, at which scale which hydrological components or resources have to be managed and whether the proposed methods account to these resources. In this context also the usefulness of hydrographs for investigations concerning water and land use management has to be discussed. As the ratio of runoff to rainfall is small in subhumid to semiarid regions (smaller than 0.15), runoff and discharge have only a limited significance with regard to water management purposes (in arid regions almost no significance except for erosion processes). Groundwater resources for instance are much more significant. Because the reproduction of hydrographs is not important in such areas, the focus should be set on the optimisation of the internal model validity, especially for the use of models during scenario studies. Therefore an improved understanding of interactions between hydrological processes and catchment properties is required, which has to be translated into existing or new modelling approaches (Sivapalan, 2002). The uncertainties incorporated in this model application and validation process of course have to be accepted (Sivapalan, 2002), but also quantified. With regard to internal model validity the lack of gauges is only is only one of the numerous problems. In the presentation the questions describe before concerning ungauged catchments are discussed considering the background of water management issues in Benin (West Africa). The presentation focuses on the interactions between data availability, model restrictions and expected environmental changes with the objective of making realistic predictions of future water fluxes in ungauged catchments with regard to management options.

HW07/11P/D-011 Poster 1400-147

ON THE SCIENCE FOR SUSTAINABLE DEVELOPMENT AND MANAGEMENT OF WATER RESOURCES IN UNGUAGED WATERSHEDS

Constantine C. MBAJIORGU (Department of Agricultural Engineering, University of Nigeria)

Access to water and improvement of water management have been directly linked to poverty eradication, biodiversity, public health, agricultural productivity, and environmental and world gender issues. Water is the essential and critical element, which ties together all these areas of sustainable development. Hydrologic science provides the analytical tools for water management, tools that shape and are used to evaluate management practices. Earlier, a shift in water management practice occurred with the development of Watershed Hydrology, when whole-of-the-catchment approaches replaced field and farm level understanding of hydrologic phenomena, and the watershed became a basic unit for water management. Now a new shift is imminent, as the paradigm of sustainable water management recognizes that the primary resource is the natural endowment of climate, geology and ecosystem processes in a given region. To determine the quantity, quality, timing and spatial distribution of the readily available water in a region, new methods of integrating the physical and climatic factors governing hydrologic processes with biotic processes over varied spatial and temporal scales are required. How can the unique composition of plants and animals in a given region, and its effect in retaining/utilizing water and nutrients, as well as the impacts of human activities, be integrated with climatic factors along with the physics and chemistry of hydrologic processes in order to determine the flow and distribution of water, sediments and nutrients across the landscape? The science providing an answer to this question will eliminate, to a large extent, the need for much of the gauged data required in calibration and validation of hydrologic models. Factors such as the effect of biotic communities on hydraulic processes and on water quality, e.g. moderation of nutrient loads and flood peaks, will need to be reflected in predictive models.

WAYS TO USE THE DISCIPLINE OF COMMUNICATION TO MAKE A GREATER CONTRIBUTION TO THE PACE OF PUB

Natalia V. PENKOVA[1], Anna KURTYCH[2], Michael NARODOSLAWSKY[3], Reva S. PETROVA[4]

([1]State Hydrological Institute, Saint-Petersburg, Russian Federation, [2]Paris University (XIII), Paris, France, [3]Graz University of Technology, Graz, Austria, [4]Institute for Ecology of Natural Systems, Tatarstan Republic, Russian Federation)

An evolution of communications methodology began in the first quarter of the 20th century with the use of publicity tools to bring attention to social problems. It grew to a reliance on public relations, more recently, development and strategic communications took center stage. Several networks of professionals (social activists, academics, journalists, electronic communications experts, professional communicators, etc.), who test innovative communication concepts, committed to a new agenda for global communication that is empowering, horizontal versus top-down, gives voice to previously unheard, and has a bias toward local content and ownership. Modern communication programming has tended to fulfill three roles: to inform and persuade people to adopt certain beneficial practices; to enhance image and profile of the work of organizations involved in development; to enable community consultation over specific initiatives. All these roles are important within water development domain and are essential for PUB targets, but work on communication methodology in the field remains underfunded and undervalued. The "communication" is being understood as it was originally defined: as exchange of information. A general idea is being exploited that mass media play strategic role in promoting the process. However, researches show that mass media are not efficient, they may be considered both as an actor (with its owns interests) and as tool for actors in public, political, scientific and economical spheres with which they interact. Mass media efforts would be complemented by other types of communication and aducation strategies in order to be reflected in resolving of water-related tasks. New fundamental advances in PUB are possible on the basis of research about particular communication dynamics around water in particular geographical settings under widening the concept for all exchange processes (exchange of matter, energy, information, culture, persons and/or capital) between different process units. The transfer of site-based knowledge (both scientific and indigenous) about past and present natural-climatic and man-induced hydrological and ecological regimes should attract main attention, especially in developing nations with scarce human and financial resources. So, a PUB science programme should include topic on interdisciplinary studies aimed at linking hydrological methodologies with those under development in Social science and Economics (theory of communication, concept of environmental responsibility, the "nature-friend" principle, eco-economy, etc.), in Ecology (concept of ecologically destabilized environment, reductionists approaches in Plant science, etc.), in Physical geography (Landscape science), and others. The "language" should be the main subject of concern: the notion of how to explain hydrological phenomena in terms that can be readily accessible and used by other professionals and general public as easily as by hydrologists. In the contribution, some innovative ways to change hydrologic research and observations methodology are sited, that may be considered as "starting points", with examples on different regions in Austria, Mexico, and Russia.

GEOMORPHOLOGIC APPROACH TO HYDROGRAPH PREDICTION IN UNGAGED BASINS

Praveen KUMAR, Kyungrock PAIK (Department of Civil and Environmental Engineering, University of Illinois)

The direct runoff hydrograph of a basin is a result of complex interaction between precipitation and runoff generation processes, and hillslope and channel dynamics. Both network and hydraulic geometry interact to shape the runoff process at the shorter time scales, while the runoff variability shapes the hydraulic geometry at the longer time scale.Evidence for the latter is provided by the widely observed fact that the bankfull channel geometry corresponds to a flow with a typical return period of one to two years.Flow transport equations with various degrees of approximation have been combined with the systematic organization of the planar network geometry, as characterized through the Horton´s ratios, width function and self-similar trees.Recent work by Saco and Kumar [2002] has shown that the spatial variability of flow velocities, arising from the systematic downstream variations of hydrologic geometry, within a basin induce a dispersive effect that impacts the residence time of water and consequently the time to peak and peak flow of a hydrograph.They characterized this phenomenon as kinematic-geomorphologic dispersion to signify that it arises due to the interplay of the celerity variation arising from the variation of the hydraulic geometry and the stream network.This dispersion is the predominant mechanism, along with hillslope controls in determining the peak time and peak flow in a basin and is prevalent at all scales from very small to large basin sizes.Theoretical formulations that combine channel flow dynamics with the network and hydraulic geometry open up the possibility of addressing the long standing problem of ˝prediction in ungaged basins˝ for hydrograph prediction by taking advantage of the signatures of the streamflow variability as evidenced through the existing characteristics of planar network topology and (bankfull) hydraulic geometry.The network characteristics are relatively easy to extract using digital elevation model (DEM) data that are becoming widely available at high resolutions. However, the hydraulic geometry relations are not available as easily and they correspond only to the bankfull flow conditions when available.However, significant work has been done in the past to develop prediction equations for the hydraulic geometry. These include statistical estimates using data samples as well as theoretically predicted equations using hypotheses such as minimum entropy production, minimum variance, maximum transporting capacity, minimum stream power per unit channel length and minimum energy expenditure among others.These relationships are available for both at-a-station (i.e., variation at a specific location for different flows) and downstream (i.e., variation along the stream for flow with a specified return period) hydraulic geometry variations. We discuss how these can be used for hydrograph prediction in ungaged basins. Saco, P. M., P. Kumar, Kinematic Dispersion in Stream Networks, Part 1: Coupling Hydraulic and Network Geometry, Water Resources Research, 38(11), 1244, doi:10.1029/2001WR000695, 2002.

STUDY ON A SYNTHETIC SEDIMENT ROUTING MODEL IN A WHOLE RIVER SYSTEM

Kengo SUNADA[1], Katsuhiko KOMATSU[2] ([1]Department of Civil and Environmental Engineering, University of Yamanashi, [2]Engineering Section, Kokusai Kogyo Consultant Co., Ltd.)

It is needed to evaluate the complicated situations of water and material circulation in a basin for getting an appropriate way of better river basin management. In this study, in order to estimate the amount of sediment transport in a whole river system having poor information about sedimentation, a synthetic sediment routing model based on the river channel networks obtained from the digital elevation models is proposed. Authors have already developed an original basic sediment routing model which can take spatially distributed topographical feature of a basin into account, and it can also consider hydrological and geological response to strong storms in the basin system. Assumptions and procedures of the basic model are as follows. a) The digital terrain map is used for expressing basin topography. b) The steepest descent method is applied to tracing pseudo channel network. c) Width of channel element is calculated by an empirical equation. d) Significant riverbed variation is caused only if rainfall is stronger than 100mm a day. e) Runoff discharge at each channel element is estimated by the runoff function method with the heavy rainfall sequence.

f) Non-dimensional shear stress is computed using quasi uniform flow depth for the discharge at each time step. g) Sediment supply par unit area at each grid point is estimated by using another empirical equation. First, the basic model was examined from the viewpoints of model performance such as computational time interval, tuning hydraulic parameters, effects of computational mesh scale on the results of simulation of riverbed variation, channel network made from DEM and so on. Then in this study, further analysis regarding scale effects of pseudo stream channel element, distribution of sediment production area and channel width were carried out. Next, the model was applied to a couple of river basins, the Haya river (area: 509.1km^2, tributary of the Fuji river) and the Abe river (area: 518 km^2) both in the central Japan. The both river basins are producing large amount of sediment production because of the fragile rock due to the great geological default line through the basins. Through the applications using two kinds of scale of channel network element and the different catchments conditions, effects of these elements on the simulation of riverbed variation were discussed. The results of the simulations of riverbed variations in the two kinds of scale, 250m and 500m meshes, shows roughly same behavior except upper part of the basins. Last, the model was also applied to the larger river basin, the Fuji River basin (3,571km^2) by using a new method of automatically tracing of channel networks. Results showed fairly good agreement between the calculated riverbed elevation and the observed one in the Fuji River. It is concluded that the model has possibility of practical application.

MULTIFRACTAL,DAM MANAGEMENT AND PREDICTION IN UNGAUGED BASINS

Angelbert Chabi BIAOU[1], Pierre HUBERT[1], Daniel SCHERTZER[2], Frederic HENDRICKX[3], Ioulia TCHIGUIRINSKAIA[4] ([1]CIG. Ecole des Mines de Paris, [2]Meteo France; LMM, Universite Paris VI, [3]EDF R&D, LNHE Chatou, [4]LGA, Universite Paris VI)

In order to get a more efficient production management of reservoirs, it would be helpful to apply long-term meteorological forecasts to hydrological models. Unfortunately, the explicit scales of present meteorological models are quite larger than those of hydrological models. Therefore it is indispensable to proceed to a downscaling of the output of the former in order to obtain an input for the latter. In this paper, we discuss a multifractal downscaling procedure. The site of the study is the area of Doubs basin, with the help of a dense local hydrological network, but in order to get a larger spatial scale ratio we extend our multifractal analysis to France, with the help of Météo-France PRECIP data base. We first argue that it is indispensable to consider a multifractal downscaling procedure in order to respect the scaling properties of the hydro-meteorological fields. We performed time, scale and time-space multifractal analysis of the available data and evaluate the corresponding universal exponents, as well as the dynamical exponent of the time-space generalized scale. We show that these exponents are quite robust and allow to perform space-time downscaling down to micro-scale of meso-scale data. We greatly acknowledge the financial support from Electricité de France, as well as Météo-France for providing access to its PRECIP data base.

NEW SYSTEM OF HYDROLOGICAL COMPUTATIONS FOR UNGAUGED BASINS IN RUSSIA

Vladimir Alexeevich LOBANOV, H.V. LOBANOVA, A.V. ROZHDESTVENSKY (IAHS member, Leading Scientist)

Hydrological computations for ungauged basins include two vectors of prediction: temporal (probabilistic limit for period of future operation of water project) and spatial (data interpolation or extrapolation on ungauged area). Problem of ungauged basins is the most actual for Russia reasons by its large area, rare hydrological network (in northern and eastern parts especially), which is reduced today. Therefore the large attention was given traditionally for a development of effective regional methods of hydrological computations for different climate conditions. In Russia two levels system of official documents for hydrological computations are developing in present time. The first level includes the federal guidebooks, such as Building Norms and Rules and Code of Rules, which consist of main general methods and their description. The documents of the second level is Territorial Building Norms (TBN), which will be developed for each region with the particular methods, databases and software for a realisation of new water projects and monitoring of the existing ones. TBN is represented in two forms: methodological (as a document) and computational (as regional GIS). General methodology of development of the models for ungauged basins includes two main steps: - determination of design hydrological characteristics in the site of observations (including restoration of long-term time series, assessment of homogeneity and stationarity, design values and their errors, etc); - transition from the information in observation sites to any ungauged basin on the basis of different kinds of models. System of methods and models has been used and developed, including deterministic and stochastic space models, regionalisation, analogues. New principle is suggested for generalisation of the results obtained by different models and field data. Assessment of impact of modern changing conditions (man's activity, climate change) on design hydrological characteristics in ungauged basins is discussed. The technological scheme of environmental GIS for regional hydrological computations is presented. Some examples of computations for ungauged basins are given in case study of different models and regions over the Russian area. Suggestions for the joint international programme of collaboration in frame of the PUB project have been developed and given for discussion, which include: - methodology, ways and approaches for transition from point to area (development of the general model); - different methods for temporal modelling in changing conditions; - main indexes of spatial classifications in modern changing conditions; - different methods of spatial generalisation and modelling in homogeneous regions; - methods for assessment of results and their generalisation.

RIVER-LIKE GROUNDWATER FLOW PATTERNSAT THE JUDEA DESERT, THE DEAD SEA RIFT

Haim GVIRTZMAN, Leehee LARONNE (Inst. of Earth Sciences, Hebrew University of Jerusalem)

The groundwater hydraulic gradient at the Eastern Judea Mountain aquifer(adjacent to the Dead Sea Rift Valley) is very steep, from approximately 400 m above sea level in the Jerusalem-Hebron area to 400 m below sea level near the Dead Sea, along a distance of about 30 km. A simple west to east flow direction would have caused a continuous groundwater leakage from the exposed aquifer along the base of the cliffs near the shore. However, such a leakage does not occur. The annual recharge of approximately 85 million cubic meters emerges through three large springs: Fescha, Kane and Samar, all located in the northern part of the Dead Sea. The scarcity of data atthis region makes it very difficult to understand the subsurface flow field. Previous attempts to explain the flow field both conceptually and numerically using 2D flow simulations, have left unanswered questions. We claim that the geologic structural characteristics of the area plays a major role in the subsurface flow regime. Groundwater flows along the syncline axes towards the northeast, exhibiting a subsurface river-like flow pattern. Based on this conceptual model, we have

constructed a 3D hydrogeological model, for both the upper and lower sub-aquifers, using theMODFLOW code above the GMS platform. The model was calibrated using the few available boreholes. Thereby, we have quantified the water mass balance,including recahrge amounts, leakages between sub-aquifers and between basins,as well as spring discharges and subsurface leakages towards the Deas Sea.Better understanding of the groundwater flow field would benefit both, Israeli and Palestinian water supply. Planning of better groundwater pumping schemes would now be possible.

HYDROLOGICAL FORECASTING USING DISTRIBUTED MODELS IN THE GREAT LAKES BASIN

Alain Claude PIETRONIRO[1], Herman GOERTZ[2], Paul PILON[2], Harold RITCHIE[3], Pierre PELLERIN[3], Paul CAMPBELL[2], Nick KOUWEN[4], Paul FORD[2] ([1]National Water Research Institute, [2]Meteorological Service of Canada - Ontario Region, [3]Meteorological Service of Canada, [4]Department of Civil Engineering, Uniiversity of Waterloo)

Hydrological models are integral components of water management and monitoring strategies. In particular, distributed hydrological models allow for detailed description of the hydrological and energy cycle and provide opportunities for dealing with forcing variables that fluctuate strongly in space and time, such as precipitation. Hydrologists and water resources specialists increasingly implement these models as a means to ameliorate the state of knowledge on basins of interest, and provide valuable information regarding hydrological state variables and potentially important distributed information on existing and future streamflow conditions.. Also, there is increasing interest in using spatially distributed meteorological data from diverse sources such as weather radar, Numerical Weather Prediction (NWP) models and traditional rain gauge networks to drive these distributed models. This paper examines the feasibility of implementing a distributed hydrological model for estimating streamflow in unregulated basins and the accuracy of short-term hydrological-forecasting in the Great Lakes Basin of North America. The platform for hydrologic assessment in the Great Lakes Basin is the WATFLOOD hydrological forecasting system. The focus of this study is to provide initial testing of the hydrological model including calibration and validation of the model parameters using historic data. The meteorological forcing data sets include distributed Quantitative Precipitation Estimates (QPE) derived from rain gauge and ground-based radar data. NWP model input from the Canadian Global Environmental Multi-scale (GEM) model and nested high-resolution GEM runs during our initial testing phase (summer of the year 2000) for limited time periods of extreme precipitation also are used as forcing. Initial results to assess the applicability of distributed hydrological modeling and to provide the framework for testing the hydrological aspects of integrated hydrological and atmospheric models, are presented.   Routing and regulation considerations including stream network conceptualization and lake routing are also discussed.

INVESTIGATING PEAK DISCHARGE FLOOD HYDROGRAPHS IN SELECTED UNGAUGED BASINS OF BALOCHISTAN (PAKISTAN)

Syed Muhammad Saeed SHAH[1], Hazael Firoton GABRIEL[1], Iftikhar AHMAD[3] ([1]Centre of Excellence in Water Resources Engineering, University of Engg. & Tech.,, [2]Centre of Excellence in Water Resources Engineering, University of Engg. & Tech., Lahore, Pakistan, [3]Department of Mining & Geology, University of Engg. & Tech., Lahore, Pakistan)

Balochistan is the biggest province of Pakistan in terms of its area. It lies in arid to semi-arid region where the rainfall is scanty. Due to little rainfall, most of its streams remain dry and flows only for a short period when the rainfall occurs. Due to high intensity of rainfall, these streams carry flash floods. Water is scarce in Balochistan and therefore these flash short duration floods are precious resource for the inhabitants and should be exploited through diversion structures or storage dams. Peak discharge flood hydrographs are required to design these structures.Due to lack of funds in developing countries like Pakistan, most of these streams are ungauged. But rainfall data and physical parameters/G.T sheets are available. Considering the limitations of hydrologic data availability in ungauged basins a technique is investigated that may be useful to derive peak flood hydrographs in ungauged basins. The procedure starts from evaluating quality of data, estimating the frequency of rainfall, volume of runoff and peak discharge flood hydrograph. The methods employed in the proposed procedure have four main components: outliers and consistency testing program, an autoregressive model, a statistical distribution analysis and a runoff computation program. To test the usefulness of the proposed procedure, it is used to estimate peak discharge rates in selected 18 ungauged basins of Balochistan. For the test cases, there is an indication that the proposed procedure is effective. The results obtained from proposed procedure is then used to investigate a simple equation that may be used to determine peak discharge rates in Balochistan basins with the help of easy to estimate physical parameters.One of the purpose to present this study is to explain the main difficulties to adopt the proposed procedure regarding the calibration of Rainfall Runoff computation program that was based on US Soil Conservation Services (US SCS) Curve Number method.

DESIGN FLOOD CALCULATION FOR UNGAGED SMALL BASINS IN CHINA

Yuanfang CHEN[1], Guoxing CHEN[1], Zengchuan DONG[1], Shenghua GU[2] ([1]Department of Hydrology and Water Resources, Hohai University, [2]SHANGHAI GENERAL HYDROLOGICAL STATION)

The two main methods to calculate the design flood in ungaged watershed are introduced in this paper. Concerning the rational method which is widely used in China, its design storm formula form and parameter estimation method, its derivation process of design peak flood Qmp rational formulae ,and a case study in Jiangxi Province are introduced in details. Concerning the second method –the empirical formula method, a brief introduction is made. Some comments are also done in the final part of this paper.Keywords: Design flood calculation, ungaged basin, rational formula, empirical formula method, case study.

EFFECTS OF SPATIAL VARIETY IN INSTANTANEOUS UNIT HYDROGRAPH TYPES FROM FIRST-ORDER BASIN ON FLOOD PEAK IN SELF-SIMILAR RIVER NETWORKS

Yosuke KOMATSU[1], Yasuhisa KUZUHA[2], Tokuo KISHII[2], Kunio TOMOSUGI[3] ([1]Disaster Prevention Research Group, National Research Institute for Earth Science and Disaster Prevention, [2]DPRG, National Research Institute for Earth Science and Disaster Prevention, and the Cooperative Graduate School, University of Tsukuba, [3]DPRI, Kyoto University)

Many hydrographs in first-order basins have been observed in the field catchments, although the physical and hydrological processes have not been completely revealed because many natural factors are involved in the complexity of water movements: soil, landform, lithology,

---

vegetation, and climate. Therefore, in this study, scaling exponents of flood peak generated on idealized self-similar networks are simulated using an experiential simplified instantaneous unit hydrograph from a unit-basin (IUHU), excepting physical processes on hillslopes from consideration. In addition, since Komatsu and Onda (1996) reported high spatial variability of discharge in a basin underlain by fractured rocks, we investigate the effects of distribution and combination of multiple IUHUs on scaling exponents of flood peak. The hydrologic response of a drainage network to impulsive net precipitation may be considered the function of travel time to the outlet of water distributed uniformly in space. This study applied a self-similar and deterministic Peano network, which has a ternary tree structure and is applied in many reports on flood analysis. A Peano network basin is divided into small similar unit basins. IUHUs are defined as various simplified rectangular hydrographs whose runoff ratio is 1, and the water reaches the basin outlet via the channel networks. We further assume that the relative velocity through the channel is constant and no water is stored in the network. A geometrical consideration of the peak flow properties via the width function maxima leads to a scaling exponent value of 0.7925. Width function is defined as the total number of channel links at a distance x from the outlet. The first experiment is simulated using only single rectangular IUHU. This assumption led to two regression lines between catchment area and peak flow, the scaling exponents were 1 and 0.7925AD The latter value is governed by the geometric structure of a Peano network. The larger relative flow velocity through a channel: Vc, and longer duration of IUHU: Td, make the join of two regression lines vary toward a smaller drainage areaAD The travel times of water particles and all water depend on Vc and Td, respectively. These results suggest that the effects of the two factors on peak flood are essentially synonymous with the effects of rainfall duration. The second experiment uses random distribution of two different IUHUs. Three regression lines were obtained; these scaling exponents were 1, a range from 0.7925 to 1, and 0.7925. The tendency of Vc and Td was similar to the result of the first experiment.

METHODICAL APPROACHES TO PREDICTION AND COMPUTATION OF HYDROLOGICAL CHARACTERISTICS IN UNGAGED BASINS

Tatyana FASHCHEVSKAYA[1], Boris FASHCHEVSKY[2] ([1]Department of Ecology, Ufa State Aircraft University, [2]Department of Environmental Management, International Sakharov Environmental University)

This paper considers a perennial experience of development of computation methods of the different hydrological characteristics (maximum and minimum flow, average annual flow and its distribution in months, temperature water, ice regime and etc.) on the territory of the former USSR in ungaged river basins. Over recent 70 years hydrological predictions were developed for ungaged basins on the territory of the former USSR. This approach came into being as it was impossible to cover the vast territories with measurement, yet the knowledge of designed hydrologic characteristics was prerequisite for economic development (construction of bridges, roads, railways, settlements, etc.)The basic inputs to such predictions and computations are as follows: 1. Method of hydrological analogy that implies choosing another water body with analogous physical-geographical and hydrological conditions and having a long series of observations; 2. Method of hydrological characteristics mapping on the basis of their parameter distribution following the latitude zoning on the plain and the high-altitude zoning in the mountain areas. The azonality factor is accounted for by introducing correction coefficients for fissured rocks, developed carst phenomena, etc. 3. Method of empirical formulas, in particular for maximum and minimum flows under homogenous natural conditions as based on the generalization of available observation series at separate river sections; 4. Method of maximum discharge determination on the high water marks, i. e. on the traces left upon natural and artificial objects: rocks, trees, buildings, pillars, etc. 5. Method of determination of annual and maximum flows in relation to climatic characteristics (precipitation, temperature, air humidity, height of firn line). 6. Method of remote sensing based on the simultaneous generalization of the hydrological regime characteristics and of aerial-space survey and generation of discharge-level and river-flooding relations. The report will be illustrated with different methods of forecasting and computing for various territories of Russia, Brazil and Belarus.

ENVELOPE CURVES OF FLOOD WAVE VOLUMES IN THE DANUBE RIVER BASIN IN CROATIA

Danko BIONDIC[1], Darko BARBALIC[1], Josip PETRAS[2] ([1]INSTITUTE OF WATER MANAGEMENT, CROATIAN WATERS, [2]UNIVERSITY OF ZAGREB, FACULTY OF CIVIL ENGINEERING)

The Danube River basin in Croatia comprises more than 35.000 km [2] which represents about 62 % of the country's land area, where approximately 69 % of the total population of the Republic of Croatia live (data from 2002). It is located in the Pannonian plain and its marginal areas, with the water divide separating it from the Adriatic catchment running through the Dinaric karst. A particular socio-economic significance of this area not only for the Republic of Croatia but also for a greater region requires efficient protection against flood and torrents. Gradual development of protection systems in the last four decades has significantly reduced potential damages, a fact proven by sucessful evacuation of numerous recent floods. The constructed systems are for the most part only partially completed, which leaves larger areas still at a significant risk of flooding. Further development and improvement of the flood and torrents protection system remains therefore one of the strategic tasks of Croatian water management. Basic hydrological informations for further planning and designing of flood control systems are maximum discharges, maximum volumes and maximum durations of flood waves of required return periods in adequate locations along the watercourses. Those can be estimated by applying stochastic methods for sufficiently long homogenous time series of measured data at gauged locations or by different PUB methods on locations where time series of measured data are insufficiently long or non-existent. Common hydrological practice also recognizes the use of various methods for evaluation of reliability of such calculated values. This paper presents comparison of Creager's and Francou-Rodier's envelope curves for evaluation of reliability of previously estimated flood wave volumes at subject area. Envelope curves were defined for average maximum annual volumes, for highest observed volumes, and for maximum annual volumes of the 10, 100 and 1000-year return periods over characteristic discharge thresholds ($Q_{10\%}$, $Q_{20\%}$, $Q_{30\%}$, $Q_{40\%}$ and $Q_{50\%}$). Those are calculated on the basis of approximately a hundred available sufficiently long homogenous time series of measured daily disharges on gauging stations at investigated area. This work is a continuation of the investigations focused on maximum discharges in the Danube River basin in Croatia which were presented on the PUB Kick-off Workshop in Brasilia, 20-22 November 2002.

THE STATE-OF-THE-ART IN PREDICTING BLUE NILE LOW FLOWS: A STRATEGIC IMPORTANCE FOR THE WATER RESOURCES MANAGEMENT IN SUDAN

Anil MISHRA[1], A.W. ABDELHADI[2], Takeshi HATA[1], O.E. HAMAD[3] ([1]Division of Regional Environment, Graduate School of Science and Technology, Kobe University, [2]Agricultural Research

H

Corporation, Sudan, [3]Ministry of Irrigation and Water Resources, Sudan)

The Blue Nile River originates from Lake Tana, in the Ethiopian Highlands and is one of the most important tributaries of the main Nile. The river provides a vital source of freshwater to the downstream riparian users, Sudan and Egypt. However, only a few studies in its upper basin within Ethiopia have been conducted and the information available on the climatic, hydrologic, topologic, and hydraulic characteristics of the river and the basin is incomplete. Thus the hydrologic assessment of the upper Blue Nile is dependent on downstream measurement. The Blue Nile is characterized by severe seasonality and about 70% of the runoff occurs between July and September. Peaking in August, after which the Blue Nile start to fall as rain water supply to the river begins to decline. Flow in the river rises again in March-May because of equatorial spring rains on the southern tributaries. There are two reservoirs in the Sudanese territory along the Blue Nile, Roseires and Sennar, with a combined storage capacity of 3 km[3]. The reservoirs are operated in series. Operating rules have been developed to minimize sedimentation and to optimize hydropower production in terms of water availability and irrigation demands. The problem is complex because energy demand increases during the recession time and doesn't coincide with irrigation releases. The water stored from the previous season in the two reservoirs is essential for irrigation and for hydropower generation. Thus the aim of the Sudanese authorities is to maximize irrigation, hydropower and water supply while minimizing sedimentation within the framework of Sudan's share in the 1959 River Nile water agreement between Egypt and Sudan. Since the combined capacity of the two reservoirs falls short of the total requirements the gap has to be supplemented from the natural river flow during the recession time. Several attempts have been made to forecast the Blue Nile low flows for this purpose. About two decades ago two methods were commonly used to forecast the recession flows: ´similar year´ or a recession constant linking successive 10-days flows. Recently several models, which were derived from the linear and nonlinear storage-outflow relationship, were studied and applied to forecast the recession flow of the river. Similarly an autoregressive AR (2) model was also introduced to model the recession flow using parallel linear reservoir algorithm. This paper reviews 20-year efforts made in predicting recession flows and presents a comparison of reviewed models. The development of the recession modelling has greatly simplified the methodology and improved the forecasting accuracy. The study shows that the management of water resources in Sudan can be improved by better forecasting the low flows of the Blue Nile river, which can be achieved by the use of a more accurate, simple and reliable method.

DISCHARGE PREDICTION USING COMPARISON OF CALCULATED-HISTORICAL DATA (CASE STUDY: KRAMAT MICRO-DAM, MADURA - INDONESIA)

Tri Budi PRAYOGO (Department of Water Resources Engineering University of Brawijaya)

In the arid areas of Indonesia, the role of micro-dam for water domestic and irrigation supply is very significant. Micro-dam in Indonesia is called 'embung´ is usually built in the small watershed and used to store rain water and/or river discharge. However, small watershed with very small river is usually not completed with rain gauge or hydrometric data recorder. Due to this limitation, hydrometric and hydrologic data for 'embung´ design is usually calculated using stations outside the watersheds or predicted based on the discharge history. This paper aims to describe the process of discharge prediction in the design of 'embung´ in the Kramat watershed, Madura Island, East Java, Indonesia. Discharges are modeled by using rainfall data and discharge data from the closest watershed called experimental watershed. Empirical Tank Model is used for the modeling. The adjustment for Kramat watershed discharge data is proceeded by comparing watershed characteristic data between Kramat watershed and the experimental watershed. The adjusted discharge data is furthermore compared with the daily discharge data predicted from the history discharges in the river. This history discharge data is predicted based on the descriptions from the people living near the watershed or based on the morphology exposure of the river. The adjusted discharge data is considered valid if it is not exceeded the historical discharge data.

HW07/11P/D-026	Poster	1400-162

AN EMPIRICAL EQUATION FOR UNGAGED BASINS TO FIND THE MAXIMUME RUNOFF DISCHARGE

Abdulghani A. HASAN, Anas M. RASHEED (Saddam Research Center for Dams and Water Resources, University of Mosul)

In this paper a numerical modeling technique using (finite elements) have been used to calculate the maximum runoff discharge for three ungaged basins, northern Iraq. All data results that produced from a very big number of rainfall depths have been used tom find an empirical equations for these basins. Depending on basins characteristics and curve number the model calculations and discharge prediction has been achieved. This equation could be used in the future to calculate the maximum discharge produced from any rainfall depth that occur in those basins and maybe we can check its validity for other basins northern Iraq.

HW07/11P/D-027	Poster	1400-163

APPLICATION WATERSHED MODELLING SYSTEM IN PREDICTING FLOWING SEDIMENT HYDROGRAPH , NORTH IRAQ

Thair Mahmood AL-TAIEE[1], Anas Mahmood RASHID[2] ([1]Head of Water Resources Department in Saddam Research Center for Dams and Water Resources, [2]Water Resources Department, Saddam Research Center, Mosul University)

The watershed area of Fayda and Al-Baqaq wadies were selected as a case study in the eastern area of Saddam lake North Iraq to estimate the average sediment yield resulted from the surface erosion processes during rainfall and also to predict a standard unit sediment hydrograph flowing in those wadies. The research work introduce computer topographical and morphological simulation using Watershed Modeling System feeding this model with a hydrological and physiographical data concerning the case study area. Such model is defined as a simple compound system in which its behavior is represented by number of equations contribute with logical aspects and relations between the variables to predict the required results. The simulation process in the model is considered an alternative tool than carrying out comprehensive continuous field studies and experiments which is often be costly and difficult to use.An aspectable model for the case study area is used. This process is one of the essential steps in the whole modeling processes. The aspectable model is a simple representation for the study site throughout prediction of the watershed border and the surface runoff movement over the basin , in addition to the topography of soil type. Number of assumptions and simplifications to get this model where depended. A common world depended approaches were used to predict the sediment yield in the drainage basin. This is a useful tool for the evaluation of the future influences of the flowing sediments in those wadies on Saddam lake and may aid in the suggestion of many treatments to eliminate eroded sediment quantities from the drainage basin. Empirical relations to estimate runoff coefficient and peak discharges in addition to sediment yield related with peak discharges only were predicted. A non dimensional sediment hydrograph was

predicted to calculate the sediment curve for any rainfall storm on those wadies. Recommendation concerning performing field sediment transport measurement at the outlet of these wadies were suggested.

INTRODUCTION OF SEASONALITY INTO A UNIFYING THEORETICAL FRAMEWORK FOR WATER BALANCE PREDICTIONS IN UNGAGED BASINS

Yoshiyuki YOKOO[1], Murugesu SIVAPALAN[2] ([1]Institute of Industrial Science, University of Tokyo, [2]Centre for Water Research, University of Western Australia)

This paper addresses the role of seasonality on water balance prediction in ungaged basins and introduces a unifying theoretical framework through the use of a simple, physically based water balance model (Reggiani et al., 2000). Given measures of the basic properties of basins, such as soil type and depth, basin topography, as well as climatic features, it investigates the key roles of the climatic and landscape features on water balances. In particular, the paper focuses on the effects of seasonality of climate on the overall water balance. Precipitation and potential evaporation are assumed to vary seasonally with specified amplitudes and phase differences, mimicking realistic conditions. Results of the simulations demonstrate that the net effect of seasonality is to decrease annual evaporation and increase annual runoff, and with the largest impact occurring when seasonal variations of precipitation and potential evaporation were completely out of phase. These results confirm trends seen in observed data as well as results of previous simulation exercises. We also investigate the effects of storminess of climate, soil type and soil depth, and found that the effects of seasonality are amplified with more permeable and shallower soils, and with increased storminess. We also investigated the effects of these factors on mean monthly variation of water balance, including the magnitudes of seasonal fluctuations of both soil moisture and streamflow. These results are presented in terms of a number of dimensionless similarity indices: the climatic dryness index, a storage index, a drainability index, and a storminess index. Interpretation of the results in terms of these indices enables a more physically meaningful classification of catchments for first-order predictions in ungaged catchments. Reggiani, P., M. Sivapalan and S. M. Hassanizadeh (2000). Conservation equations governing hillslope responses: Exploring the physical basis of water balance. *Water Resources Research*, Vol. 36, No. 7, pp. 1845-1864.

MULTIVARIATE ESTIMATION OF FLOODS

Jose A. RAYNAL (Department of Civil Engineering, Universidad de las Americas, Puebla)

Flood frequency analysis has been carried out by using wide-known univariate probability distributions for the maxima. A few examples of that are: Three-parameter Log-Normal, Pearson Type III, Log-Pearson Type III, Wakeby and the Extreme Values Types I (Gumbel) and II (Frechet). The methods for estimating theparameters of such distributions vary from the old method of moments to new options like the probability weighted moments and maximum entropy methods. Multivariate extreme value models for flood and drought frequency analyses have been explored towards their application in hydrological problems. Thatis the case of the bivariate and trivariate extreme value distribution functionsfor the maxima which were explored towards their application in solving hydrological problems. The characteristics, properties and construction of themodels are quite suitable to provide a powerful tool for flood frequency analysis. The selected method of estimation of parameters is the method of maximum likelihood. From the study reported here, it has been shown the suitability of using multivariate modeling of extremes when it is needed to improve the estimation of parameters and confidence limits of design values of agauging station with short records when gauging stations with longer records are available in its neighborhood. In the paper an example of application is given to show the suitability of the model in engineering practice.

PREDICTION OF SEDIMENTGRAPH IN SMALL UNGAUGED BASINS

Kazimierz BANASIK[1], Mariusz BARSZCZ[1], Marek MADEYSKI[2], J.Kent MITCHELL[3] ([1]Dept. of Water Engineering and Environmental Recultivation, Warsaw Agricultural University, [2]Dept. of Water Engineering, Cracow Agricultural University, [3]Dept. of Agricultural Engineering, University of Illinois at Urbana-Chapmaign)

Estimates of sedimentgraphs (graphs of suspended sediment load associated with hydrographs caused by rainfall) are essential for sediment yield assesments, for providing input data for prediction models of sediment deposition in reservoirs, for designing efficient sediment control structures, and for water quality predictions. In these cases, and specially in the frequently considered non-point pollution models, in which sediment is a pollutant and a carrier for other pollutants, it is important to estimate sediment transport accurately during individual storms. The sedimentgraph model, which was developed for predicting ungauged basin response to heavy rainfall consists of two parts: a hydrological submodel and sedimentology submodel. The hydrological submodel uses the Soil Conservation Service CN method to estimate effective rainfall, and the instantaneous unit hydrograph (IUH) procedure to transform the effective rainfall into a direct runoff hydrograph. The sedimentology submodel uses a for of modified universal soil loss equation to estimate the amount of suspended sediment produced during the rainfall-runoff event, and the instantaneous unit sedimentgraph (IUSG) procedure to transform the produced sediment into a sedimentgraph. The instantaneous unit sedimentgraph (IUSG) has been developed by using the concept of instantaneous unit hydrograph (IUH) and dimensionless sediment concentration distribution (DSCD). New equation of IUSG is presented, and a procedure for estimating sediment routing coefficient, which is a key parameter of the IUSG, based on measuremed data of rainfall-runoff-suspended sediment (i.e. based on lag times), is applied. Field data from small basins of three different locations (south and centre of Poland and Central Illinois, USA), and different land management, were used to investigate lag times. The analysis of rainfall-runoff-sediment yield data from small basins shows that (i) a significant linear relationship exists between the lag time for hydrorahs LAG and lag time of the sedimentgraphs LAGs, (ii) the values of LAGs/LAG are for most cases smaller as 1.

HW07/11P/D-031	Poster	1400-167

CLIMATE AND LANDSCAPE CONTROLS ON SPATIAL (SUB-BASIN) VARIABILITY OF WATER BALANCE WITH CHANGING TIME SCALES: APPLICATION OF THE DOWNWARD APPROACH

Darren FARMER, Murugesu SIVAPALAN (Centre for Water Research, University of Western Australia)

The south-west of Western Australia has a semi-arid, Mediterranean climate with cold, wet winters and hot, dry summers. Both the climate and the landscape feature significantly in a highly heterogeneous regional hydrology. Local hydrological understanding and prediction is

hampered by irregular gauge data for rainfall and streamflow. This paper deals with the application of a ˝downward˝ or top-down approach for the systematic analysis of space-time variability of observed streamflows across the region The analysis identifies the key climatic and landscape (soils, topography and vegetation) controls on runoff variability, with a view to quantifying local runoff characteristics for varying landscapes across a region. The downward approach involves the use of conceptual (storage based) water balance models of increasing complexity with decreasing timescales (annual, monthly daily etc.) to investigate discrete signatures of streamflow variability at various timescales. Parameters extracted a priori from measurable landscape features are evaluated in order to infer local sensitivities and thus establish local landscape parameterization needs. A benefit of the approach is the ability to derive this knowledge from gauged locations removed from the area of immediate interest. The paper uses the 7,000 sq. km Murray River Basin (WA) to demonstrate how the method is used to evaluate significant east-west trends driven by climate variability, soils, topography, vegetation and land use. The systematic analysis clearly identifies local requirements for parameter variability and permits appropriate parameter sets to be determined for local ungauged catchments in order to portray variability in sub-catchment runoff generation and basin contribution.

HW07/11P/D-032 — Poster — 1400-168
WIDE UNCERTAINTY OF STEEP UNGAUGED INDUS BASIN

Shaukat A. AWAN (HYDROLOGICAL ADVISOR OF PAKISTAN WITH WMO (PAKISTAN MET DEPARTMENT))

In South-Asia since Indus basin is very widespread (970,000 KM²) with drainage basin located in (HKH) Hindu Kush Himalayan region. The upper reaches and tributaries, which are located in populated areas, have gauges site for river flows and telemetric station for precipitation reporting for effective flood forecasting. The Ungauged basin area in Indus Basin (Main) is 46410 KM² and its tributaries sub-basins Jhelum (23000 KM²), Chenab (24000 KM²), Ravi (5000 KM²) and Sutlej (13000 KM²). The hilly and inaccessible stations being ungauged a very tricky problem both for rainfall and channel runoff reporting. This problem is further compounded by the fact that upper drainage basin are located across the boarder, where the slope is of the order of 20 to 30 m/km, which often causes flash flows thus giving a time lag of only 3 to 4 hours for peak flow to buildup and enter the country over the rim station. Normally dam/reservoir authority and river regulating authority are caught unaware. Flood forecasting division has been entrusted with the responsibility to predict the flash flows for whole of the country. Knowing the equipment limitations ungauged, unmanned and inaccessible basin a methodology has been devised with some empirical/statistical relationship. The technique for gauging the ungauged basin is twofold, which is being practically implemented by this organization. One of them is the Radar-Based and the other is isohyetal analysis based. The S-band radar and C-band radar are both used. The reflectivity in dB (decibel) is calibrated with precipitation rate are mm/hr. The enormous ungauged basin of the tributaries is further sub-divided in the sub-basin areas. The precipitation rate in each sub-basin is integrated and hence an average rainfall rate is calculated and translated into runoff by keeping the previous rainfall runoff relationship. Also VIL feature (vertically integrated liquid content in Kg/m³) is used. This methodology has been of great success in the limited time period and has been actually used in the current flood season 2002. In extreme flashy and sloppy drainage basin isohyetals are also used by first locating the precipitation recording station encircling the ungauged basin area and later on give a reasonable idea of flood causing precipitation and resultant channel flow. In the recent flood season a new situation was found where in the cloud cell detected by the radar, gave no rainfall at the recording stations but gave rainfall in between the recording stations, this made the gauged basin appear as ungauged basin. Consequently the technique used for ungauged basin was applied here also with considerable success. This new technique has yet to be put in full practice to make it more effective in both gauged and ungauged basin area.

ESTIMATION OF DESIGN DISCHARGE IN UNGAGED BASINS USING GIS

Umamahesh Venkata NANDURI, Naga Malleswara RAO (Department of Civil Engineering, Regional Engineering College, Warangal)

Rainwater harvesting through indigenous methods has been the tradition in Warangal District in the State of Andhra Pradesh, India, developed and practiced by the rulers of Kakatiya Dynasty about 800 years ago. Unfortunately many of these techniques are forgotten today. Warangal District is semi-arid and drought prone. The water harvesting techniques have helped in sustaining the agriculture activity even under drought conditions. But today the district faces severe water crisis along with the problem of soil erosion in agricultural lands. The local government has taken up watershed development project in many parts of the district to tackle these two problems. The objective of this project is to revive the water harvesting techniques practiced earlier and to protect the agricultural lands from erosion. Planning and construction of water harvesting and soil and water conservation structures requires estimation of the quantity of runoff and peak discharges. Most of the watersheds where these structures are constructed are ungaged and do not have any records of runoff. During the last few years the Geographic Information System (GIS) technology has emerged as an extensively effective tool for analyzing and prioritizing natural resource management alternatives. The present paper describes the use of GIS in estimating the peak discharge from an ungaged watershed. The study is taken up in six villages of Warangal District covering an area of about 6000 hectares. The daily rainfall data of 30 years is available, which is used to develop the intensity-duration-frequency relationship. Spatial database of the study area is developed from digitized maps pertaining to topography, soils, land use and land cover, drainage system and hydrogeomorphology. The GIS created from these data is used in estimating the peak flow from the watershed. Three methods are used for estimating the peak flow. The first method is based on SCS curve number technique. In the second method a synthetic unit hydrograph is developed based on the technique developed by Central Water Commission, New Delhi. In the third method the various geomorphological parameters are estimated and these parameters are then used to construct Geomorphological Instantaneous Unit Hydrograph (GIUH). The peak runoff at different sites are computed using these three methods and they are compared.

HW07/11P/D-034 — Poster — 1400-170
REGIONALIZED REGRESSION RELATIONSHIPS FOR STREAMFLOW ESTIMATION IN UNGAGED BASINS OF COASTAL KARNATAKA, INDIA

Lakshman NANDAGIRI, Ram Mohan RAO (Department of Applied Mechanics & Hydraulics, NITK, Surathkal, India)

The need for estimating streamflow arises in situations where water resources projects are planned at ungaged locations. Although several methods have been developed for streamflow prediction in ungaged basins (PUB), practicing engineers in India still prefer to use simple regionalized rainfall-runoff relationships that were developed during the colonial era. Such equations will continue to remain popular till such time as recently installed

networks and proposed ones begin to provide hydrometeorological data at desired spatial and temporal scales for operational hydrological models to be used. Therefore, the immediate task is to improve the predictive capabilities of this approach by re-formulating such relationships considering smaller hydroclimatic regions and using more recent measurements of streamflow and rainfall.In this study, we undertook the task of developing Regionalized Regression Relationships (RRR) for the hydroclimatically homogeneous coastal districts of Dakshina Kannada and Udupi of Karnataka state, India. Our approach involved developing linear regression models between daily streamflow and basin average daily rainfall for eight gaged basins in the region using data for the period from 1970 onwards. Two linear regression models, one relating streamflow on any day to rainfall of the same day and, the second including an additional term for rainfall lagged by one day, were developed. For each basin, such relationships were derived for each month of the monsoon season (June to September) and also for the monsoon season as a whole. Fairly reasonable model performances were noted both during the calibration and validation phases. Statistically significant relationships (both linear and non-linear) were then established between the regression coefficients of these linear models and physical characteristics of the basins. Regionalized regression relationships developed in this manner were validated and found to perform well. Inspite of their simplicity, these relationships will provide reasonably accurate estimates of daily streamflow in ungaged basins in the region. As part of the IAHS Decade on Prediction in Ungaged Basins (PUB), work needs to be initiated to develop such simple prediction tools in other regions of India and also in other countries possessing sparse data networks.

HW07/11P/D-035 — Poster — 1400-171
A NEW WEIGHTED FUNCTION MOMENT METHOD BASED ON L-MOMENT FOR PEARSON-III DISTRIBUTION

Yuanfang CHEN[1], Shenghua GU[2], Zhigui SHA[3], Shengbin XU[1] ([1]Department of Hydrology and Water Resources, Hohai University, [2]SHANGHAI GENERAL HYDROLOGICAL STATION, [3]BUREAU OF HYDROLOGY ,YANGTZE RIVER COMMISSION)

The defect of a weighted function moment method for Pearson –III distribution developed by Chinese hydrologist MA Xiufeng is that the parameter of Cv is negatively biased, especially when the population parameter Cv0 is large. In order to overcome it, A new weighted function moment method is proposed ,where the parameter Cv is estimated by L-moments method . A lot of Monte-Carlo calculation shows that the new weighted function moment method based on L-moment is better than the conventional one in the bias of the quantiles and the parameter Cv ,but the effectiveness of the quantiles and the parameter Cv of above two estimation methods are almost the same. Key words: Weighted function moment method ; L-moment ; bias, effectiveness; Person-III distribution.

HW07/11P/D-036 — Poster — 1400-172
APPLICATION OF REGIONAL FLOOD FREQUENCY ANALYSIS METHOD BASED ON L-MOMENT IN THE REGION OF MIDDLE AND LOWER REACHES OF YANGTZE RIVER

Yuanfang CHEN[1], Qingrong WANG[1], Zhigui SHA[2], Jiangchi CHEN[2] ([1]Department of Hydrology and Water Resources, Hohai University, [2]BUREAU OF HYDROLOGY,YANGTZE RIVER COMMISSION)

The regional flood frequency analysis method based on L-moment proposed by Hosking in 1997 is applied to the flood frequency analysis of annual maximum flood volume for five hydrological stations ,including Yichang , Shashi et al , in the middle and lower reaches of Yangtze river. The method of Hosking is a new one for Chinese traditional regional flood frequency analysis. The calculated results shows that the five stations could be considered as in an homogeneous region for frequency analysis, so the index-flood method is used to calculated design values for each station, and the Wakeby distribution is recommended to be population grow-curve (or distribution),because the others distribution ,i.e., Pearson-III,GLO,GEV,GPA, and GLN are not accepted by Z statistics test .

HW07/11P/D-037 — Poster — 1400-173
A TENDENCY OF COEFFICIENT OF VARIATION (CV) OF ANNUAL FLOOD AND IMPROVEMENT OF EAGLESON'S CLASSIC MODEL

Yasuhisa KUZUHA[1], Yosuke Komatsu[2], Kunio TOMOSUGI[3], Tokuo KISHII[1] ([1]National Research Institute for Earth Science and Disaster Prevention, and the Cooperative Graduate School, University of Tsukuba, [2]National Research Institute for Earth Science and Disaster Prevention, [3]DPRI, Kyoto University)

Regional flood frequency analysis is a useful method of predicting flood discharge from ungauged basins. According to Gupta and co-workers [1998], flood discharge data in a snow-melt dominant region exhibit simple scaling, and those in a storm dominant region exhibit multiscaling. We confirmed this using data in Japan by moment-based and quantile-based analyses. Mean annual flood versus catchment area and CV versus catchment area for Japan exhibit the same tendency as shown by Smith [1992] and Bloschl and Sivapalan [1997]; CV increases below a critical catchment area and decreases above the critical value with area. Even if this tendency were not true (namely; there is not a critical area), decreasing tendency with area seems to be natural. However, if we calculate CV using Eagleson's classic model, CV increases with area [Kuzuha et al. 2000]. To investigate the reason for this we developed a simple precipitation-runoff model consisting of a square catchment and a channel along the diagonal. Flow velocity is assumed to be 3 (non dimension) on the slope and unity in the channel. We carried out numerical integrations and obtained mean and CV using their definitions, namely; without the assumption of Gumbel distribution, which Eagleson assumed. Note that we converted the distribution for annual exceedance series into annual maximum series. The result shows an increasing tendency for small basins and constant tendency for large basins. First, we thought that this tendency, which is not consistent with observations, results from the simplicity of the model, namely; this model doesn't include a channel network; and so we introduced the Peano network. The result indicated that the scale exponent is about unity for small basins and 0.7925 for large basins, which is a characteristic value for Peano basins, but the decreasing tendency could not be reproduced. Secondly, we assumed that rainfall intensity obeys a kind of Gamma distribution whose CV decreases with increasing area. As a result, we could reproduce the increasing-decreasing tendency of CV. According to Robinson and Sivapalan [1997], increasing CV for a small basin results from PDR (peak discharge response) function's behavior. Eagleson's classic model and our model take account of this PDR's effect. On the other hand, because the classic model assumed the exponential distribution for rainfall intensity, the model could not reproduce decreasing CV. To improve the classic model, a different type of distribution for rainfall intensity is necessary, and the simplicity of the model, (namely; not including channel network) is not the main reason for being inconsistent with observations. Bloschl and Sivapalan (1997): WRR, 2967-2980, Eagleson (1972): WRR, 878-898, Gupta and Waymire (1998): in Scale Dependence and Scale Invariance in Hydrology, Kuzuha et al. (2000):Ann. J. Hydraul. Eng., JSCE, 7-12, Robinson and Sivapalan (1997): WRR. 1045-1059, Smith (1992): WRR, 2993-2999.

HW07/11P/D-038 — Poster — 1400-174

LONG TERM WATER BALANCE PREDICTION OF POORLY GAUGED MOUNTANEOUS BASIN IN THAILAND

M. Husni IDRIS[1], Kuraji KOICHIRO[2], Kowit PUNYATRONG[3], Thada SUKHAPUNNAPHAN[4], Suzuki MASAKAZU[1] ([1]Department of Forest Science, The University of Tokyo, [2]University Forest, Graduate School of Agricultural and Life Sciences, The University of Tokyo, [3]The Royal Initiative and Security Project Division, National Park, Wildlife and Plant Conservation Department, [4]Hydrological Center 1, Royal Irrigation Department)

The long-term water balance of poorly gauged basin in mountainous area in Northern Thailand has been described. The Mae Chaem watershed with catchment area 3853 km^2 was selected as study area. The relatively dense rainfall gauges in the watershed is available for the last three years, while only few gauges are exist for long-term rainfall record. Discharge data have been continuously collected at the outlet of the whole watershed by Royal Irrigation Department (RID) Thailand. This study involved spatial rainfall distribution and long-term rainfall analyses. Spatial rainfall over whole basin were developed using 11 rain gauges of the present intensive measurement. The basin was divided into grids with about 1 km in size. Several interpolation methods (e.g. linear regression, inverse distance, Thiessen polygon and krigings) were applied to provide rainfall at all grids. Cross validation that allow the calculation of root mean square error (RMSE) was used to compare the performance of each interpolator. Long-term basin average rainfall was estimated based on (1) a relationship between rainfall at long-term observation site and rationally interpolated basin average rainfall during intensively observed period and (2) an appropriate interpolation from long-term rainfall data recorded at outside the basin. Long-term water balance were assessed from the estimated average rainfall and observed discharge. Result on spatial rainfall distribution during dense rain gauge measurement period showed that linear regression between rainfall and elevation gives simple and a good prediction for annual rainfall rate. The interpolators considering the effect of elevation (e.g. linier regression, linier regression and simple kriging and external drift kriging) have small and slightly different in RMSE. On the other hand, the interpolator, which regardless the effect of elevation (e.g. inverse distance, ordinary kriging and thiessen polygon, arithmetic mean) resulted in higher RMSE and inadequate water budget which shows too large in evaporation rate.

HW07/11P/D-039 — Poster — 1400-175

AN APPROACH FOR GROUNDWATER PROSPECTING

Sanjeev KUMAR[1], Shakeel AHMED[1], Anand JOSHI[2] ([1]I.F.C.G.R.,NATIONAL GEOPHYSICAL RESEARCH INSTITUTE,, [2]KURUKSHETRA UNIVERSITY KURUKSHETRA,INDIA)

Groundwater resources are extremely important in Rajasthan as almost the entire region lies in arid/semiarid tropics of Rajasthan especially in the hard rock areas. The recharge is less due to scanty rainfall. The study has revealed the advantages of remotely sensed data in identifying the prospects of groundwater in geologically and structurally complex terrain. Remote Sensing & Geographic Information System (GIS) is a dynamic tool for facilitating the generation and use of thematic information, has been applied to groundwater potentiality of the Upper Kali Sindh Chauli watershed in the Jhalawar district of Rajathan,India. The role of different parameters namely geology, geomorphology, structures, lineaments, slope, land use & land cover, digital elevation model, digital terrain model etc. have been emphasized for delineation of the groundwater potential zones. The groundwater potential zone map was prepared based on the visual interpretation of satellite Geocoded data of IRS-1D, LISS III, FCC and the topographic map (54D/2, 54D/3, 54D/6, and 54D/7)on 1:50,000 scales.In the study area major lineaments are identified from the satellite data interpretation, which are surface manifestation of some structural features in the bedrocks as fractures and joints. The study area is divided into mini-watershed and micro-watershed on the basis of area and stream channels. Groundwater prospects are controlled by the lineaments/joints, as the lithology is not much suitable for groundwater development. Ultimate groundwater prospecting map indicate a variable groundwater potentiality in the area i.e *good, moderate, limited,* and *poor* and based on these categorization the depth of wells for drilling are suggested.

ADVANCES IN AUTOMATIC CALIBRATION OF WATERSHED MODELS

Hoshin V. GUPTA[1], Soroosh SOROOSHIAN[1], Thorsten WAGENER[1], Jasper A. VRUGT[2] ([1]Department of Hydrology and Water Resources, The University of Arizona, [2]Institute for Biodiversity and Ecosystem Dynamics, University of Amsterdam)

There is an urgent need to develop reliable automatic methods for the identification of watershed models. The goal of such research should be to develop strategies that explicitly account for all of the following - a priori model uncertainty, input, state, structure, parameter and output uncertainties, and multiple sources and types of information, while allowing recursive processing of data as they become available, and providing quantified (perhaps probabilistic) estimates of model output uncertainty. The 'Turing Test of such a strategy would be its ability to provide reliable model performance that is indistinguishable from, or demonstrably superior to what can be obtained by an expert hydrologist. Traditional automatic methods based on techniques of non-linear regression fail in this regard. Major weakness include their underlying assumption that the model structure is correct, an inability to handle various sources of uncertainty, a dependence on a single aggregate measure of model performance, and an emphasis on identifying a unique optimal parameter set. The multiple-criteria approach offers a way forward by emulating the ability of manual-expert calibration to employ a number of complementary ways of evaluating model performance, thereby compensating for various kinds of model and data errors, and extracting greater amounts of information from the data. The outcome is a set of models that are constrained (by the data) to be structurally and functionally consistent with available qualitative and quantitative information and which simulate, in an uncertain way, the observed behavior of the watershed. Additionally, Bayesian methods allow a progressive reduction of model (and hence forecast) uncertainty through stepwise recursive (in time) processing of the input-output data as they become available. We will present the historical development of current perspectives on calibration and raise questions for further investigation.

HW08/07A/C28-002 — 0930

APPLICATIONS OF THE NEW REDUCED RANK SQUARE ROOT KALMAN FILTER TO THE PROBLEM OF PARAMETER ESTIMATION IN HYDROLOGICAL MODELS

Dimitri TREEBUSHNY (Department od Enviromental Modeling, Institute of Mathematical Machines and System Problems, NAS Ukraine)

It is known, that parameter estimation problem can be reformulated in terms of Data Assimilation approach. The augmented stochastic model is able to correct parameters of interest but becomes nonlinear in general case, even if the initial model is linear one. From the other hand, hydrological models are known to be large-scale or very large-scale ones. There are two Kalman filter based approaches able to deal with large-scale nonlinear models: Ensemble Kalman filter (EnKF, Evensen, 1994) and reduced rank square root filter (RRSQRT, Verlaan, 1995). The reduced rank square root filter is a special formulation of the Kalman filter used for Data Assimilation in large-scale models. In this formulation, the covariance matrix of the model state is expressed in a small number of modes, stored in a lower rank square root matrix. The RRSQRT algorithm includes a reduction part that reduces the number of modes if it becomes too large in order to ensure that the filter problem is feasible. In the classical implementation the problem of proper normalisation of the square-root matrix arises in the reduction step when variables of different scales are considered in the model, which is the case for parameter estimation problems. A new filter with more appropriate truncation procedure is presented. According to this approach one completely avoids normalisation problems, and, even more, the new truncation step needs much less computational time than the original procedure. The filter is applied for parameter estimation in the pollution transport model RIVTOX and verified against the Ensemble Kalman filer. RIVTOX one-dimensional model of pollutant transport based on advection-dispersion equation. The basic model´s parameters are dispersion coefficient and the coefficients of the pollutant exchange between solute and solid phases. Some synthetic experiments are conducted for the verification. It is shown that the new filter is capable to estimate the system parameters and to predict the evolution of the system with about the same accuracy that the EnKF while consuming less computational time.

HW08/07A/C28-003 — 0950

DEVELOPMENT OF A HYBRID GENETIC ALGORITHM (HGA) TRANSFER FUNCTION MODEL FOR RAINFALL-RUNOFF PARAMETER ESTIMATION

Sohrab HAJJAM (Department of Space Physics, University of Tehran)

In this paper an extensive investigation the application of genetic algorithms to the rainfall-runoff transfer function model has been presented. A new parameter estimation technique (Hybrid Genetic Algorithm) has been developed by combining conventional procedures with a genetic algorithm. The HGA has been successfully used both in identification (calibration) and simulation (updating) of the TF model. The new genetic algorithm techniques of interview and scaled procedures as well as random bit mutation and multiple crossover are included in HGA. Furthermore, both binary and real numbers encoding techniques have been used. Finally four software packages including two packages for the model identification phase both in binary and real number encoding and two packages for model updating phase have been developed. Extensive development and testing has shown that the performance of HGA is more accurate and powerful than conventional procedures and HGA guarantees that model estimation error will be less than current method because it is programmed that the RMSE of HGA to be less than RMSE of current method. **Keywords:** rainfall-runoff, genetic algorithm, transfer function, parameter estimation, simulation.

HW08/07A/C28-004 — 1010

EVALUATION OF PARAMETER CONSISTENCY IN THE TANK MODEL OPTIMIZATION

Haruya TANAKAMARU (Graduate School of Science and Technology, Kobe University)

In this study, the parameter consistency was evaluated in the Tank Model optimization. The Tank Model is a conceptual rainfall-runoff model developed by Sugawara. The model for long-term simulation consists of four tanks and has 16 parameters including 4 initial storage depths. The previous study (Tanakamaru and Burges, 1996) showed that the SCE-UA method (Duan et al., 1992) and the multi-start Powell method provided superior performance to six other algorithms of local and global search in the numerical experiments of the Tank Model optimization using synthetic data. Thus, the SCE-UA method and the multi-start Powell method were compared in the following historical data study. The root mean square error (RMSE) and the root mean square of relative error (RR) of simulated daily runoff hydrograph, which show obvious trade-off relationship, are adopted as objective functions and these objectives are minimized under the constraint of the permitted water balance error. The 131.5 km^2 Eigenji Dam basin in Japan was chosen for a study basin and hydrological data (daily mean inflow, daily precipitation and monthly evaporation) of 4 years are used for parameter calibration. At first, the performance of single-objective optimization using RMSE and RR was examined. 100 independent trials with different initial search points were run to evaluate the consistency of estimated parameters. Results showed that the SCE-UA method is obviously superior to the multi-start Powell method in the consistency of estimated parameters and the parameter consistency in the trials using RMSE were relatively higher than that using RR. Secondly, the optimization using multi-objectives of RMSE and RR was also examined. The multi-objective problem can be converted into a single-objective problem by the weighting method. The weighting method using the SCE-UA single-objective scheme was applied here for solving the multi-objective problem because the good parameter consistency of the SCE-UA method is an important advantage for estimating reasonable parameter space of Pareto solutions. In the ordinary use of the weighting method, one optimization run is required to obtain one Pareto solution (it is called the ordinary Pareto solution, here). But, in this study, 100 independent optimization trials were run for one Pareto solution and the best one which has the minimum objective function value were adopted in order to calculate strict Pareto solutions. Here, 21 strict Pareto solutions were obtained changing the weight value and these solutions were compared with the ordinary Pareto solutions to evaluate effectiveness and consistency of the optimization. Some of ordinary solutions did not satisfy the necessary conditions of non-dominated solutions due to small fluctuation in the single-objective optimization. But, in the objective space, the Pareto front of the ordinary solutions were almost same with that of the strict solutions. Therefore, the multi-objective optimization using the weighting method and the SCE-UA scheme are considered to be approximately effective and consistent.

HW08/07A/C28-005   1030

AUTOMATIC PARAMETER ESTIMATION FOR A DISTRIBUTED HYDROLOGICAL MODEL AND APPLICATION TO AN ALPINE WATERSHED

Harald G. KUNSTMANN, Jan C. KRAUSE (Institute for Meteorology and Climate Research (IMK-IFU), Karlsruhe Research Center)

Efficient parameter estimation techniques are a basic prerequisite for the successful application of distributed hydrological models to questions of sustainable water management, such as assessments on water availability, flood risk or hydrological impact analysis of regional climate change. Even in physically based hydrological models, a set of parameters generally remains that must be calibrated. Lumped parameters (like e.g. storage coefficients) even must be calibrated for each subcatchment, which can be a tremendous effort. Against this background, we combined the nonlinear parameter estimation tool PEST with the distributed hydrological model WASIM. PEST is based on the Marquardt-Levenberg method, a gradient based nonlinear parameter estimation algorithm. WASIM is a fully distributed catchment model using physically based algorithms for most of the process descriptions. WASIM solves the Richards-equation for water fluxes in the unsaturated zone and couples to a 2-dimensional groundwater model as lower boundary condition. Beside of meteorological input data it requires gridded information on soil properties, land use and topography. We applied WASIM to the alpine/prealpine catchment of the river Ammer (Southern Germany, 700 km[2]). It is characterised by physiographic heterogeneity in terms of geology, pedology and land use and shows complex orography (the difference of elevation is around 1600 m). Using the developed PEST-WASIM interface, the hydrological model was calibrated by comparison of simulated and observed runoff at eight gauges for the hydrologic year 1997. For each subcatchment four parameters had to be calibrated: the storage constants of direct runoff and interflow, the drainage density, the recession constant for decrease of saturated hydraulic conductivity with depth, and the hydraulic conductivity of the uppermost aquifer). Additionally, three snow-melt specific parameters were calibrated for the entire catchment. PEST successfully fitted the observed runoff curves and showed tremendous time saving against the default manual ″trial and error″ calibration. Additional a-priori information (e.g. from flood hydrograph analysis) narrowed the parameter-space of the solutions and improved the non-uniqueness of the fitted values.

HW08/07A/C28-006   1110

ON ESTIMATING BASIN PARAMETERS FOR OPERATIONAL HYDROLOGICAL MODELLING

Sandra G. GARCIA (Department of Thermic Engineering and Fluids, Technical University of Cartagena)

In hydrological modelling, the most limiting factor does not correspond to the ability to characterize the hydrological processes but to the methodology to determine the suitable parameters of the models. The Geographical Information Systems (GIS) present digital data analysis techniques, which greatly facilitate this task. The development and application of methodologies to achieve a priori estimates of hydrological and geomorphological parameters, is fundamental in ungaged basins. In this paper, different methodologies and automatic processing tools for raster Digital Elevation Models for the topographical parameterisation of hydrological models are presented, together with examples of their application. In hydrometeorological alert situations in the Mediterranean basins characterized by flash flood type events, decisions have to be taken in short periods of time. It is absolutely vital to be able to make use of systems which act as a support when taking decisions in real-time. This type of system should combine the latest information treatment technologies with the most efficient and precise simulation and parameterisation techniques. Currently, we are researching the exploitation of satellite information for the analysis of soil moisture spatio-temporal evolution and its influence on flash flood hydrographs. The main objective is to improve the forecast of flash floods applying a decision support tool in real-time named *Shyska*, developed with GIS-embedded functions. New spatial analysis modules oriented to estimate and treat the spatial distribution of soil moisture and the flow in the unsaturated zone, are being studied for their integration in the Shyska environment. One of the objectives of this new research project, is the development and application of methodologies that facilitate the real (or near real) time decision taking on the most suitable parameters of hydrological models oriented to flood forecasting in South-East Spain. Finally, the results of spatially distributed rainfall-runoff transformation models, where inputs partially come from a real-time flood warning system, are presented.

HW08/07A/C28-007   1130

PARAMETER ESTIMATION OF RAINFALL-RUNOFF MODELS USING THE EVOLUTION STRATEGY

Yoichi FUJIHARA[1], Haruya TANAKAMARU[1], Takeshi HATA[2], Akio TADA[2] ([1]Graduate School of Science and Technology, Kobe University, [2]Faculty of Agriculture, Kobe University)

In this study, we discuss the use of the Evolution Strategy (ES) (Schwefel, 1977, 1995), which is one of the non-linear optimization methods, for the estimation of rainfall-runoff model parameters. The algorithm of the ES is similar to the Genetic Algorithm (GA) in the respect that multipoint search and recombination used in the GA are also adopted. But, the main feature of the ES is that its principal search procedure of the ES is mutation, which is conducted by adding perturbation of normal random variable to the design variable, and the standard deviation of random variable, which is a mutation parameter, is updated by self-adaptation. First, we apply the ES to the single-objective optimization of the Tank Model, which has 16 unknown parameters including 4 initial storage depths. The Eigenji Dam Basin and the Osako Dam Basin in Japan were chosen as study basins. The data of 4 consecutive water years were used for the estimation of rainfall-runoff model parameters. The root mean square of relative error (RR) was used as an objective function. We also obtained the parameter estimates using the SCE-UA method (Duan et al., 1992). 100 runs with different initial populations were conducted for those two methods to check the consistency of optimization results. The calibration results of the ES and the SCE-UA method are compared. Results show that the search ability of the ES is equal or superior to that of the SCE-UA method in the consistency of estimated parameter values and the ES is effective in single-objective optimization of rainfall-runoff model parameters. Next, we apply the ES to the multi-objective optimization of the Tank Model parameters. The root mean square error (RMSE) and RR were used as objective functions. Before the application of the ES, we obtained the Pareto-optimal solutions using the weighting method with the SCE-UA method. For the purpose to search strict solutions, 100 optimization runs with different initial populations were conducted for one of the weight parameters and the run of minimum function value was adopted. Consequently, it was needed about 21×10^7 function evaluations to obtain 21 strict Pareto-optimal solutions. In the ES algorithm for the multi-objective optimization, we adopted the Pareto ranking suggested by Goldberg (1989) as fitness evaluation like the MOCOM-UA method (Yapo et al., 1998). In the application of the ES, when the number of function evaluations reached 10^6, the optimization run was terminated and about 200 Pareto-optimal solutions were obtained. Results show that parameter estimates by the ES are almost the same as parameter estimates by the weighting method

and a large number of Pareto-optimal solutions are obtained by relatively small amount of calculation. Therefore, the ES is considered to be also effective and efficient in multi-objective optimization of rainfall-runoff model parameters.

HW08/07A/C28-008   1150

APPORT D'UN CRITERE A PAS VARIABLE AU CALAGE DES PARAMETRES D'UN MODELE JOURNALIER A PARTIR DE DONNEES ANNUELLES

Antoine HREICHE[1], Claude BOCQUILLION[1], Wajdi NAJEM[1], Eric SERVAT[2], Alain DEZETTER[2] ([1]Ecole Superieur d'Ingenieurs de Beyrouth, Saint-Joseph University - Lebanon, [2]Institut de Recherche et de Developpement - IRD - France)

La modélisation conceptuelle des bassins versants comporte un certain nombre de paramètres identifiés généralement avec un critère de choix à partir de séries de mesures de pluie et de débit du bassin à un pas de mesures défini. Une des difficultés de cette démarche est souvent liée aux problèmes d´équifinalité : des jeux de paramètres différents sont « équivalents » en termes de comparaison de valeurs simulées par le modèle aux valeurs mesurées. Cette équifinalité a été mise en évidence sur le modèle à 4 paramètres, MEDOR, spécifique au climat méditerranéen, comportant : une production ne dépendant que de la pluie et de l´état hydrique et privilégiant ce dernier par rapport aux variables climatiques, et un transfert modélisé par deux réservoirs en parallèle. Elle est détaillée sur le bassin libanais du Nahr-Beyrouth et a été vérifiée sur huit bassins méditerranéens. L´analyse exhaustive de la fonction critère dans l´espace des 4 paramètres a montré l´existence de relations d´équifinalité entre paramètres de production (REP) d´une part, et de transfert d´autre part. L´indépendance des paramètres de production vis à vis de ceux de transfert permet de déterminer les paramètres de production préalablement et indépendamment de ceux de transfert. L´ajustement des bilans simulés - mesurés sur des pas variables avec un critère « Nash aggloméré » permet de réduire l´information nécessaire au calage. Au pas journalier, ce critère est le Nash habituel, et permet de déterminer une REP journalière. L´analyse à pas variable montre que cette REP est indépendante du pas, jusqu´au pas annuel, pour lequel le transfert est éliminé. Au pas annuel, les écarts de bilans ont des valeurs successives indépendantes et une répartition gaussienne. Le critère de Nash aggloméré annuel maximum entraîne une moyenne nulle des écarts et un écart type minimum. La REP annuelle, donc journalière, est confondue avec la relation de bilan global nul. La zone d´adéquation liée à l´intervalle de confiance du critère peut être définie à partir de l´expression de l´écart type des bilans. En conclusion, on a défini une méthodologie de recherche des paramètres de production du modèle journalier à partir de la seule connaissance des bilans annuels. Le problème de la détermination à priori des paramètres de production est reporté sur celle de la connaissance des bilans, plus simple à régionaliser.

HW08/07A/C28-009   1210

OPTIMIZATION OF SOIL HYDRAULIC PARAMETERS FROM IN-SITU DATA

Kun YANG, Toshio KOIKE (River Lab., Department of Civil Engineering, University of Tokyo)

As an important component of water cycles, soil moisture is often observed in field experiments for hydrological studies, while corresponding laboratory experiments are not always carried out for determining soil hydraulic parameters. This study presents an inverse system to optimize soil hydraulic parameters from observed soil moisture and temperature data. The system consists of a land surface model to predict soil moisture profile, and an optimization method to minimize an objective function, which is defined as the discrepancy between observed and model predicted values of soil moisture and surface temperature. The value of an objective function is affected by soil thermal parameters, hydraulic parameters and observation errors, which have to be optimized simultaneously. The objective function is highly nonlinear and contains many local minima, so we use simulated annealing algorithm to search the global minimum among many local minima of the objective function. Idealized case studies shows that the system can estimate soil hydraulic parameters and correct systematic errors of moisture measurement, and the optimized parameters are not sensitive to model errors and small disturbances. Because the inverse method avoids tedious and expensive laboratory experiments, it is attractive in field experiments whenever soil moisture data are available.

GEOELECTRICAL PARAMETERS ESTIMATION IN HYDROGEOLOGICAL INVESTIGATION USING FUZZY LOGIC TECHNIQUE

Moruffdeen Adedapo ADABANIJA (Department of Pure and Applied Physics, Ladoke Akintola University of Technology, Ogbomoso, Nigeria.)

Fuzzy logic technique was designed, implemented using MATLAB and applied to estimate the geoelectrical parameters in terms of linguistic variables high, medium, low and very low for hydrogeological investigation. This was accomplished by hydrogeological and geoelectrical characerization of the subsurface earth layers using the layering parameters inferred from the approximate and computer assisted interpretation of the vertical electrical sounding curves; synthesis and fuzzification of rules and antecedents of the subsurface layering characteristics; and eventual defuzzification of the rules. The procedure yielded degree of membership graph for each geoelectrical parameter from which their degree of fulfillments (DOFs) and the actuated data range in the form of linguistic variables high, medium, low and very low were established. With this approach, hydrogeological appraisal of an area can be instantly carried out for optimum groundwater prior to holes/wells boring.

OVERVIEW OF MODEL PARAMETER ESTIMATION EXPERIMENT (MOPEX)

Qingyun DUAN, John SCHAAKE (Hydrology Laboratory, NOAA/NWS/OHD)

How to estimate model parameters that vary spatially and are unique to each computational element is a key issue in all computer-based hydrological modeling. An international Model Parameter Estimation Experiment (MOPEX) was established to develop techniques for the a priori estimation of the parameters used in land surface parameterization schemes of atmospheric models and in hydrological models. The major effort to achieve this goal involves assembling a large number of historical hydrometeorological data sets and river basin characteristics data sets for a wide range of river basins representing different climatic and hydrologic conditions throughout the world. These data sets are intended for developing model parameter estimates and for developing relationship between model parameters and basin characteristics. This paper presents the rationale, science strategy and MOPEX´s links to other international programs such as Global Energy and Water Cycle Experiment (GEWEX), Predictions for Ungaged Basins (PUB) and Coordinated Enhanced Observations Period (CEOP).

HW08/07P/C28-003 — Invited — 1500

REVIEW OF RESULTS FROM THE SECOND MOPEX WORKSHOP IN TUCSON, AZ, APRIL 8-10, 2002

Qingyun DUAN, John SCHAAKE (Hydrology Laboratory, NOAA/NWS/OHD)

The Second International MOPEX Workshop was held in Tucson, Arizona, April 8-10, 2002. This workshop was designed to bring together interested US and international hydrologists and land surface modelers to exchange experience in developing techniques for a priori estimation and calibration of hydrologic model parameters. Participants of the MOPEX project were given data for 12 basins selected in the Southeastern United States and were asked to carry out a set of numerical experiments using a priori parameters as well as calibrated parameters developed for their respective hydrologic models. More than 30 scientists from 8 countries directly participated in the workshop and a few more have submitted results of their hydrologic model simulations to the workshop. The results from the workshop are summarized in this presentation. Attempts are made to understand the differences in the results from different models. It is also hoped that we learn how to use model calibration to enhance a priori parameter estimation and to benefit from the expertise from different modeling groups.

HW08/07P/C28-004 — 1550

DEVELOPMENT AND TESTING OF A PRIORI PARAMETER ESTIMATION METHODS FOR DISTRIBUTED-PARAMETER MODELS: A COMPARISON AMONG 20 HYDROLOGIC LANDSCAPES DEFINED FOR THE UNITED STATES

George H. LEAVESLEY, Lauren E. HAY, Roland J. VIGER, Steven L. MARKSTROM, Thomas C.WINTER (U.S. Geological Survey)

Model over-parameterization, ungauged basins, and the assessment of the impact of land-use and climate change are a few of the problems that limit the use of calibration techniques for distributed-parameter models. One approach to addressing these problems is the use of a priori parameter-estimation procedures to minimizing the number of parameters to be calibrated, or to obtain parameter values where calibration is not possible. A set of modeling and analytical tools is being developed using the US Geological Survey´s Modular Modeling System to facilitate the development and evaluation of objective a priori methods. Initial testing of these tools is being conducted using multiple basins in each of the 20 hydrologic landscapes defined for the United States. Hydrologic landscapes provide a conceptual framework for describing and classifying landscapes in terms of land-surface slope, hydraulic properties of soils and geologic framework, and the difference between precipitation and evapotranspiration. A priori parameter estimates were made for the USGS distributed-parameter model PRMS using available digital datasets of terrain, soils, vegetation type and density, and climatological data. Parameter sensitivtiy and model performance are being evaluated within and among the hydrologic landscapes at incremental levels of calibration ranging from no calibration to the calibration of all senstitive parameters. A total of 67 basins are currently included in the evaluations. Twelve of these 67 basins are MOPEX basins. Tools, techniques, and results will be presented to facilitate workshop discussion.

HW08/07P/C28-005 — 1610

AN ATTEMPT TO RELATE THE MOPEX BASIN FEATURES WITH THE BTOPMC MODEL PARAMETERS

Kuniyoshi TAKEUCHI[1], Tianqi AO[2], Hiroshi ISHIDAIRA[1], Junichi YOSHITANI[2], Kazuhiko FUKAMI[2], Hiroshi OKUMURA[2], Taichi TEBAKARI[2] ([1]Department of Civil and Environmental Engineering, Yamanashi University, [2]Hydrologic Engineering Team, Hydraulic Engineering Research Group of Public Works Research Institute,Japan)

For physically based hydrological models, it is desirable that the model parameters are identified from physical features of river basins without calibration. This is essential for prediction in ungauged basins (PUB) and for simulating the effects of watershed development scenarios. In practice, however, such quantitative relationship is not available as most of physically based model parameters are immeasurable. The identification of model parameters is a major challenge for any hydrological modelers. BTOPMC is a physically based distributed hydrological model developed for large river basins. A modified TOPMODEL is used for flow generation at each grid cell and the Muskingum-Cunge method for flow routing. Watershed is described by drainage networks and automatically subdivided into either rectangular blocks or natural sub-basins. Model parameters are manually calibrated or automatically optimized by the SCE-UA algorithm, and a reference table is under preparation relating the basin features with model parameters. In this study, the MOPEX (http://www.nws.noaa.gov/oh/mopex/, MOdel Parameter EXperiment) basins were analyzed. The *a priori estimation* procedure that was suggested by MOPEX was used to explore the possibility of parameter transferability between different basins; the strategy for inverse problems was used for relating parameters with basin characteristics and some information on the scale dependent reference table is identified through the trial.

HW08/07P/C28-006 — 1630

A ROBUST TECHNIQUE FOR MODEL STRUCTURE IDENTIFICATION AND CALIBRATION

Emiel E. VAN LOON, Paul TORFS, Peter A. TROCH (Department of Environmental Sciences, Wageningen University)

Using the MOPEX data sets for 12 basins, a technique for model-structureidentification and calibration is demonstrated. The technique is based thedecomposition of a model in separately identifiable parts, such as a fastflow component, a slow flow component, soil moisture storage (recharge minusactual evapotranspiration and drainage) - all conditioned on rainfall.Each model part is characterized by one dependent variable that is a functionof one to three independent variables. This function is represented by a sumof Gaussian kernels (as such, it is a probability density function).The different model parts are related via the dependent variables. Thisrelationship is also described by a sum of Gaussians. The fact that eachmodel component can be identified separately, makes that structurallydifferent models can be composed and evaluated.For each of the twelve MOPEX basins, the best model structure is determined.Next, the MOPEX basins are subdivided into three main classes on the basis ofcorresponing model structures. For each of the main classes theidentification technique is repeated, leading to a limited number ofgeneralized models.The success of the identification technique is based on the predictivestrength of the independent variables chosen. The fact that predictivestrength can be evaluated separately for each model component as well asthefact that a sum of Gaussians gives a very general and flexible functionrepresentation, makes the proposed technique robust.

PARAMETER ESTIMATION AND MODEL DIAGNOSTIC TECHNIQUES

HW08/08A/C28-001 — Invited — 0830

IDENTIFICATION AND EVALUATION OF HYDROLOGICAL MODELS

Thorsten WAGENER[1], Hoshin V. GUPTA[1], Jasper A. VRUGT[2], Terri S. HOGUE[1], Howard S. WHEATER[3], Soroosh SOROOSHIAN[1] ([1]Department of Hydrology and Water Resources, The University of Arizona, USA, [2]Institute for Biodiversity and Ecosystem Dynamics, University of Amsterdam, NL, [3]Department of Civil and Environmental Engineering, Imperial College London, UK)

Hydrological modeling requires the identification of a suitable model structure mainly based on current hydrological understanding and the estimation of parameter values (and their uncertainty), usually through calibration against observed data. The reduction of uncertainty in current modeling procedures is hindered by a lack of objective approaches to evaluate parameter sets and model structures while making optimum use of the information present in time-series data. This is further complicated by the increasing awareness of model structural inadequacies. There has been recent progress in the form of multi-objective optimization algorithms, improved adaptive techniques, wavelet analysis and the use of field (soft) data. The general idea behind these approaches is to make better use of the available information to yield models which are not optimal in a statistical sense, but are consistent with our understanding of the hydrological system. Application examples of these approaches are multi-objective optimization algorithms and adaptive approaches. Multi-objective algorithms enable the comparison of individual model components instead of just the overall model performance. Adaptive approaches allow periods of high information content for specific parameters to be identified and model structures to be evaluated with respect to the failure of individual components by tracking parameter variation in time. In this talk we explore the historical development of current perspectives on model evaluation and highlight opportunities for future research. Examples of the areas of rainfall-runoff and land surface modeling are used to demonstrate some of the recent developments.

HW08/08A/C28-002 — 0900

A TOOL FOR DIAGNOSING THE SIGNALS IN HYDROLOGIC TIME SERIES

John SCHAAKE, Qingyun DUAN (Hydrology Laboratory, NOAA/NWS/OHD)

It is essential to develop improved diagnostic tools to get every possible piece of information from hydrologic time series. Such tools are also necessary to understand the differences between simulation results and observations and between simulation results from different models. A diagnostic tool, called Variance Decomposition, is developed for such a purpose. The basic idea of variance decomposition is to use a transformation in this case a wavelet transformation -- to decompose a time series into different temporal frequency components and then to compute the seasonal variance of each frequency component. This produces a 2-dimensional pattern showing how the total variance of a time series depends on frequency and season and that can be visualized graphically. Variance decomposition can be applied to any time series (e.g. precipitation, streamflow, evaporation, soil moisture, base flow, surface flow, or differences between observed and simulated flow). Functions of variance decomposition can illustrate how input variance is transferred to model output variance. They can be used to show how the Nash-Sutcliff efficiency for a given model varies with both frequency and season. This can be used as the basis of a filter to post-process model output to improve its validation statistics. This presentation describes how variance decomposition method works. Its use is demonstrated by some examples from the evaluation of results from the second international workshop on Model Parameter Estimation Experiment (MOPEX).

HW08/08A/C28-003 — 0920

SIMULATION OF HYDROLOGICAL PROCESSES BY THE LAND SURFACE MODEL SWAP USING AN APRIORI ESTIMATED MODEL'S PARAMETERS FOR BOREAL CATCHMENTS

Yeugeniy M. GUSEV, Olga N. NASONOVA (Institute of Water Problems, Russian Academy of Sciences)

The boreal zone is characterised by a cool and cold climates with low temperatures during the cold season, deep seasonal snow cover and frozen soil. These circumstances complicate the problem of modelling hydrological processes especially with respect to the forested areas where the problem is much more complicated due to a lack of measured characteristics of hydrological regime as well as appropriate soil and vegetation parameters. The aim of this work is to investigate the ability of the land surface model SWAP (Soil Water - Atmosphere - Plants) to simulate hydrological processes occurring in boreal regions on a catchment and river basin scales using apriori estimated model´s parameters. On a small catchment scale, the validation of SWAP was performed using a set of hydrometeorological data measured during 18 years (1966-1983) at the Tayozhniy catchment (covered by boreal forest, mainly composed by spruce) and the Usadievskiy catchment (grassland), both situated in the central part of Valdai Hills, Russia. On a river basin scale, the validation of SWAP was performed for the Polomet river basin (1215 km^2), also situated in Valdai and covered by mixed forest and grass vegetation. The river basin area was divided into 14 cells (small catchments) with different soil, vegetation and geomorphological characteristics. In this case a set of hydrometeorological data (excluding precipitation), measured at the Usadievskiy catchment during the period 1966-1971 was used. The data on precipitation

were taken from 13 gauges located within the Polomet river basin. None of soil and vegetation parameters (soil hydraulic conductivity at saturation, Clapp-Hornberger B-parameter, soil water potential at saturation, depth of soil root zone, annual dynamics of leaf area index, etc.) was measured at the catchments. Soil parameters were computed empirically using information about soil texture and density . Vegetation parameters were estimated using literature data, experience of the authors and information about vegetation type. For the Tayozhniy and the Usadievskiy catchments, simulations of different characteristics of heat and water regime, in particular, snow water equivalent, snow surface temperature, evaporation from snow cover, water yield of snow cover, depth of soil freezing and thawing, soil water storage, daily surface and total runoff from the catchment, monthly evapotranspiration from the catchment, and precipitation intercepted by spruce forest on an annual and monthly basis were validated against observations. As to the validation on a basin scale, daily discharge, measured by 7 gauges from 1966-1971 within the Polomet river basin, was used. The results of validation have showed that the model SWAP is able to reproduce hydrological processes in the boreal zone on a catchment and river basin scales quite reasonable using an apriori estimated model´s parameters.

HW08/08A/C28-004   0940

ON SEMI-DISTRIBUTED RAINFALL-RUNOFF MODELLING: 'SATURATION PATH' PERSPECTIVE ON TOPMODEL AND VIC

Dmitri KAVETSKI, George KUCZERA, Stewart W. FRANKS (School of Engineering, University of Newcastle)

The conceptual foundation, behaviour and implementation of semi-distributed models such as TOPMODEL and VIC are revisited from a 'saturation path' perspective. A general family of models is analysed, based on the assumptions that i) an event-invariant relationship between the saturated area and catchment storage exists (which may include hysteretic and stochastic components) and ii) quickflow is generated from precipitation on the saturated areas. The VIC and TOPMODEL equations are obtained by substituting particular constitutive functions describing the saturation mechanism, as well as applying specific numerical approximations. In general, the saturation path perspective leads to compact model equations in canonical ODE form, making the behaviour of the models, including ill conditioning due to parameter correlations and non-robust numerical implementations, very transparent. Avenues for substantial improvements in computational performance are detailed, yielding substantial reduction of model runtime and increased stability and robustness. Moreover, the generality of the proposed 'saturation path' modelling is demonstrated by a 'non-parametric' fit of constitutive relationships.

HW08/08A/C28-005   1000

ON THE PARAMETERIZATION OF DISTRIBUTED MODELS

Fekadu G. MOREDA, Ziya ZHANG, Victor KOREN, Seann REED, Michael SMITH (Office of Hydrologic Development, National Weather Service)

The Hydrology Lab (HL) of the National Weather Service (NWS), Office of Hydrologic Development is currently developing and testing the HL Research Modeling System (HL-RMS). HL-RMS is a modeling framework for testing fully distributed, semi-distributed, and lumped modeling approaches. The system is designed in such a way that different models can be used to generate runoff. Currently, the system has two surface runoff models: the Sacramento Soil Moisture Accounting (SAC-SMA) and the Continuous Antecedent Precipitation Index (CONT-API).The NWS Antecedent Precipitation Index model is one of the earliest conceptual rainfall runoff models and has been operational in a few NWS River Forecasting Centers (RFCs) in the United States. This study deals with the derivation of distributed parameters of the CONT-API model. For some of the parameters, a priori estimates have been derived in other research efforts. For the remaining parameters, we derive initial parameters based on the calibrated parameters of the lumped CONT-API. Results using initial lumped parameters of eleven subbasins in the Juniata River Basin (8687 km^2) located in Pennsylvania show that the shape and timing of the hydrographs are captured well. However, as expected, direct use of lumped parameters in each of the grid cells results in oversimulation at the subbasin outlets. Techniques to adjust these initial parameters in order to obtain accurate simulation of runoff at the subbasin outlets are presented. The relationship between the final calibrated and initial parameter estimates will also be discussed.

HW08/08A/C28-006   1040

RESEARCH OF THE HYDROLOGICAL MODELING IN NORTHERN REGION

Xieyao MA[1], Yoshihiro FUKUSHIMA[2], Tetsuzo YASUNARI[3] ([1]Frontier Research System for Global Change, [2]Research Institute for Humanity and Nature, [3]Hydrospheric Atmospheric Research Center, Nagoya University)

A combined model considered the climate phenomenon of cold region like snow-cover, river frozen and permafrost was built in order to understand the hydrological cycle processes of a river basin in northern cold region. The model is composed of four components: one-dimensional soil-vegetation-atmosphere transfer (SVAT) model, runoff formation model, river ice model and river routing model. The SVAT model is a simple biosphere model, in which the land surface is described by a big-leaf and a soil layer. The SVAT model provides estimation of latent and sensible heat fluxes between the land surface and the atmosphere, and thermal regimes in the snow-cover and soil layer. A conceptual model is used to determine the formation of runoff for a grid box. It is a reservoir system representing each of the four runoff components, which are saturated land surface runoff, infiltration runoff from the topsoil zone, base runoff and direct runoff from the water surface. In order to consider the permafrost condition, a parameter-related mean effective soil depth was designed as a function of the active layer depth. A simple method using accumulated degree-days is used to determine river ice growth and decay processes. The flow velocity in the river network is set as a constant and the number is depended on the depth of runoff. In the paper, we would like to introduce the results of the model application to the Lena River basin located in east Siberia, the Selenge River basin in Mongolia and the Yellow River basin in China.

HW08/08A/C28-007   1100

ESTIMATION OF HYDROLOGIC PARAMETERS RELATED TO SOIL AND VEGETATION USING REMOTELY-SENSED DATA AND GIS - AN EXPERIENCE AT MOUNTAINOUS WATERSHEDS IN JAPAN

Kazuhiko FUKAMI[1], Kazuhiko FUKAMI[1], Yoko HIROSE[2], Takuya OKADA[3], ZhiQiang CHEN[4], M. Levent KAVVAS[4], Junichi YOSHITANI[1] ([1]Hydrologic Engineering Research Team, Public Works Research Institute, Japan, [2]Kokusai Kogyo Co.,Ltd., [3]Asia Air Survey Co.,Ltd, [4]University of California at Davis)

Distributed models are now indispensable for hydrologists to understand hydrologic environment considering basin-wide interactions among hydrologic processes in a variety of

temporal/spatial scales. However, the distributed models are still regarded as difficult to apply to operational hydrologic problems because of the existence of many parameters. Here, a priori estimation of parameters related to land-atmosphere interactions, i.e. soil and vegetation system, are tried using GIS analysis. This is based upon the idea that real situations near ground surface are relatively easily reflected in GIS with in situ and/or remotely-sensed data. This study focuses on hydrology in mountainous forest-covered watersheds in Japan and consists of two experiences there in long-term riverflow simulation and in flood (dam-reservoir inflow) forecasting. In the long-term riverflow simulation study, a new version of PWRI distributed hydrologic model (PWRI model), a conceptual distributed model, was applied to two small mountainous forest-covered watersheds in the Kanto district, the Kusaki-dam watershed (254km2) and the Shiobara-dam watershed (120km2). The former watershed consists of old geologic condition and the latter has relatively new volcanic geology. The PWRI model seems a kind of tank model, but the land-atmosphere interactions are modeled on the basis of Noilhan and Planton (1989) scheme. The scheme requires some geophysical & biophysical parameters. LAI was estimated by Ishi et al. (1999) method with Landsat-TM images. The satellite images were also used to update land-use (forest cover) conditions. Soil hydraulic parameters were grouped into three categories based on soil map and sample data. Parameters for groundwater were set based on the system of the old version of PWRI model, which had been optimized for several Japanese rivers. Flow network was estimated by DEM. The long-term riverflow simulations of the two watersheds were both quite successful by just one-parameter tuning. The flood forecasting study was made at the Shiobara-dam watershed with a physically-based Watershed Environmental Hydrology (WEHY) Model. The model requires not only the similar information such as topography, soil hydraulics, vegetation but also soil-depth distribution for each hillslope modeling computational unit (MCU). A soil-depth ranking matrix table was created on the basis of empirical knowledge about the relationship among soil-depth, topographical feature, slope, land use (vegetation type), the soil and in-situ soil depth measured at 36 points for each ranking-category of soil-depth. The flood simulations using the parameters were also successful. The method to estimate areal distribution of soil depth was tested at the Kusaki-dam watershed as well. According to the results, the parameter estimation methods above are expected to be applicable at least to the regions around the Kanto district of Japan.

CLIMATE CHANGES IMPACT ON THE WATER RESOURCES

Cvetanka POPOVSKA (Department of Hydraulics, Hydrology and River Egineering, Faculty of Civil Engineering, University of Ss. Cyril and Methodius)

Climate changes as a result of global warmth will cause significant changes in the hydrological cycle and water resources. Republic of Macedonia is small, but geologically and climatically variable country. Until now, climate changes impact on the water resources and hydrology in the Republic of Macedonia, has not been carried out. This paper deals with some results obtained within the UNDP Project: ˝Vulnerability of the Climate Changes and Adaptation Measures in the Republic of Macedonia˝. Climatic factors are presented with the rainfall characteristics and evaporation components and with their time and space distribution. Hydrological parameters have been analyzed with historical measured data of the selected hydrological stations in the representative river basins for the period 1950-2000. Trend lines of the annual discharges and water levels in the main rivers and natural lakes, have been obtained. Besides analysis of the real parameters, the simulating scenarios have been investigated to predict the future influence of the climate changes on the water balance components. According to the performed analysis it can be stated that the climate changes as a result of global warmth will cause significant changes in hydrology and water resources and with that in water economy planning as well. Droughty seasons are more frequent and with longer duration and floods are with rare re-appearance. The most vulnerable segments in water economy have been identified and adaptation measures have been proposed. Action plan of the climate changes impact should be carried out on the national level and adaptation measures should be implemented with priorities. The action plan should present the knowledge in investigation methodologies, measurement techniques and management of the water resources. Achievement of those goals will help the long-term planning of water resources utilization and will provide public, professional and open discussion of all partners in the society.

HW08/08A/C28-009   1140

A METHOD FOR PARAMETER ESTIMATION IN URBANISED CATCHMENTS

Dirk MUSCHALLA, Manfred OSTROWSKI (Inst. of Hydraulic and Water Resources Eng., Section for Hydrology and Water Management, Darmstadt University of Technology)

The prediction of surface runoff from small urbanised catchments depends on the correct choice of the degree of imperviousness. As fast flow reactions from impervious areas are disturbing receiving water bodies hydraulically and pollution wise, the investment for storm water retention measures and treatment facilities is immense in Germany and elsewhere to reduce these negative impacts. In most cases this investment is based on modelling results, performed with storm water modelling techniques. In the past, the water administration authorities considered a system acceptable, when it did not exceed a threshold value. As neither flows are measured under normal planning conditions, nor exact values for impervious areas were available e.g. form airborne or ground surveying, imperviousness had to be estimated. At the end of a decade of planning and construction, a large sample of data sets was available for most of the communities in the Federal State of Hessia, Germany. This sample has been analysed and distribution functions for sensitive parameters (imperviousness, population density, domestic waste water, etc.) have been derived. Assuming that the expectation value corresponds to the arithmetic mean, outliers and implausible values can now be identified and questioned. In addition, interrelationships between single parameters could be identified. This supports the approving authorities which have to check incoming planning proposals and a model data set for plausibility and correctness. Finally, the distribution functions determined were used for Monte Carlo Simulations and an existing deterministic pollution load model was enhanced to an hybrid model by means of stochastic components. Input values were randomly drawn from the functions to produce a distribution output function for overflow volumes and pollution loads.

HW08/08A/C28-010   1200

DETERMINATION OF NON PHYSICAL VAN GENUCHTEN PARAMETERS IN HETEROGENEOUS SOILS

Joseph POLLACCO (School of Civil Engineering and Geosciences, University of Newcastle)

Modelling the highly heterogeneous unsaturated zone (vadose zone) is difficult especially with the presence of macropores. The usage of well logging is well suited to determine van Genuchten parameters used in studies of soil moisture activities. In the study we determine the impact of afforestation through the usage of time series neutron probe data. An inverse modelling technique was developed to determine the non physical van Genuchten parameters. Given the equifinality of the van Genuchten parameters and that no measured

values of the soil parameters are available, two soil parameters are redundant therefore they are presently kept fixed. A calibration procedure enables the replacement of residual soil moisture parameters for each of the 40 soil layers by only two parameters, by using compiled data from the observed soil moisture. The finding of the optimum soil parameters is complicated due to presence of macropores. A temporary and synthetic solution to this macropore modelling problem is to optimise the different layers, where the layers are optimised at first in large groups then split into individual layers. It was shown by successive trials that optimising from top-to-bottom produces satisfactory results. This provides an approach to represent these processes at a scale appropriate to calculate total recharge through the vadose zone. Once the heterogeneous unsaturated zone is modelled to a satisfying level, an attempt will be made to remove the heterogeneity and to build the simplest model that will be representative catchment scale processes by using well logging techniques in a more efficient way.

UNCERTAINTIES IN MODELING AND INFORMATION IN DATA

| HW08/08P/C28-001 | Invited | 1400 |

TEASING OUT UNCERTAINTIES IN THE MODELLING PROCESS

Keith J. BEVEN, Jim FREER (Lancaster University, UK)

It has been a common assumption in parameter calibration that all of the model error can be treated as if it were measurement error. In this way, the powerful tools available for statistical inference can be used directly. Such a simple assumption has served to hide some very real problems with calibration based on such methods because the implication is, therefore, that the model is a true representation of the processes under study. In most environmental modelling situations this is evidently not the case with the result that model and parameter uncertainties are generally underestimated in calibration. This may be important when derived variables (that do not have independent calibration data) are required to be predicted. However, neither environmental modellers nor statisticians have done much towards developing methods to deal with model structural error in parameter calibration. The different source of error in the modelling process - initial and boundary condition error, model structural error and true measurement error - are commonly recognised in discussions of modelling methodologies but have proved to be very difficult to tease out in practice. Teasing out sources of error requires strong a priori assumptions and the results will depend on the nature of those assumptions. The discussion of these problems will be illustrated by some representative examples from rainfall-runoff modelling.

CONFRONTING UNCERTAINTY IN ENVIRONMENTAL MODELLING

Dmitri KAVETSKI, Stewart W. FRANKS, George KUCZERA (School of Engineering, University of Newcastle)

The majority of environmental models require calibration of some or all of their parameters before meaningful predictions of catchment behaviour can be made. Despite the importance of reliable parameter estimates, there are growing concerns about the ability of objective-based inference methods to adequately calibrate environmental models. The problem lies with the formulation of the objective or likelihood function, which is currently implemented using essentially ad-hoc methods. We outline limitations of current calibration methodologies, including least squares, multi-objective, GLUE and Kalman filter schemes and introduce a more systematic Bayesian Total Error Analysis (BATEA) framework for environmental model calibration and validation. BATEA imposes a hitherto missing rigour in environmental modelling by requiring the specification of physically realistic uncertainty models with explicit assumptions that can and must be tested against available evidence. Distinguishing between the various sources of errors will reduce the current ambiguity about parameter and predictive uncertainty and enable rational testing of environmental model hypotheses. A synthetic study demonstrates that explicitly accounting for forcing errors leads to immediate advantages over traditional least squares methods that ignore rainfall history corruption and do not directly address the sources of uncertainty in the calibration. We expect that confronting all sources of uncertainty, including data and model errors, will force fundamental shifts in the model calibration/verification philosophy.

PROBABILISTIC STREAMFLOW PREDICTIONS IN UNGAUGED WATERSHEDS

Jasper A. VRUGT[1], Thorsten WAGENER[2], Hoshin V. GUPTA[2], Willem BOUTEN[1], Soroosh SOROOSHIAN[2] ([1]Institute for Biodiversity and Ecosystem Dynamics, University of Amsterdam, NL, [2]Department of Hydrology and Water Resources, The University of Arizona, USA)

Conceptual rainfall-runoff models can be applied to ungauged watersheds by developing statistical relationships between model parameters and watershed characteristics. However, the predictions will contain uncertainties which are likely to be considerably larger than for gauged watersheds. While probabilistic predictions in gauged watersheds can be commonly found, predictions in ungauged watersheds are almost always given as simple point estimates, ignoring the large uncertainty involved. New Monte Carlo Markov Chain optimization algorithms produce reliable estimates of posterior parameter distributions in gauged watersheds. These probabilistic estimations of parameter distributions in gauged watersheds can be transferred to ungauged watersheds while recognizing the additional uncertainty through the regionalisation process. We analyze options for regionalisation approaches which allow for the propagation of these distributions into predictions for ungauged watersheds. This stochastic estimate of the hydrological response of the watershed is more useful for decision-making since it considers the confidence in the model predictions. The approach is demonstrated in a pilot study using MOPEX data and a rainfall-runoff model structure with typical conceptual components.

IDENTIFYING HYDROLOGIC MODEL PARAMETERS FROM INTRA-ANNUAL STREAMFLOW ANALYSES

Eylon SHAMIR, Eylon SHAMIR, Efrat MORIN, Bisher IMAM, Hoshin VGUPTA, Soroosh SOROOSHIAN (Department of Hydrology, University of Arizona)

Current efforts to estimate physically plausible model parameters focus on incorporating a priori information from the observed data, into the parameter estimation process. Our study extracts intra-annual information on streamflow indicators that were tested to be intrinsic and representative of the basin hydrological response. These indicators are implemented in

parameter estimation to initial a plausible parameters space that ensures the indicators values in the simulation for consistent model performance. Minimal conditions have to be met in order to favor a streamflow indicator: (a) easy to derive from raw streamflow data with minimum presumptions; (b) have a strong central tendency with small dispersion when evaluated in a range of climatic conditions to represent basins property; (c) sensitive enough to vary among basins and behave as a unique description of a basin. Four indicators that satisfy the above requirements and are dominated by different hydrological processes were selected for this study. The validity of the indicators was evaluated using long-term daily streamflow data from multiple mid-size unregulated headwaters in the US. Subsequently, the parameter posterior distribution of the Sacramento Soil Moisture Accounting (SAC-SMA) model was derived for each indicator. The combine posterior distributions show a significant reduction in the plausible range of some parameters while other parameters were not sensitive to the streamflow indicators.

CONSTRAINING PARAMETER VALUES WITH SOFT DATA: AN EXPERIMENTALIST'S VIEW OF PARAMETER ESTIMATION

Jeffrey J. MCDONNELL[1], Kellie B. VACHE[1], Jan SEIBERT[2] ([1]Department of Forest Engineering, [2]Swedish Agricultural University)

Multi-criteria calibration of runoff models using continuous time series of streamflow and groundwater well data has been proposed as a way to constrain parameter values and to ensure the realistic simulation of internal variables. Nevertheless, in many cases the amount of such available 'hard data' is limited. We argue that experimentalists working in the catchment 'to be modeled' often have much more knowledge of catchment behavior than is currently used for model calibration and testing. While potentially highly useful, this information is difficult to use directly as exact numbers in the calibration process. We present a framework whereby these 'soft' data from the experimentalist are made useful through fuzzy measures of model-simulation and parameter-value acceptability. The use of soft data is an approach to formalize the exchange of information and calibration measures between experimentalist and modeler. This dialog may also greatly augment the traditional and few 'hard' data measures available. We illustrate the value of 'soft data' withthe applications to watersheds in New Zealand, Oregon and Alaska. We show how these techniques may allow one to make a priori parameter estimates (and thereby to simulate streamflow effectively) for watersheds encompassing different climatic and physiographic regions.

A PRIORI PARAMETER ESTIMATION AND REGIONALIZATION OF MODEL PARAMETERS

| HW08/09A/C28-001 | Invited | 0900 |

REGIONALIZATION OF HYDROLOGICAL MODEL PARAMETERS

Guenter BLOESCHL, Ralf MERZ (Institute for Hydraulics, Hydrology and Water Resources Management, Vienna University of Technology)

In this talk I will present recent results of a comprehensive test of parameter estimation methods for both gauged and ungauged basins. In a case study we analysed more than 500 catchments in Austria. 30 years of daily data (runoff, precipitation, air temperature, air humidity) were analysed. A spatially lumped, conceptual, HBV style soil moisture accounting scheme was used which involved 11 calibration parameters including snow processes. Prior information on the parameters was included in terms of a beta distribution. In a first step the calibrated parameters from two independent calibration periods of 11 years each were compared. These comparisons suggest that some of the parameters (such as the recession parameters and the degree-day-factor) are quite stable and hence well identifiable while others (such as the routing parameters) are not. The more reliable parameters were spatially clustered and these clusters could be interpreted on hydrological grounds. This lends additional credence to these parameter values. In a second step we examined the median Nash-Sutcliffe efficiency of a number of regionalisation methods for finding model parameters for ungauged basins. The performance of the methods was evaluated by jack-knifing where gauged basins were treated as ungauged and the streamflow simulated using the regionalised parameters was compared with observed streamflow. When using preset parameters (based on a prior guess without using any streamflow data), the model efficiency was 0.15. When using the same parameter value for all catchments equal to the mean of the calibrated values, the efficiencies for the calibration and verification periods were 0.19 and 0.19, respectively. When using multiple regression with catchment attributes (such as land use, geology and topography), the efficiencies were 0.32 and 0.32, respectively. When using Kriging for transposing the parameters in space (without the use of catchment attributes), the efficiencies were 0.44 and 0.41, respectively. When using the average of the calibrated parameters of the upstream and the downstream neighbours, the efficiencies were 0.46 and 0.42, respectively. These results imply that spatial distance is a better predictor than catchment attributes. This adds a caveat on the reliability of ˝physically based˝ models at the regional scale. Even though the comparisons suggest that most of the spatial variability of the (identifiable) model parameters is a result of real physical controls rather than an artefact of the calibration procedure, very little of it can be explained by those catchment attributes that are usually available at the regional scale. The challenge is to identify those controls, perhaps by using data that are not routinely available to date. It is likely that soil depths, stream - aquifer connectivity and the degree of fracturedness of the bedrock are important controls but these variables are difficult to come by at the regional scale.

ESTIMATION OF HYDROLOGICAL MODEL PARAMETERS USING REGIONAL INFORMATION

Andras BARDOSSY (Institute for Hydraulic Engineering, University of Stuttgart)

Catchments with similar characteristics show a similar hydrological behaviour. Therefore a regionalisation of the hydrological model parameters on the basis of cachment characteristics is plausible. However due to the non-uniqueness of the parameters (equifinality) a procedure of parameter estimation by model calibration and a subsequent function fit is not appropriate. In this paper different regionalisation functions are estimated simultaneously for a set of different catchments. A generalised likelihood as in the GLUE methodology is assigned to each regionalisation function. The likelihood of a function is calculated from the likelihood of the corresponding parameters for the different catchments. The methodology consists of the following steps:
• definition of a similarity measure for the catchment characteristics,
• the choice of the parametric form of the regionalisation function,

• the assessment of the likelihood function for the different cachments,
• the estimation of the regionalistation function parameters and
• the assessment of the likelihood of the regionalisation function.
Using the regionalisation functions hydrological parameter sets and their likelihood can be estimated.
The methodology is applied to selected mesoscale subcachments of the Rhine catchment.

HW08/09A/C28-003   0950
REGIONALISATION OF RAINFALL-RUNOFF MODELS: IDENTIFIABILITY ANALYSIS, MODEL SELECTION AND CATCHMENT CHARACTERISTICS

Neil Robert MCINTYRE[1], Howard S. WHEATER[1], Hyosang LEE[1], Andrew R. YOUNG[2], Thorsten WAGENER[3] ([1]Department of Civil and Environmental Engineering, Imperial College London, [2]Center for Ecology and Hydrology, Wallingford, UK, [3]SAHRA Hydrology and Water Resources, University of Arizona)

Recent developments in modelling tools provide a powerful analytical capability to support rainfall-runoff model development and application. Stochastic methods are now available to explore model structure and parameter uncertainty, and hence the trade-off between model complexity, performance and identifiability. Dynamic identifiability analysis has been developed to track parameter variability and identifiability through time. The information content of hydrological data has been increased by the use of multiple objectives, which in turn provide further insight into model structures and performance. These developments provide support for the regionalisation of rainfall-runoff models for application to ungauged catchments, and recent work has led to the formalisation of a general methodology for regional analysis. Analysis of the trade-off between performance and identifiability has led in the UK to the development of parsimonious local rainfall-runoff models capable of regionalisation. An important question concerns the selection of appropriate local model structures for regional application. Are different model structures required to represent different catchment types? And what are appropriate criteria to find catchment clusters which can be represented by particular model structures? A formal experiment has been designed, based on a data set of 277 UK catchments and sampling from a three-dimensional space of catchment characteristics, to address these questions. Results will be presented, based on 12 candidate parsimonious model structures. Calibration and validation performance is evaluated with respect to model complexity, identifiability and internal consistency, using different performance criteria. This is a precursor to further work to develop the theoretical framework for regional analysis, and for full use of the database in regional analysis.

HW08/09A/C28-004   1010
A PARAMETER ESTIMATION OF VIC MODEL FOR RIVER BASINS IN CHINA

Zhenghui XIE, Fengge SU (Institute of Atmospheric Physics, Chinese Academy of Sciences)

Research has shown that land surface schemes perform well when their model parameters are appropriately estimated based on calibrations with observations, but perform poorly when their parameters are not calibrated properly. In this work, soil and vegetation parameters needed by the land surface scheme VIC (Variable Infiltration Capacity) model for the mainland area of China are given to predict the discharge of the major river basins in China where the new surface runoff parameterization of VIC that represents both Horton and Dunne runoff generation mechanisms with the framework of considering subgrid spatial scale soil heterogeneity is applied. The mainland area of China is represented by 2604 cells with a resolution of 60km×60km for each cell. The VIC model is applied to each grid cell over each basin. A routing scheme is run offline which takes daily VIC surface and subsurface runoff as input to obtain model simulated discharge at the outlets of study basins. The VIC discharge simulations over Huaihe, Yellow river, and Yangtse river basin will be presented and compared with the observations.

HW08/09A/C28-005   1030
REGIONALIZATION OF WATER BALANCE MODEL PARAMETERS FROM GEOGRAPHIC INFORAMTION AND ITS PROCESS-BASED VERIFICATION

Yoshiyuki YOKOO[1], So KAZAMA[2], Masaki SAWAMOTO[3] ([1]Institute of Industrial Science, University of Tokyo, [2]Graduate School of Environmental Science, Tohoku University, [3]Graduate School of Engineering, Tohoku University)

This research suggested a regionalization method of lumped water balance model parameters. We developed this method assuming that precipitation data were available as well as geographic information. An international project named ˝Prediction of Ungauged basins (PUBs)˝ is running from 2002 under the International Association of Hydrological Science (IAHS) at the present. Our method, for runoff predictions in runoff-ungaged basins, can contribute to this project. Firstly, we suggested a regionalization method of a water balance model parameters. The regionalization was based on multiple regression analysis between tank model parameters and geographic characteristics in 12 Japanese basins. The model employed in this study was Sugawara's tank model, which had a vertical series of 4 tanks. The modified Powell method optimized tank model parameters in the basins. Geographic data set in Japan provided the geographic characteristics of the basins. The characteristics included areal ratios of 9 land use types, 3 soil types, and 3 geology types, as well as basin area and a representative gradient of a basin. The representative gradient was a ratio calculated by the elevation difference between maximum elevation on the basin boundary and dam top over the horizontal distance between these two points. The 9 land use types consist of rice paddy, field, orchard, shrub and orchards, forest, waste or vacant or naked land, building, road or railroad, and water body (river or lake). The classifications of soil types and geology were on the basis of contribution degrees of soil and geology to subsurface flow and base-flow, respectively. The extracted regression equations performed well to simulate runoff only from rainfall data and geographic characteristics in two test basins, indicating the applicability of the regionalization method. Secondly, we conducted process-based verifications on the multiple regression equations that relate tank model parameters with geographic characteristics of a basin. These verifications utilized a physically distributed runoff model, which is developed in this research as a quasi-three dimensional model that consists of one-dimensional channel runoff model and vertically two-dimensional slope element models placed along the channel runoff model. Numerical experiments verified the effects of a single geographic parameter of the distributed model on hydrographs. The geographic parameters contained surface roughness, hydraulic conductivities, basin area, and representative gradient mentioned above, which corresponded to geographic characteristics used in the regression analysis. Representations of the hydrograph by tank model derived the relationships between distributed model parameters and tank model parameters, and the relationships partially supported the physical meanings of 6 multiple regression equations. A series of numerical experiments with respect to basin area concluded that the multiple regression equations for tank modeling were applicable for the basins up to 1,000 km².

HW08/09A/C28-006   1050
REGIONALIZATION OF RAINFALL-RUNOFF MODEL PARAMETERS: APPLICATION TO NORTHEASTERN OHIO, USA

Richard M. ANDERSON, Victor I. KOREN, Seann M. REED, Michael B. SMITH, Vadim KUZMIN (NOAA/National Weather Service)

Regionalization of hydrologic model parameters is an active area of research. It is important in efforts to obtain a priori estimates of model parameters in order to model the rainfall-runoff process in ungauged catchments, predict hydrologic effects of land use change, and model the hydrologic land surface component in global atmospheric models. Previous efforts to regionalize model parameters have been hampered for a number of reasons. For example, uncertainty in the quality of data used in model calibration leads to additional, unquantified uncertainty in relationships between landscape attributes and model parameters. Recent research within the National Weather Service (NWS) takes the approach of first using physical reasoning to obtain a priori estimates of model parameters. This should provide the starting point for subsequent statistical or calibration approaches to constrain and improve parameter estimates. This approach has been applied to the Sacramento Soil Moisture Accounting (SAC-SMA) model by using a multilayer soil characteristics dataset for the conterminous USA, which was derived from the State Soil Geographic Database (STATSGO) developed by the U.S. Department of Agriculture. First, this paper discusses efforts to improve such starting point a priori estimates by using data of finer resolution, such as that available within the Soil Survey Geographic Database (SSURGO) that uses county-level survey data. Though not currently available in a centralized national format, availability of this data is increasing rapidly. A priori model parameters for SAC-SMA, a conceptual model, are derived using finer scale SSURGO data, and improvements compared to previous NWS results are presented. Second, model parameters for IHACRES (Identification of unit Hydrographs And Component flows from Rainfall, Evaporation and Streamflow data), a model that uses a transfer function/unit hydrograph approach, are regionalized using a regression approach based on the same SSURGO data. Performance improvements relative to the STATSGO case as well as significance of region characteristics for establishing regional relationships are discussed. Both models are applied within the same region in the Lake Erie basin in northeastern Ohio, USA.

MOPEX'S CONTRIBUTION TO PUB AND MOPEX FUTURE PLAN AND DIRECTION

HW08/09P/C28-001   Invited   1420
MOPEX'S CONTRIBUTIONS TO PUB: FROM GAGED TO UNGAGED BASINS

John SCHAAKE, Qingyun DUAN (Hydrology Laboratory, NOAA/NWS/OHD)

One of the most important issues in making predictions for ungaged basins is how to transfer information from gaged to ungaged areas. Predictions are made using data as input to an appropriate model. All models are imperfect. All models have parameters (coefficients and exponents) that must be specified and that control the model´s approximation of the real world. The primary goal of the International Model Parameter Estimation Experiment (MOPEX) is to develop improved approaches to estimation of parameters of hydrologic models that can be applied to ungaged areas. This paper presentsthe implementation strategy for MOPEX, some results of recent workshops and suggestions for how MOPEX can contribute to the development of the science strategy for PUBs and subsequent achievement of PUBs objectives.

HW08/09P/C28-002   1450
RIVER FLOW SIMULATION WITHIN UNGAUGED CATCHMENTS; THE UTILITY OF GENERALISED MODELS

Andy R. YOUNG (Centre for Ecology and Hydrology - Wallingford)

Access to daily stream flow data, at the river reach scale is a central component of many aspects of water resource and water quality management. However, the majority of river reaches are ungauged and hence there is an operational requirement for a quick, consistent and reliable method for simulating historical stream flow records within ungauged catchments. Furthermore, the coupling of hydrological models into land-surface schemes for Regional Climate Models (RCM) is central to improving the utility of these models in predicting the potential impacts of future climate change and variability on river flows. The information content of hydrological data has been increased by the use of multiple objective functions which lead to trade off strategies during model calibration. Uncertainty within input data, model calibration and structure and parameter regionalisation schemes all led to uncertainty within model simulations when used as predictive tools. However, model success and failure is commonly determined not by abstract fit statistics but by the sensitivity of subsequent analyses to the uncertainty in the simulated stream flow data. Our paper will explore some of these issues using the results from a UK case study on generalising model parameters based on a catchment data set of 277 catchments. The paper will compare the impact of parameter uncertainty on stream flow simulations obtained using calibrated model parameters with that observed when using regionalised parameter sets. These uncertainties will then be compared with the strength of signals observed in model output data when the historical input data are perturbed using scenarios for predicted changes in precipitation and evaporation for the 2020s derived using a RCM. The paper will conclude with some comment about the utility of regionalised hydrological models for evaluating the impact of potential climate change scenarios and outline future directions for work in this area.

ATMOSPHERIC CHEMISTRY DATA AT THE NASA GODDARD EARTH SCIENCES DAAC

James E. JOHNSON[1], Suraiya P. AHMAD[1], Steven J. KEMPLER[2] ([1]NASA/GSFC/SSAI, [2]NASA/GSFC)

The NASA Goddard Earth Sciences Distributed Active Archive Center (GES DAAC) includes a vast collection of atmospheric chemistry data. Among the holdings are data from various heritage and current sensors. Among these are ozone products from the Backscatter Ultraviolet (BUV) instrument flown on Nimbus-4, the Solar Backscatter Ultraviolet (SBUV) and Solar Mesospheric Explorer (SME) instruments aboard Nimbus-7, and the Shuttle Solar Backscatter Ultraviolet (SSBUV) instruments. The Nimbus-7 Limb Infrared Monitor of the Stratosphere (LIMS) instrument measured profiles of O_3, H_2O, NO_2 and HNO_3. The Spacelab-3 Atmospheric Trace Molecule Spectroscopy (ATMOS) data provide profiles of over 25 atmospheric species, including CO and halogenated hydrocarbons. The Total Ozone Mapping Spectrometer (TOMS) data set spans an impressive 25 years from instruments flown on Nimbus-7, Meteor-3 and ADEOS 1, as well as the still operational TOMS Earth Probe instrument. The comprehensive 10 year Upper Atmosphere Research Satellite (UARS) mission includes atmospheric chemistry data products from four of its 10 instruments: the Cryogenic Limb Array Etalon Spectrometer (CLAES), the Halogen Occultation Experiment (HALOE), the Improved Stratospheric and Mesospheric Sounder (ISAMS), and the Microwave Limb Sounder (MLS). The UARS atmospheric chemistry data products include mixing ratio profiles of O_3, H_2O, CH_4, HF, HCl, chlorofluorocarbons, and various nitrogen and chlorine compounds. Of these UARS instruments, HALOE is still actively taking measurements under the UARS expanded follow-on mission. The EOS Aura satellite, to be launched into Earth orbit in early 2004, will expand upon atmospheric chemistry observations made during the UARS mission. Aura or the EOS chemistry mission includes four instruments: the High Resolution Dynamics Limb Sounder (HIRDLS), a Microwave Limb Sounder (MLS), the Ozone Monitoring Instrument (OMI), and the Tropospheric Emissions Spectrometer (TES). The first three instruments will focus on measuring various chemical species in the stratosphere and will be archived at the NASA Goddard Earth Sciences DAAC, while TES will measure pollutants and trace gases in the troposphere and will be archived at the NASA Langley DAAC. This presentation will provide an overview of the atmospheric chemistry data available at the NASA GES DAAC, including applications and services provided by the DAAC in support of users of these data. All data products from the NASA GES DAAC are available free to the public (see http://daac.gsfc.nasa.gov/).

SAGE III FIRST YEAR OF MEASUREMENTS: OVERVIEW OF THE MISSION AND EARLY RESULTS

William P. CHU[1], Chip R. TREPTE[1], Joe M. ZAWODNY[1], Larry W. THOMASON[1], Mike C. PITTS[1], Mike S. CISEWSKI[1], Didier F. RAULT[1], Ghassan TAHA[2], J.R. MOORE[3], Allan D. RISLEY[3] ([1]NASA Langley Research Center, [2]University of Arizona, [3]SAIC)

The Stratospheric Aerosol and Gas Experiment III/Meteor (SAGE III) mission is part of the NASA EOS program to provide vertical profile measurements of key constituents of the atmosphere such as ozone, aerosol, water vapor, NO2, NO3, OCIO, and atmospheric temperature. The SAGE III instrument was successfully launched on a Russian Meteor 3M spacecraft from Baikonur, Kazakhstan on December 10, 2001. After initial commissioning phase activities, it began routine solar occultation measurements by March 2002. During the first year of operation, additional measurement capabilities such as lunar occultation and limb scattering were successfully implemented with the SAGE III instrument. This paper will present a summary of the various data sets gathered from the SAGE III instrument during the first year of operation. Measurements of ozone, aerosol, and nitrogen dioxide from solar occultation, lunar occultation, and limb scattering techniques will be presented and discussed.

POLAR CHEMISTRY BY THE 4D-VAR CHEMICAL DATA ASSIMILATION OF MIPAS OBSERVATIONS

Frank W.R. DAERDEN[1], Dominique FONTEYN[1], Quentin ERRERA[1], Simon CHABRILLAT[1], Stijn BONJEAN[1], Niels LARSEN[2] ([1]BIRA-IASB, Brussels, Belgium, [2]DMI, Copenhagen, Denmark)

The Belgian Assimilation System of Chemical Observations from Envisat (BASCOE) is a four dimensional chemical data assimilation system in which a chemistry and a transport module are coupled to a detailed microphysical model (N. Larsen, DMI). This microphysical model describes the formation and evolution of four types of polar stratospheric cloud (PSC) particles, and its coupling to the chemistry module allows an interactive calculation of chlorine activation and denitrification that are responsible for polar ozone destruction. After a study of CRISTA (1994) and MLS (1995-1996) observations, we are currently following the Envisat mission from the start. BASCOE is processing the MIPAS observations in an operational set-up. In this talk we will present results from both the 2002 Antarctic winter (including the exceptional splitting of the polar vortex) and the 2003 Arctic winter. The added value of chemical data assimilation is demonstrated with an analysis of various fields in function of equivalent latitude.

CLIMATE IMPLICATIONS OF MOVEMENT OF THE UPPER TROPOSPHERE FRONTS DEDUCED FROM TOTAL OZONE DATA

Robert D. HUDSON, Marcus F. ANDRADE, Melanie B. FOLLETTE, Alexander D. FROLOV (Department of Meteorology, University of Maryland)

Analysis of the total ozone field obtained from the TOMS and Dobson data sets has shown that one can deduce the movement of the upper troposphere subtropical and polar fronts as a function of time. It has been shown, for example, that between 1980 and 1992 both fronts

moved northward. Any such movement implies that the weather patterns associated with these fronts will also have moved northward, i.e. that a climate change has taken place. In this paper, the movement of the fronts between 1965 and 2002 will be compared with climate indices. Initial results indicate a solar cycle dependence of the movement of both the polar and subtropical fronts. The subtropical front also shows a correlation with both the Quasi-Biennial Oscillation, and the Southern Oscillation.

NOX PRODUCTION BY LIGHTNING OVER THE INDIAN REGION

Suvarna Sushil KANDALGAONKAR, Md. Iqbal Rasul TINMAKER, Asha Shashi NATH (Indian Institute of Tropical Meteorology, Pune 411 008)

The importance of NOx production by lightning over the Indian region covering from 8 to 30 deg. N has been assessed by using satellite lightning measurements from the Lightning Imaging Sensor (LIS) and Optical Transient Detector (OTD). The lightning data from LIS/OTD for 4/5 year (1998-2001)/(1995-1999) period are analysed and partitioned, based on the latitude, to obtain the number of cloud to ground (CG) and cloud to cloud (IC) flashes. The annual total lightning counts by LIS/OTD during the period of study are 1.12 x10^7 / 7.12 x 10^6 respectively. Similarly, the annual IC and CG lightning count during 4/5 year period from two different sensors (LIS/OTD) are 9.4 x 10^6 / 5.9 x 10^6 and 1.8 x 10^6 /1.15 x 10^6 respectively. The total lightning count and the differential count from two different sensors are employed to calculate the production of NOx. We obtain the total annual lightning NOx production of 0.175 Tg N/yr by LIS and 0.1105 Tg N/yr by OTD over this latitudinal region, using the representative values of NO production and energy as 10^{17} molecules and 6.7 x 10^9 J. The NOx production values obtained by using differential count are 0.028 Tg N/yr from IC flashes and 0.018 Tg N/yr from CG flashes by using LIS Sensor and 0.146 Tg N/yr from IC flashes and 0.0913 Tg N/yr from CG flashes by using OTD sensor. The results of thisstudy suggests that though the orbiting period of OTD satellite is more than the LIS satellite by 19%, OTD could record 37% less lightning activity in total and corresponding NOx yield is also ~37% less than the NOx produced by LIS. Similar feature has also been observed from the differential count of each sensor. The NOx value obtained in the present study are more or less comparable with the values reported (displayed) by Bond et al., 2002 for the Indian region. The observed difference in NOx from the two sensor may be due to lower detection efficiency (40-60%) of OTD sensor. Thus LIS is perhaps the best lightning sensor with a high detection efficiency.

MI03/08A/B18-006 — 1050
LIGHTNING AND OTHER INFLUENCES ON TROPICAL TROPOSPHERIC OZONE:EMPIRICAL STUDIES OF COVARIATION

Robert B. CHATFIELD[1], Hong GUAN[2], Anne M. THOMPSON[3], Robert D. HUDSON[4], Jacquelyne C. WITTE[5] ([1]NASA (Ames Research Center), [2]BAER Inst. and NASA (Ames), [3]NASA (Goddard Space Flight Center), [4]Univ. of Maryland, [5]SSAI and NASA (Goddard))

Tropical and subtropical tropospheric ozone are important radiativelyactive species, with particularly large effects in the upper third ofthe troposphere. Temporal variability of O3 has proved difficult tosimulate day by day in process models. Thus, individual roles oflightning, biomass burning, and other pollution in providing precursorNOx, radicals, and chain carriers (CO, hydrocarbons) remainunquantified by simulation, and it is theoretically reasonable thatindividual roles are magnified by a joint synergy. We use waveletanalysis and Burg-algorithm ˝maximum entropy˝ spectral analyses todescribe time-scales and correlation of ozone with proxies for processescontrolling its concentration.Our empirical studies link time variations apparent in severaldatasets: the SHADOZ (Southern Hemisphere Additional Ozonesondes)network stations (Nairobi, Fiji), and auxiliary series with power toexplain ozone-determining processes, with some interpretation based onthe TTO (Tropical Tropospheric Ozone) product derived from TOMS (theTotal Ozone Mapping Spectrometer). The auxiliary series are The OTD/LIS(Optical Transient Detector/Lightning Imaging Sensor) measurements ofthe lightning NOx source, the OLR (Outgoing Longwave Radiation) measurement of high-topped clouds, and standard meteorological variablesfrom the United States NCEP and Data Assimilation Office analyses.Concentrating on equatorial ozone, we compare the statistical evidenceon the variability of tropospheric ozone. Important variations occur onapproximately two-week, two-month (Madden-Julian Oscillation) and annualscales, and relations with OLR suggest controls associated withcontinental clouds. Hence we are now using the Lightning Imaging Sensordata set to indicate NOx sources. We report initial results defining relative roles of the processes mentioned affecting O3 using their covariance properties.

MI03/08A/B18-007 — 1110
A SIGNIFICANT INCREASE OF CARBON MONOXIDE TROPOSPHERIC CONCENTRATION IN THE NORTHERN HEMISPHERE DETECTED BY TOTAL COLUMN AND SURFACE LAYER MEASUREMENTS IN 1998

Thomas BLUMENSTOCK[1], Evgeny GRECHKO[2], Yutaka KONDO[3], Justus NOTHOLT[6], Paul NOVELLI[9], Curtis RINSLAND[8], Ralf SUSSMANN[4], Hiroshi TANIMOTO[10], Leonid YURGANOV[7], Rodolphe ZANDER[5] ([1]IMK, Forschungszentrum Karlsruhe, Germany, [2]Obukhov Institute of Atmospheric Physics, Russia, [3]University of Tokyo, Japan, [4]Institut fuer Meteorologie und Klimaforschung Atmosphaerische Umweltforschung, Germany, [5]Institute of Astrophysics and Geophysics, Belgium, [6]University of Bremen, Germany, [7]Frontier Research System for Global Change, Japan, [8]Langley Research Center, NASA, USA, [9]Climate Monitoring and Diagnostic Laboratory, NOAA, USA, [10]National Institute for Environmental Studies, Japan)

Carbon monoxide in the troposphere of Northern Hemisphere was investigated using two different measurement approaches. First, absorption spectra of the total atmospheric depth using the Sun as a light source were measured at the Network for Detection of Stratospheric Change (NDSC) in USA, Switzerland, Germany, Sweden, Japan, Spitsbergen (Norway), and Russia. Total column amounts of CO above the measurement stations were retrieved from the spectra. Second, CO mixing ratios were measured in the surface layer using continuous instruments or by regular grab sampling and gas chromatography analysis at the CMDL laboratory in Boulder, Colorado. Sites of sampling were located between 31'N and 82'N in North America, Europe, Asia, Arctic, and North Pacific. All the data show abnormally high CO abundances in 1998. The CO ´anomalies´ i.e., monthly means, divided by the average over 1996, 1997, 1999 - 2001 for corresponding months. The anomalies for all the stations reached maximum between August and October 1998. It was found that the average hemispheric mean maxima for total column and surface anomalies amounted to 1.4 and 1.7, respectively, during late summer/fall 1998; the effect decreases with the altitude. The measurements at mountain stations (e.g., Niwot Ridge and Jungraujoch) confirm lower enhancements in the free troposphere. The column CO anomaly diminished exponentially between September 1998 and July 1999 with the time constant of 2-5 months, presumably due to a removal by OH. Monthly means of the atmospheric extra burden of CO in the NH were calculated by averaging all the available data. A ´top-down´ estimate for an additional CO source was obtained using a box model for a reservoir between 30'N and 90'N. This source had 2 maxima, in April and in August, 1998 and total annual magnitude between 70

M

and 140 Tg CO (for assumed life times 4.7 and 2.3 month, respectively). Extremely strong forest fires took place in 1998, especially in Siberia. The report indicates that the fires significantly affected the CO total column over the whole hemisphere in 1998.

MI03/08A/B18-008 — 1130
SEASONAL PERSISTENCE OF MIDLATITUDE TOTAL OZONE ANOMALIES

Vitali FIOLETOV[1], Theodore SHEPHERD[2] ([1]Meteorological Service of Canada, [2]University of Toronto)

The seasonal persistence of interannual variations in total ozone is investigated by analyzing temporal autocorrelations of monthly mean total ozone anomalies over the 35-60S and 35-60N latitude bands. It is found that anomalies established in the wintertime midlatitude ozone buildup persist (with photochemical decay) until the end of the following autumn, and then are rapidly erased once the next winter´s variability begins. The photochemical decay rate is found to be identical between the two hemispheres. Particularly in the northern hemisphere, there is high predictability of ozone through late summer based on the late-spring values. In the northern hemisphere, extending the 1979-2001 springtime ozone trend to other months through regression based on the seasonal persistence of anomalies (with the trend removed) captures the seasonality of the long-term ozone trends remarkably well. This suggests that the northern hemisphere trends in all months can be understood in terms of trends in the wintertime buildup. In the southern hemisphere, this mechanism only accounts for part of the summertime trends. There is a strong correlation between the ozone anomalies in northern hemisphere spring and those in the subsequent southern hemisphere spring, but not the converse. This suggests that some of the southern hemisphere variability is driven by the same mechanism as the northern hemisphere variability, or even by the northern hemisphere variability itself.

THE DETECTION OF THE POLAR ORIGIN AIR AT WAKKANAI, JAPAN, SECOND REPORT. THE OBSERVATION OF VERTICAL OZONE PROFILE AT WAKKANAI, JAPAN FROM FEBRUARY 15 TO 24, 2001

Shigeru CHUBACHI[1], Kouji MIYAGAWA[2] ([1]Atmospheric environment and applied meteorology Division,Meteorological Research Institute, [2]Ozone and radiation Division, Aerological Observatory)

In order to get better understandings of the ozone layer in the northern hemisphere, the observation of vertical ozone profiles at Wakkanai (45.4N, 141.7E), the northernmost city in Japan was conducted during the period from February 15 to 24, 2001 (Chubachi et al. 2002). In this paper, we report that the air mass detected at Wakkanai in Japan, though Wakkanai is located in the middle latitude, has the same characteristics of the air mass which is originated over polar stratosphere. In addition, TOMS data showed that the low ozone (below 250 DU) area appeared over Europe (around 55N, 20E) in February 14, one day before the observation taken at Wakkanai. We showed that the high latitude air mass on the 700K potential temperature surface moved to Europe with the low ozone area on February 14, further moved over to Wakkanai on February 19 at 700 potential temperature surface. We present the results based on the ozone sonde data set for the period February 14 to 24 through potential vorticity analysis technique. Finally, we suggest that it is possible to detect or observe the polar air at Wakkanai, in Japan, if we conduct dense and careful observation at Wakkanai, Japan.Reference Chubachi, S., Y. Sawa, T. Sekiyama, Y. Makino, and K. Miyakawa, Preliminary results of vertical ozone soundings at Wakkanai, Japan, Polar Meteorol. Graciol., 16, 149-164., 2002.

MODELLING TROPOSPHERIC AND STRATOSPHERIC CHEMISTRY IN THE UM

Peter BRAESICKE, Guang ZENG, John PYLE (Centre for Atmospheric Science, University of Cambridge)

We will present results from a hierarchy of chemistry modules used with the Met Office Unified Model (UM) to model the chemistry of the troposphere and stratosphere. Problems studied include the role of dynamics in middle latitude ozone decline and the change in oxidising capacity of the Troposphere. The tropospheric setup comprises a comprehensive chemistry in a 19 level version of the UM and is used to predict future changes in surface ozone and changes in the ozone budget. The stratospheric setup is based on the 58 level version and can be used with either a simple stratospheric chemistry for sensitivity studies on longer timescales, or a comprehensive chemistry for seasonal ensemble integrations. We amalgamate results from all model systems in consideration of the UT/LS region. We find that changes in ozone in the LS are crucial for the future development of tropospheric ozone. Changes in ozone in the LS do not have a large dynamical feedback on stratospheric ozone.

CAN HETEROGENEOUS CHEMISTRY ON CLOUDS INCREASE THE OXIDIZING ABILITY OF THE TROPOSPHERE

Azadeh TABAZADEH[1], Robert J. YOKELSON[2], Hanwant B. SINGH[1] ([1]Earth Science Division, NASA Ames Research Center, [2]University of Montana, Dept. of Chemistry)

It is well known that heterogeneous chemistry in the polar stratosphere leads to the formation of the Antarctic ozone hole. However, very little is known about the effect of heterogeneous chemistry on the composition of the troposphere. Methanol is the second (methane is the first) most abundant organic trace gas found in the Earth´s atmosphere, and there appears to be a large mismatch between atmospheric concentrations and estimated sources, indicating the presence of major unknown removal processes. Using trace gas and aerosol data from the SAFARI 2000 experiment, taken in clouds impacted by biomass burning, we show clouds may provide a major sink for methanol removal through a number of plausible heterogeneous chemical processes. Further, rapid heterogeneous chemistry on cloud surfaces, involving methanol, may also cause production of photochemically active species (i.e. formaldehyde) in cloud-processed air, affecting the oxidizing ability of the atmosphere on a global scale.

SIMULATING ANTARCTIC STRATOSPHERIC OZONE LOSS IN A GCM: VARIABILITY

Stephen R. BEAGLEY[1], Jean DE GRANDPRE[2], Victor I. FOMICHEV[1], John C. MCCONNELL[1], Theodore G. SHEPHERD[3] ([1]York University Toronto, [2]McGill University, Montreal, [3]University of Toronto, Toronto)

Simulation of polar ozone loss within a GCM for time-slice conditionspermits the exploration of the interaction between radiation, dynamicsand chemistry which can produce varying ozone loss for the sameclimate conditions. Dynamical variability influences springtime polarozone abundance through both ozone transport and temperature-inducedvariability in PSC formation and consequent chemical ozone loss. Results using the Canadian middle atmosphere model (CMAM) for low andhigh chlorine loading scenarios will be presented to explore themodel´s capability in describing the dynamical and chemical evolutionof lower stratospheric polar springtime events, and to explore thevariability inherent in coupled chemistry-climate model simulations ofozone loss.

MI03/08P/B18-004 — 1500
QUANTIFYING THE TROPOPAUSE MIXING BARRIER IN THE CANADIAN MIDDLE ATMOSPHERE MODEL

David SANKEY, Theodore G. SHEPHERD (Department of Physics, University of Toronto)

Mixing barriers in the atmosphere play an important role in shapingthe large-scale dynamical circulation, and greatly affect thetransport of chemical species. While some success has been achieved inidentifying the edge of the tropical pipe and the wintertime polarvortex barrier, finding the location of the tropopause mixing barrierhas proven to be much more elusive. In this study, various methods areapplied to identify the tropopause mixing barrier in the CanadianMiddle Atmosphere Model, a three-dimensional coupled chemistry GCM. AGCM is used partly to provide a dynamically self-consistent data set,and partly because it is an important exercise in itself to assess theextent to which such models represent the tropopause mixingbarrier. The methods studied include Nakamura´s effective diffusivity, age of air, PDFs of chemical species, seasonal evolution of ozone, and investigating the balance between radiative heating and cooling. Inaddition to quantifying the tropopause mixing barrier in the model,comparison of the different methods sheds light on their commonalities and differences.

MI03/08P/B18-005 — 1520
THE SEPARATE CLIMATE EFFECTS OF THE STRATOSPHERIC AND THE TROPOSPHERIC CO2 INCREASE AS SIMULATED WITH THE MA-ECHAM4 MODEL

Michael SIGMOND[1], Peter Christiaan SIEGMUND[2], Hennie KELDER[2], Elisa MANZINI[3] ([1]Eindhoven University of Technology (TUE), [2]Royal Netherlands Meteorological Institute (KNMI), [3]Max-Planck-Institut für Meteorologie)

The effect of the separate stratospheric and tropospheric CO2 increase on, respectively, the troposphere and the stratosphere has been investigated with the middle atmosphere version of the ECHAM climate model. Hereto, the CO2 is separately doubled in, respectively, the troposphere, the middle atmosphere and the entire atmosphere, and the results are compared to a control run. In addition, the linearity of the results is investigated. The results show that the tropospheric CO2 doubling causes a significant increase in the residual circulation in the stratosphere, leading to an increase in the stratospheric temperatures at high latitudes. The stratospheric CO2 doubling causes a significant increase in the tropospheric extratropical zonal wind. Results from an additional experiment show that also the doubling of CO2 above 10 hPa, which is close to the top of many GCM's, significantly influences the tropospheric climate.

MI03/08P/B18-006 — 1610
SIMULATION OF FUTURE DISTRIBUTIONS OF TROPOSPHERIC OZONE AND SULFATE AEROSOL: IMPACTS OF EMISSION CHANGE AND CLIMATE CHANGE

Kengo SUDO[1], Masaaki TAKAHASHI[1], Toru NOZAWA[2], Hiroshi KANZAWA[2], Hajime AKIMOTO[3] ([1]Center for Climate System Research, University of Tokyo, [2]National Institute for Environmental Studies, Japan, [3]Frontier Research System for Global Change, Japan)

We performed experiments of future tropospheric chemistry involvingozone (O_3) and sulfate aerosol with a coupled chemistry general circulation model (GCM). Future change in tropospheric ozone and aerosols distributions is of critical importance both for climate and atmospheric environment. Ozone and aerosols in the troposphere, having much short residence times relative to other principal greenhouse gases, are controlled by emissions of precursors and also by natural meteorological conditions (temperature, humidity, transport, etc.). In this study, we conducted simulations of tropospheric ozoneand sulfate distributions for the next hundred years to 2100 using acoupled chemistry GCM (the CHASER model) which has been developed in theframework of the Center for Climate System Research/National Institutefor Environment Studies (CCSR/NIES) atmosphere GCM. To evaluate impactsof emission change and of climate change independently, two kinds ofexperiments were carried out. In the first experiment (Exp1), the GCMsimulates present-day meteorological conditions using constantgreenhouse gases, but in the second experiment (Exp2) it simulatesclimate change based on the IPCC SRES A2 scenario. Trace gas emissions of CO, NO_x, methane (CH_4), non-methane hydrocarbons, and SO_2 in both experiments are prescribed by the SRES A2 scenario. In Exp1 with no climate change, global tropospheric ozone burden increasedalmost linearly from 325 Tg in 1990 to 397 Tg (22%) in 2050 and to 467 Tg(+44%) in 2100, showing significant increases in the low to midlatitudes in the Northern Hemisphere including eastern Asia (+53% in 2100). In Exp2 with climate change, the ozone increases predictedin Exp1 are generally reduced 10-20% in the lower troposphere after around2050, due to water vapor increases causing more efficient ozone destruction. However, Exp2 calculates additional ozone increases of 5-10% in the boundary layers around the polluted regions as eastern Asia relative to Exp1 (after 2050), showing moreenhanced ozone production due to temperature and water vapor increases.Exp2 also predicts additional increases in upper tropospheric ozone in the midlatitudes as a result of enhanced ozone transport from the stratosphere due to intensification of the Hadley Circulation and stratospheric circulation in the model.The model predicted an increase in the sulfate burden from 0.55 TgS in1990 to 0.91 TgS in 2050 with showing pronounced increases in India andChina. This experiment indicated that the sulfate formation in liquidphase was enhanced by the increases in H_2O_2 after around 2050 particularly in the lowlatitudes as in India. Global mean methane concentration increased to about 4 ppmv in 2100 withemission change only (Exp1), but to 3.3 ppmv with climate change as well (Exp2), reflecting the impact of temperature and water vapor increases on the CH_4 lifetime against the reaction with OH.In Exp1, CH_4 lifetime increases from 9.2 years in 1990 to 11.4 years in 2100, whereas Exp2 shows reduction in CH_4 lifetime (8.6 years in 2100).

MI03/08P/B18-007   1630

CHANGES IN THE STRATOSPHERIC OZONE EQUILIBRIUM CAUSED BYGREENHOUSE GAS INCREASES BETWEEN 1979 AND 2060

Michel S. BOURQUI[1], Chris P. TAYLOR[2], Keith P. SHINE[2] ([1]Institute for Atmospheric and Climate Science, ETH Zurich, [2]Dept of Meteorology, University of Reading)

The depletion of stratospheric ozone due to chlorine emissions whichstarted in the early eighties is now slowing down and is expected toend up near the 2050s thanks to emission cuts that followed theratification of the Montreal Protocol. Stratospheric ozone mayhowever recover towards a distribution substantially differentfrom the pre-depletion one because of the concurrent increasein greenhouse gases (GHG). BR >Here, a new coupled three dimensional chemistry - generalcirculation model has been developed. The new chemistry modelFASTOC (FAst STratospheric Ozone Chemistry) represents thechemistry of stratospheric ozone in terms of constituentrelationships derived from an accurate chemical box model. Thecirculation is performed by the IGCM (Intermediate GeneralCirculation Model) of the University of Reading. This modelis used in its T21 version with 26 levels from the surface upto 0.1hPa. The thrust of this coupled model is the combinationof a high computational speed and a realistic representation ofozone chemistry. In this study, changes in the stratospheric ozone equilibriumdue to GHG increases between 1979 and 2060 are investigatedin the context of time-slice experiments using our new coupledmodel. The emphasis is placed on the understanding of thethree ways along which the GHG increase affects ozone chemistry:(i) by chemically and (ii) thermodynamically interacting withthe ozone production/loss chemistry, and (iii) by changingthe constituents circulation.

INITIAL DATA COMPARISON OF SAGE III AND VARIOUS SATELLITES, GROUND-BASED AND BALLOON MEASUREMENTS

William P. CHU[1], Chip L. TREPTE[1], Joe M. ZAWODNY[1], Larry W. THOMASON[1], Ghassan TAHA[2], J.R. MOORE[3] ([1]NASA Langley Research Center, [2]University Of Arizona, [3]SAIC)

The Stratospheric Aerosol and Gas Experiment III (SAGE III), which was launched on Dec 10, 2001 on the Russian spacecraft Meteor 3M, is an important part of NASA's Earth Observing System (EOS) mission to develop an understanding of the total Earth system and the effects of natural and human-induced changes on the global environment. The instrument make use of Solar occultation observations to provide high resolution vertical profiles of multi-wavelength aerosol extinction, the molecular density of ozone, nitrogen dioxide, and water vapor, as well as profiles of temperature, pressure, and cloud presence. The instrument is also capable of performing lunar occultation and limb scattering measurements. In this work, the latest SAGE III solar and lunar occultation measurements will be presented. In an early evaluation of the measurements, comparisons will be made between SAGE III level 2 solar products (version 2.0) and SAGE II, HALOE, POAM III, and GOMOS satellites. Comparisons also include balloon and ground-based measurements.

DIURNAL VARIATION ON THE SUBTROPICAL BRO

Manuel GIL, Olga PUENTEDURA, Margarita YELA (INTA. Dep. de Observación de la Tierra: Teledetección y Atmósfera)

A BrO column measurements programme by zenith sky UV spectroscopy at the Northern Subtropical belt (Izana Observatory, 28°, 16°W, 2370 m.a.s.l) started on December 2001. The instrument set upand parameters used for BrO retrieval followed the recommendations by Aliwell et al. Data show aclear signature of the BrO cross sections structures in the recorded spectra but retrievedamounts are lower than at higher latitudes. The shape of the diurnal variation in the slantcolumn display a marked seasonal dependence. Values are generally larger in the morning twilight,being the largest am-pm asymmetry in the summer solstice. This behaviour cannot be reproduced bythe gas phase photochemical models assuming all the BrO in the stratosphere. Additionally,Langley plots at solar zenith angles between 60° and 85° yields values of the vertical columnabove 5xE13 molec.cm-2 in mid summer, while estimated stratospheric column for the same seasonis below 2xE13 molec.cm-2. The difference between both, larger than 3xE13 molec.cm-2,is attributed to BrO residing in the free troposphere. This significant amount of troposphericBrO is also inferred from the shape of the column around twilight, and from limited off-axismeasurements.

MI03/09A/D-003   Poster   0900-246

LONG TERM TRENDS OF NITROGEN DIOXIDE LEVELS OBSERVED AT MID- AND HIGH-LATITUDE STATIONS FROM GROUND-BASED SPECTROMETER DATA

Daniele BORTOLI[1], Andrea PETRITOLI[2], Giorgio GIOVANELLI[2], Ivan KOSTADINOV[3], Fabrizio RAVEGNANI[2], Ana Maria SILVA[1] ([1]Geophysics Centre of Evora, University of Evora, [2]ISAC-CNR, via Gobetti 101, Bologna , Italy, [3]STIL-BAS, 6000, Stara Zagora, Bulgaria)

The interactions between mid- and high-latitude atmospheric changes are going to be one of the main issues for the future of stratospheric and tropospheric chemistry research. A more detailed study of the ozone trends and those of the chemically-related compounds (NOx, chlorine and bromine oxides) as well as a greater comprehension of their interactions at lower and higher latitudes, are important issues which should be addressed to build-up a more detailed picture of possible scenarios which we may have to face in the near future.Nitrous oxide (N2O), an important greenhouse gas, has been increasing since 1980 at a rate of about +3% per decade. Recently, a notably greater rate of increase of about +5% per decade since 1980 was reported for measurements of stratospheric nitrogen dioxide (NO2). However, since N2O is the dominant source of odd-nitrogen compounds in the stratosphere, including NO2, a more complex approach would seem to be necessary. These apparently conflicting trends are, in fact, generally consistent when viewed within a wider framework with the inclusion of concurrent trends in stratospheric ozone and halogens.GASCOD spectrometers (Gas Analyzer Spectrometer Correlating Optical

Differences) have been installed at the ˝Ottavio Vittori˝ Research Station at Monte Cimone, Italy (44.11N, 10.42E, 2165 m asl) since June 1993, at the Italian Antarctic Station, Terra Nova Bay (74.69S, 164.12E) since December 1995 and at the STIL-BAS station at Stara Zagora, Bulgaria (42.42N, 25.63E) since 1999. The instruments measure zenith scattered solar radiation between 407 and 464 nm (occasionally measurements at 330-390 nm are performed) and the nitrogen dioxide total column is retrieved with Differential Optical Absorption Spectroscopy.The seasonal trend of NO2 vc values is reported and it shows the expected behaviour: maximum values during the summer period with the minima occuring during the winter season in both hemispheres. A typical behaviour of the AM/PM ratio at high latitudes is highlighted. The application of a simple photochemical model confirms that the NO2 AM/PM ratio can be modelled with temperature at the NO2 bulk altitude, the ozone concentration at the same altitude and the hours of darkness.A Fourier analysis is proposed as a tool to investigate the long-term components of stratospheric nitrogen dioxide levels. Results are presented and the NO2 trend is shown and discussed.Measurements such as these are essential for identifying global change and provide a lesson in understanding it: careful simulation of the time, location, and geometry of measurements must be combined with concurrent trends in related chemical species and climatic parameters. ACKNOWLEDGEMENTS The author Daniele Bortoli gratefully acknowledges financial support from the Subprograma Ciência e Tecnologia do 3° Quadro Comunitário de Apoio. The Quantification and Interpretation of Long-Term UV-Vis Observations of the Stratosphere (QUILT) project supported this research.

MOVEMENT OF THE SUB-TROPICAL AND POLAR FRONTS DEDUCED FROM TOTAL OZONE RECORDS

Melanie B. FOLLETTE, Marcos F. ANDRADE, Alexander D. FROLOV, Robert D. HUDSON (Department of Meteorology, University of Maryland)

Analysis of the ozone field in the Northern Hemisphere outside of the polar vortex, using both TOMS and Dobson data, has shown that the total ozone field can be separated into three distinct meteorological regimes. These are defined as (1) the tropical regime - between the equator and the upper troposphere subtropical front (2) the midlatitude regime - between the subtropical and polar fronts, (3) the polar regime - between the polar front and the polar vortex. Within each regime, the daily mean total ozone value is relatively constant, with a clearly separate value for each regime. It has also been shown both from rawinsonde and ozonesonde measurements, that the tropical, mid-latitude, and polar regimes are identified with a distinct tropopause height. The trends in total ozone between 1979 and 1992 within each regime are much less than the overall mid-latitude trend obtained from zonally averaged data. Much of the observed zonal trend is due to the movement of the subtropical and polar front northward, causing more low ozone in the tropical regime, and less high ozone in the polar regime, to be included in the zonal average. This paper presents an analysis of the movement of the polar and sub-tropical fronts for the period between 1965 and 2002 deduced from both the TOMS and Dobson data sets.

MODELING THE EFFECT OF A PINATUBO LIKE VOLCANIC ERUPTION WITHIN THE NEXT DECADE USING A COUPLED CHEMISTRY-CLIMATE MODEL

Hamish STRUTHERS[1], John AUSTIN[2] ([1]National Institute of Water and Atmospheric Research, New Zealand, [2]The Met Office, UK)

A future major volcanic eruption, if it were to occur within the nextdecade, could potentially have a significant impact on stratosphericozone amounts, due to the activation of halogen compounds on the surfaceof the volcanic aerosol cloud (Tabazadeh et al 2002). Accurately modeling the response of the stratosphere to a major volcaniceruption is difficult (Bodeker et al 2001, WMO 2002). Coupled chemical-dynamical models are required to simulate to radiative-chemical feedbacks present in the atmosphere (Rosenfield et al 1997, Al-Saadi et al 2001). We use the UMETRAC, coupled chemistry-climate model (Austin 2002) to simulate a Mt. Pinatubo like volcanic eruption (Knight et al 1998), starting the model from 2010 initial conditions and future boundary forcing (sst, ice, stratospheric halogen loading etc). Comparisons will be made with acontrol run of the model to clarify the impact of stratospheric sulphateloading on ozone and temperature. VALIDATION OF THE NEWLY DEVELOPED CLIMATE-CHEMISTRY MODEL (SOCOL) AGAINST OBSERVED CLIMATOLOGY

Tatiana A. EGOROVA[1], Eugene V. ROZANOV[1], Thomas PETER[2], Werner SCHMUTZ[3] ([1]PMOD-WRC, Davos and IAC ETH Zuerich, Switzerland, [2]IAC ETH Zuerich, Switzerland, [3]PMOD-WRC, Davos , Switzerland)

Predictability of climate and ozone changes in the future is one of the importantand challenging problem in modern science that requires the development,implementation and validation of very sophisticated, computationally efficient,three-dimensional climate models with interactive chemistry (CCM). Here wepresent a newly developed CCM SOCOL (model tool for evaluation of the SOlar-Climate-Ozone-Links), which is a combination of MAECHAM-4 GCM with atmospheric chemistry and transport model developed in Switzerland. This spectral global model has T30 horizontal representation and 39 levels in the vertical direction. SOCOL enables simulating of the temperature, dynamics and photochemistry of the troposphere, stratosphere and lower mesosphere up to 85 km. When the development of such a complicated model is completed it isimportant to verify how well it reproduces observed climatology. With SOCOL we have performed a 40-year long simulation with prescribed sea surfacetemperature, sea ice and greenhouse gas distributions. The simulated winds, temperature, ozone and other trace species have been validated against available observations obtained from different satellite instruments and compared with other CCMs results. The comparison showed that SOCOL simulates photochemistry, temperature and dynamics of the troposphere, stratosphere and lower mesosphere reasonably well and can be used to address chemistry-climate interaction issues.

LARGE SCALE PATTERNS OF ATMOSPHERIC VARIABILITY: DYNAMICS, CLIMATE IMPACTS, AND ROLE IN RECENT CLIMATE CHANGE (ICCI)

ON THE PHYSICAL REALITY OF ANNULAR MODES

Walter A. ROBINSON (Department of Atmospheric Sciences, University of Illinois at Urbana-Champaign)

Several authors have recently challenged the physical reality of annular modes. The crux of these challenges is that the low-frequency component of the atmospheric flow is not annular (zonally symmetric), and that the annular modes are, therefore, an artifact of empirical orthogonal function (EOF) analysis. The flow during individual annular mode events, periods when the projection on the annular mode EOF is unusually strong (positive or negative),displays zonally localized structures (Cash et al. 2002), as do teleconnection patterns obtained from one-point correlation analyses (Deser 2000). Here, it is argued these results are insufficient to show that annular modes are not real. While they are consistent with the absence of physical annular modes, they are also consistent with a system wherein annular and strong non-annular variability coexist. If annular and non-annular variability are mutually independent, then the presence of robust non-annular variability makes the annular modes no less real. In a very simple system (a coarsely resolved two-level model on the sphere) the annular and non-annular variability are nearly, but not completely, independent. For this model, at least, the annular mode is a physically useful concept. This independence requires, first, that the annular modes have only weak direct interactions with non-annular low-frequency variability, a condition unlikely to be satisfied in the Northern Hemisphere (DeWeaver and Nigam 2000), and, secondly, that interactions of both annular and non-annular low-frequency variability with transient eddies are approximately linear in the strength of the low-frequency flow. Again, this is true for the two-level model, but perhaps not in better-resolved models or in nature. If the above conditions are violated, it may still prove useful to focus on annular variability, if the annular (m=0) components of originally localized disturbances are more persistent than non-annular components, and if this annular residual is significant in organizing weather at longitudes remote from the initial disturbance. Based on experiments with the two-level model, model experiments and diagnostic analyses are proposed that could be used to assess the physical reality and utility of annular modes in more realistic models and perhaps in nature. Cash, B.A., P.J. Kushner, and G.K. Vallis, 2002: The structure and composition of the annular modes in an aquaplanet general circulation model. J. Atmos. Sci., 59, 3399-3414. BUDGET OF OMEGA ANGULAR MOMENTUM: ANOTHER WAY TO ASSESS THE DYNAMICSOF THE ANTARCTIC AND ARCTIC OSCILLATIONS

Jin-Song VON STORCH (Institute of Meteorology, University Hamburg, Germany)

Both the Antarctic and Arctic Oscillations (AO and AAO) reveal notableanomalies of axial angular momentum. When decomposing these anomaliesinto a part related to Oemga angular momentum (the matter term) and apart related to relative angular momentum, one finds that the formeris much larger than the latter. The large anomalies of Omega angularmomentum result from mass conservation constraint. The mass (zonallyaveraged pressure) anomalies related to the AO and AAO reveal ameridional dipole structure such that the mass in the high-latitudecenter is equal to and has opposite size of the mass in themid-latitude center. This structure make the global Omega angularmomentum be significantly non-zero, as the high-latitude mass isrelatively close to the rotation axis.Given the significance of mass anomalies, the budget equation of omegaangular momentum is used to study the maintenance of the two modes.Three types of mass transports are identified. The first one emergesfrom ageostrophic flow in conjunction with tropospheric eddies. Thesecond one, which is related to the friction torque, results frommeridional Ekman velocities. The last one, which gives rise to themountain torque, is induced by meridional geostrophic flow withinmountainous barriers. The first two types of mass transport aredirectly related to the structure of zonal-mean zonal flow. They tendto balance each other and result in a persistence dipole structure inmass (pressure). This is the situation observed for the AAO. Theemergence of the third type of mass transport destroys the balancebetween the first two mass transports. The dipole structure inpressure anomalies is much less persistent. This is the situationobserved for the AO.The consideration of mass transports suggests that the AAO and AO aretwo internal modes of the atmosphere, which are differently modifiedby the lower boundary conditions.

ANALYSIS AND MODELING OF THE ARCTIC OSCILLATIONUSING A SIMPLE BAROTROPIC MODELWITH BAROCLINIC EDDY FORCING

Hiroshi L. TANAKA (Institute of Geoscience, University of Tsukuba)

In this study, a numerical simulation of Arctic Oscillation (AO) isconducted using a simple barotropic model that considers thebarotropic-baroclinic interactions as the external forcing.The model is referred to as a barotropic S-modelsince the external forcing is obtained statistically from the long-term historical data, solving an inverse problem.We have integrated the barotropic S-model for 51 years under a perpetual January condition and analyzed the dominant EOF modes in the model.The results are compared with the EOF analysis of the barotropiccomponent of the real atmosphere based on the daily NCEP/NCAR reanalysis for 50 years from 1950 to 1999. According to the result, the first EOF of the model atmosphere appears to be the AO similar to the observation.The annular structure of AO and the two centers of action atPacific and Atlantic are simulated nicely by the barotropic S-model.Therefore, the atmospheric low-frequency variabilities havebeen captured satisfactorily even by the simple barotropic model. The EOF analysis is further conducted to the external forcingof the barotropic S-model.The structure of the dominant forcing shows the characteristics of synoptic-scaledisturbances of zonal wavenumber 6 along the Pacific storm track.The forcing is induced by the barotropic-baroclinic interactionsassociated with baroclinic instability. The result suggests that the AO can be understoodas the natural variability of the barotropic component of the atmosphereinduced by the inherent barotropic

dynamics which is forced by the barotropic-baroclinic interactions.The fluctuating up-scale energy cascade from synoptic-scale disturbances to the zonal motion plays the key rolefor the excitation of the AO.

VERTICAL STRUCTURE OF THE ARCTIC OSCILLATION AND COLD OCEAN WARM LAND REGIMES AND THEIR ROLE IN CLIMATE CHANGE

Susanna CORTI (ISAC Institute of Atmospheric Sciences and Climate, CNR National Research Council)

When examined in terms of diagnostics of the atmospheric circulation, recent climate change may be interpreted in terms of increases or decreases in the frequency of occurrence of pre-existing preferred modes of atmospheric behaviour rather than a simple linear shift in the mean climate with superimposed noise. This contrasts with the characteristics of the observed changes in temperature-related diagnostics, which appear much closer to the simple linear picture. While not necessarily inconsistent, the implications of these two views of the nature of climate change need to be explored.In this framework the main purpose of this paper is to use a 40-yr NCEP reanalysis dataset in order to explore the vertical structure of circulation regimes and (at the same time) illustrate the potential role of weather regimes and non-linearity in the emerging anthropogenic signal. An empirical orthogonal function (EOF) analysis is first applied in order to define, for each variable, a reduced phase space based on the leading modes of variability. Then a simultaneous analysis of the four fields is carried out performing a further EOF analysis in the subspace spanned by the leading EOFs of each field. This produced a multi-variable EOF picture of the large-scale vertical (and thermal) structure of the atmosphere. With the three-dimensional structure available, it is possible to assess whether the observed temperature changes are consistent with an increase in certain regime frequencies. Moreover the hypothesis that regime frequency change more than regime structure is checked by performing a regime analysis separately on the first and last 25-yr periods.

DYNAMICAL PROTOTYPE OF THE ARCTIC OSCILLATIONAS REVEALED BY A NEUTRAL SINGULAR VECTOR

Masahiro WATANABE (Department of Ocean and Atmospheric Science, Hokkaido Univeristy)

Toward understanding dynamical origin of the **A**rctic **O**scillation (**AO**),a dynamical analysis was conducted by means of a linear primitive equation model.**T**his work is to extend our previous results (**K**imoto et al. 2001, **GRL**) in whichsingular vectors have been computed for a zonal mean part of the linear dynamical operatorthat incorpolates feedback from anomalous stationary eddies. **I**n order to verify a hypothesis that the **AO** essentially originates from the zonally imhomogeneous time mean state, we again computed singular vectors of the dynamical operator but now linearized about thenon-zonal winter climatology; that is, the operator includes both the zonal flow-waveinteraction and the wave-wave interaction. **T**he leading singular mode, which is close to neutraland dominates over others under stochastic forcing, has a considerable resemblance to theobserved **AO**. **S**everal processes, such as an interaction with transient eddies and a thermalforcing either in the stratosphere or at the surface, may preferably excite the **AO**, thesingular vector analysis performed here strongly suggests that the origin of the **AO** residesin dynamics of a slowly-varying, non-zonal time mean state in the troposphere. **F**urther diagnoses were made to the singular mode to clarify the role of zonal flow-stationary wave interaction, divergence in the upper troposphere, and so on.

TOPOGRAPHIC EFFECTS ON ANNULAR VARIABILITY IN A COUPLED ATMOSPHERE-OCEAN GCM

Seiya NISHIZAWA[1], Shigeo YODEN[1], Akio KITOH[2] ([1]Department of Geophysics, Kyoto University, [2]Meteorogical Research Institute, Tsukuba, Japan)

Thompson and Wallace (1998, 2000) pointed out that the most dominant mode of low-frequency variability in the extratropical troposphere is the ˝annular mode˝ both in the Northern Hemisphere (NH) and the Southern Hemisphere (SH). Although the annular mode in the both hemispheres has some similar structures, there exist differences between the two hemispheres due to the surface conditions.Nishizawa and Yoden (2003) noted that annular variability depends on the number and spatial structure of storm tracks in a simplified global circulation model with some idealized topographic conditions. In this study, we examine the topographic effects on the annular variability with a coupled atmosphere-ocean GCM (MRI-CGCM2). The control run (M10) was integrated for 50 years with realistic land-sea distribution and topography (Kitoh 2002). In the M0 run, the worldwide mountain height was set to zero, but keeping the land-sea distribution. Similarly 20% of the topography in the M0 run were assumed in the M2 run, and 40%, 60%, 80%, 120% and 140% were in the M4, M6, M8, M12 and M14 runs, respectively. The monthly averaged data in winter season of the last 40 years for the eight runs are analyzed. An EOF analysis is done for the sea-level pressure field in the NH. Some characteristics of EOF1 depend on the amplitude of the topography, and there are switchings in the order of the EOFs.The leading EOF1 shows annular pattern except in the M0 and M4 runs,and second mode of EOF shows annular pattern in these two runs.It is note that contribution rate of the first two EOFs are very similar in the M0 run; 22% and 21%. The switching in the M4 run is similar to that in the previous work with simple model. EOF analysis for the zonal-mean zonal wind field from the surface to 50hPa in the NH also shows dependence on the topographic amplitude. Latitude of the node of the EOF1 tends to shift equatorward with increasing the amplitude. The domain of the EOF analysis for the sea-level pressure field was swept by changing the latitude of northern boundary in the NH (cf. Itoh 2002). In the M8 run, the leading two EOFs for the domain without the polar region are dominant over the Pacific or the Atlantic sector, respectively. These two modes are well separated, although the leading mode of the hemispheric EOF shows annular pattern. In the other runs, the hemispheric EOF and the midlatitude EOF have similar pattern. Same analyses are also done for the SH, and the difference of the amplitude dependence between the NH and the SH is identified to understand the annular variability in the real atmosphere more clearly.

MI05/09A/B17-008   **1150**

DECOMPOSITION OF THE ARCTIC OSCILLATION INTO INDEPENDENT COMPONENTS

Atsushi MORI[1], Nobuaki KAWASAKI[2], Kensuke YAMAZAKI[3], Meiji HONDA[4], Hisashi NAKAMURA[5] ([1]Department of Astronomy and Earth Science, Tokyo Gakugei University, [2]Senior High School at Otsuka of Tsukuba University, [3]Department of Mathematics and Informatics, Tokyo Gakugei University, [4]Institute for Global Change Research, Frontier Research System for Global Change, [5]Institute for Global Change Research, Frontier Research System for Global Change, and Department of Earth and Planetary Science, University of Tokyo)

Arctic Oscillation(AO) is known to be the most dominantvariability over the northern hemisphere in winter(Thompson and Wallace, 1998). However, recently, physicalentity of AO comes into question from various points ofview. One of the major questions is whether there exists alinkage between the North Atlantic and the Pacific,because the correlation between the signals at the NorthAtlantic and the North Pacific are quite weak(Deser, 2000;Ambaum et al., 2001; Itoh, 2002). We propose another way to check the validity and toidentify independent modes from a view point ofstatistical independence. The method, called ″Independent Component Analysis(ICA),″ is developed in the field ofneuro-science and, now, it is widely used for multi-variateanalysis(e.g. Hyvaerinen and Oja, 2000). In principle, ICAdifferentiate independent components according to the shape of distribution function on the assumption that the probability of any natural independent component must bein a non-Gaussian distribution, though the conventional EOF analysis relies on the amplitudes of the components. Applicability of ICA to artificial simple AOdata proposed by Itoh(2002) is studied and the result isquite successful. Applying ICA to the real observed monthly-mean sea levelpressure data(NCEP/NCAR reanalysis data), it is strongly suggested that AO is in fact a superposition of two statistically independent modes. In spite of the low correlation between the SLP data of the Atlantic and the Pacific, both two modes seems to have tight linkage between the two oceans. One of them corresponds to seesaw-like relation between the intensities of the surface Aleutian and Icelandic lows(Honda et al., 2001); the relation accounts for most of the variation of AO(Honda andNakamura, 2001). The other mode has in-phase relations between the two lows. A notable trend in the AO time series as noted in Thompson and Wallace(1998) and Thompsonet al.(2001) may be a manifestation of this second mode that represents the recent long-term deepening of the two lows.

THE NAM AND PNA-LIKE PATTERNS AS A FRAMEWORK FOR INTERPRETING WINTERTIME LOW FREQUENCY ATMOSPHERIC VARIABILITY

Roberta QUADRELLI, John M. WALLACE (Department of Atmospheric Sciences, University of Washington, Seattle)

The NAM and PNA-like patterns, as defined by the two leading EOF´s of themonthly sea-level pressure field, together define a two-dimensional phasespace that provides a framework for interrelating some of the moreimportant patterns of Northern Hemisphere wintertime low-frequencyvariability. We show that these two modes have a significant influence on theatmospheric variability observed in the 1958-99 record over a range offrequencies. For example, they affect the occurrence ofextreme cold events in 5 and 10-day mean temperature data. These two modes also have astrong impact on longer term variability. For example, they account for most of the hemisphericsea level pressure and surface temperature trends observed during this period. The non-linear interactions between these modes, as well as theirdependence on the mean state are also addressed. The ENSO cycle is shownto significantly affect the structure of the NAM on the intraseasonal timescale. Warm winters of the ENSO cycle account for a disproportionate share of the strong SLP and SAT trends observed during the past four decades.

UNDERSTANDING ANNULAR VARIABILITY IN THE TROPICS

David W.J. THOMPSON[1], David LORENZ([1]Dept of Atmospheric Science, Colorado State University, [2]Dept of Atmospheric Science, University of Washington)

The Northern and Southern Hemisphere annular modes are associated with marked anomalies in the circulation of the tropics. Their high indexpolarity is characterized by westerly wind anomalies in the easterntropical Pacific, and by negative temperature anomalies throughout the tropical troposphere with distinctive subtropical cooling maxima. Thedynamics and climate impacts of the remote linkages are examined. It is argued that the tropical signature of the annular modesreflects the impact of waves propagating from the extratropical NH. Evidence ispresented that suggests the tropical signature of the annular modesreflects a preferred pattern of variability of the tropical circulation.

THE SYNOPTICS INDIVIDUAL PNA EVENTS

Steven B. FELDSTEIN (EMS Environment Institute, The Pennsylvania State University)

The synoptic characteristics of individual PNA events are investigatedby examining potential temperature on the nominal tropopause (the2 potential vorticity unit surface). This variable is calculated from the NCEP/NCAR Reanalysis dataset for the winter season.Both PNA phases evolve from breaking synoptic scale waves. The wavebreaking is cyclonic for the positive phase, and anticyclonic forthe negative phase. There are also differences in the longitude ofthe wave breaking for the two phases. For the positive phase, this wave breaking occurs off the Asian coast, and for the negative phase the wave breaking takes place off the west coast of North America. For both phases, it is the remnants of the breaking wave that comprisethe optimal structure in the North Pacific which then evolves intothe PNA teleconnection pattern. Throughout the wave breaking, North Pacific anomalies become increasing circular in spatial structure. These structural changes are followed by dispersion downstream over North America.These results are also compared with those of individual NAO events. Themain similarities between the PNA and NAO are that both teleconnectionpatterns arise from the breaking of synoptic scale waves. Key differences include the much stronger dispersion and the relative absence of replenishingsynoptic-scale waves for the PNA. Plausible explanations for these differences are presented.

ATMOSPHERIC BLOCKING - A DYNAMICAL PERSPECTIVE ON CLIMATE MODES?

Cornelia SCHWIERZ, Mischa CROSI MASPOLI, Huw C. DAVIES (Atmospheric and Climate Science, ETH Zuerich)

Persistent large-scale anomalies of the west to east flow in themidlatitudes with a weakening and meridional splitting of the jet arespecified as atmospheric blocking. Blocking anomalies significantlyaffect downstream weather and climate conditions. From a synopticperspective blocked flow situations are long-lived (up to severalweeks) and therefore singular strong events can determine a (monthly)climate index value (e.g. NAOI). The dynamical mechanismscontributing to the establishment, maintenance and breakdown ofblocking are still not completely understood. Also, their predictionremains a major task for medium-range and seasonal forecasting and achallenging feature under potential climate change. In an attempt to relate processes on synoptic and planetary scales,insight is sought here into the connection of the blocking phenomenonwith the dominant planetary-scale patterns of

atmospheric variabilityas well as with relevant synoptic-scale processes. The investigation is conducted over the period 1979 to 2001 usingECMWF (re-)analysis data by applying both Lagrangian and Euleriandiagnostics. A potential vorticity (PV) perspective is adopted andblocking is regarded as persistent anomaly of low PV in the uppertroposphere. Our analysis seeks to shed more light on the relativeimportance of Rossby-wave breaking and diabatic heating which both canmodify the upper-level PV structures. Together the results providenovel synoptic insight into the dynamics of modes of atmosphericvariability.

STORM TRACKS AND PATTERNS OF CLIMATE VARIABILITY

Brian HOSKINS[1], Kevin HODGES[2] ([1]Dept. of Meteorology, University of Reading, [2]ESSC, University of Reading)

An objective feature tracking methodology has been applied to several of the recent re-analysis data sets to produce diagnostics of the NH winter storm tracks over the 79-present period. Many fields have been used and many diagnostics obtained to explore the effect of large scale patterns of variation on the storm tracks from the weather system perspective. The track ensembles have been stratified with respect to various teleconnection indicies before the calculation of diagnostics such as track density and mean intensities which are the main diagnostics considered here. The calculation of the statistics makes use of the teleconnection indicies in a more objective way than has been done in the past. The patterns considered are NAO, AO, PNA, Scandinavian pattern (SCN) and NINO3. The NAO and AO are found to produce very similar results. Their N Atlantic storm-track signatures are consistent with previous results and also highlight some new aspects. The PNA signatures are significant in the N Atlantic as well as in the N Pacific whilst the NINO3 signature is weak with only some coherence over the southern US which is also the only region that the NINO3 results have any correspondance with the PNA. Also considered is the impact of the stratospheric index of Baldwin and Dunkerton on the storm tracks and its relationship to NAO.

MI05/09P/B17-006		1630

THE TRANSITIONAL PROCESSES OF THE SOUTHERN HEMISPHERE ANNULAR MODE

Hideo SHIOGAMA[1], Toru TERAO[2], Hideji KIDA[3], Tatsuya IWASHIMA[1] ([1]Disaster Prevention Research Institute, Kyoto University, [2]Faculty of Informatics, Osaka Gakuin University, [3]Graduate School of Science, Kyoto University)

The effects of low- and high-frequency eddies (time scales longer and shorter than 10 days, respectively) on the transitional processes of the Southern Hemisphere annular mode are investigated, based on NCEP/NCAR daily reanalysis data for the period 1979-1999. At first, the poleward transitional processes are studied.Special attention is focused on the zonal asymmetry and temporal evolution of the eddy forcing.The effects of low-frequency eddies precede those of high-frequency eddies in driving the transitional events.The low-frequency eddies are regarded as quasi-stationary Rossby waves propagating along the polar jet, with wavelengths of 7000 km.The waves dissipate equatorward over the central and eastern Pacific Ocean, while they originally come from the Indian Ocean through the waveguide associated with the polar jet.This anomalous equatorward dissipation of wave activity induces an anomalous poleward momentum flux, which is responsible for changes in the polar jet over the Pacific Ocean during the beginning stage:the polar jet expands eastward and becomes separated from the subtropical jet over Australia and New Zealand. After the initial stage, momentum forcing anomalies due to high-frequency eddies rapidly appear.This forcing continues to drive the core of the polar jet poleward, while the low-frequency eddies have completed their role of inducing the anomalous poleward momentum flux during the earlier stage. Next, the equatorward transitional processes are examined.Special efforts are made to detect the precursors and the trigger processes of the equatorward transitional events.The well observed precursors of the transitional events are found to be positive height anomalies south of Australia.Those anomalies are associated with frequently observed blocking anticyclones.The transitional events are triggered by quasi-stationary Rossby waves with wavelength of 7000 km emitted by them.The wave activity of those Rossby waves propagates eastward along a waveguide over the Pacific Ocean.The forming and breaking of the Rossby waves over the Pacific Ocean directly disturb westerly circulation around Antarctica, kicking off the transitional events.After the start of the equatorward transitional events, high-frequency eddy forcing is responsible for the equatorward migration of the polar jet. These results make an important suggestion; the transitional processes of the Southern Hemisphere annular mode are essentially zonally asymmetric processes.

MI05/09P/B17-007		1650

THE ARCTIC OSCILLATION AS A RESPONSE TO TROPICAL FORCING

Hai LIN, Jacques DEROME (Department of Atmospheric and Oceanic Sciences, McGill University)

A primitive equations dry atmospheric model is used to investigatethe atmospheric response to a diabatic forcing that is linearly associated with the second EOF of SST in the tropical Pacific.Analysis is made for 51 winter seasons (DJF) from 1948/49 to1998/99. For each winter a time-averaged model forcing is first calculatedempirically from the NCEP/NCAR reanalyses. Regression coefficients of this forcing field upon the Principal Components (PC) of the second EOF of SST in the tropical Pacific are calculated. By multiplying theregression coefficients with yearly values of the PC, we obtain timeseries of the forcing anomalies at each grid point that representsa linear fit of the forcing to this tropical SST pattern.With this forcing anomaly for each winter, an ensemble of 30 integrations of 120 days are performed with different initial conditions. EOF analysis of theensemble mean of the 90-day averaged SLP after a 30-day spinup shows that the leading mode of the forced variability resembles the Arctic Oscillation (AO), and its interannual variability is significantly correlated with thatof the observed AO.

OBSERVED INFLUENCES OF AMAZON RAINFALL ON NORTH ATLANTIC OSCILLATION AND THE WINTER CLIMATE OVER NORTH ATLANTIC AND ADJACENT CONTINENTS

Rong FU, Mingxuan CHEN, Hui WANG (Georgia Institute of Technology)

We suggest based on an analysis of state-of-art satellite observations that a change of South American wet season rainfall can contribute to the NAO during boreal winter. Specifically, an increase of the South American rainfall is followed by stronger atmosphere circulation patterns associated with the NAO several days later. This influence occurs for both positive and negative phases of the NAO. This correlation is established on a synoptic time scale and after the Pacific influences on both regions are largely removed. Thus, it is not dominated by changes of sea surface temperature over Atlantic and atmospheric convection over tropical Pacific. The maximum correlation coefficients between NAO index

and lagged anomalous South American rainfall by 2-7 days are much stronger than those leading the latter. The upper troposphere streamfunction anomalies lagging the anomalous South American rainfall as shown to resemble those simulated by a time-dependent barotropic model, so apparently are carried by the latitudinal propagation of Rossby waves in the upper troposphere. An influence function analysis also suggests that effect of the anomalous South American rainfall on the extrotropical North Atlantic and neighboring continents is about a half of that exerted by disturbances over the North Pacific-North American region.

MI05/09P/B17-009   1730
INTRASEASONAL INFLUENCES OF TROPICAL CIRCULATIONS ON THE NORTHERN ANNULAR MODE

Shuntai ZHOU, Alvin J. MILLER (NOAA/NCEP/Climate Prediction Center)

Based on 21 northern hemisphere winter-spring seasons (1979-1999) of pentad data, including outgoing longwave radiation, zonal wind, velocity potential, etc., tropical and extratropical interactions on the intra-seasonal time scale are studied in the context of the Arctic oscillation (AO) and the Madden-Julian Oscillation (MJO). By using a similar terminology to the AO, a high (low) MJO phase is defined as that strong (suppressed) convective activity over the Indian Ocean. It is shown that the high (low) AO phase occurs more frequently in the high (low) MJO phase. The AO pattern of sea level pressure anomaly is subtly affected by the MJO. When the AO and the MJO are in the same phase, the Atlantic action center becomes much weaker. When the AO and the MJO are in opposite phase, the Pacific action center becomes weaker and even broken apart. The coupling or decoupling of the two modes has different influences on the weather anomalies, such as surface air temperature and precipitation, downstream of the MJO activity. In the upper troposphere, the east-west oscillations of tropical and subtropical systems regulate local eddy momentum flux either poleward or equatorward, which may affect the phase of the northern annular mode.

SOME ISSUES IN STRATOSPHERE-TROPOSPHERE COUPLING

Theodore G. SHEPHERD (Department of Physics, University of Toronto)

There has been considerable recent interest in the possibility that stratospheric variability may significantly affect tropospheric variability. Given the rapid timescale of the apparent linkages, any such stratosphere-tropospherecoupling must be essentially dynamical in nature. Possible mechanisms that could lead to such coupling will bedescribed, and the current evidence from both observations and idealized modelling studies reviewed. The emphasis will be ondeveloping testable hypo theses to identify well-definedmechanisms, assess their robustness, and quantify their significance.

PREDICTABILITY OF THE ARCTIC OSCILLATION

Mark P. BALDWIN[1], David B. STEPHENSON[2], Timothy J. DUNKERTON[1], David W.J. THOMPSON[3], Andrew J. CHARLTON[2], Alan O'NEILL[2] ([1]Northwest Research Associates, [2]University of Reading, [3]Colorado State University)

We use an empirical statistical model to demonstrate significant skill in forecasts of the monthly-mean Arctic Oscillation (AO). Forecast skill derives from long-lived circulation anomalies in the lowermost stratosphere and is greatest during the winter season. A comparison to the Southern Hemisphere, together with modeling evidence, indicates that both the timescale and predictability of the AO depend on the presence of long-lived circulation anomalies just above the tropopause. These circulation anomalies appear to affect the troposphere through a mechanism involving changes to synoptic-scale and planetary-scale waves in the upper troposphere, which induce surface pressure changes corresponding to the AO. We find that the timescale of the AO is much longer during winter than in other seasons and we hypothesize that this longer timescale is related to both the size and persistence of Northern Annular Mode (NAM) anomalies in the lowermost stratosphere, and is not caused primarily by tropospheric processes or an enhanced annual cycle. Under this hypothesis NAM anomalies in the stratosphere are caused mainly by upward-propagating planetary scale waves of tropospheric origin, which interact with the stratospheric flow. We use linear regression, based on the present values of the NAM in the troposphere and stratosphere, to predict the monthly-mean AO 10-40 days in the future. The long timescale of the AO during winter provides some forecast skill simply from persistence, but we find that best forecasts use the NAM in the lowermost stratosphere (150 hPa). Forecasts that use stratospheric NAM values and account for ~20% of the variance of the monthly-mean AO during December – February and substantially better than AO forecasts based on persistence. The effect of NAM anomalies in the lowermost stratosphere is to cause a bias toward tropospheric NAM anomalies of the same sign. On average the AO during winter tends to be of the same sign as the NAM in the lowermost stratosphere. The AO time series during winter can be viewed as a linear combination of short-time scale tropospheric processes (with an autocorrelation function similar to that seen outside the winter season) and the 150-hPa NAM (which has a much longer time scale). Our results also have implications for numerical extended-range weather forecasting. Forecast models that do not resolve the stratosphere (or that do not have realistic NAM anomalies in the lowermost stratosphere) will likely not be able to simulate the stratosphere-troposphere coupling and the effect on the AO. On longer timescales, our hypothesized mechanism would presumable allow stratospheric signals (e.g., greenhouse gas and ozone changes, solar/UV variations, and the quasi-biennial oscillation) to affect surface climate. Observations show that in both hemispheres that stratospheric and tropospheric annular mode time series are correlated on interannual timescales, and our results provide a mechanism for trends in the stratospheric NAM to be reflected in the AO index.

PROBABILISTIC SEASONAL FORECASTS OF THE NORTH ATLANTIC OSCIALLTION INDEX

Christof APPENZELLER, Wolfgang MUELLER, Mark Andrea LINIGER (Federal Office of Meteorology and Climatology (MeteoSwiss))

The North Atlantic Oscillation (NAO) explains a substantial part of the inter-annual variability in European winter climate. In this work the seasonal forecast system II of the European Centre for Medium Range Weather Forecast (ECMWF) was used to examine the skill of NAO predictions and its impact on European temperature. The system used was a fully coupled ensemble prediction system consisting of 40 operational ensembles members and a hindcast database covering the period 1987 to 2001. The results were interpreted in terms of the ensemble median and in probabilistic space using the ranked probability skill score. First the leading mode in the model climate hindcast data was defined by an EOF analysis of the DJF mean z500 geopotential field. The spatial structure found agrees favourable with the observed NAO pattern. The seasonal NAO Index forecasts were calculated by regressing the observed pattern to each ensemble member. Correlation between the predicted ensemble median and the observed index reach weakly significant values for the first 3 integration months and subsequently decrease to non significant values. The skill based on the ranked probability measure suggests a prediction benefit of about 15% for forecasts started in December. Predictions started in September show no benefit relative to the climatology. The spatial impact of the NAO on the European 2 metre temperature distribution was also recovered in the hindcast data. Although the skill of the grid point based forecasts is low in the extra-tropics, it seems that weakly positive skills are collected in coherent areas of maximum NAO correlation. Finally the potential predictability of the NAO within the probabilistic framework of the RPSS was examined.

ROLE OF THE POLAR-NIGHT JET OSCILLATION ON THE FORMATION OF THE ARCTIC OSCILLATION IN THE TROPOSPHERE

Yuhji KURODA, Kunihiko KODERA (Meteorological Research Institute)

Slow variability of the zonal wind, characterized by the poleward and downward movement of the zonal-mean zonal wind and called the Polar-night Jet Oscillation (PJO), is known to exist in winter stratosphere. On the other hand, in the troposphere of the northern hemisphere, hemispheric variability known as the Arctic Oscillation (AO) exists. Though these are different mode of variability, there appears strong interaction between these two modes in winter of northern hemisphere. Downward propagation of the annular mode (AM) signal from the stratosphere to surface is such example. We have examined from the observational data, how the PJO and AO are related each other in the northern winter. It is shown that the AO of specific phase preferably appears corresponding with the appearance of the PJO of specific phase. It is also found that the AO tend have longer life time when the coupled PJO have sufficiently large amplitude. Although there are some exceptions, these results suggest the existence of strong interaction between the stratospheric variability (PJO) and the AO. To see how the PJO influence the polarity of the AO, we have examined the change of the E-P flux, wave forcing and the meridional circulation due to the time evolution of the PJO. It is suggested that the change of the zonal wind in the lower stratosphere due to the PJO and the resultant change of the wave propagation and the formation of the wave forcing in the upper troposphere around 60N are keys for the formation of the AO.

MI05/10A/B17-005   1040
SIMULATING THE SOUTHERN ANNULAR MODE RESPONSE TO STRATOSPHERIC OZONE DEPLETION

Nathan Peter GILLETT[1], David THOMPSON[2] ([1]School of Earth and Ocean Sciences, University of Victoria, Canada, [2]Department of Atmospheric Sciences, Colorado State University, USA)

Recent observations indicate that climate change over the high latitudes of the Southern Hemisphere is dominated by a strengthening of the circumpolar westerly flow that extends from the surface to the stratosphere. Here we demonstrate that both the seasonality and structure of the observed climate trends are simulated in a state-of-the-art climate model run with high vertical resolution that is forced solely with prescribed stratospheric ozone depletion. As in observations, the modelled tropospheric response reflects a shift in the Southern Hemisphere annular mode towards stronger circumpolar westerly flow that peaks several months after the most pronounced ozone depletion.

MI05/10A/B17-006   1100
THE ROLE OF LARGE-SCALE TOPOGRAPHY IN THE NORTHERN HEMISPHERE ANNULAR MODE

Koji YAMAZAKI[1], Atsushi OGASAWARA[1], Rui NAKAZAWA[2], Hitoshi MUKOUGAWA[3] ([1]Graduate School of Environmental Earth Science, Hokkaido University, [2]Hewlett-Packard Japan, Ltd., [3]Disaster Prevention Research Institute, Kyoto University)

Effects of large-scale topography on the Arctic Oscillation (AO) or the NH annular mode are examined using an atmospheric general circulation model under the perpetual January condition. Four experiments are done with and without North American orography and Eurasian orography. All experiments show a AO-like variation pattern as the first EOF of the 30-day mean sea level pressure field of the Northern Hemisphere. The AO in Himalaya experiment which includes only Eurasian orography is the most dominant and that in No-mountain experiment is the least. The teleconnectivity analysis reveals that the teleconnectivity over the Atlantic, i.e., the North Atlantic Oscillation (NAO), is robust in all experiments. Connection between the troposphere and the stratosphere is strong in Control and Himalaya experiments, while it is weak in other two experiments. This indicates that planetary waves generated by large-scale topography, especially by Eurasian topography, are indispensable for the troposphere-stratosphere connection. Overall, the Himalaya experiment shows similar variability to the Control run, probably because the climate in the Himalaya experiment reasonably simulates Icelandic and Aluetian lows, while Rockies experiment and No-moutain experiments show a poor simulation for these lows.

MI05/10A/B17-007   1120
LIFE CYCLE OF NORTHERN HEMISPHERE STRATOSPHERIC POLAR WARMING

Varavut LIMPASUVAN[1], David W.J. THOMPSON[2] ([1]Coastal Carolina University, [2]Colorado State University)

The present observational study examines the dominant structure of the atmospheric flow and wave fluxes related to the climatological life cycle of stratospheric sudden warming in the Northern Hemisphere. Following the pre-conditioning of the polar stratosphere, poleward heat and momentum flux anomalies (of mainly zonal wavenumber 1) in the upper stratosphere greatly intensify as wave activity is confined over the pole and the vortex weakens. Stratospheric wave activity significantly declines when the vortex eventually recovers. Through wave-mean flow interactions, zonal wind, temperature, and geopotential height anomalies over the pole exhibit downward descent from the upper stratosphere during the vortex's demise. As these anomalies reach the upper troposphere, significant growth of anomalous equatorward momentum flux and anomalous poleward meridional flow occurs near 300 hPa. Concurrently, anomalous equatorward meridional flow increases near the surface. Associated mainly with zonal wavenumber 3 and greater disturbances over the North Atlantic, the equatorward momentum flux anomalies and corresponding wave forcing promote amplification of the negative Northern Hemisphere Annular Mode (NAM) phase during which the entire atmospheric flow becomes dominated by zonal symmetry. The accompanying meridional winds are results of anomalous mean meridional circulation that

maintains zonal wind anomalies near the surface. Overall, a 15-day day lag exists between greatest polar warming at 10 hPa and strongest negative NAM index.

MI05/10A/B17-008   1140

VERTICAL STRUCTURES OF ANNULAR-MODE VARIABILITY AND THE CONTRASTING ROLES OF EDDY MOMENTUM AND HEAT FLUXES

Timothy J. DUNKERTON, Mark P. BALDWIN, David A. ORTLAND (NorthWest Research Associates)

Lag-zero regression of Eulerian mean meridional circulation with respect to the annular-mode index of surface pressure demonstrates that this circulation opposes the mean-flow anomaly in the upper troposphere and stratosphere, implying that eddy fluxes are responsible for maintenance of the annular mode, as first suggested by Thompson and Wallace. The sense of induced circulation responsible for the transport of mass is nevertheless consistent with the surface pressure anomaly over the polar cap. This ´static´ picture of annular-mode anomalies of mean flow, induced circulation and surface pressure -- with troposphere and stratosphere apparently acting in concert -- can be uniquely explained by eddy momentum fluxes. More detailed examination of observations and model simulations demonstrates a richer spectrum of annular-mode behavior variously characterized by in-phase, delayed, and out-of-phase relationships between tropospheric and stratospheric anomalies. An out-of-phase relationship is uniquely explained by eddy heat fluxes, representing a flux of wave activity from troposphere to stratosphere, or vice versa. According to the theorem of Charney and Drazin, vertical fluxes of wave activity into the stratospheric polar vortex are limited to the gravest zonal wavenumbers of planetary scale. On the other hand, synoptic-scale waves contribute significantly to the horizontal flux of wave activity in the troposphere. The role of synoptic-scale waves in amplifying and maintaining the tropospheric annular-mode anomaly is discussed. At times when anomalies in the troposphere and stratosphere are coupled via planetary-wave propagation, as in winter, the synoptic-scale waves may play an important, if not essential, role in producing the predominant ´in-phase´ relationship of anomalies in the two layers.

MI05/10A/B17-009   1200

INTERANNUAL VARIATIONS OF PLANETARY WAVE ACTIVITY IN THE NORTHERN HEMISPHERE WINTER AND THEIR RELATIONS TO THE NAM AND SST

Wen CHEN[1], Masaaki TAKAHASHI[2], Hans-F. GRAF[3] ([1]Institute of Atmospheric Physics, Chinese Academy of Sciences, [2]CCSR, University of Tokyo, [3]Max-Planck-Institute for Meteorology)

With NCEP-NCAR reanalysis data from 1958 to 1998, two teleconnection patterns in the EP flux divergence field due to planetary waves with wavenumbers (WNs) 1 to3 were studied in the Northern Hemisphere winter. After the data are detrended by subtraction from linear trends, the interannual variations indicate that both appear as dipole structures with divergence of EP flux in the north and convergence in the south, or vice versa. One dipole evolves mainly in the stratosphere and is referred to as the stratospheric interannual oscillation (SIO). The other evolves mostly in the troposphere and is referred to as the tropospheric interannual oscillation (TIO). The TIO and the SIO are shown to be associated with anomalous meridional planetary wave propagation in the troposphere and stratosphere, respectively. Meanwhile the upward and poleward refraction of planetary waves into the polar waveguide across the tropopause is shown to be closely linked to the meridional propagation of planetary waves in the troposphere. Examination of individual waves indicates that the tropospheric dipole of EP flux divergence comes basically from WN 3, whereas the stratospheric one comes totally from WNs 1 and 2. And the reduced refraction of planetary waves into the polar waveguide across the tropopause associated with positive TIO index is dominantly contributed from both WNs 1 and 2. Regression and correlation analyses suggest that the TIO is mainly an internal mode of the atmosphere and is closely related to the Northern Annular Mode (NAM). In the winter, this atmospheric process has a significant influence on the sea surface temperature (SST). The regressed SST upon the TIO index exhibits clearly a sandwich pattern in the North Pacific and a tripole pattern in the North Atlantic, and these patterns can persist to the following season especially in the North Atlantic. On the other hand, the SIO is shown to be closely associated with anomalous zonal mean winds in the subtropics of the mid-upper stratosphere and has a moderate correlation with an augmented PNA pattern in 500hPa geopotential height. Significant correlation of SIO with tropical SST (basically the ENSO pattern) reveals that tropical SST is leading the SIO by up to around 9 months, which suggests a strong impact of ENSO on the SIO. Planetary waves tend to be bent poleward (equatorward) in the middle and upper stratosphere when there is a warm (cold) event.

A NEW INTERPRETATION OF THE PACIFIC SOUTH AMERICAN PATTERN AND ITS ROLE IN ENSO TELECONNECTIONS

Carlos Roberto MECHOSO[1], Andrew W. ROBERTSON[2], Gabriel Cazes BOEZIO[1] ([1]Department of Atmospheric Sciences, University of California, Los Angeles, USA, [2]International Research Institute for Climate Prediction, Palisades, New York, USA)

Studies of the Southern Hemisphere extratropics based on Empirical Orthogonal Functions (EOFs) have found in the South Pacific structures that are referred to as the Pacific South American (PSA) patterns by similarity with the well-know Pacific North American pattern. There are two PSAs corresponding to the leading EOFs: PSA1 and PSA2. The phases of PSA1 and PSA 2 are approximately in quadrature, which has lead to the suggestion that they represent a propagating wave. It is argued that this suggestion is not supported by analyses of observational data for the South Pacific in view of quasi-stationary circulation regimes and of oscillatory behavior. One of the regimes has a structure that consists of a meridionally elongated ridge centered near 110oW flanked by troughs to the west and east, thus resembling PSA1. Other regimes resemble the opposite phase of PSA1 and PSA2. It is shown that during southern spring, the frequency-of-occurrence of the PSA1-like regime and that of its opposite are positively correlated with the warm and cold phases of ENSO, respectively. Therefore, it is proposed that PSA1 and PSA2 represent nearly stationary circulation regimes, of which the former is associated with ENSO and the latter is not. It is further conjectured that the impact of ENSO over southern South America is through the preference for development of particular nearly stationary circulation regimes over the South Pacific and downstream effects associated with the regime evolution.

MI05/10P/B17-002   1440

DYNAMIC RELATIONSHIP BETWEEN THE ANOMALIES OF THE ZONAL AND MERIDIONAL WINDS IN THE LOWER TROPOSPHERE OVER THE WESTERN EQUATORIAL PACIFIC DURING THE EL NINO ONSET PERIOD

Kyung-On BOO, Gyu-Ho LIM (School of Earth and Environmental Sciences, Seoul National University)

Westerly wind anomalies over the western equatorial Pacific(WEP) during boreal winter and spring are known as an important indicator related to the onset of El Niño (EN) events. Comparing the evolutions of zonal wind anomalies over the WEP and Niño-3 SSTA, it is evident that the positive SSTA is closely related to westerly anomalies over the WEP by a time lag of almost three months with the maximum correlation lag of 0.51. These westerly anomalies which are an element of the monsoon circulation of the Asia-Australian region are attributed to the frequent appearance of the energetic active westerly wind occurrence. Therefore, the horizontal wind anomalies originated from the monsoon system revealed to be related to the SST evolution over the Pacific Ocean and determine the onset time of EN events. Here there was a previous document suggested as the precursor of the westerly anomalies strengthening the condition that northerly anomalies from the western North Pacific converge with southerly anomalies from the northeast coast of Australia. But the study did not deal with the detailed dynamical structure of the circulation itself. So, we aim to examine the dynamic relationship between the zonal and meridional wind anomalies over the WEP at 850 hPa and investigate whether the meridional convergent flows tend to increase the westerly anomalies or not. The datasets are the monthly mean 850 hPa wind, geopotential height, the sea surface temperature field derived from the NCEP/NCAR reanalyses data with a horizontal resolution of 2.5° x 2.5°. To estimate the dynamic balance, we evaluate the zonal momentum budget based on the monthly mean values of wind and geopotential anomalies relative to the climatological annual cycle. Then composite map is constructed by calendar month from February (0) to July (0) during the EN onset year 1965, 1972, 1982, 1991, and 1997. From our results, the coriolis force as well as zonal momentum flux convergence decrease the westerly anomalies driven by the pressure gradient force. The easterly acceleration increased in proportional to the speed of the meridional wind anomalies.That is, meridional wind anomalies emanating from the monsoon system are apparently related to the EN onset. But the meridional wind anomalies are formed to maintain dynamic balance in response to the zonal wind anomalies development rather than intensify the westerly anomalies.

MI05/10P/B17-003   1500

SEASONAL CYCLE AND EL NIÑO TERMINATION

Gabriel Andres VECCHI[1], D.E. HARRISON[2] ([1]JISAO, University of Washington, [2]NOAA/PMEL/OCRD)

We explore the processes that lead to the termination of El Niño events, and propose a mechanism in which the seasonal cycle of solar heating drives changes in the meridional location of anomalous winds, resulting in the end of the events. The focus is on the 1997-8 El Niño event, as well as on comparing that event to others in the historical record, developing a generalized mechanism for El Niño termination, and applying the generalized mechanism to the current 2002-3 El Niño event. The characteristics of El Niño termination are explored using satellite, in situ and operational model data; and the impact of the proposed mechanism is tested using an ocean general circulation model (OGCM). The termination of the 1997-8 El Niño event was characterized by strong changes in the meridional structure of the wind and convective anomalies, corresponding to the seasonal evolution of solar heating. These meridional changes - though not incorporated in the dominant published mechanisms for El Niño phase transition - drove oceanic changes that resulted in the characteristic termination of the 1997-8 El Niño event. Similar changes in the meridional structure of anomalies, associated with the seasonal migration of maximum solar insolation, have been evident in every El Niño on record. These results suggest that the interaction between the seasonal cycle of solar heating and anomalous conditions during El Niño events is fundamental to their termination. We have developed a generalized conceptual theory of the role of the seasonal cycle in El Niño termination. This new mechanism for El Niño termination argues that the phase transition from warm to normal conditions in the tropical Pacific results from forcing external to the coupled ocean-atmosphere system, thus - in this view - El Niño is an event. The effect of the seasonal cycle on El Niño termination is evident in the evolution of the 2002-3 El Niño event, and suggests strong predictability of the termination of El Niño events once they are underway.

MI05/10P/B17-004   1520

1997-98 EL NINO AND THE INDIAN MONSOON: A CASE STUDY

Sooraj K. P, Rajan C.K. (Dept. of Atmospheric Sciences, Cochin University of Science and Technology)

The World Meteorological Organisation reported that the 1997-1998 El-Nino was the strongest of the 20th century. The estimated average surface temperature for land and sea worldwide was 0.80F (0.4oC) higher than the 1961-1990 average of 61.7ºF (16.50C). 1998´s temperature anomaly of 1.2ºF (0.70C), above the long-term (since 1880) mean of 56.9ºF (13.830C), is the 20th consecutive year with an annual global mean surface temperature higher, than the long-term average. Based on this fact, a case study has been carried out for the monsoon season of 1998, by analyzing parameters such as Total Precipitable Water Vapour (TPW), Sea Surface Temperature (SST) and wind (Ocean Surface) over the Indian Ocean using the Tropical Rainfall Measuring Mapping- Microwave Imager (TMI)(1998-2002) data to get the effect of this, on these parameters. In situ measurements and recent satellite data have revealed that the Bay of Bengal (BOB) exhibits large-amplitude variations in SST on subseasonal timescales (Bhat et al., 2001; Hareesh Kumar et al., 2001; Vecchi and Harrison, 2002). These SST variations occur in association with changes in monsoon circulation. In connection with this, time series of space averaged SST over the BOB and Arabian Sea (AS) is analysed. While the SST over AS shows no well-marked oscillation, BOB SST exhibits a prominent 10-12 days oscillation. Hovmuller diagram of SST in the longitudinal belt of 60-75E is used to get SST distribution and hence in turn meridional gradient. During the initial stages of the monsoon onset, the diagram exhibits a strong meridional gradient over the AS, while over the BOB (80-90E) belt, the diagram reveals a week north-south gradient. It is also observed that the convection forms over an area, where SST had large north-south gradient, as suggested by Lidzen and Nigram (1987). Anomaly of 1998 SST (from 1998-2002 SST climatology) is also plotted to see the SST behaviour. It is inferred that the anomalous rise of SST may be due to the 1997-98 El Nino. Time series of space averaged TPW over the AS shows the existence of a well-marked oscillation of 10-12 days and 30-40 days. It also appeared on the surface wind. The cycle around 30-40 days shows the active/break cycle of the monsoon. This oscillation propagates northward towards India, after originating from the Equatorial Indian Ocean. It is also suggested that this cycle might be related to the date of onset of the monsoon. The former cycle appears to be associated with a westward propagating mode north of the equator.

MI05/10P/B17-005   1610

INTER EL NINO/SOUTHERN OSCILLATION (ENSO)VARIABILITY IN THE SUBTROPICAL AMERICAS

Tercio AMBRIZZI[1], Victor MAGANA[2] ([1]Department of Atmospheric Sciences, University of Sao Paulo, [2]Center for Atmospheric Sciences, National Autonomous University of Mexico)

During boreal winter, the occurrence of El Niño/Southern Oscillation (ENSO) reflects as enhanced precipitation in various regions of the Americas. Anomalous convective activity in the central-eastern Pacific forces quasi-stationary Rossby waves following paths to North and South America. The so-called Pacific-North American (PNA) pattern forces a southward shift in the mean position of the subtropical jet, as well as ascending motion and enhanced precipitation over California and around the Gulf of Mexico. From December through February a weak quasi-stationary wave train is observed over southeast South America, resulting in enhanced precipitation around southern Brazil, northern Argentina and Uruguay. Finally, in Central America and northeast Brazil, the effects of enhanced subsidence associated with ENSO inhibit the development of deep convection and produce precipitation deficit and drought. Changes in the phase and amplitude of the quasi-stationary Rossby waves over the subtropical Americas from one ENSO event to another result in inter El Niño variability. Ray tracing analyses were performed and they showed how the characteristics of quasi-stationary waves are mainly affected by the structure of the mean flow. However, numerical experiments with a baroclinic model indicate that the location and horizontal structure of the anomalous convective forcing in the central Pacific may also affect the phase and amplitude of these quasi-stationary circulations. Using output from the NCAR Community Climate Model (CCM3), forced with observed monthly sea surface temperatures, it is shown that errors in simulations of the mean flow affect the phase of the quasi-stationary waves and result in poor long-term precipitation predictions during El Niño boreal winters. The importance of these analyses for long term predictions of regional climate in the subtropical Americas is discussed.

MI05/10P/B17-006   1630

RECENT CLIMATIC CYCLES IN ASIAN SOUTHWESTERN-MONSOON REGION AS INDICATED BY THE SPECTRUM ANALYSIS OF DIFFERENT CLIMATE DATA

Zhonglin ZHANG, Yuanqing HE, Hongxi PANG (Cold and Arid Regions Environmental and Engineering research Institute, Chinese Academy of Sciences)

Observed temperature and precipitation in China and India, ice core records, tree ring index and other proxy data has be used for spectrum analysis, to recover different scale of climatic cycles in Asian southwestern monsoon region including southeastern Tibetan plateau and northern India during the recent 400 years. Some parameters, such as the regional climate and topography conditions, sea surface pressure, the earth surface temperature ENSO events, have been considered for the analysis. The results indicate that there are apparent temporal and spatial variations of the monsoon intensity in the southwest-monsoon system, with different scale cycles. There is an apparent 2-3 year periodic change for temperature, with a similar pattern in different parts of whole region. However, precipitation varies more complexly, in 2-3 years, the shortest sub-cycle, 10-11 years and 22 years, and with non-uniform pattern in the region, corresponding to the periodic solar activities, special events on earth's surface, varied atmospheric circulations and vapor sources. Some drought and wet stages are evident in the analyzed sequences. In addition, analyzed results suggest that the study region are influenced not only by the southwest monsoon from Indian Ocean, the major source for precipitation, but also by the westerly circulation especially in winter and the southeast monsoon from the Pacific with partial vapor. Accordingly, the relation between temperature and precipitation is unclear.

MI05/10P/B17-007   1650

WHY DOES EL NINO EVENT OCCUR IN APRIL 2002

Xiuexiamg YANG[1], Zhen CHEN[2], Dianyou CHEN[3], Qiyuan QIAO[4] ([1]Department of Geo-exploration, University of Jilin University., [2]Department of Computer, University of Jilin University, [3]Department of Mathmas, University of Jilin University, [4]2. National Astronomical Observatory, Chinese Academy of Science, Beijing100012, P. R. China)

The closed North Pacific Ocean and opened South Pacific Ocean are the tectonic basis of El Nino. It makes thermal energy amass in the North Pacific Ocean and disappear in the South Pacific Ocean. The harmonious effect caused by strong tide is the excitation mechanism of El Nino. Strong tide can increase the horizontal mixing of the seawater, drawing warm seawater from the North Pacific Ocean to the South Pacific Ocean. When the sun, the moon and the earth are in a line, and the moon is at perigee, tidal is the strongest and El Nino would occur at the time. It is shown by the calculation that half day tide caused by the moon at the equator makes the troposphere, hydrosphere and liquid core move westwards around the solid earth at the volumes of 54181864, 43257, and 3103 km[3] respectively. Moreover, the lithosphere and lower mantle expand and contract with volumes of 2745 km[3] and 10599 km[3] respectively. These are the driving forces for partial melting mass to flow, swell up and erupt. The sway of the sun between the tropic of Capricorn and Cancer relative to the earth results in the vibration and mixing of fluid in the south and north direction relative to the solid. The flattening of the earth is in its maximum status at vernal equinox and autumnal equinox. At the time, the strongest equator tide is formed and the air, seawater and fluid from the core liquid at high latitude area and two poles areas move towards equator through the critical latitude (35°) with their volume 6605998, 5251 and 368 km[3] respectively. There are 6~8 months from strong tide to weak tide. Solar eclipse and moon eclipse make it stronger. Since 1980, the two strongest El Nino events occurred in 1982~1983 and 1997~1998, and in both the amplitudes of interannual variation in day-length change and tidal strength change were larger. Using astronomical data, strong tide and El Nino will occur in end of April 2002 and develop in September 2002. The strongest El Nino from 1982~1983 and from 1997 to 1998 make Ozone Hole over the South Pole expand and the El Nino in 2002 will make the South Pole Ozone Hole expand in September, too. In front and behind of El Nino event, the oceanic water in East Pacific Ocean and West Pacific Ocean may rise or fall 40cm oppositely, which make oceanic crust fall or rise 13cm. It is the reason that El Nino events are interrelated with the earthquakes and volcanoes. This phenomenon is just like "seesaw". This paper is supported by National Natural Science Fund of China(No.49774228).

MI05/10P/B17-008   1710

ENSO SIGNATURE IN NORTH EUROPEAN TIME SERIES OF ICE CONDITIONS DETECTED BY SINGULAR SPECTRUM ANALYSIS AND WAVELET TRANSFORM

Svetlana JEVREJEVA[1], John Christopher MOORE[2], Aslak GRINSTED[2] ([1]Proudman Oceanographic Laboratory, Birkenhead, UK, [2]Arctic Centre, University of Lapland, Rovaniemi, Finland)

Variability in long-term time series of ice conditions in the Baltic and Barents Seas is examined within the context of atmospheric circulation. The study involves analysis of both modern (instrumental), historical and proxy data covering 300 years and application of new advanced statistics techniques - Monte Carlo Singular Spectrum Analysis (MC- SSA) and Wavelet Transform (WT) to these climatological time series. We develop methods of assessing statistical significance and confidence intervals of crosswavelet power and wavelet coherence phases. Crosswavelet power for the time series indicates that the times of largest variance in ice conditions are in excellent agreement with significant power in the AO at 2.2-3.5, 5.7-7.8 and 12-20 year periods, similar patterns are also seen with the Southern Oscillation index (SOI) and Niño3 sea surface temperature (Niño3) series. Wavelet coherence shows in-phase linkages between the 2.2-7.8 and 12-20 year period signals in both tropical and Arctic atmospheric circulation and also with ice conditions in the Baltic and Barents Seas. These results are consistent with GCM simulations showing dynamical connections between high latitude surface conditions, tropical oceansea surface temperatures mediated by tropical wave propagation, the wintertime polar vortex and the AO, and with models of sea ice and oceanic feedbacks at decadal periods.

BIENNIAL AND LOWER-FREQUENCY VARIABILITY IN THE MERIDIONAL FLUCTUATION OF BAIU FRONT

Tomohiko TOMITA[1], Takao YOSHIKANE[2], Tetsuzo YASUNARI[3] ([1]Department of Environmental Sciences, Faculty of Science, Kumamoto University, [2]Frontier Research System for Global Change, Institute for Global Change Research, [3]Hydrospheric Atmsopheric Research Center, Nagoya University, [4]Institute of Geoscinece, University of Tsukuba)

The interannual meridional fluctuation of Baiu front and the related large-scale circulation are examined using empirical orthogonal function (EOF) analysis and composite or correlation analyses based on the EOF time coefficients. The first EOF mode, which explains 37.8% of the total variance, indicates the low-frequency fluctuation with a period of four to five years (LF mode) appearing to the south of 35°N. The development is concurrent with the horseshoe SST anomalies (SSTAs) in the entire tropical Pacific that are associated with the El Nino/Southern Oscillation (ENSO). The most west SSTAs control the anomalous southward expansion of Baiu front in the LF mode through the modification of convection around 20-30°N in the western Pacific. On the other hand, the second EOF mode explaining 32.5% is characterized by the meridional seesaw-like fluctuation with a node around 28°N and by the timescale of biennial oscillation (BO mode). The SSTAs again show the horseshoe pattern but with the different spatial phase in the tropical western Pacific. The teleconnection similar to the Pacific-Japan pattern controls the meridional seesaw fluctuation of anomalous Baiu precipitation, in particular, through the convection along 20°N in the western Pacific. The anomalies associated with the BO mode tend to appear in the tropical western Pacific, while the signals of LF mode rather expand in the entire basin, suggesting that the biennial oscillation is the aborted ENSO confined in the western Pacific.

THE CONNECTIVITY OF WINTERTIME NORTH ATLANTIC OSCILLATION (NAO) WITH SUMMERTIME ATMOSPHERIC AND OCEANIC CONDITIONS

Masayo OGI[1], Yoshihiro TACHIBANA[2], Koji YAMAZAKI[1] ([1]Graduate School of Environmental Earth Science, Hokkaido University, [2]International Arctic Research Center, Frontier Research System for Global Change/Liberal Arts education Center, Tokai University.)

It is widely known that the North Atlantic oscillation (NAO) is closely related to the wintertime surface air temperature field over the Eurasian continent. We investigate the persistency of the temperature anomaly from winter through following summer. Our findings show that when the wintertime NAO is in a positive phase, the summertime sea level pressure (SLP) over the Eurasian continent, especially in Western Europe, central Siberia, and eastern Siberia, is higher. These patterns of SLP are similar with those of at higher levels geopotential heights and surface air temperature. The summertime SST anomalies surrounding the northern Eurasian continent after the winter of the positive NAO are also positive. The snow-cover anomaly over Siberia in early summer and the sea-ice concentration and the SST anomaly in the Barents Sea in early summer after the winter of the positive NAO are also negative. These results suggest that the wintertime NAO is memorized in the sea ice, the ocean surface and the snow, and then these memorized anomalies influence the interannual variation of the summertime atmospheric circulation over the Eurasian continent.

TESTING OF THE NAO AND ENSO IMPACT ON THE WINTER CLIMATE ANOMALIES IN ROMANIA

Ileana MARES[1], Constantin MARES[1], Mihaela MIHAILESCU[2] ([1]National Institute of Meteorology and Hydrology, [2]Agicultural Science University)

In the present paper, there has been tested the simultaneous influences of the ENSO and NAO events upon the monthly temperature and precipitation anomalies in Romania for January, February and March. The NAO used in this study is defined (Jones et al., 1997) as the difference of normalised pressure between Ponta Delgada (Azores) and Reykjavik (SW Iceland). The ENSO events have been quantified both by means of the Southern Oscillation Index (SOI) and by using the Trans Nino Index (TNI), defined by Trenberth and Stepaniak (2001). There have been analysed through canonical regressions and composite analyses, function of El Nino, La Nina and the positive neutral and negative NAO. The classification of NAO is achieved according to Bonsal et al. (2001). The predictands for Romania have been considered the first principal components of the EOF decomposition of the temperature and precipitation anomalies for the period 1950-1997. Another predictand at the level of Romania, has been also represented through the values of a drought index, calculated by means of the first EOF of temperature and precipitation anomalies. This index is similarly with Palmer drought severity index. For all the three months, a general characteristic feature for the temperature field is the fact that a cold phase of the ENSO event associated with a normal state of the North Atlantic Oscillation may favour positive temperature anomalies, especially in the central and western part of Romania. For the pluviometric field, the results

depend on the month, for instance for March, for which the moisture state is very important for the agricultural sector; the highest anomalies are recorded in the intercarpathian areas in the case of the El Nino phenomenon associated with the negative NAO phase. El Nino in the positive NAO case favours positive precipitation anomalies in the southeast country and negative in the rest. **References Bonsal, B., Amir Shabbar and Kaz Higuchi, 2001:** Impacts of low frequency variability modes on Canadian winter temperature. *International Journal of Climatology*, 21, 95-108. **Jones,P.D.,T.Jonsson and D. EAST EURASIAN SNOW COVER TRIGGERING THE NORTHERN ANNULAR MODE ?

Eun-Jeong CHA (Center for Climate System Research, University of Tokyo)

A sequence of cold waves hit the East Asian countries in early winter of 2000/01 as a result of cold waves, a number of low-temperature and snowfall records were broken. It is noted that a large increase in snow cover over the East Eurasia occurred in early October and continued to November 2000 prior to the 2000/01 winter. Then, negative SLP anomalies prevailed over the East Eurasia and the North Pacific concurrently, positive height anomalies were located around the Arctic Ocean in December-February 2000/01. Such anomaly configuration characterized by a dipole between middle and polar latitudes resembled well the negative phase of the Arctic Oscillation (AO). The 2000/01 case suggests that the AO like anomalies could be triggered by the autumnal snow cover. Therefore the winter of 2000/01 is a good example of the contradiction proposed earlier, i.e., how could the AO both originate in the lower troposphere and mid-upper stratosphere? Furthermore, it is noted that smaller than normal snow cover appeared in October 1988 succeeded by SLP anomalies over the midlatitudes in 1988/1989 winter; namely, the autumnal snow cover and winter height anomalies in 1988/89 were opposite to the those of 2000/01 and in the case of 1976/77 was similar to those of 2000/01, except for SST distribution, the mature phase of El Nino. These contrasting and similar cases have been chosen to examine predictability of the leading mode of winter by observational analyses and model experiments. The main features reproduced by 10 ensemble experiments for the 1976/77, 1988/89 and 2000/01 cases show general similarities to the observation. The polarity between the polar region and midlatitues is captured well by the simulation, except for over the North Atlantic. The results of run for 50-year with the monthly varying SSTs also show quite resemble anomalies to the observation.

DOWNSCALING ANALYSIS FOR DAILY AND MONTHLY VALUES USING CLIM.PACT-V.1.0

Rasmus E. BENESTAD, Ole Einar TVEITO (Department of Climatology, Norwegian Meteorological Institute)

An analysis tool, clim.pact , has been developed for empirical downscaling and analysis of local and regional climate on both a daily and a monthly basis. This tool is built in the dataanalysis environment R, and consists of a contributed package. The R-software is freely available (A ˝GNU version of Splus˝) from the Internet (URL: http://cran.r-project.org), and runs on both Linux and Windows platforms. Since R and Linux require no license, this approach provides a low-budget tool for data-analysis. The clim.pact package is tested with both monthly and daily data and a number of different scenarios are compared. Empirical downscaling has been carried out with clim.pact on January mean temperature in Bergen, Copenhagen, Helsinki, Oslo, Stockholm, and TromsAE using single field as well as mixed-field predictors and with predictors that cover different regions. The package can easily employ a new common EOF approach for empirical downscaling. A comparison has been made between the various results in order to study the robustness of the method. Furthermore, the residuals from the model calibration has been examined for remaining trends or biases. These tests indicate that clim.pact skillfully reproduces local climate variations with a linear model when these are near-normally distributed. Tests with skewed data such as daily precipitation show that a linear model does not give a good description the local series. New models, however, are easily incorporated in the clim.pact framework, such as analogs and conditional weather generators. The empirical downscaling is fast, and clim.pact hence facilitates downscaling analysis on multi-model ensembles.

NAO IMPACT TOWARDS THE SEASONAL EVOLUTION OF THE EURASIAN CONTINENT DURING THE NORTHERN HEMISPHERE SPRING

Masatake E. HORI (Enviromental Science, University of Tsukuba)

The impact of North Atlantic Oscillation (NAO) towards theseasonal evolution of the Eurasian continent is examinedbased on 51 years of NCEP/NCAR reanalysis data.While there has been many studies of NAO impact towards thesurface temperature in the downstream Eurasian continent during winter,its impact towards the transition period of winter through springis not well known. Such seasonal evolution is essential in understandingthe recent high correlation between the Eurasian surface temperatureand the Asian monsoon. Composite analysis of seasonal evolution in NAO indices during fivestrong monsoon years show a positive NAO condition during the seasonalmarch of January through March.Snow cover composite for these years show an early snow retreat overEurope in January. Such anomaly is localized in a window region wherethe temperature anomaly accompanying a strong NAO condition is able topenetrate the seasonal evolution of the snow line to retreat earlierthan normal. This window region is signified with a warmer troposphere and increasedsurface temperature which leads to more warm advection to flow intothis region, thus advancing the snow line 2-3 weeks earlier than normalyear throughout the following season. Following March and April shows a negative snow cover anomaly overcentral and eastern Europe and also in western Siberia.It is shown that such anomaly in the surface snow cover condition isaccompanied by a early surface heating in the region acting as an apparentheat source.The atmosphere adjusts to such forcing with a northward shift in thesubtropical jet. Also the blocking effect of the Tibetan region creates ananticyclonic anomaly over the Tibetan plateau and the surrounding region. In the following spring, composite analysis shows a wave guide likedisturbance pattern along the southern slope of the Himalayas,creating a east-west temperature contrast over the Tibetan plateau. Such prominent seasonal evolution is triggered by a positive NAOextreme and has been dominant during 1978-1998,whereas its effect is not as clear during 1958-1978 period. Principal component analysis of these two period shows that the zonalstructure of the temperature anomaly accompanying an NAO extremehas changed over the years, where in the recent years theAnnular structure has become stronger, thus enabling the window regionin western Europe to be directly influenced through such NAO extreme.Apparent correlation of the surface temperature and monsoon indexmay be a result of such change in seasonal evolution over the years. Relationship with the Siberian high and the activity of the EU

patternwill also be shown during the poster session.

THE INFLUENCE OF THE BASIC WIND ON THE PROPAGATION OF PJ-LIKE ROSSBY WAVETRAIN

Yosuke KOSAKA, Yoshihisa MATSUDA (Department of Science, University of Tokyo)

The influence of the convective activities in the subtropics on the northern hemisphere summer circulation is studied. In the time-scale of the interannual variation, there is positive correlation between the convective activities in the subtropical western Pacific around Philippines, and the height field in East Asia. Moreover, in the time-scale of the intraseasonal variations, we can see the barotropic wavetrain which is generated in subtropical western Pacific and propagating over the North Pacific to North America. This is called PJ pattern. It takes about 5 days or a week for this wave to arrive at North America (Nitta,1987). It is also known that PJ pattern appears more frequently in the East Asian mid-summer than in the rainy season (Tsuyuki and Kurihara, 1989). We have examined the impact of the heating around the subtropical western Pacific, using a numerical model. The linear and stationary model on the northern hemisphere is adopted. In this model, quasi-geostrophic approximation is assumed. When the observed zonal wind around the East Asia is used as the basic field, a Rossby wavetrain is generated by the heat source placed on Philippines, but its anomaly is cyclonic around Japan. This is opposite to the observed PJ pattern. Moreover, it is shown by the comparison of the results calculated with the wind fields in the East Asian rainy season and the mid-summer that the amplitude of the wavetrain is larger in the rainy season. Further, we have studied the relationship between the baroclinic forcing and the barotropic wavetrain, using the model with some idealized basic field. It is found that for the appearance of PJ pattern as stationary wavetrain, the following condition should be satisfied: the westerly wind in the lower layer in the subtropics is strong, and connected with the mid-latitude westerly region, so that the stationary Rossby wave can propagate into the mid-latitudes. When the ideal basic wind field that satisfies the above condition is used, the PJ-like Rossby wavetrain is obtained. Since PJ pattern is observed as intraseosal variations, the validity of the stationary model is questionable. Hence, we reexamine PJ pattern with linear, quasi-geostrophic and prognostic model. In the results with this model, there appears the Rossby wavetrain, whose sign is opposite to PJ pattern, again. On the other hand, when the ideal basic wind field mentioned above is used, the PJ-like Rossby wavetrain is obtained again. These calculations suggest the following possibility: for the appearance of PJ pattern, in addition to active cumulus convection in subtropical western Pacific, it is required that in the mean wind field the lower layer westerly in the subtropics connects with the mid-latitude westerly.

IMPACTS OF THE THERMOHALINE CIRCULATION ON ATMOSPHERIC VARIABILITY OVER THE NORTH ATLANTIC

Pascal YIOU[1], Pascale BRACONNOT[1], Masa KAGEYAMA[1], Yvonnick LE CLAINCHE[2], Olivier MARTI[1] ([1]Laboratoire des Sciences du Climat et de l'Environnement, [2]Institut Maurice-Lamontagne)

The northward heat transport associated to the thermohalinecirculation (THC) largely affects the North Atlantic regionclimate. We investigated the impact of a change of the THC on climatevariability around the North Atlantic, with aparticular emphasis on the North Atlantic Oscillation and theassociated atmospheric circulation.We used a 250 yr control simulation of the IPSL coupled model with alow resolution and a thermodynamic sea ice parameterization, as well as reanalysis data. Thissimulation offers the peculiarity of a sudden jump of the THC (from 15 Svto 30 Sv) after 140 yr of run. This jump is observed through a shiftof the convection zone from the Greenland-Iceland-Norwegian Sea to theLabrador Sea.To a first order, the mean climatic impact is mostly localized in theLabrador region. We focussed ourstudy on variability diagnostics like frequency spectra, statistics of extremes intemperature and precipitation, and weather regimes around the North Atlantic.Thus in this simulation, the THC might have a negligible effect on meanregional climates such as Western Europe, but its impact ispotentially important on the description of climate variability andthe statistics of short lived events.This study addresses the interactions between a mean state andvariations around the mean.

ANALYSIS OF THE CLIMATOLOGY OF EXTREME WEATHER EVENTS AFFECTING BARROW, ALASKA

Elizabeth Noel CASSANO, Amanda H. LYNCH, Melinda R. KOSLOW, Casey THORNBRUGH (CIRES, University of Colorado)

Barrow, Alaska is located on the northernmost tip of Alaska at the intersection of theBeaufort and Chukchi Seas. The coastal geography of this region makes Barrow quitevulnerable to extreme weather events, which can result in significant flooding anderosion. This study is an analysis of high wind events in Barrow in the context of thesynoptic climatology of the Western Arctic. The analysis uses the Self-Organizing Map (SOM) algorithm - an unsupervised learningprocess that groups large, multivariate datasets onto a 2-dimensional array or map. Astrength of this algorithm is there are no assumptions made as to the structure of theclusters of the data. The SOM algorithm is used here to produce a synoptic climatology of sea level pressure patterns for 53 years for the Western Arctic. The same clustering is used to examine the decadal variability of the synoptic climatology, and relate this to the observed variability in temperature, circulation and other climatic parameters. Using this methodology, we study the extreme events that affect Barrow by including local variables, such as Barrow winds and fetch to the ice edge, in the SOM analysis. The highest winds and greatest fetch events can be weighted in order to find the patterns that cause the most significant damage. Hence, a map can be constructed that is representative of the synoptic patterns that produce extreme events in Barrow. It is intended that such an analysis will allow an assessment of the likely temporal variability of extreme events in Barrow into the future.

CLIMATE ON ABNORMAL OCCURRENCE OF WILDLANDFIRE IN SIBERIA

Keiji KIMURA[1], Hiroshi HAYASAKA[2], Koji YAMAZAKI[3], Masami FUKUDA[4] ([1]Department of Geography, Tokyo Metropolitan University, [2]Graduate School of Engineering, Hokkaido University, [3]Graduate School of Environmental Earth Science, Hokkaido University, [4]Institute of Low Temperature Science, Hokkaido University)

A great many wildfires occurred in Siberia and Mongolia in 2002 summer. Especially in Mongolia, the Prime Minister declared that the whole area should ready for civil defense to assist fighting the wildfires from August 16. Generally speaking, the wildfires are caused by extreme hot and dry conditions, but few analyzed climatic data can be seen as the reason. For example, in Ulaanbaatar, the capital of Mongolia, it rained only 10mm (it rains 68mm in

M

normal years) July, 2002: the monthly mean temperature was 21.7 degreeC (the average is 17.7 degreeC). We can see the similar phenomenon was happened in 1998 recently, and we suspect that it will occur once in some years. Now we can use the climatic data of 1998, but cannot use the data of this year yet. Today, we have presentation about the analysis of 1998 summer. We use the dataset below: (1) Global Surface Summary of Day Data compiled by NCDC (2) ECMWF Reanalysis Data (3) JMA Historical Map (4) Wildfire Area Data analyzed by Remote Sensing data As we can use ECMWF Data from 1987 to 2001 (not yet in 2002), mainly we start analyze the summer in 1998. And we can get the Hot Spot Data around Yakutsk, Siberia by Dr. S. Tashilin. Now we have started to analyze around Yakutsk. Dr. S. Tashilin analyzed wildfires as Hot Spots from the satellite image data around Yakutsk. His analysis area is 58N-66N: 122E-136E. Indeed, in 1998 summer it was high temperature and little precipitation, and it was hotter and drier than that of 2002 summer. We can see the pressure distribution in August, 1998. The ridge at 500hPa level is seen from 80N, 0E strait to 50N, 130E over Yakutsk. It corresponds to the high pressure area at Sea Level. It is considered as the blocking high centered around 65N, 110E. It changed to abnormal circulation. Next, seasonal change in summer, 1998 is picked up. Wildfire had seasonal change. Every component of the climate was changed seasonally. Sometimes it rains, but like as from Aug.10 (Day Number=222) to Aug.27 (DN=239) no precipitation continued even 18 days. During this period, the SLP had been high level, and southern component of wind continued to blow. This phenomenon means hot and dry condition was kept. As typical case study, wildfires grew from Aug.12 to Aug.14, 1998. How was the climatic condition in this period? We analyze about the SLP, relative humidity and wind distributions. It was illegible high pressure around Yakutsk, but one after another low RH air mass attacked this area.

NORTH ATLANTIC OCEAN-ATMOSPHERE INTERACTIONS IN TWO COUPLED MODELS

Laurent Z.X. LI, Sebastien CONIL (LMD)

The Northern Hemisphere climate variability is dominated by some few prefered modes of the atmospheric circulation like the North Atlantic Oscillation and the Pacific/North America pattern.These teleconnections are the dominant internal variability patterns of the atmosphere as shown by a number of study using atmospheric GCM´s. External forcing such as ENSO tropical diabatic heating or anthropogenic influence is thought to modify natural and preexisting forms of internal variability. However the relationhips of these dominant patterns of atmospheric variability with the underlying oceans is still unclear with the current scientific knowledge. Recent results using lead/lagged Singular Value Decomposition technique confirm that, in the North Atlantic basin, oceanic variability is mainly controlled by atmospheric forcing.But they also show a significant relationship between SST anomalies preceding by few months the atmospheric anomalies, reflecting the forcing of the NAO by the extratropical Atlantic ocean (Czaja and Frankignoul, 2002). In this study, the same methodology (delayed SVD) is employed to analyse extratropical air-sea interaction in two ocean-atmosphere fully-coupled climate models. The two models share a commun oceanic component but they use two different state-of-the-art atmospheric general circulation models. A sequence of 100 years is extracted from both models and used to study the relationship between extratropical oceanic and atmospheric variability. In addition we use 100 years of Sea Surface Temperature and Sea Level Pressure reanalysed data from CRU. These two GCM´s reproduce well the dominant teleconnections patterns of the Northern Hemisphere. We focus on the North Atlantic basin where extratropical local ocean-atmosphere coupling is particularly strong. The ability of the two models in reproducing the main behaviours of the North Atlantic ocean-atmosphere interactions is evaluated through a comparaison with observations. The same analysis is also applied to the North Pacific where El Nino Southern Oscillation signal acts as a perturbation for the local extratropical processes.

TRANSIENT RESPONSE OF AN ATMOSPHERIC GCM TO NORTH ATLANTIC SST ANOMALIES

Laurent Z.X. LI, Sebastien CONIL (LMD)

A high-resolution atmospheric General Circulation Model (GCM) is used to evaluate the atmospheric response to North-Atlantic Sea Surface Temperature (SST) anomalies. The transient evolution of the response is studied in detail. The linear and non-linear effects can thus be contrasted and separated by their different time scales. Baroclinic patterns related directly to the surface anomalies reach quickly their maximum manifestation. Barotropic patterns related to the mid and upper troposphere eddy vorticity fluxes however have longer time scales with much more important amplitude,able to replace the initial baroclinic response. This study thus provides a comprehensive picture to reconcile the twotypes of response in GCM.

MI05/11A/B17-003　　　　　　　　0910
MECHANISMS FOR THE NAO RESPONSES TO THE NORTH ATLANTIC SST TRIPOLE

Shiling PENG[1], Walter A. ROBINSON[2], Shuanglin LI[1] ([1]NOAA-CIRES Climate Diagnostics Center, [2]Department of Atmospheric Sciences, University of Illinois)

Large (100-member) ensembles of GCM experiments reveal that the North AtlanticSST tripole, with warm anomalies off the US coast flanked by cold anomalies offNewfoundland and in the subtropics, can induce a significant NAO response inlate winter (Feb-Apr) when the model´s intrinsic variability projects stronglyon the NAO. The tripole-induced NAO response exhibits an intriguing asymmetryabout the sign of the SST anomaly, manifested in the weaker and more wavetrainlike response to the positive tripole in contrast to the stronger and morezonally-elongated response to the negative tripole. Mechanisms for developingand maintaining these GCM responses are elucidated through diagnosticexperiments using a linear baroclinic model and a statistical storm track modelbased on GCM intrinsic variability.

The NAO-like symmetric response is primarily maintained by a dipolaranomalous eddy forcing that results from interactions between the heating-forced anomalous flow and the Atlantic storm track, as expected from an eddy-feedback mechanism. To account for the asymmetry of the responses about thesign of the SST tripole, a nonlinear eddy-feedback mechanism is proposed thatextends the previous mechanism to include the nonlinear self-interaction of theheating-forced anomalous flow and its effects on transient eddy feedbacks. Theresults of idealized model experiments demonstrate that, due to its nonlinearself-interaction, the tripole heating induces a much weaker response in thepositive phase than in the negative phase. Interactions of these nonlinearheating-forced anomalous flows with the Atlantic storm track result inasymmetric eddy vorticity forcings that in turn sustain asymmetric eddy-forcedanomalous flows in the two cases.

A NEGATIVE FEEDBACK BETWEEN THE NORTHERN HEMISPHERE SEA ICE AND THE NAO

Kentaro YAMAMOTO[1], Yoshihiro TACHIBANA[2], Meiji HONDA[2], Jinro UKITA[3] ([1]University of tokai, [2]Frontier Research System, [3]NASA)

Temporal and spatial variability of sea ice in the northern hemisphere is a critical component of the global climate. This study presents a hemispheric scale modal structure in wintertime sea ice variability on interannual time scales and discusses its interaction to the NAO. The leading spatial structure given by an EOF analysis for the SMM/R-SSMI satellite dataset of the sea ice shows a seesaw (an out-of-phase) pattern in the field of hemispheric scale sea ice concentration.The seesaw consists of one polarity in Eurasian side, i.e., from the Sea of Okhotsk through Barents Sea, and the other polarity in American side, i.e., the Bering and Labrador Seas. A regression map of the time series of the EOF leading mode of the sea ice onto the global atmosphere in December and January are remarkably similar to the NAO pattern, whereas the regression of the time series of the ice EOF with the SLP field in February and March shows no connection to the NAO. We further execute an ideal AGCM in order to isolate the influence of the hemispheric ice seesaw upon the global atmosphere. In the model, an ideal seesaw-like sea-ice distribution based on the EOF leading mode is used as the surface boundary condition. The response of the SLP pattern to the sea-ice seesaw is similar to the NAO pattern, however the phase is opposite to the pattern shown above. These results suggest that in the first half of the winter the hemispheric ice seesaw is built in response to the NAO, whereas in the latter half of the winter, the ice seesaw destroys the NAO. Therefore, a possible cause of the less persistency of the NAO through the winter is in the negative feedback between the NAO and the hemispheric sea-ice seesaw.

ATMOSPHERIC RESPONSE TO ZONAL VARIATIONS IN MIDLATITUDE SST: TRANSIENT AND STATIONARY EDDIES AND THEIR FEEDBACK

Masaru INATSU[1], Hitoshi MUKOUGAWA[2], Shang-Ping XIE[3] ([1]Graduate school of Environmental Earth Science, Hokkaido University, [2] Disater Prevention Research Institute, Kyoto University, [3]International Pacific Research Center/SOEST and Department of Meteorology, University of Hawaii)

We have investigated midwinter storm track and stationary eddyresponse to zonal variations in mid-latitude sea surface temperatures(SSTs) conducting atmospheric general circulation model experimentsunder the conditions with an aqua planet of the whole surface coveredby water and with the perpetual January of isolation fixed at January.Zonal wavenumber-one SST variations with a meridionally confinedstructure are placed at various latitudes. Having these SSTvariations centered at 30N leads to a zonally localized storm track,while the storm track becomes nearly zonally uniform when the same SSTforcing is moved further north at 40N and 50N. The zonally localizedstorm track prefers high baroclinicity zone in the planetary boundarylayer. Following to high-frequency eddy kinetic energy (EKE) budgetanalysis, large (small) baroclinic energy conversion north of the warm(cold) SST anomaly near the axis of storm track (near 40N) isresponsible for the large (small) storm growth. The equatorwardtransfer of EKE by the ageostrophic motion and the mechanical dampingare important to diminish the storm track activity in the zonaldirection. Significant stationary eddies form in the uppertroposphere, with a ridge (trough) northeast of the warm (cold) SSTanomaly at 30N, while they are much weakened with the SST forcingshifted more northward. Heat and vorticity budget analyses indicatethat zonally localized condensational heating in the storm track isthe major cause for these stationary eddies, which in turn exert apositive feedback to maintain the localized storm track bystrengthening the vertical shear near the surface. These resultsindicate an active role of synoptic eddies in inducing deep,tropospheric-scale response to mid-latitude SST variations. Wefinally discuss the application of the model results to the realatmosphere, especially to the Southern Hemisphere.

LARGE-SCALE INTERANNUAL CHANGES IN OCEAN WIND WAVES OVER THE NORTH ATLANTIC AND NORTH PACIFIC: LINKS TO THE NORTHERN HEMISPHERE CYCLONE VARIABILITY

Sergey K. GULEV[1], Vika GRIGORIEVA[1], Olga ZOLINA[2] ([1]P.P.Shirshov Institute of Oceanology, [2]University of Bonn)

Variability in the characteristics of the wind waves over the Northern Hemisphere is studied on the basis of the Global Climatology of Ocean Waves, derived from the Voluntary Observing Ship (VOS) data for the period from the end of 19th century to present. Waves observations in VOS are taken visually by marine officers, and in a lesser degree than winds are influenced by historical changes in observational practices. An outstanding feature of visual wave observations is the availability of separate estimates of the wind sea, associated with the local wind, and swell, integrating the wind forcing over the larger domain. Traditionally analysed from the model and satellite data significant wave height (SWH) results from these two components and does not allow for the understanding of mechanisms driven the variations on surface roughness. We studied long-term trends in wind sea, swell, and SWH for the period from 1880 to 1940s along major ship routes and from 1950s to present over the whole North Atlantic and North Pacific. Decadal scale variations were studied for the last 50 years using EOF and SVD analysis. Special attention is given to the effects of sampling errors in variability of ocean waves. Wind sea and swell demonstrate different patterns of variability, associated with the North Atlantic Oscillation (NAO) and Pacific Oscillation. In particular, swell variability is clearly associated with the storm frequency, while wind sea reflects the local wind signal. In order to project the NAO signals onto wave variability, joint analysis of the climate variability in the characteristics of atmospheric cyclones over the Northern Hemisphere and of the wind wave parameters has been performed.

MULTI-DECADAL MODULATION IN THE ALEUTIAN-ICELANDIC LOW SEESAW AND RELATED MODULATIONS IN THE EOF STRUCTURE OF THE NORTHERN HEMISPHERE TROPOSPHERIC VARIABILITY

Hisashi NAKAMURA[1], Shozo YAMANE[2], Meiji HONDA[2] ([1]IGCR, Frtontier Research System for Global Change, also in Department of Earth, Planetary Science, University of Tokyo, [2]IGCR, Frontier Research System for Global Change)

It has recently been argued that interannual variability in the tropospheric circulation over the wintertime North Atlantic, including the intensity of the surface Icelandic Low (IL), is strongly influenced by the Northern Hemisphere annular mode (NAM). As recently found by the authors, the North Atlantic circulation is also under the significant influence of the North Pacific in the form of a late-winter seesaw between the IL and the Aleutian Low (AL). In recent decades the NAM and the upper-tropospheric manifestation of the AL-IL seesaw (i.e., a combination of the PNA pattern and NAO) were the most dominant anomaly patterns in the early and late winter periods, respectively, but their dynamics are fundamentally different. Unlike the NAM, the seesaw formation is through propagation of stationary Rossby wave trains across North America with strong feedback forcing from storm tracks, as clearly seen in the seesaw formation that occurred in late January of 2002. Which of the two dominant anomaly patterns is more dominant in the tropospheric variability has been changed on multi-decadal scales during the last century. The NAM was predominant and the seesaw formation was unlikely in the 1950s and 1960s, during which the first EOF of sea-level pressure (SLP) includes no significant AL anomalies. After that the seesaw became more dominant. The first EOF of SLP includes strong AL anomalies, and the PNA-NAO combination characterizes the wintertime first EOF in the free troposphere. In the 1930s and 1940s the seesaw was as dominant in the SLP variability as in the period since the 1970s. In those periods of the seesaw domination, the IL anomalies in a month of the seesaw completion were significantly correlated only with the AL anomalies with the opposite sign in the previous month, but not with the IL anomalies. The multi-decadal modulation observed in the AL-IL co-variability during the postwar period seems to be related to the corresponding modulation in the effectiveness of the atmospheric teleconnection across North America in the presence of a strengthening tendency of the midwinter planetary waves over the western hemisphere. Before the 1970s the midwinter westerlies were more zonal over the western hemisphere with weaker diffluence of the Pacific jet. Anomalies developing in the exit of the Pacific jet tended to be isotropic and a substantial fraction of Rossby wave activity emanated from those anomalies was dispersed into the lower latitudes. Since the 1970s, anomalies developing in the strongly diffluent westerlies over the North Pacific tended to be more zonally elongated and thus more persistent. The westerlies strongly meandered in such a way that most of the Rossby wave activity emanated from those anomalies tended to be advected effectively into the IL region across North America.

ALEUTIAN-ICELANDIC LOW SEESAW BEHAVIOR IN AGCM ENSEMBLE SIMULATIONS

Meiji HONDA[1], Yochanan KUSHNIR[2], Hisashi NAKAMURA[3], Shozo YAMANE[1], Stephen E. ZEBIAK[4] ([1]IGCR, Frontier Research System for Global Change, [2]LDEO, Columbia University, [3]Department of Earth and Planetary Science, University of Tokyo, [4]January 1, 1990IRI, Columbia University)

Behavior of an interannual seesaw-like oscillation between the surface Aleutian and Icelandic lows (AL and IL, respectively) is investigated on the basis of 50-year AGCM climate simulations, by separating them into an external part due to the variability of sea surface temperature (SST) forcing and an internal part due to atmospheric dynamics only. Our study is based on 24-member ensemble hindcast runs forced by observed SST anomalies with different atmospheric initial conditions. The external variability defined as the ensemble mean of the 24 members is characterized as significant negative correlation between the AL and IL intensities in latewinter (it reaches -0.8 in March). The seesaw is gradually formed toward March through a PNA-like wavetrain development by a remote influence of ENSO and its extension to the North Atlantic. However, the amplitudes of the North Atlantic anomalies are nearly half of the corresponding Pacific anomalies. Signal to noise ratio estimated as the SST-forced variance to the total variance does not exceed 15% over the North Atlantic. On the other hand, the internal part of 24 ensemble members defined as deviations from the ensemble mean is characterized by weak, but still significant, negative correlations between the AL and IL anomalies through winter (December to March). This suggests that the AL and IL anomalies associated with the internal variability are not mutually independent, either. It is confirmed that, whenever the AL-IL seesaw occurs, the IL anomalies are formed through eastward propagation of wave activity released from the AL anomalies in the form of stationary Rossby wavetrains. Downstream influence of the North Pacific on the North Atlantic is still important for formation of the AL-IL seesaw as the internal variability. The most important trigger for the seesaw formation seems to be persistent AL anomalies lasting more than one month over the North Pacific so as to sustain eastward wave-activity propagation to the North Atlantic.

A SIMULATED SEESAW BETWEEN THE ALEUTIAN AND ICELANDIC LOWS AND MULTI-DECADAL MODULATIONS

Shozo YAMANE[1], Hisashi NAKAMURA[2], Meiji HONDA[1], Wataru OHFUCHI[3] ([1]IGCR, Frontier Research System for Global Change, [2]Department of Earth, Planetary Science, University of Tokyo, [3]Earth Simulator Center)

The authors have recently found that the variability associated with a late-winter seesaw between the surface Aleutian and Icelandic Lows (AL and IL, respectively) was predominant over the last 30 years in upper-tropospheric interannual variability over the wintertime extratropical Northern Hemisphere. Here, we examine how realistically the seesaw is simulated in an AGCM and how significantly its appearance is modulated on multi-decadal scales. The AGCM integrations are composed of a set of seven 50-year control experiments with global SST fixed to the climatological seasonal march and another set of thirteen 50-year hindcast experiments forced by global SST anomalies observed since 1949. The NCEP/NCAR reanalysis data for 1948-2000 are also used. Though not necessarily significant, negative correlation was found between interannual anomalies of the AL and IL intensities for any winter month in any member of the AGCM ensemble. In many of the members the seasonality of the seesaw formation is not as distinct as observed in the recent decades. Still, some of them exhibit a clear tendency in the negative correlation becoming stronger towards the latter part of the winter as observed. In the real atmosphere, multi-decadal modulations were apparent in the strength and seasonality of the seesaw signature. The negative AL-IL correlation has been strongest in late February since the 1970s, but it was so in January before the mid-1950s. In the 1960s, the negative correlation was almost diminished. Our hindcast integrations were, however, unable to reproduce the observed modulated behavior, exhibiting no systematic multi-decadal tendency in the AL-IL correlation. Interestingly, clear multi-decadal tendencies in the correlation were found in

---

some of the control runs. Reflecting those tendencies, the leading EOF for the wintertime Northern Hemisphere defined for each of the mutually overlapping 15-year periods changes its structure from a more zonally-symmetric pattern representing the annular mode to a wavier pattern representing the AL-IL seesaw or the other way around. The leading wintertime EOF for any of the 15-year periods based either on the observation or simulations can be interpreted as a linear combination of the annular mode and the seesaw. Our AGCM experiment suggests that the remote ENSO influence does not set a necessary condition for the seesaw formation, which is possible solely through the internal atmospheric dynamics. It will be discussed in the presentation whether the simulated multi-decadal modulation in the seesaw is related to modulated behavior of wave-activity propagation across North America and, if so, it is attributable to any modulations in waveguide structure and the least dumped mode of the basic state.

FORMATION MECHANISM OF VORTICITY ANOMALIES ON THE SUBTROPICAL JET IN THE MIDSUMMER NORTHERN HEMISPHERE

Naoki SATO, Masaaki TAKAHASHI (Center for Climate System Research, University of Tokyo)

Some previous studies revealed that stationary Rossby waves over the North Pacific are related to the midsummer climate over Japan. In the present study, EOF analyses were performed for midsummer pressure anomaly patterns near the tropopause around Japan, so that a Rossby wavetrain which propagates from east Asia to North America was detected on the subtropical jet. The analyses detected a series of wave train which continues from Europe to North America through east Asia. Examination of the time evolution of the anomaly by calculating lag regressions revealed the propagation of a wave packet from west to east. The wavepacket slowly develops eastward in the region with a small gradient of absolute vorticity (or PV) to the west of Caspian Sea. Then, it fast propagates eastward on the Asian jet where the PV gradient is large. From these results, we can interpret the wave-like anomaly pattern as a stationary Rossby wave train on the subtropical jet. The EOF analyses don´t detect a wave-like pattern which is shifted by a quarter wavelength from the original anomaly pattern mentioned above. Only a wave-like anomaly with a certain phase is likely to appear on the jet. In order to understand a mechanism of this phase dependency, barotropic energy conversion from the basic field to the anomaly field is estimated near the jet entrance around the Caspian Sea. A net positive energy conversion is estimated from the climatological field to the wave-like anomaly pattern. On the other hand, no significant energy conversion is detected when we use a wave-like pattern which is virtually shifted zonally by a quarter wavelength. Another estimation is performed between the smoothed climatological field and the original anomaly pattern. Here, the climatological field is spatially smoothed by a lowpass (total wavenumber $K \leq 8$) filter. No significant conversion is obtained in this case. From these results, it is deduced that the phase dependency is caused by the energy conversion corresponding to a smaller-scale distortion of the basic field. The distortion of the basic field seems to help an anomaly pattern with a certain phase to grow through barotropic energy conversion. This mechanism can be interpreted as a wave-wave interaction between the basic and anomaly fields. The small-scale distortion of the climatological vorticity field near the jet entrance may be related to the ``monsoon-desert dynamics´´ or the ``Silk Road pattern´´. In other words, it is possible that the diabatic heating related to the Indian monsoon plays an important role in forming the distortion of the basic field.

CHANGES IN ARCTIC RIVER DISCHARGE FROM A CATCHMENT MODEL AND THE INFLUENCE OF ATMOSPHERIC MODES OF VARIABILITY

Jessica Ellen CHERRY, Marc STIEGLITZ, Stephen DERY (Lamont-Doherty Earth Observatory, Columbia University)

A snow model is used to estimate Arctic precipitation from multi-decadal snow depth station data. The derived precipitation record is then used to drive a catchment hydrological model. Spatial and temporal patterns of river discharge, and their association with the dynamics of the North Atlantic Oscillation, Pacific North American pattern, and global climate change, are described, including differences between coastal and inland regions. Finally, mechanisms are proposed which could explain the observed changes in Arctic river discharge as a response to variability in atmospheric dynamical modes.

RECONSIDERATION OF TRUE VERSUS APPARENT ARCTIC OSCILLATION

Hisanori ITOH (Department of Earth and Planetary Sciences)

Extending Itoh (2002), the reality of the Arctic Oscillation (AO, or annular mode) is reconsidered. Data used are the monthly-mean values of the 500hPa and 30hPa geopotential height and the 850hPa temperature, in addition to the sea level pressure (SLP). First, considering the relationship between NAO (North Atlantic Oscillation)-PNA (Pacific/North American Oscillation) and AO-NCM (negative correlation mode between the Atlantic and the Pacific) in the simplest version of the 3-point seesaw system, a schematic figure is presented. From this figure, we can visually understand why AO-NCM is extracted from NAO-PNA by EOF (Empirical Orthogonal Function) analysis. Although NAO-PNA (apparent AO-NCM) and true AO-NCM give the same 3-point EOF, the time coefficients of the first and second EOF modes (PC1 and PC2) are differently distributed. Namely, PC1 and PC2 for apparent AO-NCM are dependent on each other, while those for true AO-NCM are independent. We then arrange the issues about the configuration of NAO-PNA and true AO-NCM in phase space and the possibility of their discrimination. It is explained that the discrimination is possible in principle irrespective of the configuration, and two-point or midlatitude EOF is a method to extract true AO-NCM on a different plane in phase space, if it exists, from NAO-PNA. In order to examine the significance of NAO-PNA obtained by midlatitude EOF, the sensitivity is checked for real data. The result shows that mistake of true AO-NCM on a different plane in phase space for NAO-PNA never occurs, and NAO-PNA is considerably robust. It is ascertained from several pieces of evidence that NAO-PNA and AO-NCM are located on the same plane in phase space in the real world. This means that NAO-PNA and AO-NCM have the same variations on the plane in common, implying that when NAO-PNA is real, AO-NCM is unlikely to be real. Next, we extend analysis fields other than the monthly-mean SLP field. First, we treat the winter-mean SLP field, for which EOF does not show AO-NCM but NAO-PNA. This may come from the fact that the winter-mean NAO and PNA patterns have little spatial correlation. Second, using the 500hPa height and the 850hPa temperature, it is considered how hemispherically dominant modes should be interpreted; the synthesis of NAO and PNA can explain larger hemispheric variations than the regression of AO and NCM. Finally, midlatitude EOF analysis is carried out for the Northern stratosphere and the Southern troposphere, where it is said that there are similar

annular patterns. Then, the annular modes can be reproduced there. The peculiarity of the Northern troposphere, where AO is not reproduced by midlatitude EOF, is thus clarified. All the above results show that almost all characteristics of AO-NCM can be explained from those of NAO-PNA, hence concluding again that AO is almost apparent, which is extracted by EOF analysis from almost independent variations of NAO and PNA.

A POSSIBLE CAUSE OF THE ANTARCTIC OZONE HOLE DIMINISHING IN 2002

Pavel N. VARGIN, Evgeni N. JADIN (Central Aerological Observatory, Dolgoprudny, Russia)

Analysis of the total ozone and stratospheric circulation changes is performed for August-October 1998 (year with the large ozone hole in the Antarctic) and 2002 (year with the very small ozone hole) using the daily means of geopotential height and zonal wind (NCEP reanalysis) and total ozone (TOMS). Obtained results showed that the stratospheric circulation over the southern polar region during August-October 2002 characterized by high activity of planetary quasi-stationary wavenumber 1(hereafter wave 1) and eastward traveling wavenumber 2 (wave 2). The maximum intensities of both planetary waves were observed simultaneously 22-28 September 2002. Wave 1 displayed eastward shift from ~50W longitude 20 September to ~50E longitude 5 October 2002 and peaked at 80-70S. Traveling wave 2 moved eastward with the period of ~20 days and maximized nearly 65S. Analysis of spatial structure of wave 1 and wave 2 showed the phases of both waves overlapped when its largest amplitudes occurred. As it known 24 September 2002 the Antarctic ozone hole split into two holes for the first time since satellite measurements have been taken. The stratospheric angular momentum (SAM) determined as the atmospheric angular momentum above 100 hPa was calculated as the identificator of stratospheric circulation and wave activity variations. Strong nonlocal correlations were indicated between the total ozone and SAM anomalies outside the polar vortex in the Antarctic by means of the singular valued decomposition (SVD) of these fields. Westerly (easterly) SAM anomalies are dominated during August-October 1998(2002) at 60S-40S. This result is in good accordance with those obtained by Jadin (1996) for the monthly mean total ozone and SAM anomalies in 1979-1992. A cause of the unexpected ozone hole diminishing in September-October 2002 might be associated with the V-shaped decadal propagation of the strong easterly SAM anomalies which arose nearly the equator in 1990-1991 and then propagated toward the middle-high latitudes during subsequent decade (Jadin, 2002a). Relatious of the ozone layer changes with the Arctic and Antarctic Oscillations and sea surface temperature (SST) anamalies are discussed (Jadin, 2002b). Reference. 1. POTENTIAL VORTICITY INTRUSION INDICES AND CLIMATE VARIABILITY OF SURFACE TEMPERATURE

Ming CAI (Department of Meteorology, University of Maryland)

Daily pressure fields on a constant potential vorticity (PV) surface (PV = 2.5 unit) are analyzed using NCEP/NCAR reanalysis II (1979-2002) dataset. Potential vorticity intrusion (PVI) indices are developed to measure the mean latitudinal position, area, and intensity of the subtropical and polar front zones, as well as the equatorial convection zones. It is found that the polar front indices are closely related to the interannual and decadal variability of the cold air temperature anomalies over the high latitudes. In general, more (fewer) of extreme cold surface air temperature episodes in high latitudes coincide with a high (low) extratropical PVI index. The interannual variability of the extratropical PVI index exhibits a strong QBO- like signal. The high (low) PVI index prevails when the equatorial zonal mean zonal wind at 50 hPa is easterly (westerly). The composite anomaly surface air temperature maps of high versus low extratropical PVI indices exhibit a pattern resembling to the familiar regression map against the AO index found in Thomson and Wallace (1998). However, the composite maps of surface pressure anomaly show a different pattern: the circulation anomalies over the north Atlantic basin are very like NAO but the anomaly pattern over the Pacific shows a dipole that is out of phase with the pattern over the Atlantic basin. The probability distribution map of PV intrusion activities shows a shift of the preferred regions of frontogenesis from the oceans to the continents when the extratropical PVI index is high. This explains directly why more extreme cold events are observed over the northern Eurasian and Northern America continents when the PVI index is high or the QBO is in the easterly phase. The equatorial PVI indices exhibit a pure QBO signal as one may expect. It shows that in the easterly phase of QBO, the equatorial air expands while subtropical front moves equatorward and polar frontogenesis area increases and intensifies. This is particularly evident in the Northern Hemisphere. The reverse is observed in the westerly phase. It is found that the observed warming trend in the high-latitudes in the last two decades can be explained an upward trend of the PVI index of subtropical fronts.

CLIMATE CHANGE IN THE NORTH PACIFIC REGION OVER THE LAST THREE CENTURIES

Kent MOORE[1], Gerald HOLDSWORTH[2], Keith ALVERSON[3] ([1]Department of Physics, University of Toronto, [2]Arctic Institute of North America, University of Calgary, [3]PAGES International Project Office)

The relatively short length of most instrumental climate records restricts the study of climate variability, and it is therefore essential to extend the record into the past with the help of proxy records. Only since the late 1940s have atmospheric data been available that are sufficient in quality and spatial resolution to identify the dominant patterns of climate variability such as the Pacific North America pattern and the Pacific Decadal Oscillation. Here we present a 301-year snow accumulation record from an ice core at a height of 5,340 m above sea level, from Mount Logan, northwestern North America, which is closely linked with the Pacific North America Pattern for the period of instrumental data availability. Our record extends the instrumental data back in time, covering the period from the closing stages of the Little Ice Age to the warmest decade in the past millennium. We find a positive, accelerating trend in snow accumulation after the middle of the 19th century. This trend is paralleled by a warming over northwestern North America which has been associated with secular changes in both the Pacific North America pattern and the Pacific Decadal Oscillation.

NAO AND ENSO PROJECTION ON IRAN CLIMATE PREDECTIBILITY

Iman BABAIYAN, Javad BODAGHJAMALI, Sohaila JAVANMARD, Leili KHAZANEDARI (Climatological Research Institute (CRI), I. R. of Iran Meteorological Organization (IRIMO), P. O. Box 91735-491, Mashhad, I. R. of Iran)

North Atlantic Oscillation (NAO) is the dominant mode of Variability over the Atlantic-European region. A number of studies have shown that most of cooling in the northwest Atlantic and the warming across Europe and Over Eurasia since the mid 1970s results from changes in the NAO. Besides, the EL Nino-Southern Oscillation (ENSO) exerts a profound on global weather and climate patterns A great dealt of time and effort here been spent investigating the phenomenon with benefits in terms of economics public safety and the environment. However, a more detailed regional projection of NAO and ENSO related climate fluctuations and predictability is still needed. In the present research, NAO and ENSO signal impacts on precipitation and other related elements, over I. R. of Iran in Climatological Research Institute (CRI), have been carried out. We choose 36 synoptic station of IRAN for this study. We found that for the Elnino events with SOI <-5 the mean annual rainfall of Iran increase about 63 percent, and for Lanino events with SOI >+5, the rainfall decreases about 67 percent. We found that there is a weak and reliable correlation between NAO and annual rainfall of Iran, which is about 20 percent.

MI05/11P/B17-007   **1630**

DYNAMICS OF INTRA-SEASONAL VARIABILITY OF THE SIBERIAN HIGH

Koutarou TAKAYA[1], Hisashi NAKAMURA[2] ([1]Institute for Global Change Research, Frontier Research System for Global Change, [2]Department of Earth and Planetary Science, University of Tokyo)

The Siberian high is a cold, semi-permanent surface anticycloneresiding over the Asian continent in winter. The high is known as one of the crucial factors for wintertime climatic conditionover the Far East and Northwestern Pacific, as it influences the strength of the winter monsoon. However, our understanding is rather limited with respect particularly to the mechanism howthe surface cold high develops under the influence ofcirculation anomalies in the upper-troposphere. In this study,time evolution and dynamical mechanism of intraseasonalamplification of the high are investigated on the basis ofthe circulation data observed over the 40 recent years.For each grid point over Siberia, a composite analysis was performed for the 20 strongest anticyclonic events separatelyat the 1000- and 250-hPa levels. At every location, a surface high was found to amplify in association with formation ofa blocking ridge aloft. The evolution of the upper-levelblocking was found quite different between the east and westof the climatological upper-level trough over the Far East.To the west, what may be called ″wave-train type″ is common,in which a blocking ridge forms near the leading edge ofa quasi-stationary Rossby wavetrain propagating eastwardacross the Eurasian continent. To the east of the trough, in contrast, what may becalled ″Pacific-origin type″ dominates, in which a blocking ridgeforms in association with a westward extension of anticyclonicanomalies from the North Pacific. We have shown through ″potentialvorticity (PV) inversion″ technique that an interaction of theupper-level wavetrain with pre-existing surface cold anomalies isessential for the extreme amplification of the surface high of the ″wave-train″ type. Surface circulation anomalies induced by upper-level PV anomalies associated with the wavetrainacts to reinforce the pre-existing cold anomalies by inducinganomalous cold advection, which counteracts the tendency of thesurface anomalies to migrate eastward as″surface thermal Rossby waves″. The surface cold anomalies thusintensified, in turn, act to induce anomalous circulationin the upper troposphere that reinforce the blocking ridge andcyclonic anomalies downstream. The above mechanism may be viewedas kind of thermal destabilization of barotropic Rossby waves.Similar interaction mechanisms between the upper-level and surfaceanomalies were found instrumental also in amplification of a surfacehigh of the ″Pacific origin″ type. Regardless of a type of upper-level blocking formation in the upper troposphere, a cold-airoutbreak tends to occur, once anomalously cold air reachesthe northeastern slope of the Tibetan Plateau. Pre-existing coldanomalies at surface are found essential for the extremeamplification of the Siberian high. Extreme blocking events withno pre-existing cold anomalies at surface can cause rather weakamplifications of the high and cold-air outbreaks.

NORTH ATLANTIC OSCILLATION PREDICTABILITY IN THE CLIMATE CHANGE PERSPECTIVE

Roxana A. BOJARIU (Research Department of Dynamic Meteorology and Climatology, National Institute of Meteorology and Hydrology)

The magnitude of the recent observed upward trend in the North Atlantic Oscillation (NAO) index is inconsistent with the results obtained from control run experiments of global climate models implying that either the models are deficient or that external forcing is responsible for this variation. In this study, observational evidence is presented for the role of boundary variables such as Eurasian snow cover, Arctic sea-ice extent and Atlantic sea surface temperature (SST) in the NAO variability of the last decades. The analysis of boundary variables and NAO index suggests a pattern of change which has modified the NAO predictive potential in the last half century. Predictive signals are identified based on this pattern and a methodological framework is built to predict the NAO phase on interseasonal time scales in a hincast experiment. The methodological framework uses the climate state vector concept of Barnett and Preisendorfer to select analogs in the interval 1973-2002.

ASYMETRIES IN THE TEMPERATURE PATTERN ASSOCIATED WITH THE NORTHERN ANNULAR MODE

Judah Levi COHEN (AER, Inc.)

Since the influential paper of Hurrell (1995), and reinforced by the paper of Thompson and Wallace (1998) and subsequent papers by the same authors, it has been widely accepted that the negative (positive) phase of the NAO/AO produces cold (warm) temperatures across all the major land areas of the mid-high latitudes of the Northern Hemisphere, including Europe, Siberia and eastern North America, giving the appearance of annularity. We demonstrate that this temperature pattern is mostly an artifact of multi-year averaging, which results in the superpositioning of two distinctive patterns. In fact a negative (positive) NAO can also produce sub-seasonal warm (cold) temperatures for Europe, Siberia and eastern North America depending on the dynamic evolution of the NAO/AO. Separation of the two patterns allows for more accurate representation of temperature anomalies associated with the NAO/AO and introduces a spatial and temporal resolution in seasonal forecasts previously not possible.

CHANGES IN PROPAGATION PATH OF UPPER-LEVEL SYNOPTIC EDDIES AND INTERANNUAL VARIATIONS IN WINTERTIME STORM TRACK ACTIVITY OVER THE NORTH PACIFIC

Takeaki SAMPE, Hisashi NAKAMURA (Department of Earth and Planetary Science, University of Tokyo)

In the wintertime Northern Hemisphere, activity of synoptic-scale eddies with subweekly periods is mostly confined in two major ´storm tracks´. The eddy amplification has been interpreted based on linear theory of baroclinic instability; i.e. the growth rate of baroclinic waves increases with the vertical shear of the mean westerlies. As already pointed out, however, the storm track activity over the North Pacific tends to be suppressed in midwinter despite the enhancement of the upper-level jet and associated lower-level baroclinicity, as opposed to the theory. One of the possible mechanisms suggested is changes in eddy structure under the strong subtropical jet, which act to reduce conversion of available potential energy from the basic state to the eddies. In this study, using reanalysis data, we examine how the propagation path of upper-level eddies changed in association with variations in the Pacific subtropical jet intensity, and how those changes are related to the observed modifications in eddy structure. Upper-level subweekly eddies are found to enter the North Pacific storm track mainly from Siberia, and their propagation path over the Far East and Northwestern (NW) Pacific is found sensitive to the intensities of the planetary-wave trough and subtropical jet aloft. In midwinters with suppressed storm track activity over the Pacific during the early and mid-1980s, upper-level eddies propagating from Siberia were steered southeastward by the deepened trough and tended to be trapped into the subtropical jet core with extremely tight potential vorticity (PV) gradient. Since the jet core was located at around 32ºN and at 12 km above the surface, the eddies propagating through the mid-latitude tropopause into the jet core were lifted up by ~3 km and kept ~800 km away from the surface baroclinic zone that was anchored at ~40N by the oceanic subarctic frontal zone. The trapping thus hindered those eddies from interacting with the surface baroclinic zone, acting to distort eddy structure and weaken near-surface wind fluctuations and lower-tropospheric poleward eddy heat fluxes. In this manner, midwinter storm track activity tended to be suppressed in the presence of the deep upper-level trough and excessively strong subtropical jet. In addition, reduced near-surface baroclinicity over the anomalously cold continental surface acted to weaken synoptic disturbances coming into the NW Pacific storm track. Since the late 1980s, the winter monsoon was weakened and both the subtropical jet and associated PV gradient were relaxed. Thus, under the reduced trapping effect by the subtropical jet, synoptic eddies coming from Siberia could propagate through mid-latitude tropopause right over the surface baroclinic zone even in midwinter as in spring and autumn. In fact, poleward shift of the Pacific storm track axis was observed in the late 1980s. Consequently, strong interaction were likely between the upper-level eddies and the surface baroclinic zone, leading to enhanced storm track activity over the North Pacific, observed as the disappearance of the midwinter minimum of that activity since the late 1980s.

AN EXCITEMENT OF THE GRAVITATIONAL AND ACOUSTIC WAVES IN THE EARTH ATMOSPHERE CAUSED BY HORISONTAK AND VERTICAL SHEAR FLOW

Tamara A. PATARAIA[1], Avtandil D PATARAIA, Tamara A PATARAIA ([1]department of Plasma Phisics, Tbilisi State Univestiy, [2]1. Centre for Plasma astrophysics, abastumani Astrophysical Observatory, 2a Al. Kazbegi Ave., Tbilisi, 380060, Georgia)

In the paper is investigated the excitement of the gravitational and acoustic waves in the earth atmosphere in linear approximation.The atmosphere is assumed to be ideally non-isothermally stratified and waves are excited by horizontal and vertical shear flow. Calculations are maade in a local Cartesian frame with the unit vector along x in the horizontal direction, the unit vector along z in the vertial direction. The x component of velocity has linear dependence on y and z components, y and z components of the velocity are zero.

ANALYSIS OF THE UPPER COLD LOW IN THE SUMMER NORTH PACIFIC

Kei SAKAMOTO, Masaaki TAKAHASHI (Center for Climate System Research, University of Tokyo)

Upper cold lows (UCLs) are generated near the tropopause in the midlatitude westerlies. These cyclonic circulations are seen at upper level. UCLs have a warm core around 150hPa, a cold core around 200~250hPa and have cirrus clouds (Shimamura,1981). But the generation mechanism of UCLs have not been clear yet. Nishimori and Ishihara (1997) showed that UCLs came close to Japan when the Tibetan High and the subtropical high are toward north. Using ECMWF Operational datasets, the UCLs generated in 1999 in the summer north Pacific were analyzed. In June and July, the Tibetan High was toward north, UCLs traveled westward along 25~30 oN latitude and 4 UCLs came close to Japan. One of UCLs in Aug 1999 was studied in detail. High PV was extended by advection at west of a synoptic disturbance and anti-cyclonic circulation was intensified at east of high PV. Then the tip of high PV was cut off and the UCL was generated. The UCL structure of cyclonic circulation, warm and cold cores and cirrus clouds are identified. The UCL had updraft in the

direction of movement. Convective clouds were seen at north of the UCL. To investigate the role of cirrus clouds and convective clouds in the UCL, the UCL and clouds were simulated using a meso model. Cirrus clouds were not so important for the UCL. But a cold core of the UCL was weakened by latent heat of convective clouds and the UCL was separated because of the cold core weakness.

NUMERICAL STUDIES OF ATMOSPHERIC KELVIN WAVES OFF THE WEST COAST OF GREENLAND

Rebekah E. MARTIN, G.W.K. MOORE (Department of Physics, University of Toronto)

Atmospheric Kelvin waves have been tracked and studied in the marine boundary layer of coastal regions of South Africa, the west coast of North America, and Australia. One characteristic of these regions that is crucial for the propagation of these waves is that the height of the boundary layer is below that of the coastal topography, which becomes the wall against which the Kelvin wave is trapped. With its very high topography, the west coast of Greenland is a good candidate for the development of atmospheric Kelvin waves. In particular, an atmospheric Kelvin wave would propagate northwards along this coast. This sense of propagation is actually retrograde to the prevailing winds in the region, which are directed southwards along the coast. As a result, a northward traveling mesoscale low pressure region could be the signature of a Kelvin wave. In this presentation we will show one such example of a weather system. On December 28, 1997 a synoptic-scale low collided with the southern tip of Greenland, and subsequently was spilt into two separate lows. The remains of the synoptic-scale system on the west side of the island spawned a polar low in the Davis Strait and excited a disturbance that propagated northwards along the west coast of the island. Both station data and high-resolution numerical simulations with MM5 show the propagation of the wave along the coast in the pressure, temperature, and wind fields.

ATMOSPHERIC RESPONSE TO MID-LATITUDE THERMAL FORCING: IMPLICATIONS FOR CLIMATE REGIMES

Peter G. BAINES (CSIRO Atmospheric Research)

In mid-latitudes the atmosphere is dominated by the zonal mean circulation forced by the latitudinal heating distribution, and large synoptic scale eddies that are attributable to its instability. It is also influenced by local topography and heating. On the quasi-geostrophic scale, the effects of the latter are manifested in forced barotropic and baroclinic Rossby waves. In this presentation I describe the effects of periodic and isolated thermal forcing in realistic sheared mid-latitude wind profiles, and the associated wave and flow fields that are produced. Typically, this consists of lee-side Rossby waves, and columnar upstream motions that may be identified with observed quasi-stationary high pressure systems, such as those upstream of Australia and in the Great Australian Bight, particularly in summer. The analysis shows that when the atmosphere is highly sheared and the mean flow near the ground is reduced to small values (< 1 ms[-1]), as it is in the mid-latitude zonal high pressure belt, higher order vertical modes may become subcritical (that were formally supercritical). This means that they will form part of the stationary response to thermal forcing from the Australian continent, or parts of it. In these conditions, a reduction in the mean surface wind speed due to a movement in the latitude of the high pressure belt, may cause abrupt changes in the flow field. In particular, this may cause a change in the direction of the forced surface wind from, say, southerly to northerly. The systematic effects of such changes at particular times of the year may result in effective changes in climate and rainfall. Hence, a systematic change in the mean position of the high pressure belt may cause abrupt changes in regional wind fields, for given seasons.

ON THE ROLE OF SYNOPTIC DISTURBANCES AND LOW-FREQUENCY VARIATIONS IN BLOCKING FLOWS

Miki ARAI, Hitoshi MUKOUGAWA (Disaster Prevention Research Institute, Kyoto University)

We examine the formation and maintenance mechanism of blocking flowsby using a β-channel barotropic model with an isolated topography.In particular, we focus upon the role of synoptic disturbances and low-frequency variations to the blocking formation in this model. This model has stationary solutions and periodic solutionswith dominant zonal wavenumber 4 components for h=900 m in the rangeof 10 m/s $< U < 20$ m/s, where h and U denote the topographic heightand the prescribed uniform zonal wind speed, respectively. Severaltime integrations are performed with an imposed eddy forcingrepresenting synoptic scale disturbances just downstream of thetopography. In the range of 10 m/s $< U < 15$ m/s, distinct diffluentflows similar to the blocking frequently appear and persist more than10 days. In fact, the EOF analysis to 10-day low-pass filteredstreamfunction field for U=14 m/s reveals that the most dominantvariability associated with the EOF1 component is closely related tothe occurrence of the distinct diffluent flow. Thus, we define theblocking event when the projection of the streamfunction field to EOF1for U=14 m/s and h=900 m becomes greater than one standard deviationof the corresponding principal component variability. By usingthis definition, we find that the formation of the blocking event inthis model crucially depends on the prescribed uniform zonal windspeed U. The time evolution of the streamfunction field decomposedinto the high- and low-frequency part is examined based upon thevorticity equation. This analysis indicates that the advection ofrelative vorticity associated with the high-frequency eddies by thelow-frequency flow field is the most important for the formation ofthe blocking flow. On the other hand, the development of thelow-frequency field reveals that the eddy straining mechanism due tohigh-frequency eddies is not essential for the formation of theblocking event, but plays an important role for the maintenance of thediffluent flow after the onset of the blocking event. Thus, this studyindicates that the effectiveness of the eddy straining mechanismcrucially depends on the basic flow, and suggests the important roleof the low-frequency variability to trigger the onset of the blocking.

ANALYSIS OF THE ORIGIN STRUCTURE AND MOVEMENT OF THE MEDITERRANEAN DEPRESSIONS

Farhang AHMADI-GIVI, Mohammad Ali NASR ESFAHANI (Department of Space Physics, University of Tehran)

A climatological analysis of Mediterranean cyclones and their impacts on the Middle East weather patterns is carried out. The dianostic tools used in this study are the monthly mean geopotential height and relative vorticity at 850 and 500 mb as well as the monthly mean 1000-850 mb thickness. Using an objective method about 30 cyclones were identified that occured in the Mediterranean region for a period of one year (july 2001- July 2002). The characteristics of each cyclone, such as duration, intensity, path, source region and its

dynamic were examined. The results show that the strength and the number of cyclones in the whole Mediterranean region are significantly decreased during the period of early June by the end of September, largely due to the movement of the subtropical highs to the higher latitudes. Also, the Persian Gulf pressure trough, which is an extension of the southwest Asian monsoon, acts to weaken the intensity of cyclogenesis and slow down its eastward movement in the eastern Mediterranean region. During early October until the end of January, as the effect of subtropical high seems weak in the northern Mediterranean, cyclogenesis activity increases over the Aegean Sea and the Gulf of Genoa. Since these cyclones move northeastwards, their effects are rather weak in the Middle East weather. From February to May, the cyclonic occurences in the northern Africa increase, largely due to the strong temperature gradient between the North Africa coast and the southern Mediterranean. As these cyclones move eastwards over the Saudi Arabia and the Red Sea, the Middle East weather is affected.

POLAR LOW GENESIS OVER THE EAST COAST OF ASIAN CONTINENT SIMULATED IN AGCM

Kozo NINOMIYA, Teruyuki NISHIMURA, Takeshi ENOMOTO, Tuneaki SUZUKI, Shinji MATUMURA (Frontier Research System for Global Change)

This report presents cases of polar low genesis over the eastern coast of the Asian Continent simulated in the seasonally varying climatological SST run by an AGCM (atmospheric general circulation model: T42L52 and T106L52). We study the simulation in January of the forth and seventh year integration after the 10-year period of the spin-up. We compare features of these polar lows with the features described in several observational studies. In the simulations, the polar low is formed over the coastal sea area ~1500 km west of the major extratropical cyclone that developed over the Northwestern Pacific Ocean, under the influence of a short wave trough, which propagates along the rim of the large-scale upper cold low. The polar low genesis takes place first as the deepening of the surface trough, which extends westward from the major cyclone. The deepening of the surface trough in the zone of strong low-level thermal gradient over the coastal sea area suggests the important role of the low-level baroclinicity for the polar low genesis. The strong heating due to the energy supply from the sea surface contributes for the genesis of the polar low through the decreasing of the vertical stability and the sustaining the thermal gradient. Meanwhile, the heating around 700 hPa associated with the precipitation concentrated within the polar low indicates the influence of the condensation heating for the development of the polar low. Aforementioned various processes work together to generate and develop the polar low. The structure and the evolution process of the simulated polar low are consistent with those of the observed polar low. It is concluded that the realistic polar low genesis takes place in the AGCM, when the large-scale phenomena such as the upper cold low, the short-wave trough, parent major cyclone and polar air outbreak are reasonably simulated. The present study has significant meaning in presenting the AGCM simulation of polar low for the first time.

SHORT-WAVE BAROCLINIC DEVELOPMENT OVER A WARM OCEAN

Maurizio FANTINI (ISAC - CNR)

Baroclinic waves can be unstable in a saturated environment at wavelengths much shorter than the common midlatitude cyclones. The presence of sensible and latent heat input from a warmer oceansurface reduces the length of possible growing baroclinic perturbations maintaining the saturatedenvironment necessary, and further by providing an additional source of energy. The mechanism by which this additional energy is made available to baroclinic development is studied in a PE modelin simplified geometry.

DEFORMATION AND MOBILE TROUGH SUPPRESSION OVER EAST ASIA

Boksoon MYOUNG, John W. NIELSEN-GAMMON (Department of Atmospheric Sciences, Texas A&M University)

The midwinter suppression of baroclinic activity over the North Pacific storm track is a paradox that tests our understanding of the role of baroclinic instability in the atmosphere. Existing theories for midwinter suppression have assumed that the suppression mechanism is local, through a jet-induced change in the linear or nonlinear instability characteristics or an alteration of the structure and role of moist processes. We examine the hypothesis that suppression is caused by a lack of suitable upper-tropospheric triggering disturbances due to extreme stretching deformation in the entrance region of the North Pacific storm track. A statistical climatology shows that upper-tropospheric mobile troughs approaching the western North Pacific are weaker in winter than in fall and spring, but that they intensify more rapidly than in the fall and spring when they reach the open ocean and interact with surface baroclinic zones. However, their more rapid intensification is insufficient to overcome their initial intensity deficit. We also show that the magnitude of this initial intensity deficit is strongly correlated to the strength of the background stretching deformation over Asia.

CYCLONES OVER THE FRAM STRAIT

Burghard BRUEMMER, Gerd MUELLER (Meteorological Institute, University of Hamburg)

The Fram Strait between Greenland and Spitsbergen is the main gate of water mass exchange between the Arctic Ocean and the Atlantic Ocean. Per annum about 3.000 km³ of freshwater in form of sea ice drift into the Atlantic. This freshwater supply into the world ocean is only surpassed by the Amazon river. The interannual variation is large and amounts to +/- 50 per cent. The Fram Strait is also a region of high cyclone activity. The variability of the cyclone activity may be one reason for the variability of the Fram Strait sea ice transport. This hypothesis is investigated by statistical methods and cyclone case studies. The case studies are based on measurements in two Fram Strait cyclone experiments, called FRAMZY 1999 and FRAMZY 2002, in which in situ measurements by aircraft, ship and an array of automatic sea ice buoys as well as satellite imagery (NOAA AVHRR, Radarsat, SSM/I) were taken. Generally, Fram Strait cyclones moves from south to north through the region. Most cyclones develop at the ice edge of the East Greenland Current and finally decay over the Arctic sea ice. The cyclones are small (diameter of a few hundred km) but can be very intense with wind speeds of more than 25 m/s. The horizontal temperature contrast between the warm and cold side of the cyclone can be up to 30 K, but is confused to a rather shallow layer of about 500 m. Comparing the in situ cyclone measurements with operational weather forecast models and analyses shows that some cyclones were not simulated by the models. In one extreme case, weak surface pressure differences around 1025 hPa were forecasted (24 h forecast) but a cyclone with wind force 7 was found by the aircraft. Such discrepancies have severe consequences for coupled of uncoupled sea ice-

models.

COMPARATIVE CLIMATOLOGY OF SYNOPTIC AND MESO-SCALE CYCLONIC EDDIES OVER NORTHERN AND SOUTHERN ICE OCEANS

Victor E. LAGUN, Eduard I. LOUTSENKO (Arctic and Antarctic Research Institute, Air-Sea Interaction Department)

Increasing in recent time interest to synoptic eddy-wave activity in atmosphereis explained by the significant role which the synoptic disturbances play in formation of climatic fields and of their anomalies. Changes in seasonal variations of extreme values of synoptic climatology parameters are used as indicators and possible predictors of low-frequency climatic variability. On the base of twice-daily NCEP reanalysis data set for period 1967-2000 the spatial distribution and temporal variations of extra-tropical cyclone parameters in global atmosphere are calculated. Using satellite imageries of cloudy cover for 1981-2000 the statistical characteristics of sub-synoptic and of polar low type meso-scale eddies are estimated. The original methods for mean sea level pressure and geopotential fields analysis were developed to indicate the cyclone position. Applied numerical methods are based on the synoptic meteorology traditional definition: eddies boundaries are considered as first external closed isobaric line. As a result, the time frequency, pressure anomaly, cyclones square and corresponding horizontal squared mean scale, drift speed, cyclones form parameters, total cyclone number, duration, Hemispheric cyclone parking parameters, mean cyclonic trajectories and their variability are estimated as monthly, seasonal, annual and decadal values. For meso-scale eddies the frequency, shape parameters, number and linear size are estimated. The tendency of the cyclonic parameters variability for atmospheric warming condition is shown. Possible connection between synoptic climatology parameters and ENSO, Arctic and Antarctic Oscillations events and sea ice extent variation and air-sea interaction processes are discussed. The results demonstrate that the number of mature extratropical cyclones is increasing under global warming conditions. The possible reasons of cyclonic eddy activity increasing over Northern and Southern Ocean are discussed.

UPPER-LEVEL DYNAMICAL EFFECTS OF A HURRICANE UPON THE EXTRATROPICAL DOWNSTREAM EVOLUTION

Cornelia SCHWIERZ, Olivia MARTIUS, Huw C. DAVIES (Atmospheric and Climate Science, ETH Zuerich)

In the beginning of November 2001 the transition of a hurricane fromthe tropics into the extra-tropics in the western Atlantic triggered(by way of upper-level downstream development) a succession ofdynamically noteable phenomena. The event is examined from the potential vorticity (PV) perspective,and both Lagrangian and Eulerian techniques are applied using 6-hourlyECMWF analysis data. The northwards moving storm system acted as a significant source ofdiabatic processes. Downstream of the area of the most intensediabatic heating a large negative PV anomaly was built up thatextended up to the tropopause level and covered an area encompassingGreenland and the eastern North Atlantic. The severe storm also led toincreased warm-SST advection and enhanced heat fluxes that helped inthe intensification of a rapidly deepening Icelandic cyclone. Downstream of the upper-level low-PV ridge the formation of ameridionally elongated intrusion of stratospheric PV (i.e. aPV-streamer) was initiated at tropopause level over Europe. Intenserainfall over northern Algeria caused severe floods that wereaccompanied by and linked to the wrapping-up of the upper levelstreamer´s tip over the southern Mediterranean and the concomitantformation of a low-level cyclone. During the whole episode an upper-level jet streak propagateddownstream along the band of enhanced PV gradient, following the ridgeand the streamer. The evolution of this feature is tracked furtheralong the dynamical tropopause to examine a dynamical link between theobserved positive wind velocity anomaly over Europe and a strong jetover Japan two days later.

COMBINED PASSIVE/ACTIVE MICROWAVE REMOTE SENSING APPROACH FOR SURFACE PARAMETER RETRIEVAL FROM TROPICAL RAINFALL MEASURING MISSION (TRMM)

Khil-Ha LEE, Emmanouil N. ANAGNOSTOU (Department of civil and Environmental Engineering, University of Connecticut)

The backscattering measured by radar technique and the emission measured by a radiometer show significant promise for the estimation of the surface parameters such as near surface soil moisture, vegetation characteristics. Both the dual-polarized 10GHz (X-band) Tropical Rainfall Measuring Mission (TRMM) microwave imager (TMI) and 13GHz (Ku-band) precipitation radar (PR) data are used for the estimation of the near surface soil moisture and vegetation properties, which leads to the potential advantage of simultaneous active/passive observations. In turn the retrieved complementary information included in both the emission and backscattering can retrieve the surface roughness properties. A simple Fresnel model for soil and modified simple model for vegetation are used to estimate the microwave emission and a theoretically based Geometric Optics Model (GOM) for soil and the semi-empirical water-cloud model for vegetation are used to estimate the backscattering signal of the land surface. The model parameters required to specify the nature of the soil and vegetation are not usually available from the data taken in the field experiments. Thus the parameters are optimized using either numerically derived or remotely sensed data. This study presents the combined active/passive approach is a good tool to estimate the surface parameters.

WATER-USE EFFICIENCY OF LAND-ATMOSPHERE CARBON EXCHANGE IN THE WORLD'S MAJOR RIVER BASINS: A SIMULATION STUDY

Akihiko ITO (Ecosystem Change Research Program, Frontier Research System for Global Change)

Water-use efficiency (assimilation of atmospheric carbon dioxide per unit water loss by evapotranspiration) is a physiologically, ecologically, and agriculturally important index of terrestrial vegetation. As freshwater is less accessible in the future, due to human utilization, water pollution, and climate change, the water-use efficiency (WUE) becomes more and more important for the sustainability of natural and cropland ecosystems. In this study, WUE of the world's major river basins is estimated with a process-based terrestrial model (Sim-CYCLE), which incorporates not only carbon dynamics (i.e. photosynthesis, allocation, respiration and decomposition) but also energy and water budget (i.e. evaporation, transpiration, and runoff). Based on datasets of actual biome, soil property, topography, and long-term climate, we estimate carbon and water budget of terrestrial ecosystems globally, at a 0.5-degree (longitude and latitude) horizontal resolution. At the present condition, global annual carbon assimilation rate (GPP) and net primary production (NPP) are estimated as 131.8 and 63.7 Pg C, respectively, at the cost of evapotranspiration (ET) by 69200 km3. Then, average WUE (=NPP/ET) is calculated as 0.92 g C per kg H2O. This is smaller than the instantaneous WUE (=GPP/transpiration) of leaf stomatal gas exchange, 3.55 g C per kg H2O. Here, the global basin maps are adopted to aggregate the global results for the world's major 53 river basins: for example, Amazon, Mississippi, Lena, and so on, covering about 40 % of the world land area. In this study, three different river basin maps, developed independently by the University of Texas, University of New Hampshire, and University of Tokyo, are used and compared. In the river basin analysis, it is apparent that the Amazon basin has the largest contribution to the atmosphere-biosphere exchange of water and carbon: 8.3 % of global GPP and 11.8 % of global ET. Among the river basins, dryer ones (i.e. precipitation < potential evapotranspiration) have higher values of WUE (approximately 5 g C assimilated per 1 kg transpiration) than moist/wet ones. The difference in WUE among the river basins is attributable to the differences in stomatal aperture of leaves and composition of C3/C4 plant species. The global and basin-specific results are validated by comparing with observations of stream discharge, which is strongly affected by vegetation activity. In spite of a simple representation of soil water with 2-layer model, the model shows good performance to capture broad-scale water budget. At last, the model study carries implications for management of water and carbon yields from terrestrial ecosystems. For example, when we plant to sequester 1 Pg of atmospheric carbon by increasing plant assimilation, it may require on average 280 km3 of water for solely transpiration.

MI07/10P/D-003   Poster   1400-178

COMPARISON OF WATER AND HEAT BALANCE ON GRASSLAND AND FOREST IN CENTRAL YAKUTIA, EAST SIBERIA

Hironori YABUKI[1], Yoshiyuki ISHII[2], Tetsuo OHATA[3] ([1]Frontier Observational Research System for Global Change, [2]Institute of Low Temperature Science, Hokkaido University, [3]Frontier Observational Research System for Global Change / Institute of Low Temperature Science, Hokkaido University)

Siberian region is an area dominated by taiga forest but the percentage of it is 70%, other being bare land, grassland and water bodies such as rivers and lakes. These regions were underlain by permafrost. Especially, in right bank of the Lena River region which is the opposite side of the Yakutsk City, there are many concave landform called ″alas″. An alas is formed after the forest has been cleared by natural collapse and forest fire, cultivation in an area where the ice content of permafrost was high. The alas occupying up to 20% of this area. Most alas have lakes and marshes near the center, and the surround of lake is covered in the grassland. When we consider the water and heat circulation of this region, it is necessary to clarify water and heat characteristics of the forest and grassland. In this study, the water and heat flux observation was carried out in the forest and grassland area, and the water and heat balance characteristics was compared. Until now, the simultaneous measurement of sensible heat and latent heat fluxes in forest and grassland was little, where weather condition seemed to be almost similar. Observation site in the right bank of the Lena River is called ″Ulakhan Sykkhan″, located 50km north east part of the Yaktusk city. The field observation was carried out from April to September 2000. In forest site, we install observation tower in a flat larch forest. The stand density was 4200 tree ha[-1]. The mean basal diameter of tree was 7.6cm. The mean stand height was 7.6m. The maximum stand height was 17.3m. In grassland site, we installed observation mast in the center of alas. This alas has oval shape and 0.64km[2] area including a 0.1km[2] lake at the center. The tower and mast were used 1-D scale flux observations of forest canopy and grassland, respectively. Both sites have separated as a distance about 2km. Air temperature and humidity were measured at 22m and 17m in forest site, and 2m and 0.5m in grassland site, respectively. We measured the downward and upward short-wave/long-wave radiation on top of tower and upward short-wave/long-wave radiation at grassland. Latent heat and sensible heat fluxes were obtained by the BOWEN ratio method. And those flues were compared with between forest and grassland sites. At the grassland the sensible heat flux was smaller and latent heat flux larger than those at the forest site. PAI in forest and grassland were 3.5 and 3.2, respectively, this value of the grassland was smaller than that of the forest site. However, the area of trunk and branch at forest were big, LAI of the forest which contributes to the evapotranspiration was 2.0, this value was smaller than grassland. The difference of this LAI seems to appear the difference in the latent heat of the forest and the grassland.

MI07/10P/D-004   Poster   1400-179

NET CO2 EXCHANGE OF CANOPY AND FOREST FLOOR OF A LARCH FOREST IN NORTHERN JAPAN

Ryuichi HIRATA[1], Takashi HIRANO[1], Junichi MOGAMI[1], Naishen LIANG[2], Yasumi FUJINUMA[2], Nobuko SAIGUSA[3], Susumu YAMAMOTO[3] ([1]Graduate School of Agriculture, Hokkaido University, [2]CGER, National Institute for Environmental Studies, [3]National Institute of Advanced Industrial Science and Technology)

CO2 flux measured above a forest ecosystem is the sum of net CO2 exchanges occurring between surrounding air and each part of the forest, such as canopy, understory, and soil, with a different physiological and structural function. The CO2 exchange should be measured separately to investigate CO2 dynamics in the forest and to establish a model for evaluating the CO2 balance of the forest. We measured CO2 flux above and below a larch forest in Hokkaido, northern Japan and evaluated the contribution of net ecosystem CO2 exchange of the forest floor (NEEf) including understory and soil to that of the whole forest ecosystem (NEEw). The study site is a larch plantation (42o44′N, 141o31′E) with an area of 100 ha and a canopy height of 15 m. Understory consists primarily of fern with a height of 0.5 ~.8 m in summer. Soil is an immature volcanic soil with high water permeability and poor nutrients. The maximum LAI was measured at 2.3 and 3.0 for canopy and understory, respectively, in June. CO2 and energy fluxes have been measured at heights of 27 and 2 m by the eddy-covariance technique with an open-path CO2/H2O analyzer, for about seven months between April and November in 2002. After larch leaves emerged in mid-April, daily NEEw changed gradually from positive (upward direction) to negative (downward direction),

and daytime NEEw became more negative rapidly with leaf expansion in May. The change in daytime NEEw became smaller as LAI approached a peak value of 2.3, and it increased in mid-June. Daytime NEEf was negative in late-April when solar radiation penetrated into the forest floor and soil temperature was still low because photosynthesis of ferns with expanded leaves was larger than soil respiration. NEEf increased gradually with increases in canopy LAI and soil temperature from May to July, in spite of an increase in understory LAI; understory photosynthesis decreased by insufficient light condition and soil respiration increased. However, a significant diurnal variation in NEEf with the minimum around noon was observed, while the minimum NEEf was still positive. Daytime NEEf never returned to be negative even in fall when canopy was opened by defoliation and soil temperature decreased. In total for the seven months, about 35 % of the CO2 absorbed by canopy leaves was originated from the forest floor. In particular, the percentage increased up to 70.0 % in summer when soil respiration was large.

MI07/10P/D-005   Poster   1400-180

SEASONAL AND INTERANNUAL VARIATIONS IN CARBON DIOXIDE EXCHANGE AND CARBON BALANCE IN A COOL-TEMPERATE DECIDUOUS FOREST IN SAPPORO, JAPAN

Yuichiro NAKAI, Kenzo KITAMURA, Satoru SUZUKI (Hokkaido Center, Forestry and Forest Products Research Institute)

Net ecosystem carbon dioxide exchange (NEE) was measured in a secondary deciduous broadleaf forest for three years (2000-2002) using eddy covariance technique. The study objectives were to document how NEE and its major component processes-gross photosynthesis (GPP) and total ecosystem respiration (RE)- vary seasonally and interannually. Annual NEE′s were -269(gC m[-2] y[-1]) in 2000, -420(gC m[-2] y[-1]) in 2001, and -508 (gC m[-2] y[-1]) in 2002. Annual mean air temperature were 17.5 (deg.C) in 2000, 16.2 (deg.C) in 2001, and 15.7 (deg.C) in 2002. In general, RE highly depends on temperature and its annual values were in the same order as the air temperature and were 1067 (gC m[-2] y[-1]) in 2000, 990 (gC m[-2] y[-1]) in 2001, and 932 (gC m[-2] y[-1]) in 2002. On the other hand, annual GPP values were in the inverse order to RE and were 1336 (gC m[-2] y[-1]) in 2000, 1410 (gC m[-2] y[-1]) in 2001, and 1440 (gC m[-2] y[-1]) in 2002. Various factors as the timing of leaf expansion, the photosynthesis avialable radiation in the growing season, and etc. were examined how GPP′s were determined. However, critical factors have not narrowed down to a few issue.

CO2 AND ENERGY EXCHANGE OF A TROPICAL PEAT SWAMP FOREST IN A DEVASTATED PEATLAND IN CENTARL KALIMANTAN, INDONESIA

Takashi HIRANO[1], Hendrik SEGAH[2], Tania JUNE[3], Suwido LIMIN[2], Ryuichi HIRATA[1], Mitsuru OSAKI[1] ([1]Graduate School of Agriculture, Hokkaido University, [2]Faculty of Agriculture, University of Palangkaraya, [3]Faculty of Mathematics and Natural Science, Bogor Agricultural University)

Tropical peatlands exist under the condition of permanent waterlogging and acidification in the tropics. Indonesia contains the largest area of tropical petlands, and Kalimantan has the area of 6.7 Mha in lowlands. Toropical peatlands usually coexist a forest and have accumulated a large amount of carbon as organic matter for over thousands of years. Recently, however, deforestation in toropical peatlands is advancing rapidly owing to a growing demand for timber and farmlands. In addition, droughts caused by the El Niño event devastated tropical peatlands by the promotion of peatland fires. In Central Kalimantan a large area of peatlands was deforested to develop farmlands in late 1990's, and channels excavated for drainage dried the peat. The devastation of peatlands promotes decomposition of the peat through the disturbance of micrometeorology and water condition. The promoted decomposition increases the release of carbon fixed in tropical peat to the atmosphere as CO2. This suggests that tropical peatlands will be a major CO2 source for the atmosphere in the near future. Thus we have measured CO2, water vapor, and energy fluxes over a tropical peat swamp forest (2° 20′ 41.6″ S, 114° 2′ 11.3″ E) in a devastated peatland in Central Kalimantan, Indonesia since November 2002. The existence of the rainy season in southern-hemisphere summer and the dry season in winter was confirmed from precipitation pattern. Findings from the first eight months of the measurements, form December 2002 to July 2003, were as follows. 1) Although precipitation was quite different, diurnal variation in net ecosystem exchange of CO2 (NEE) was similar between the rainy and dry seasons. Monthly-mean daytime negative peak in NEE was about 20 μmol m[-2] s[-1], and nighttime NEE was almost constant at about 10 μmol m[-2] s[-1]; this nighttime NEE was about twice as large as that of typical temperate forests. 2) Latent heat flux was considerably larger than sensible heat flux both in the rainy and dry seasons. 3) Monthly sum of NEE was negative in December, February, May, and July, However, it was positive in January and March, and almost zero in April and June. As a result, cumulative NEE for the eight month was only -3.6 mol m[-2], which is equivalent to carbon fixation of 43 gC m[-2] by the forest ecosystem. 4) Monthly sum of evapotranspiration (ET) was between 100 and 140 mm. Difference in ET was much smaller than that in precipitation on a monthly basis. Cumulative ET for the eight months was 914 mm, which is about 75 % of the cumulative precipitation.a

A MODELLING STUDY OF THE CLIMATIC IMPACTS OF VEGETATION IN THE TROPICS: SENSITIVITY TO THE SPECIFICATION OF SOIL CHARACTERISTICS

Tom OSBORNE[1], David LAWRENCE[1], Julia SLINGO[1], Chris TAYLOR[2], Tim WHEELER[3] ([1]NCAS Centre for Global Atmospheric Modelling, University of Reading, [2]NERC Centre for Ecology and Hydrology, Wallingford, [3]Department of Agriculture, University of Reading)

Vegetation is known to have a strong influence on land-atmosphere interactions, and major changes in tropical land cover, associated primarily with deforestation, have been shown to have significant impacts on the local climate, for example over South America. This paper describes a series of sensitivity experiments with the Hadley Centre atmospheric GCM (HadAM3) in which the effects of vegetation in the tropics on the mean climate and its variability are explored. An important part of the study has been an investigation of the dependence of these effects on the specification of soil characteristics. The processes

M

through which vegetation modifies the climate and in particular the soil hydrology will be described. It will be shown that there are large regional differences in the degree to which vegetation influences the mean climate and its variability. The sensitivity of the results to the specification of soil characteristics, involving soil hydraulic parameters, has been investigated by exchanging the standard soils dataset in HadAM3 with one derived from the IGBP-DIS soil data task. The results have shown that the climatic effects of land cover change depend critically on the specification of the soil characteristics. This emphasises the importance of improving the representation of soil hydraulic parameters in climate models used to predict the effects of land use/cover change.

NUMERICAL STUDY OF THE IMPACT OF VEGETATION CHANGES ON CLIMATE IN ASIAN TROPICAL REGION

Kazuo MABUCHI[1], Yasuo SATO[1], Hideji KIDA[2] ([1]Meteorological Research Institute, [2]Kyoto University)

A land surface model (Biosphere-Atmosphere Interaction Model: BAIM) has two vegetation layers and three soil layers, and for each layer predicts the temperature and stored moisture. In the presence of snow cover, the snow layer is divided into a maximum of three layers, with the temperature and amount of snow and water stored in each layer being predicted. Use of BAIM can result in estimates of not only the energy fluxes, but also the carbon dioxide flux between terrestrial ecosystems and the atmosphere. The photosynthesis processes for C3 and C4 plants are adopted in the model. The model can also predict the accumulation and melting of snow on the ground, and the freezing and melting of water in the soil. BAIM was incorporated into a spectral general circulation model. This general circulation model has a triangular truncation at wave number 63 (T63) and has 21 vertical levels. The horizontal grid interval is about 200 km (192 × 96 grids). The vegetation type of each grid point is specified and the interactions between the land surface vegetation and the atmosphere are estimated by BAIM at each grid point. The integration time step interval is about 20 minutes. To estimate the initial values of soil water content, including the ice content in the soil and soil temperature, over 10-year spin-up run was carried out. Using the initial values in the soil obtained by the spin-up run, the experimental control time integration was continued for 20 years under the actual global vegetation condition. After the control time integration, 3 type vegetation change integrations were performed. The vegetation types of Southeast Asia and India areas were changed to the bare soil (BS) at the first impact integration, secondly to the C4 grass (C4), and then to the vegetation without green (NG). In each impact experiment, a 10-year spin-up run was performed, and then the experimental impact time integration was continued for 20 years under the changed vegetation condition. In these integrations, the climate SST values were used. The results of the impact experiments were compared with the results of the control. From these investigations, it was found that the regional circulation patterns in Southeast Asia and surrounding area were significantly changed by the vegetation changes. The morphological and physiological effects of vegetation in Asian tropical region are very important for the formation of climate in Monsoon Asia.

TOPIC: THE IMPACT OF CONGO BASIN DEFORESTATION ON PRECIPITATION AND OTHER CLIMATE PARAMETERS (A COMMON LAND MODEL SIMULATION.)

Willis Otieno SHEM (Earth and Atmospheric Sciences, Georgia Institutte of Technology)

ABSTRACT:Deforestation is the clearing of large spaces in the natural forest mostly through anthropogenic activities as the expanding human populations seeks to exploit the forested areas for it's own comfort and 'survival' The international community has in the past few decades campaigned vehemently against deforestation of tropical rain forest especially after most studies indicated a negative impact of this process on some climate parameters like rainfall and runoff.Despite these efforts deforestation has to a large extent persisted and more so in areas like the African tropical forests where the quest for modern living styles are quickly encroaching. The reasons for this activity range from the need for more land for agriculture, livestock and habitat to commercialization of forest products for the manufacture of paper and other wood works. In Central Africa many landless people have been moving into the once forested areas and are quickly converting them into cultivated plots using simple slush and burn methods to create more space.For the period 1980-1990 the tropical forest of the world are estimated to have been disappearing at the rate of 17 million ha annually (Lanly et al., 1991). This figure is known to have increased to 20 million ha annually in the early 1990s (Lal, 1995). While the accuracy of these figures may be open to debate, there has been a deluge of publications giving specific and vivid descriptions of environmental changes wrought by deforestation (Proctor, 1989). These publications have lead many to automatically associate tropical deforestation with negative impacts like: lower rainfall; lower water yields from springs and streams; major floods; extreme sedimentation and hence the chocking of reservoirs and irrigation canals, etc. Deforestation will add Carbon dioxide (CO2) into the atmosphere through biomass burning and hence increase the greenhouse effect, it will increase the surface albedo and will alter other climatic parameters like evaporation. This study seeks to confirm or counter (for the Congo Basin) some of these conclusions and to quantify the magnitude of these impacts on the regional rainfall regimes. The paper will also look at the impacts of deforestation on other climate parameters like temperature, evaporation, sensible and latent heat flux and runoff. The impact of this process on the Carbon-dioxide cycle will not be included in this study.Complex interactions between the soil-vegetation system plus changes in radiation and cloud regimes take place as a result of large-scale deforestation and therefore the General Circulation Models (GCMs) come in handy as a tool for simulating different climate- change scenarios. To take care of the land process that contribute to the general circulation, land surface models have been embedded in these GCMs with remarkable success. This study uses the Common Land Model (CLM2), embedded into the community climate model (CCM3), to simulate the climate change scenarios in the Congo basin when the land surface type is altered from evergreen broad leaf forest to short grassland.

SEASONALITY OF GLOBAL LAND-ATMOSPHERE INTERACTION IN NCAR CUMMUNITY CLIMATE MODEL COUPLED WITH THE COMMON LAND MODEL

Wanru WU, Robert E. DICKINSON (Earth and Atmospheric Sciences, Georgia Institute of Technology)

The coupled land-ocean-atmosphere climate system is characterized by substantial amounts of spatial and temporal variability on wide range scales. To obtain a better description of this variability and the physical mechanisms responsible for it is critical in climate research [Delworth and Manabe, 1993]. Observations have provided a description of the soil moisture profile variability in terms of amplitude damping, phase shift, and persistence increasing with soil depth. In particular, the dryness signal penetrates more deeply than the wetness signal; the phase shift with soil depth is going deeper with longer time scales; and its seasonal variation is amplified in the drought-year composite, with the phase shift increased. Such variability as a function of soil depth couples to climate variability. Meanwhile, off-line

modeling study has implied the importance to simulate the soil moisture in the context of time scales rather than the soil wetness field itself. With the understanding of the soil moisture profile variability through integrated observational and off-line numerical experiments, this study explores the seasonality of global land-atmosphere interaction with an emphasis on the soil moisture variability and its impact on such seasonality. The NCAR Community Climate Model (CCM3) coupled with the state-of-the-art Common Land Model (CLM) is used for the study. The singular value decomposition (SVD) analysis is applied to the key hydrologic components, i.e., soil moisture, precipitation and evapotranspiration, to obtain the dominant modes of their heterogeneous correlations and corresponding spatial patterns. The time series for performing the SVD analysis are derived from the 10-year simulation of the CCM3-CLM model when its equilibrium status is reached.

MI07/11A/B18-005   0950
THE INFLUENCE OF LAND EVAPOTRANSPIRATION ON CLIMATE VARIATIONS

Lan SUN[1], Guoxiong WU[2] ([1]Chinese Academy of Meteorology Science, [2]National Key Laboratory of Numerical Modeling for Atmospheric Sciences and Geophysical Fluid Dynamics (LASG), Institute of Atmospheric Physics, Chinese Academy of Sciences)

A coupled numerical model of the global atmosphere with a qualified biosphere (GOALS/LASG) has been used to assess the nature of and physical mechanisms for land-atmosphere interactions, and the impacts of the Asian/North American land-surface evapotranspiration on the regional and global climate. This sensitivity study suggests that the simulated climate would be relatively larger sensitive to land surface evapotranspiration, especially over the Asian regions. The removal of evapotranspiration in Asia would create a warmer and drier climate to a certain degree. Furthermore, the surface evapotranspiration anomalies would make a substantial contribution to the formation and variation of subtropical anticyclones through the changes in monsoon precipitation and the β-effect, but also make a large contribution to the variations of the atmospheric circulation in the Northern and even global Hemisphere. Therefore, besides the traditional perception that we have generally emphasized on the influence of subtropical anticyclones activities on the boreal summer precipitation over the regions of eastern China, the surface evapotranspiration anomalies, however, also have substantial impacts on the subtropical anticyclones through the changes in monsoon precipitation. For this reason, the variation in the internal heating sources of the atmosphere caused by the land surface evapotranspiration and the vapor phase change during the boreal summer is an important external factor forcing the weather and climate.

MI07/11A/B18-006   1050
SURFACE ENERGY BALANCE STUDIES USING ASTER THERMAL INFRARED DATA

Andrew FRENCH[1], Thomas SCHMUGGE[2], William P. KUSTAS[2], John PRUEGER[3], Frederic JACOB[4] ([1]Hydrological Sciences Branch, NASA Goddard Space Flight Center, Greenbelt, MD, 20771, [2]USDA/ARS Hydrology & Remote Sensing Lab, Beltsville, MD, 20705, USA, [3]USDA/ARS National Soil Tilth Lab, Ames, Iowa, USA, [4]Ecole Superieure d'Agriculture de Purpan, Toulouse, France, 31076)

Knowledge of the relationship between the accuracy of surface energy balance estimates and remote sensing resolution is important for the integration of instantaneous satellite observations with regional and global scale hydrological models. Higher resolution thermal infrared (TIR) imagery, such as the 90 m data from the Advanced Spaceborne Thermal Emission and Reflection (ASTER) radiometer on NASA´s Terra satellite, provide the needed observations to distinguish between hydrological end-member conditions and are expected to be more accurate than imagery with resolutions >1 km. But higher resolution observations are instantaneous and usually not repeatable at time intervals less than 2 to 4 weeks. On the other hand, lower resolution TIR imagery from sensors such as those on the geostationary GOES satellite, in combination with hydrological assimilation models, can estimate the diurnal variations in surface energy balance. To assess the relative merits of resolution vs. imaging frequency, we have collected a series of 10 ASTER observations, between May and November 2002 over the arid Jornada Experimental Range in New Mexico, and modeled the surface energy balance. Estimates of the energy components are made from the original resolution (90 m) up to an aggregated resolution of 4 km. These estimates are compared with ground based flux observations, and then compared with each other. Loss in range of data and expected biases due to resolution effects will be discussed.

EARLY RESULTS OF THE ILAS-II ONBOARD THE ADEOS-II SATELLITE

Hideaki NAKAJIMA, Takafumi SUGITA, Tatsuya YOKOTA, Hiroshi KANZAWA, Hirokazu KOBAYASHI, Yasuhiro SASANO (National Institute for Environmental Studies)

The Improved Limb Atmospheric Spectrometer-II (ILAS-II) onboard the Advanced Earth Observing Satellite-II (ADEOS-II) was successfully launched on 14 December, 2002 from National Space Development Agency of Japan (NASDA)'s Tanegashima Space Center. ILAS-II is a solar-occultation atmospheric sensor which will measure vertical profiles of O3, HNO3, NO2, N2O, CH4, H2O, ClONO2, aerosol extinction coefficients etc. with four grating spectrometers. After the checkout period of the ILAS-II which is scheduled in January-February, 2003, ILAS-II will make routine measurements from early April. An initial checkout (ICO) operation was done on 20-23 January, 2003. Preliminary data taken during the ICO period suggest good quality of the ILAS-II data. A validation campaign is scheduled to be taken place in Kiruna, Sweden in 2003, when several balloon-borne measurements are planned. Current status of the ILAS-II sensor and preliminary results using ILAS-II data for both northern and southern polar regions processed with the latest data retrieval algorithm will be presented.

SURFACE ENERGY BALANCE OF BOREAL FOREST: DEPENDENCY ON SEASON, WEATHER AND SOIL MOISTURE

Anders LINDROTH[1], Achim GRELLE[2], Meelis MOLDER[1] ([1]Department of Physical Geography and Ecosystems Analysis, Lund University, P.O. Box 118, 221 00 Lund, [2]Faculty of Forestry, Swedish University of Agricultural Sciences, Box 7077, 740 07 Uppsala)

This paper focuses on which factors that are controlling the exchange of energy between a 100-years-old boreal forest and the atmosphere. The 8-year data series from the Norunda area in central Sweden with almost continuous measurements with half-hourly time resolution was used as a basis for the analysis. Surface fluxes were measured by three eddy covariance system located at different height above the canopy from 35 m up to 102 m above ground. The storage of sensible and latent heat in the stand air was measured by a

profile system comprising 12 levels. Rate of change of heat storage in the biomass was estimated from a large number of temperature measurements in branches and trunks in two different stands adjacent to the flux tower. Soil heat flux was estimated from soil heat flux plates located in the top-soil and from temperature profiles in the soil. The long-term data was used to analyse the seasonal dependency of all components of the energy fluxes including short- and long-wave radiation. The surface and aerodynamic resistances were calculated in order to assess the controls of the partitioning between sensible and latent heat fluxes. Short-term data of sap-flow and total evaporation during optimal and sub-optimal soil water conditions were used to estimate the effect of drought on the energy fluxes. The analysis showed a weak tendency of decreasing net radiation over time. The latent heat flux showed higher correlation with the net radiation on a monthly basis and the annual variation was to some degree correlated with the number of dry days.

MI07/11P/B18-002 1420

DEVELOPMENT OF SVAT MODEL'S PARAMATERIZATION OF HEAT, WATER AND CARBON EXCHANGE PROCESSES WITHIN FOREST SYSTEMS OF THE BOREAL ZONE: SWAP MODEL

Yeugeniy M. GUSEV, Olga N. NASONOVA (Institute of Water Problems, Russian Academy of Sciences)

The boreal zone determines significantly the intensity of climatic processes on the planet and effects on stability of the Earth as a global ecological system. For these reasons, problems related to modelling of heat, water and carbon exchange within ecosystems of the boreal zone get the special importance and topicality. The goal of the present work is improving one of SVAT models, namely SWAP, developed earlier by the authors. Among the sciences questions concerned in this work are: - (1) what is the ability of the SWAP model to reproduce correctly mutual formation of heat, water, and carbon budget within boreal forest system? - (2) are the SWAP model able to reproduce the observed sink (or source) of carbon for this system? Evergreen coniferous forests represents high vegetation, including overstory and understory. That is why, two active surfaces were used to schematize the heat, water and carbon exchange within forest: a surface of crowns of trees and understory or underlying surface of the forest floor. It was taken into account that trees extinguish incoming radiation, produce longwave emission in all directions, that turbulent heat exchange between the forest floor and the forest crowns exists as well. When the water balance of forest was calculated, snowpack formation at the forest floor was simulated considering the water-ice transfer within snow cover as well as the water yield from snow located on crowns. When the carbon budget was simulated, the processes of photosynthesis (of both forest overstory and understory), autotrophic (including leaf, sapwood and root) respirations, as well as heterotrophic (produced by microorganisms related to turnover of roots, detritus production from aboveground litterfall, and humus mineralization) respiration were considered. The quality of simulation of heat and water regime of boreal forest by SWAP model was validated by the comparison of calculated and measured characteristics of heat and water exchange using observation data of the Valdai research laboratory (Russia) for Tayozhniy catchment (1966-1983, spruce forest) on precipitation, snowpack, soil water stores, ground water level, runoff. The availability of the model to treat carbon exchange processes was verified on the basis of numerical experiment of almost 100-years history of forest formation on site Loobos (Nederland, vegetation cover is a scots pine) using experimental data of ˝Euroflux˝ program network as well as the data on net ecosystem exchange of carbon on this site (1997-1998). SWAP model was provided by forcing data, soil and vegetation parameters for objects selected due to participation of authors at different stages international geophysical project PILPS, literature data, as well as own experience of authors. The validation of the SWAP model have shown that it treats hydrological and carbon exchange processes satisfactory for all selected objects.

PROGNOSTIC CANOPY AIR SPACE SOLUTIONS FOR LAND SURFACE BIOPHYSICAL EXCHANGES

Pier Luigi VIDALE, Reto STOCKLI (Institute for Atmospheric and Climate Science ETH)

The importance of the correct representation of land surface processes has been progressively recognized in atmospheric sciences: several generations of land surface models have been developed, which include increasing levels of complexity. The latest, the third generation formulations, incorporate photosynthesis and physiological responses to environmental CO_2.A new set of prognostic equations, providing a new solution core for one such land surface model, SiB2, is introduced here. The new equation set makes use of canopy air space variables which are prognostic and allow for the storage of heat, water and carbon at that level, providing both a new memory for the coupled system and a better representation of observed canopy processes.Results from off-line simulation using FLUXNET data from North America and Europe, over a range of very heterogeneous environmental and climatic conditions, indicate that the new solution core is able to represent land surface exchanges with equal or better characteristic than the set it replaces. At the same time, this new formulation provides a simplified mathematical framework, more suitable for further model development.

MI07/11P/B18-004 1500

VALIDATION OF SSIB MODEL OVER GRASSLAND WITH CHERES FIELD EXPERIMENT DATA IN 2001

Lan SUN[1], Yongkang XUE[2] ([1]Chinese Academy of Meteorology Science, [2] Department of Geography, University of California)

The simplified Simple Biosphere model (SSiB) has been validated in off-line simulations against field measurements from the China Heavy Rainfall Experiment and Study (CHeRES) over a grassland site in summer of 2001. When initialized and driven by the observed atmospheric forcing over the lower reaches of the Yangtze River, the model reproduced the observed surface energy fluxes and surface skin temperature realistically. The model ably simulated the tendency of soil water content well too. The sensitivity experiments showed that the leaf reflectance were found to be most significant parameters in improving large overestimation of surface albedo during both wet and dry periods. This study can be confirmed that the model is capable of assessing the main impact of physical processes related to land-atmosphere interaction over monsoon regions in eastern Asia and the SSiB model can provide realistic surface heat fluxes for mesoscale atmospheric models.

MI07/11P/B18-005 1540

HOW DOES THE PARTITIONING OF EVAPOTRANSPIRATION AND RUNOFF BETWEEN DIFFERENT PROCESSES AFFECT THE VARIABILITY AND PREDICTABILITY OF SOIL MOISTURE AND PRECIPITATION?

Robert E. DICKINSON[1], Guiling WANG, Xubin ZENG, Qingcun ZENG ([1]Georgia Institute of Technology, [2]University of Connecticut, [3]University of Arizona, [4]Institute of Atmospheric Physics, Beijing)

Water stored as part of the land surface is lost to evapotranspiration and runoff on different time scales and the partitioning between these time scales is important for modeling soil water in a climate model. Different time scales are imposed on evapotranspiration primarily because it is derived from different reservoirs with different storage capacities, from the very rapid evaporation of canopy stores to the slow removal by transpiration of rooting zone soil moisture. Runoff likewise ranges in time scale from rapid surface terms to the slower base-flow. The longest time scale losses of water determine the slow variation of soil moisture and hence the longer time scale effects of soil moisture on precipitation. We show with a simple analysis how shifting the partitioning of evapotranspiration between the different reservoirs affects the variability of soil moisture and precipitation. In particular, we conclude that a shift to faster time scale reservoirs shifts variance of precipitation from that which is potentially predictable to unpredictable.

MI07/11P/B18-006 1600

EFFECT OF ROOT TEMPERATURE ON WATER UPTAKE AND TRANSPIRATION OF VEGETATION

Tsuneo KUWAGATA[1], Mari MURAI[2], Takahiro HAMASAKI[3] ([1]National Institute for Agro-Environmental Sciences, [2]National Agricultural Research Center for Tohoku Region, [3]National Agricultural Research Center for Hokkaido Region)

Water uptake by plant root is one of the key processes for the land-atmosphere interaction over vegetated surface. This process not only controls the evapotranspiration, but also influences the CO_2 exchange, because stomatal behavior is sensitive to plant water status. It is commonly known by plant physiologists that the ability of roots to uptake water depends on root temperature. However, there have been few studies focusing on the effects of root temperature on the interaction between vegetation and atmosphere. In this study, we examined how the root temperature could affects water uptake, plant water status, and transpiration, in order to demonstrate an important role of root temperature on the energy and water exchange over vegetated surface. Rice plants were chosen as a plant material and were grown hydroponically in a growth chamber. The transpiration rate, E_t and the leaf water potential, ψ_L were measured under various root-temperature conditions with constant air temperature at 25 ºC (ψ_L can be used as an indicator of plant water status). Over a range of root temperature, T_R from 35 ºC to 10 ºC, E_t and ψ_L gradually decreased with decreasing T_R. Below a critical root temperature 10 ºC, E_t and ψ_L abruptly decreased with decreasing T_R, which is due to an abrupt increase in hydraulic resistance of plants. We also found that the dependency of transpiration rate on humidity became weaker below the critical root temperature. Stomatal conductance is one of the key parameters for modeling the energy and water exchange over vegetated surface. The bulk stomatal conductance of whole rice plants under experimental conditions, which was estimated from the measured transpiration rate and atmospheric conditions, could be parameterized as a unique function of only ψ_L. Finally, we constructed a simple model for the energy and water exchange of vegetation, which consists of the energy balance equation for plant leaves and the water transport equation by the root. This model simulated the experimental results fairly well. As shown in the present study, the root zone temperature has a significant impact on the energy and water exchange over vegetated surface through the changes in hydraulic resistance of plants. We suggest that the root temperature effect on the water-uptake ability should be taken into account, in order to improve present Soil-Vegetation-Atmosphere-Transfer (SVAT) models.

MI07/11P/B18-007 1620

CHANGES, CONTROLLED BY A CLIMATE, IN VEGETATIVE COMMUNITIES OF EUROPEAN NORTH OF RUSSIA

Svetlana Vladimirovna VIDYAKINA[1], Alexander Andreevich MININ[2] ([1]Center for ecological research, Pomor State University, [2]Department of Social-Ecological Systems, Institute for a Global Climate and Ecology of RAS&Rosgidromet)

A characteristic of a climate of last decades is warming (IPCC, 1996). A global increase of annual air tempera-ture for the 20th century is 0,6 °C, in the Northern hemisphere temperature has increased on 0,8 °C. Most ac-tively the warming was shown here from the middle 1970th, and 1990th -s became the warmest for all period of instrumental supervision. Distinctive features of the contemporary warming of the climate are speed of changes and its spatial - temporary heterogeneity. So substantially the warming has touched winter and spring months, the night temperatures increased faster. In the present work the results of study of phenological reactions of trees in the territory of European north of Russia (ENR) are submitted. The analysis of a low-frequency component of the meteorological long-term data also shows heterogene-ity of changes. Changes of air temperatures in XXth century (1901 - 1990 years) allocate groups of stations with dominant periodic component close to 80 years and to 30 - 40 years. The changes of air temperatures in XXth century (1901 - 1990 years) allocate groups of stations with a dominant periodic component close by 80 years and to 30 - 40 years. General contemporary increase of annual air temperatures since 60 – 70th to 1990, makes up 0,3 – 1 °C. The contemporary increase of temperatures is fixed on the data of measurements of tem-peratures at different depths in the soil for the Arctic stations ENR (Arkhangelsk, Hoseda-Hard and Kandalak-sha), 0,5 - 1,2 °C. The results of processing of the amount of atmospheric precipitation for the period from 1901 to 1990 tend to increase last decades. The condition of abiotic and biotic components of the biosphere is closely connected to variations of the climate. The long-term linear tendencies of the dates of coming phonological phenomena serve important indi-cators of changes, occurring in nature. We researched spatial - temporary regularities of changes of dates of leaf unrolling and leaf-fall of common birch ((Betula pendula Roth.), breaking into bloom of bird cherry (Padus avium Mill.), mountain ash ((Sorbus aucuparia L.), for the period from 1966 to 1995 years. In a course of research the following conclusions are received: 1) The coordination of changes of linear phenological trends with occurring warming of the climate on ENR is revealed, earlier spring and late autumn terms of the phenological phenomena are established, the duration of the vegetation period for 10-20 of days increased; 2) For long-term series of dates of breaking into bloom of bird cherry, mountain ash in conditions of city are revealed more brightly expressed trends, than in a wild nature; 3) The most sensitive to the contempo-rary climatic changes in the region are the phenological phase: leaf unrolling and leaf-fall of common birch (Betula pendula Roth.), breaking into bloom of bird cherry (Padus avium Mill.).

MI07/11P/B18-008 1640

INFLUENCES OF ELEVATED CO2 (FACE) ON TRANSPIRATION, PHOTOSYNTHESIS AND MICROMETEOROLOGY IN A RICE PADDY FIELD

Hiroki OUE[1], Mayumi YOSHIMOTO[2], Tsuneo KUWAGATA[2], Kazuhiko KOBAYASHI[2] ([1]Faculty of Agriculture, Ehime University, [2]National Institute for Agro-Environmental Sciences)

Micrometeorological conditions within and above a rice canopy, stomatal conductance (gs), transpiration (Et) and photosynthesis (CER) of single leaves were observed in paddy fields under the free air CO_2 enrichment (FACE) and the ambient (AMB) conditions at three growing stages of rice. Plant area index (PAI) was larger in FACE plot then in AMB plot until heading stage. Observed gs was lower in FACE than in AMB influenced by higher CO_2. CER

M

of single leaves were larger in FACE than in AMB. Et of single leaves were lower in FACE than in AMB. However, Et from a whole canopy was a little larger in FACE than in AMB or quite the same level in both conditions owing to larger leaf area in FACE. Observed leaf surface temperature (Ts) and air temperature (Ta) within and just above the canopy in daytime were higher in FACE than in AMB especially in the upper canopy layer, which was influenced by two processes; one is less transpiration of a single leaf caused by lower gs and the other is larger radiative energy absorbed by larger leaf area in FACE. In order to evaluate effects of elevated CO_2 and the difference of leaf area on Et and CER of a whole canopy and on micrometeorological conditions separately, a multilayer energy and mass exchange model was developed. The model could reproduce observed datasets of micrometeorological conditions within and above the canopy successfully. An example of simulation revealed that Et of a whole canopy would be 15 % smaller and CER of a whole canopy would be 40 % larger in elevated CO_2 and that Ts and Ta would be up to 3 K and 1 K higher in elevated CO_2 for the same leaf area canopy.

MI07/11P/B18-009   **1700**

THE EFFECTS OF FACE (FREE-AIR CO2 ENRICHMENT) ON CANOPY EVAPOTRANSPIRATION AND TEMPERATURE IN RICE PADDY ECOSYSTEM

Mayumi YOSHIMOTO[1], Hiroki OUE[2], Kazuhiko KOBAYASHI[1] ([1]National Institute for Agro-Environmental Sciences, [2]Ehime University)

The understanding of terrestrial ecosystem processes is important to predict the global change precisely. It is well known that elevated CO2 concentration causes the partial stomatal closure and the decrease of transpiration of each leaf, which may cause the reduction in canopy evapotranspiration (ET) and plant water requirements. However, the decrease in ET causes the leaf temperature, which stimulates the evapotranspiration through the increase in water vapor pressure deficit between leaves and the atmosphere. The change of plant growth caused by elevated CO2, also, affects the canopy evapotranspiration. The interactive effects between the atmospheric micrometeorology and plant response makes it difficult to evaluate the energy balance and temperature of terrestrial ecosystems. FACE (free-air CO2 enrichment) experiment provides us a good oppotunity to examine the interaction, since their effects of elevated CO2 can be measured in open field condition without any artificial change in microclimate. FACE experiment was conducted at rice paddy field in Shizukuishi, Iwate, Japan, from 1998 to 2000. In order to evaluate the effects of FACE on heat balance and micrometeorology, we had measurements of radiation; soil heat flux; profiles of air temperature and humidity etc., at both control (ambient CO2) and FACE (elevated CO2) plots. Stomatal conductance (gs) profiles were porometrically measured at each growing stage. gs at FACE plot were usually smaller than that at control plot, whose difference was the largest in earlier growth stage and became smaller as rice growing stage progressed. gs was modeled as a function of solar radiation, water vapor deficit of the air, leaf height and growing stage, at both control and FACE plots. The gs-model was combined to bulk energy budget model, which gives 2 stream energy flow from vegetation and soil layers to the atmosphere. Bulk canopy conductance for water vapor transfer at FACE plot was smaller by 10 to 20% than control. The elevated CO2 effect on bulk conductance was more significant when the air was dry and wind speed was high. The canopy temperature increased by 0.3 to 0.5 degree in daily mean by FACE, which caused the increase in water vapor pressure deficit between canopy and the atmosphere (LVPD), by 5 to 10%. The canopy evapotranspiration as multiplication of bulk conductance by LVPD, decreased by 5 to 10% by FACE. Seasonal trend of the FACE effect on canopy evapotranspiration was different from that of leaf conductance. Leaf area index at FACE was larger in ealier growing stage, but became a bit smaller after heading period, which caused the cancellation for the FACE effect on leaf stomatal conductance. Simulation in case that LAI was the same, showed that the cancellation effect by plant growth stimulation was about 20%.

KINETIC LIMITATIONS TO CLOUD DROPLET GROWTH AND EVAPORATION: EXPERIMENTAL STUDIES WITH AN ENVIRONMENTALLY CONTROLLED LEVITATION CELL

Dennis LAMB (Department of Meteorology, Penn State University)

Electrodynamic levitation affords a unique opportunity to observe individual aqueous-solution droplets throughout their lifetimes without influences from chamber walls, thus permitting simulations of direct relevance to atmospheric phenomena. A combination of AC and DC voltages on the six faces of a cubic cell gives complete control over droplet position in space and measures of the forces needed to keep the droplet centered against gravity and aerodynamic drag in the imposed gas flow. Each droplet is observed optically as it evaporates under disequilibrium conditions, precise measurements of droplet size (+/- 0.06 micron) being derived from data captured on video tape of the structural-resonances (Mie-scattering patterns) induced by illumination from an argon-ion laser. The experimental data (drop radius versus time), taken over a range of temperatures (-35 to 25 C) and pressures (200 to 1000 hPa), are analyzed by fitting them to theoretical condensational growth models, using the mass accommodation coefficient and ambient humidity as free parameters. The evaporation/growth of pure water droplets is best characterized by a mass accommodation coefficient of 0.2 +/- 0.1 at temperatures near -35 C. The mass accommodation coefficient of nitric acid evaporating at 22 C from solution droplets with initial acid weight percent between 5 and 22 was found to be 0.1 +/- 0.05. Nitric acid additionally lowers the water activity in the solution droplets, thereby causing the time scales for evaporation of solution droplets to be much larger than those of pure water droplets. The findings from these laboratory experiments suggest that the growth/evaporation of atmospheric haze and cloud droplets are likely to be kinetically limited under some environmental conditions, especially when the saturation ratio changes rapidly. The moderately large mass accommodation coefficients for water and nitric acid mean that only the smaller droplets (i.e., haze and CCN) will be substantially influenced by surface-kinetic effects. However, it may well be the cloud droplets that are affected by the presence of nitric acid vapor in the lower atmosphere, because of the larger solubility of nitric acid in more dilute solutions. Modeling studies are being initiated to explore the impacts of kinetic and thermodynamic limitations on the early drop size distribution of clouds, radiation balances, and precipitation initiation.

LABORATORY STUDIES OF THE INFLUENCE OF CLOUD MICROPHYSICS ON THUNDERSTORM ELECTRIFICATION PROCESSES.

Clive P. R. SAUNDERS, Holly A. BAX-NORMAN (Physics Department, UMIST)

It is generally accepted that an important thunderstorm charging process involves collisions between vapour grown ice crystals and small hail pellets accreting supercooled water. The sign and magnitude of the charge transfer has been investigated in many studies over the last 50 years and with each investigation more details are discerned concerning the dependence of the sign and magnitude of the charge transfer on the microphysical conditions within the cloud. These results are interpreted in terms of a mechanism of charge transfer involving the surface properties of the interacting ice crystals and riming graupel pellets.The latest laboratory cloud studies in UMIST involve comparisons between two approaches to the method of simulating the conditions inside natural clouds. One method essentially involves ice crystals growing in the same cloud of supercooled droplets from which the droplets and ice crystals gain their vapour. This simulates certain regions of growing clouds where the particles are well mixed and able to mutually influence growth, or evaporation rates. This well mixed cloud is then used to impact the ice crystals and droplets on a riming target representing a falling graupel pellet in a growing cumulus cloud. The second method also involves the growth of ice crystals in a supercooled droplet cloud, but before the crystals and droplets impact upon the target, a second source of supercooled droplets is introduced to the cloud. The supplementary droplets have not been influenced by the presence of a growing cloud of ice crystals and so this freshly mixed cloud has a higher supersaturation than the well-mixed cloud described above. This study simulates the mixing of two cloud sources from different origins as may happen across the updraught/downdraught boundary - a region long identified with charge separation in thunderstorms. The new results from these studies show clearly how the cloud conditions influence the charge transfer. For example, the single source well mixed cloud causes the simulated riming graupel to charge positively at high droplet accretion rates and negatively at low accretion rates at all temperatures. However, in the two-cloud mixing case, the rimer charges positively above about -10 C at all cloud liquid water contents, but at lower temperatures, the sign of the charge depends on the droplet accretion rate with negative rimer charging at intermediate accretion rates.These results are consistent with a well established but recently developed charge transfer hypothesis involving the relative diffusional growth rates of the interacting ice surfaces. The experiments point clearly to the importance of using an appropriate methodology in these cloud simulation experiments. Most importantly, the role of cloud supersaturation is shown to have a dominant influence on the charging behaviour of soft hailstones in thunderstorms.

ATMOSPHERIC ICE CRYSTALS BETWEEN -20 C AND -70 C: A NEW HABIT DIAGRAM

Matthew P. BAILEY, John HALLETT (Division of Atmospheric Sciences, Desert Research Institute)

The ground breaking laboratory studies of ice crystal growth by Nakaya and others, along with the crystal classification scheme of Magono and Lee, provided the first comprehensive view of ice habits at temperatures relevant to snow and ice particles observed at ground level and in the lower troposphere. While the laboratory results generally showed good agreement with in situ observations for temperatures between -2 ℃ and -18 ℃, the habit results of some studies were skewed by the use of artificial nucleating agents and control of supersaturation, especially when the laboratory measurements were extended to colder temperatures. A new method which combines static diffusion and expansion chamber techniques has been used to nucleate and grow ice crystals under realistic atmospheric conditions of temperature, pressure, and ice supersaturation. Linear, projected area and volume growth rates as well as habit frequency and distribution have been determined for crystals growing between -20 ℃ and -70 ℃. This method has yielded results which are in excellent agreement with the vast majority of in situ observations for temperatures from 0 ℃ to -70 ℃, reproducing the well established habits observed between 0 ℃ and -18 ℃. Contrary to what is often stated in the literature though is confirmed by in situ observations, the crystal habit between-20 ℃ and -40 ℃ is not columnar but is instead dominated by plate-like polycrystals, columnar forms generally appearing with low frequency unless ˝seeding and feeding˝ from colder overlying clouds is present. Low ice supersaturation (1-2%) habits constitute a special class of crystals dominated by compact polycrystals, thick plates and short columns, nearly independent of temperature between -20 ℃ and -60 ℃. The region of bullet rosette nucleation has been determined to begin at temperatures below -40 ℃ where a new habit transition from predominantly plate-like to columnar habit forms has been identified. In situ habit observations for temperatures warmer than -40 ℃ have at times yielded erroneous correlations between habit and temperature since regions near cloud top may include this habit transition or clouds at even colder temperatures. The growth histories and modification of habit for crystals which nucleate at columnar growth temperatures below -40 ℃ and subsequently fall to warmer plate-like growth temperatures have been simulated and remarkably reproduce the unique in situ characteristics of bullet rosettes and columns which have been observed in the atmosphere after falling to temperatures between -20 ℃ and -40 ℃. All these results demonstrate the continuing utility and importance of laboratory simulations under controlled conditions which are critical to the correct interpretation of in situ observations and a better understanding of atmospheric processes in glaciated clouds.

NEW IPSL EXPERIMENTS ON GLAZE ICE ACCRETION ON A STATION POST INSULATOR

Wladyslaw J. RUDZINSKI[1], Edward P. LOZOWSKI[1], Masoud FARZANEH[2] ([1]Department of Earth and Atmospheric Sciences, University of Alberta, [2]NSERC/Hydro-Quebec/UQAC Industrial Chair on Atmospheric Icing of Power Network Equipment (CIGELE), University of Quebec in Chicoutimi, Quebec , Canada)

Dealing with ice build-up on outdoor insulators is of key importance for maintaining the reliability of power networks in many northern countries. Glaze ice accretion, with numerous icicles formed during freezing rain, is the most severe type of ice accretion for insulators, since it can considerably reduce their performance. When icicles are formed and conductive unfrozen liquid flows along the ice surface, electrical discharges and flashover can occur, frequently resulting in power failure. It is important to understand glaze ice formation in order to improve insulator design and thereby reduce flashover occurrence. Our research focuses on laboratory modelling of glaze ice accretion on a non-energized station post insulator. A series of laboratory icing experiments has been undertaken in the Icing Precipitation Simulation Laboratory (IPSL) of CIGELE at the University of Québec in Chicoutimi. The influence of air temperature, wind speed, precipitation rate and drop size on the shape, dimensions and mass of the ice accretion on the station post insulator has been investigated. The experimental results have been used to verify a novel high-resolution, full-scale 3D discrete particle model of ice accretion on a station post insulator. This model, also called a morphogenetic model, predicts the morphology of ice accretion by building it up one

particle at a time. The model is capable of predicting the shape, mass and mass distribution of the glaze ice accretion a station post insulator. While the model predictions are in acceptable agreement with the results of the laboratory experiments, their comparison has led to revealing insights into the physics of glaze ice accretions on insulators.

STUDIES ON REACTION AND PHOTODISSOCIATION PROCESSES IN THE ATMOSPHERE USING A VACUUM ULTRAVIOLET LASER INDUCED FLUORESCENCE TECHNIQUE

Yutaka MATSUMI, Kenshi TAKAHASHI (Solar-Terrestrial Environment Laboratory, Nagoya University)

We have studied reaction and photodissociation processes in the atmosphere using a vacuum ultraviolet laser-induced fluorescence (vuv-LIF) technique in our laboratory. Numbers of important atoms and radicals in atmospheric chemistry can be detected only by using vuv wavelength light. We have detected $Cl(^2P)$, $O(^3P)$, $O(^1D)$, $O(^1S)$, $N(^4S)$ and $H(^2S)$ atoms, and $ClO(X^2\Pi)$ and CO molecules using tunable vuv laser light. For example, for the detection of $O(^3P)$, the necessary tunable vuv radiation is generated by two photon resonant four-wave difference frequency mixing $(2\omega_1 - \omega_2)$ in krypton gas, using two tunable dye lasers pumped simultaneously by an XeCl excimer laser. The frequency-doubled light of the first dye laser yield $\omega_1 = 212.56$ nm, which is two-photon resonant with the atomic transition of Kr. The second dye laser is operated to generate $\omega_2 = 578.1$, 572.8, and 570.6 nm which, when mixed with two ω_1 photons, correspond to the appropriate vuv frequencies for detecting $O(^3P_j)$ atoms with $j = 2$, 1, and 0, respectively. $O(^1D)$ atoms are detected by vuv-LIF at 115.22 nm. Radiation at this wavelength is generated by phase-matched frequency tripling of the output from a single XeCl pumped dye laser (345.66 nm) in a xenon / argon gas mixture. Xenon, krypton and mercury gases have been used as non-linear optical mixing media for the four-wave mixing $(2\omega_1 \pm \omega_2)$ and tripling to generate tunable vuv laser light in various wavelength ranges. There are several superior advantages for the usage of the vuv laser over conventional atomic lamps. The narrow band width of the vuv laser allow us to measure populations among the spin-orbit levels of $Cl(^2P_j)$ and $O(^3P_j)$ independently and to measure accurate concentrations of the atoms. Doppler profiles of the atoms can be measured with the narrow band width vuv laser light, from which we can determine the product states, for example, $O(^1D) + O_2(a^1\Delta_g)$ or $O(^1D) + O_2(X^3\Sigma_g^-)$ in the photolysis of O_3. Since the time resolution between photolysis and probe vuv laser pulses is high, we can measure nascent distributions of the products and also can measure precise reaction rate constants. Representative of our studies using the vuv laser system is the measurements of $O(^1D)$ quantum yields in the photolysis of O_3 at various uv wavelengths (230 - 330 nm) and at various temperatures (227 - 295 K). We have measured photofragment excitation spectra for both $O(^3P_j)$ and $O(^1D)$ in the uv photolysis of O_3 using the vuv-LIF technique. We have determined the precise absolute $O(^1D)$ quantum yield values which are functions of the O_3 photolysis wavelength and temperature. We have also revealed the contributions of the hot-band excitation and spin-forbidden dissociation mechanisms in the photolysis of O_3.

THE LABORATORY INVESTIGATION OF CORONA DISCHARGE FROM ICE CRYSTALS

Matthew P. BAILEY[1], John HALLETT[1], Danyal PETERSEN[2], William BEASLEY[2] ([1]Division of Atmospheric Sciences, Desert Research Institute, [2]School of Meteorology, University of Oklahoma)

The initiation of lightning is likely to involve corona discharges from ice hydrometeors coupled with some mechanism whereby the local field is enhanced up to breakdown values. This process may depend on the enhancement of propagating positive streamers when the ambient electric field exceeds a certain critical value. Experimental results from Griffiths and Latham concerning the corona emission from ice crystals appeared to indicate that positive streamer emission was extinguished below approximately -18 °C, possibly related to a rapid drop in ice conductivity. However, those results were obtained under conditions of low humidity rather than near water saturation as is found in much of the ice growth regions of thunderclouds. Additionally, the crystals used for those experiments were several millimeters to over a centimeter in size which is considerably larger than the majority of large ice crystals found in clouds. A new experiment investigating the corona emission of positive streamers by crystals grown at ice supersaturations close to water saturation has been performed with crystals ranging in size from 0.3-3 mm over a range of temperatures and pressures relevant to thundercloud conditions. Positive streamer emission was directly observed with an image intensifier. Positive streamer emission was observed to occur for field strengths which ranged from approximately 450 kilovolts/meter for needles at -4 °C and a pressure of 850 mb to approximately 650 kilovolts/meter for thick plates at -30 °C and a pressure of 400 mb. Bipolar emission from thick plates was observed to begin below approximately -35 °C and a pressure of 350 mb for field strengths around 750 kilovolts/meter. Threshold field strengths varied greatly with crystal habit, thick crystals generally requiring lower threshold field values than thin crystals. Thin plates, thin plate-like polycrystals and dendritic forms growing between -15 °C and -22 °C typically required higher threshold field values than thicker forms at both lower and higher temperatures. While the mechanism of field enhancement has yet to be determined, these measurements place new limits on the field values for positive streamer emission in thunderclouds as a function of temperature, supersaturation, and crystal habit.

CAPACITANCES OF LABORATORY GROWN ICE CRYSTALS: A TEST OF THE ELECTROSTATIC MODEL OF CRYSTAL GROWTH

Matthew P. BAILEY[1], John HALLETT[1], Alexei KOROLEV[2], George ISAAC[3] ([1]Division of Atmospheric Sciences, Desert Research Institute, [2]Sky Tech Research, [3]Cloud Physics Research Division, Meteorological Service of Canada)

The electrostatic model of ice crystal growth from the vapor is constructed from the analogy between a conductor in an electric field and an ice crystal in a vapor field. This approach approximates the shape of a thick plate as an oblate spheroid and a column as a prolate spheroid, more complex forms generally not being addressed. While this model has been in the literature for sometime, there have been few attempts to verify the model through laboratory experiments. In a recent crystal growth experiment (Bailey and Hallett, this conference), average volume growth rates have been obtained for crystals with maximum sizes between 150-300 microns that were grown between -20 °C and -70 °C at ice supersaturations and pressures representative of the real atmosphere. Additionally, the time dependent growth rates for some of these crystals have been determined for crystals which grew from approximately 100 microns to1000 microns in maximum dimension. Volume growth rates were converted to mass growth rates and were then used to calculate the crystal capacitances for several different habit types including bullet rosettes. In another experiment, drops frozen between -4 °C and -15 °C at various ice supersaturations were then allowed to grow for tens of minutes under controlled conditions. From these growth experiments, it was found that the electrostatic capacitance analog accurately predicts the spherical growth of frozen drops, somewhat adequately represents the growth of very thick

plates and short columns, but typically overestimates the growth of thin plates, long columns and bullet rosettes by a factor of three to four. Complex polycrystals exhibit capacitances with great variability that are typically less than those predicted by the electrostatic model for simple habit forms. Time dependent measurements indicate that the capacitance changes as a function time and crystal size, however not in the simple manner predicted by the electrostatic analogy. These measurements clearly indicate that the boundary conditions for crystals in a vapor field are not analogous to those of a conductor in an electric field except in limited cases. However, these measurements provide effective capacitances which more accurately reflect the interaction of crystals with the vapor field as a function of crystal size and habit and are more appropriate for use in crystal growth models.

PRECISE DETERMINATION OF THE QUANTUM YIELD FOR O(1D) PRODUCTION IN THE UVPHOTOLYSIS OF O3

Kenshi TAKAHASHI, Takayuki SUZUKI, Tomoki NAKAYAMA, Yutaka MATSUMI (Solar-Terrestrial Environment Laboratory, Nagoya University)

The photodissociation reaction of O_3 following photoabsorption of the solar ultraviolet radiation produces the electronically excited oxygen atom, $O(^1D)$, that is highly reactive and has imporant roles in the chemical processes in the terrestrial atmosphere. For instance, the chemical reaction of $O(^1D)$ with H_2O is a primary source of the OH radical in the stratosphere and troposphere. The $O(^1D)$ reaction with N_2O produces NO that affects significantly stratospheric ozone concentration. Therefore, it is quite important to know the quantum yield for $O(^1D)$ production in the solar uv photolysis of ozone. In this study, we determined the $O(^1D)$quantum yield values in the wavelength region of 306-314 nm where the yield increases drastically from near-zero values around 330 nm to near-unity values around 300 nm and the solar actinic flux shows a strong wavelength dependence. The calculated atmospheric $O(^1D)$ production rate is very sensitive to changes in the quantum yield for its production in the uv photolysis of O_3 in this region and the uncertainty associated with the yield. We performed laboratory studies to determine precisely the quantum yield of the $O(^1D)$ atoms produced in the 306-314 nm photolysis of O_3, by means of a high-sensitive technique of laser-induced fluorescence spectroscopy. The results are compared with the data recommended for use in atmospheric modeling. We also present that the uncertainties associated with the yields have been reduced significantly as compared to the current recommendation data. Our new values will be helpful to calculate more precisely the OH and NO_x production rates in the atmosphere.

MI08/07P/D-002   Poster   1400-196

THE STUDY OF SEEDING EFFICIENCY OF SOME NATURAL MATERIALS IN COLD CLOUDS

Seyed Alireza SADEGHI HOSSEINI, Atoosa FERDOSIN NAJAFABADI (Institute of Geophysics University of Tehran, P. O. Box: 14155-6466, Tehran, Iran)

Despite many successes in the field of freezing nucleation during the last two decades, there are still uncertainties and questions that have been of special interest to cloud physicists. Due to the wide variety of nucleation processes, most of the concepts expressed to describe the subject, could not bring forward comprehensive explanations. Using cold plate and fishing line apparatus, the immersion freezing nucleation rates of some natural materials such as, distilled water, smog, clay and leaf mould have been studied. The seeding efficiency of natural material solutions have been studied through spraying them over the drops of distilled water suspended on the fishing line. The experimental results confirm the time-temperature dependence of freezing rate due to heterogeneous nucleation (Vali,1994). They also show that a good cloud seeding agent can be easily produced from bacterial biogenetic nuclei as effective nucleation materials. By deduction the effect of contact freezing, the biogenetic nuclei are found to have maximum activity at -5ºC and their seeding efficiency is about 80% at -9ºC. These results are more acceptable than those of mineral substances such as Silver Iodide. The performance of these experiments in a clean weather or the use of the bacteria incubation method, leads to more accurate and reliable results. Performing such low-cost xperiments, not only could bring out a better understanding of the freezing nucleation process, but it is also possible to decrease the expenses of cloud seeding projects as well as the dangers of airplane accidents inside the clouds.

MI08/07P/D-003   Poster   1400-197

AEROSOL FLOW TUBE STUDIES ON THE HETEROGENEOUS REACTION OF HNO3 AND N2O5 ON MINERAL AEROSOL

Friedrich HANISCH, Heleen DE CONINCK, John N. CROWLEY (Max-Planck-Institute for Chemistry, Dep. of Atmospheric Chemistry)

A recent study estimates that 1600-2000 Tg of mineral aerosol are emitted annually into the atmosphere (Ginoux et al., 2001). As shown by modelling studies (Zhang et al., 1994; Dentener et al., 1996), mineral aerosol can strongly influence atmospheric chemistry, especially the budgets of NOx, HOx and O_3. These modelling studies revealed the need for reliable data quantifying the heterogeneous uptake of trace gases onto mineral dust particles. Earlier laboratory studies determining uptake coefficients for the interaction between trace gases and dust were using the Knudsen reactor technique (e.g. Börensen et al., 2000; Hanisch and Crowley, 2001). The main disadvantages of this technique, however, are the use of bulk substrates instead of airborne particles and the inability to simulate atmosperic relative humidities. These problems are overcome by the use of the aerosol flow tube technique. In this study we present results for the uptake of HNO_3 and N_2O_5 onto airborne mineral aerosol, using an aerosol flow tube coupled to a chemiluminescence detector and an optical particle counter for the determination of the concentrations of NOy and mineral aerosol, respectively. Uptake coefficients for this reaction were measured and the influence of relative humidity on the reaction was investigated. References Börensen, C., U. Kirchner, V. Scheer, R. Vogt, and R. DEVELOPMENT OF A 400 MHZ-BAND WIND PROFILER RADAR AT OKINAWA IN THE WESTERN PACIFIC SUBTROPICS

Tatsuhiro ADACHI (Okinawa Subtropical Environment Remote-Sensing Center, Communications Research Laboratory)

Okinawa Subtropical Environment Remote-Sensing Center of the Communications Research Laboratory has developed a new 400 MHz-band Wind Profiler Radar (400M-WPR) at Okinawa Island, Japan, locating in the Western Pacific Subtropics, where we can observe active atmospheric phenomena such as typhoons, Asian monsoon, and Baiu fronts induced by thermal input from the warm ocean. This WPR is a monostatic Doppler radar operating at 443 MHz with peak and average transmission power of 20 kW and 2 kW, respectively. The antenna is square-shaped with sides of 10.4 m, consisting of orthogonally aligned 24-element linear arrays, which can electronically steer a radar beam in the meridional- and zonal-vertical plane. The key feature of our WPR is the enhancement of height coverage in RASS (RADIO Acoustic Sounding System). In the RASS observations using a monostatic WPR, the wave number vector of transmitted radio waves must be 1/2 that of transmitted acoustic waves, according to the Bragg condition. However, the space that satisfies the Bragg condition is not always at its zenith, but mostly limited to the windward direction, because the acoustic wavefronts are distorted by the background wind velocity profile. Therefore, we have to steer the antenna beam to an appropriate direction satisfying the Bragg condition to enhance the height coverage. To realize this adaptive beam steering according to the background wind field, the whole antenna field of the WPR is mounted onto a turntable so that the antenna beam can steer in any azimuth directions. We calculate in advance the propagation path of the acoustic wave, based on the background wind velocity and the temperature field. We then extend the altitude of the observation by predicting the space region in which the Bragg condition is satisfied and by scanning the antenna beam in that direction. We built the Ogimi Wind Profiler Facility (128.16E, 26.68N, 225 m MSL) as a base for operating various atmosphere-observation devices. Apart from a 400 MHz-WPR, this Facility is equipped with a 1.3 GHz-WPR, a Doppler Sodar, a GPS radiosonde, an ultrasonic anemometer, an optical rain gauge, a disdrometer, and a ground-based weather observation system. The 400M-WPR has continued wind velocity profiling in a few minutes´ interval with an altitude range from approximately 400 m to typically 13 km, and 10 km in summer and winter, respectively. We were successful for the wind profiling up to 16 km near the center of a typhoon Nari approached in September 2001. We were successful of preliminary RASS observations up to about 3 km, which indicated the importance of appropriate beam steering and geometric configuration between the acoustic transmitter and radar antenna in RASS.

VERTICAL WIND OBSERVATIONS USING DOPPLER SPECTRA OF VERTICALLY POINTING W-BAND RADAR

Yuichi OHNO (Communications Research Laboratory)

W-band radars are very useful instruments for cloud observations because of their higher sensitivity compared with lower-frequency radars and their higher penetrability of thick cloud layers compared with lidars. On the other hand, W-band radars have a disadvantage for rain observations because of larger attenuation compared with lower- frequency radars. However, Lhermitte (1988) found that a vertically pointing W-band radar can measure vertical wind in rainy environment using Mie scatter theory. His method uses the dip of a rain echo Doppler spectrum as an index of the specific size of raindrops that corresponds to Mie resonance. Using a relationship between drop-size and falling velocity, the Doppler velocity of the dip in still air condition is obtained. The environment air velocity can be estimated from the discrepancy between observed Doppler shift of the dip and its velocity in still air. Information of vertical air velocities is necessary to measure accurate drop-size distributions of rain from the vertically pointing radar. In 1997, Communications Research Laboratory developed a W-band (95.04GHz) cloud profiling radar called ″SPIDER″. SPIDER was mostly operated as an airborne radar, and even in the case of ground-based measurements, velocity was determined using the pulse-pair method before. In Dec 2002 and Jan 2003, SPIDER was operated pointing vertically from the ground and Doppler spectra were obtained during a few rain events. When a low pressure system passed over Japan in January, vertical winds during rain were observed by SPIDER using Lhermitte´s methods up to 1 km over 5 hours. The measured vertical winds show clear vertically coherent oscillations that have a 1 m/s amplitude and a 5-6 minute periods. The oscillation is probably related to gravity waves, but the cause of the oscillation is still unknown. By comparing these data with data from a distrometer as well as a vertically pointing L-band radar, we will be able to verify this method and investigate the change in drop-size distribution affected by vertical air motions.

MST RADAR VOLUME-IMAGING OF THE LOWER ATMOSPHERE

Richard M. WORTHINGTON[1] ([1]RASC, Kyoto University, [2]Physics Department, University of Wales Aberystwyth)

Measurements by wind profiler often assume that the background 3-d wind vector is uniform over horizontal distance of ~1km, and refractivity structures move with the wind. Volume imaging radars can remove these assumptions, by measuring full 3-d structure and dynamics of the atmosphere, on spatial scale ~0.1-10 km and time scale ~5 seconds. UHF spaced-antenna and VHF beam-steering radar both exist for volume imaging.UHF systems are generally smaller, more transportable, and sensitive to insectsand birds, whereas VHF systems offer higher power and work in all weather - andso the two are complementary, benefitting together from subtly different viewsof the same atmosphere. The MU radar at Shigaraki, Japan, can be used for volume imaging, a DBS modeallowing measurement in 64 directions in effect simultaneously. The moving andevolving structure of rain clouds, convective cells, waves, instabilities anddeep convection can be visualised. Bird echoes are similar to rain, butdiscrete and moving in mostly horizontal trajectory instead of continuouslydown. With sufficient power, measurement height can be increased from the boundarylayer and troposphere, to the tropopause region and stratosphere. In additionto the fraction revealed visually by clouds, 3-d structure and dynamics of theinvisible atmosphere can be observed.

ANALYSIS OF TURBULENCE STRUCTURE, WIND, AND WIND SHEAR USING SPACED ANTENNA OBSERVATIONS

Gernot HASSENPFLUG, Mamoru YAMAMOTO, Shoichiro FUKAO (Radio Science Center for Space and Atmosphere, Kyoto University)

Correlation lengths are important characteristics for the study ofatmospheric turbulence and the mechanisms causing it. However, thesmall-scale turbulence structure scales are difficult to observe byremote sensing methods. On the other hand, the effect of small-scalestructures has been evident as aspect-sensitive radio-wave scatteringat VHF frequencies (*Röttger*, 1980). Spaced antenna (SA)observations (*Röttger and Vincent*, 1978) with the 46.5 MHzMiddle and Upper atmosphere radar located at Shigaraki, Japan(34.85°N, 136.10°E) using the method of *Doviak et al* (1996) and *Holloway et al* (1996, 1997)permit direct estimates of horizontal correlation lengths, assumed tobe due to turbulence, independent of the antenna parameters orbaseline configuration. This is a major improvement over spacedantenna techniques that estimate only the ground diffraction patternscales. Estimates of these assumed turbulence structure correlationlengths and associated turbulence intensities in the troposphere andlower stratosphere obtained at range resolution of 150 meters and timeresolutions of between 26.2 seconds and approximately 5 minutes arecompared to background wind and vertical shear of the horizontal winddetermined by either SA or Doppler beam swinging (DBS) data. It isshown that enhanced turbulence decreases the size of scattererswithout markedly affecting the horizontal anisotropy. We examine thisanisotropy of the turbulence structures defined by the direction ofthe correlation ellipse major axis, the axial ratio, and itsrelationship to the background wind and wind shear directions. In thecomparison, the wind and wind shear information obtained from both SAand DBS data is used, while turbulence intensity estimates derivedfrom SA measurements are used to avoid the necessity of removingbeam-broadening effects from DBS spectral widths. The comparison of DBS winds and shear with the turbulence structuresize and orientation over several data sets showed consistentanisotropy with ratio of major and minor axis correlation lengthhaving values between 1.3 and 1.7, and average major axial lengths ofapproximately 20 meters. The direction of the major axis of thecorrelation ellipse tended to be aligned with the wind shear vector towithin 30 degrees, while a difference of between 10 and 50 degreesexisted for the wind vector. Enhancements in the shear intensity werecorrelated with a decrease in the scatterer correlation lengths andwith a corresponding increase in the turbulence intensity. We observethe relationship of correlation ellipse and wind in an altitude rangebetween two scattering layers where Richardson numbers close to 0.25occur. Based on these results, we illustrate the usefulness ofcorrelation ellipse parameters in studying turbulence scattering andatmospheric turbulence itself. The results also support he hypothesisthat the anisotropic turbulence which is seen during the observationswas possibly created by Kelvin-Helmholtz instabilities related tovertical shear of the background horizontal wind field.

CONTINUOUS MONITORING OF HUMIDITY PROFILES WITH THE WIND PROFILER RADAR-RASS OBSERVATION

Jun-ichi FURUMOTO[1], Kenji KURIMOTO[2], Satoshi IWAI[1], Toshitaka TSUDA[1] ([1]Radio Science Center for Space and Atmosphere, Kyoto University, [2]Now at Mitsubishi Electric Corporation)

Simultaneous observations of wind velocity, temperature and humidity are essential to study the detailed structure of atmospheric thermodynamics. A three-dimensional wind field can be observed by the wind profiler radar, while temperature profiles can be monitored by RASS (radio acoustic sounding system) with good time and height resolution. However, humidity profiles have not previously been continuously monitored with radar remote-sensing techniques. This study developed a remote-sensing technique to use radar to estimate humidity, which is aimed at enabling the simultaneous observation of wind velocity, temperature and humidity. The variation of the echo power intensity of clear air Doppler radars mainly depends on variation in the vertical humidity gradient. Then, humidity profiles can be estimated using this strong dependency. In order to achieve stable estimation of the humidity profiles, our method refers to complementary measurements such as precipitable water vapor obtained through simultaneous GPS measurement. The MU (middle and upper atmosphere) radar located in Shigaraki, Japan (36. 51'N, 146.06' E, 375 m MSL) was used for the test of the method. The MU radar is a clear air atmosphere radar which can monitor three-dimensionalwind velocity profiles, and combining RASS with the MU radar (MU radar-RASS) measures temperature profiles in the troposphere and lower stratosphere with good time and height resolution. Humidity profiles were estimated with the MU radar-RASS data obtained in July, 1999. The time-height structure of the radar-derived humidity agreed well with simultaneous radiosonde results obtained every three hours, although the radar-derived humidity revealed short-term fluctuations which could not be observed by the intermittent radiosondes. The hourly fluctuation of radar-derived humidity was consistent with the movement and the development or decay of the rain clouds as monitored by the meteorological radar. We are attempting to apply this method to other radar, such as the equatorial atmosphere radar (EAR) in the west Sumatra, Indonesia and the lower troposphere radar (LTR). This new approach is also presented.

DIFFERENTIAL ABSORPTION LIDAR SYSTEM FOR VERTICAL PROFILING OF ATMOSPHERIC OZONE

Devara China Sattilingam PANUGANTI, Raj Ernest P., Pandithurai G., Dani K. KUNDAN (Indian Institute of Tropical Meteorology, Pune - 411 008, India)

Ozone plays a pivotal role in stratospheric chemistry and the radiative balance of the atmosphere. Stratospheric ozone protects life on Earth from harmful UV radiation and controls energy balance, temperature and wind system. In the lower stratosphere and upper troposphere ozone becomes a powerful greenhouse gas and forcing function for climate change. In the lower troposphere, it is a pollutant, created through complex photochemical reactions with anthropogenic gases and sunlight, affecting humans and plants. The gradual increase of the tropospheric ozone concentration has recently given rise to research programs. Continuous monitoring of atmospheric ozone vertical distribution would be of great importance, particularly over tropics where convective circulation and dynamical processes influence the spatio-temporal distributions of chemical constituents, including those originating from the anthropogenic effects, besides high photochemical activity in this region. Such measurements are very scanty in the tropical region. Vertical profiles of ozone are generally retrieved from ground-based, balloon-sonde, rocket-sonde and satellite-borne techniques. Recently, advanced active remote sensing systems utilizing the DIfferential Absorption Lidar (DIAL) technique have successfully been used for measurements in the stratosphere / troposphere. Of these, excimer (XeCl) lasers provide substantially higher pulse energies and repetition rates and thus allow averaging times of just a few minutes. In this paper, we describe an ultraviolet (UV), rare-gas halide, excimer-Raman laser-based lidar system that is being developed at the Indian Institute of Tropical Meteorology (IITM), Pune (18°43'N, 73°51'E, 559 m amsl), India for vertical distributions of ozone and to investigate their possible impact on environment and climate. The system essentially operates in the differential absorption lidar (DIAL) mode with the laser emission at 308 nm as well as reference wavelength of 353 nm generated by stimulated Raman shifting the 308 nm radiation in hydrogen. The receiving system consists of a 30-cm diameter cassegrain telescope tailored with a detection and data acquisition / processing system with 5 ns multi-channel scaler / averager. The methodology, data inversion algorithms for retrieving altitude profiles of ozone from a lidar return signal profiles and some results obtained on typical experimental days are briefly described. The potential applications of the lidar to studies in atmospheric chemistry and its interaction with aerosols and climate in the tropical region are presented.

HIGH-SENSITIVE INSTRUMENT FOR IN-SITU MEASURING ATMOSPHERIC NO2 AND SO2

Yutaka MATSUMI, Hiroyuki SHIGEMORI, Kenshi TAKAHASHI (Solar-Terrestrial Environment Laboratory, Nagoya University)

A new *in-situ* NO_2 instrument has been developed using a laser-induced fluorescence (LIF) technique. The wavelengths for the peak and bottom features of NO_2 around 440 nm are used for the fluorescence excitation of NO_2, while previous studies used features at 564 and 585 nm. The usage of 440 nm for the excitation has several advantages over the longer wavelength excitation at 564 and 585 nm: (1) The efficiency of the photo-excitation of NO_2 is higher, since the value of the peak photo-absorption cross-section multiplied by the peak-bottom cross section ratio at the features around 440 nm is several times larger than those around 564 and 585 nm. (2) The detection efficiency of the NO_2 fluorescence using a low-noise photomultiplier with a multi-alkali photocathode is higher than the longer wavelength excitations, since the fluorescence emits in the shorter wavelength range where the quantum efficiency of the photomultiplier is high. (3) The peak and bottom features in the absorption spectrum of NO_2 is more separated (100 cm^{-1}) than those around 564 and 585 nm (< 0.1 cm^{-1}). This makes it possible to use a broad-band OPO laser which are an all solid-state system. (4) Since the broad-band laser can interact with many rotational states of NO_2, the saturation level of the laser excitation is high and strong fluorescence signal can be obtained. The NO_2 instrument developed in this study has the following features: (1) single-point, *in-situ* measurement, (2) high sensitivity of the 30 pptv in 10 s and S/N = 2, which is high enough for measurements under remote air conditions, (3) high selectivity for NO_2 using the two-wavelength measurements and no possibility of interferences by other species even with photodissociation processes, (4) wide range signal linearity from a few 10 pptv to sub ppmv levels, (5) fast response of less than 1 s, and (6) simple and easy-to-operate laser system. These features suggest the NO_2 instruments developed is suitable for the ground and air-borne measurements in clean remote and urban areas. The inter-comparison between the LIF instrument and a photo-fragmentation chemi-luminescence (PF-CL) instrument was made in the laboratory. The good linear correlation between the LIF and PF-CL instruments was obtained. We also have developed a new *in-situ* SO_2 instrument using almost same apparatus with that of the LIF detection of NO_2. The light source is the second harmonics of the OPO laser. The sensitivity of the SO_2 system which we have developed is higher than systems using other measurement techniques.

AUTOMATIC TWILIGHT PHOTOMETER FOR MONITORING METEOR SHOWERS AND VERTICAL PROFILES OF AEROSOLES

D.B. JADHAV[1], B. PADMAKUMARI[1], D.R. JADHAV[1], H.K. TRIMBAKE[1], P.R. PATIL[2] ([1]Indian Institute of tropical Meteorology, Pune, India, [2]Y C college of Science, Karad, 415124, India)

A twilight photometer consisting of 15-CM diameter light collecting lens, Red filter centered at 670 NM with 50 NM HBW and Photomultiplier Tube as detector is developed. The photometer is controlled by microcontroler based data acquisition system for zenith sky observations during twilight period. The dark current of the photomultiplier is recorded by moving aperture at focal plane of the light-collecting lens. The variations in the zenith sky level is accommodated in the observation level of 2 to 10 volts output level of the amplifier by changing PMT output voltage by feedback loop system. The multiple stages in parallel combination amplifier is developed for PMT output current measurements, which reduces the amplifier noise considerably to measure the low light level studies. The observations of zenith sky spectra during clear sky condition are taken automatically during morning and evening twilight period for 90 to 100 degree solar zenith for deriving information regarding meteor shower dust at 70 to 120 km altitude and vertical profile of the aerosols up to 150 km altitude. The photometer is controlled by microcontroler based data acquisition system and data is stored in Personal Computer. The presence of observer is not required and the photometer is fully automatic. Preliminary observations for Leonoid meteor shower during 2002 are also presented in this paper.

A LOWER TROPOSPHERE RADAR: L-BAND ACTIVE PHASED-ARRAY TYPE WIND PROFILER WITH RASS

Hiroyuki HASHIGUCHI[1], Shoichiro FUKAO[1], Toshio WAKAYAMA[2], Shinichiro WATANABE[2] ([1]Radio Science Center for Space and Atmosphere, Kyoto University, Japan, [2]Mitsubishi Electric Corporation, Japan)

Transportable L-band (1357.5 MHz) Lower Troposphere Radar (LTR) was developed for lower troposphere observations. The Japan Meteorological Agency (JMA) installed their wind profiler network, called Wind Profiler Data Acquisition System (WINDAS), which consists of 25 LTRs, covering Japan. The unique design of the LTR includes a large active phased array antenna with 4 m x 4 m square shape. The antenna can be divided into four sub-panels, and this realizes transportability of the radar system. The array antenna is composed of 96 low-cost coaxial dipole elements, and 24 solid-state transmitter-receiver (TR) modules drive them. The LTR is the first active phased-array type wind profiler in the 1.3 GHz-band. An antenna beam can be steered toward five directions (zenith, east, west, north, and south) with arbitrary zenith angle in order to measure 3-dimensional wind vectors. Total transmitting peak power is 2 kW. In addition, we use 8-bit pulse compression, and hence average transmission power becomes 16 times as large as that of the conventional L-band boundary layer radar (BLR) we have developed. The technique of Spano´s optimized complementary codes realizes data acquisition from low altitude, as well as it suppresses range sidelobes. Atmospheric winds in the lower troposphere including the atmospheric boundary layer are obtained with high time and height resolutions in real time. We confirmed the accuracy of the LTR in wind field measurement from the simultaneous observation results with the MU (middle and upper atmosphere) radar. Observations of atmospheric temperature are also possible using the radio acoustic sounding system (RASS) technique with speaker horns.

THE EQUATORIAL ATMOSPHERE RADAR (EAR): SYSTEM DESCRIPTION AND INITIAL RESULTS

Hiroyuki HASHIGUCHI[1], Shoichiro FUKAO[1], Mamoru YAMAMOTO[1], Toshitaka TSUDA[1], Takuji NAKAMURA[1], Masayuki K. YAMAMOTO[1], Toru SATO[2], Masahiro HAGIO[3], Yoshiyuki YABUGAKI[3], Munir MUZIRWAN[4], Mahdi KARTASASMITA[4] ([1]Radio Science Center for Space and Atmosphere, Kyoto University, Japan, [2]Graduate School of Informatics, Kyoto University, Japan, [3]Mitsubishi Electric Corporation, Japan, [4]National Institute of Aeronautics and Space (LAPAN), Indonesia)

The western Pacific region is a center for intense atmospheric motions that are closely associated with global atmospheric changes. The world´s most active convective clouds are generated in this region, and directly induce the global circulation. We established the Equatorial Atmosphere Radar (EAR) at the equator near Bukittinggi, West Sumatra in the Republic of Indonesia (0.20S, 100.32E, 865 m above sea level), in June 2001. The EAR uses a quasi-circular antenna array with a diameter of approximately 110 m (corresponding to antenna beam width of 3.4 deg), which consists of 560 three-element Yagi antennas. It is an active phased-array system with each three-element Yagi antenna driven by a solid-state transmitter-receiver module (TR module). With this system configuration, the antenna beam can be steered electrically, on a pulse-to-pulse basis, by controlling phase shifters in the TR modules. The beam can be steered within 200 micro sec, i.e. up to 5,000 times per second. Its operating frequency is 47.0 MHz with a bandwidth of 4 MHz. The maximum peak and average radiation powers are 100 kW and 5 kW, respectively (the maximum duty ratio is 5%). A subpulse width as short as 0.5 micro sec, corresponding to the range resolution of 75 m, can be accommodated by the 4-MHz bandwidth of the system. The EAR is now being continuously operated and provides valuable data day by day. The high-resolution observations with the EAR that have never been realized before must play an important role in various studies of the equatorial atmosphere and ionosphere. It is expected that the EAR will be operated in collaboration with other existing networks of radars and other instruments including satellites, and proceed to study the hierarchical structure of atmospheric variations in the equatorial region using the data from these networks. This paper presents the system description of the EAR, including observational results of the equatorial atmosphere made for the first time with an altitude resolution of 150 m.

VALIDATION OF THE WINDOW EMISSIVITY ESTIMATES FROM MULTI-SPECTRAL THERMAL INFRARED DATA AND ITS POTENTIAL EFFECT TO EARTH RADIATION BUDGET

Kenta OGAWA[1], Thomas SCHMUGGE[2], Frederic JACOB[2], Andrew N. FRENCH[3] ([1]USDA/ARS Hydrology and Remote Sensing Lab. and Hitachi Ltd, [2]USDA/ARS Hydrology and Remote Sensing Lab, [3]Hydrological Science Branch, NASA Goddard Space Flight Center)

Land surface window (8-12 micrometer) emissivity is an important parameter for estimating the long-wave radiation budget. With the successful launch of the NASA EOS Terra satellite in 1999, data from the Advanced Spaceborne Thermal Emission and Reflection (ASTER) radiometer became available for observing land surface emissivity. ASTER has five channel in the 8 to 12 micrometer band with 90 meter resolution. These data can be used to estimate the temperature and surface emissivity variations when used with the Temperature Emissivity Separation (TES) algorithm. We used multiple regression to relate the window emissivity to the five ASTER emissivities. This regression was developed using 257 emissivity spectra from two spectral libraries; ASTER Spectral Library and MODIS Emissivity Library. The approach was validated using a field radiometer, CIMEL CE312, which has approximately the same five channels as ASTER and a window channel. The measurements were performed during field experiment of the Jornada Experimental Range and White Sands National Monuments, New Mexico, USA. The Jornada site is typical of a desert grassland where the main vegetation componets are grasses and shrubs and White Sands National Monument is large dunes of gypsum sand. The measured window emissivity are in qualitative agreement with the estimated values using the multiple regression of the five channel emissivities. The bias was 0.003 and the RMS error was 0.0095 for 71 measurements in the range of 0.87 to 0.95. We applied this approach to produce maps of window emissivity over a 400 x 1200 km area for a desert region of North Africa using over 200 scenes of ASTER acquired in 2000 to 2002, which is the subject of another paper being

presented at this symposium.

NEW INFORMATION TECHNOLOGIES IN GEOECOLOGICAL MONITORING

Sergey Zinovievich SAVIN, Nicolay Eduardovich KOSYKH (Computing Center of Far East Branch of the Russian Academy of Sciences)

Ecosystems are characterized by interweaving of nonlinear and accidental dynamic processes inseparably connected with the genetic program of the population and the influence of the environment. There exist various approaches, in this country and in the world, to the construction of information systems of similar complexity based on multi-layer spatial models of an object, e.g. so called geoinformational systems, where the problems of matching and manipulating graphic and attributive data in the framework of a unified integrated model are to some extent solved. However, in order to solve geoecological and medico-biological tasks, it is necessary to search for an adequate ideology, and the creation of adequate instrumental means of descriptive analyses is just beginning. The systems of computer-aided reconstructive tomography, neural networks, computer radiography and the system of rendering of three-dimensional models are widespread at present. They are used for conducting ˝virtual˝ surgeries and for the automation of diagnostics in clinical research. A specialized character of such processing systems doesn´t allow using them as an instrument for developing new applications. The ideology of informational modelling of animate nature objects based on game-theoretic approach to the tasks of image identification, axonometric principles of creating specialized data bases and logical-semantic ideas of an organism´s vital activity, was developed as early as in late 1980s in the laboratory of medical informatics of Computing Center of the FEBRAS. The topicality of such approach to biological information systems (BIS) is connected with the possibility of a wide use of modern computer engineering and informational environment for health care purposes, the use of Internet information environment for improving the effectiveness of prophylaxis, diagnostics and treatment of illnesses, especially in remote districts. In this connection, the problem of adaptation of wellknown visual modeling means, approaches to organizing visual data, means of identifying half-tone images used in other fields of earth science, geoecological monitoring technology, geology, manufacturing and management to medico-ecological tasks seems important. The scientific significance of the project is connected with the development of a universal approach to creating a unified BIS for prospective research of ecological physiology of humans and animals, geoecology, physiological mechanisms of human activity, development and stability of human population, development biology, and also in the theoretical field of neurocomputer development, neurophysiology and neurobionics.

REAL TIME PROCESSING OF COLLECTED PARTICLES: MEASUREMENT OF PARTICLES AND PARTICLE FLUXES BY THE CLOUDSCOPE AND THE HOTPLATE

John HALLETT[1], Roy RASMUSSEN ([1]Division of Atmospheric Sciences, [2]National Center for Atmospheric Research)

Immediate heating and melt/evaporation of cloud and precipitation particles on collection provides a convenient way of measuring particle mass through latent heat requirement. Instruments using this technique may maintain the substrate at constant temperature during collection and particle evaporation, the power required providing a measure of the evaporation rate. The incremental density is inferred for individual ice particles from the resulting incremental change of volume from video images obtained from a video system back-viewing the collected particle. An instrument (the cloudscope) has been developed for aircraft use whereby a window (size millimeter to centimeters) faces the airstream and is maintained at a temperature sufficient to evaporate incoming particles individually and video record the particles with resolution down to a few microns. Another instrument (the hotplate), developed jointly between DRI and NCAR, measures total mass flux at the ground (precipitation rate both as rain and/or snow over a plate 10 centimeter diameter). The principle of each instrument requires a reference surface free of collecting particles to compensate for the ambient conditions - temperature, air density and air speed. Such surface also provides a direct measure of air/wind speed and also turbulence levels and momentum flux. The instruments are designed and constructed to respond at less than 0.1 seconds at typical flight speed and some 25 seconds for surface precipitation. Data is collected and processed in situ and is readily adapted to provide derived products as precipitation rate, distribution and frequency. Data from several instruments at different locations may be combined to provide precipitation gradients in the vertical (as blowing snow) and horizontal.

CONTRIBUTION OF HOT-SPOT EFFECT TO LAND SURFACE ALBEDO

Alexander P. TRISHCHENKO[1], Yi LUO[1], Rasim LATIFOVIC[1], Zhanqing LI[2] ([1]Canada Centre for Remote Sensing, Natural Resources Canada, [2]University of Maryland)

Surface albedo is an important parameter that influences solar radiation budget, hydrological cycle and defines many important surface biophysical properties. Good knowledge of surface bi-directional reflectance distribution function (BRDF) is required in order to obtain surface albedo. We analyzed data from several sensors (MISR, MODIS, VGT, AVHRR and Landsat-7) to study the variability and dynamics of the BRDF shape in various spectral bands. According to the Landsat ETM high-resolution image, several small areas with homogenous vegetation land cover (cropland, natural grassland/savannas, forest etc) were identified. Combined datasets that include multi-angular and multi-platform observations for different times of the year were generated for these areas, thus providing an opportunity to study the seasonal dynamics of the BRDF properties. Three types of the BRDF models for medium-resolution sensors (MISR, MODIS, VGT and AVHRR) were tested. They are the modified-Rahman (MISR), Ross-Li (MODIS), and model developed at Canada Centre for Remote Sensing. We will present and discuss the results of comparison between these models and their ability to reproduce shape of BRDF function is the hot-spot area. Contribution of hot-spot effect to hemispherical albedo is evaluated numerically and compared with observational data available from CERES broadband radiometer. The

optimized approach for BRDF reconstruction is proposed and applied to generate consistent surface spectral albedo/BRDF data sets.

INITIAL FLIGHT OF THE GEOSTATIONARY EARTH RADIATION BUDGET INSTRUMENT: FROM LAUNCH TO OPERATIONS

Jennifer HANAFIN[1], J.E. RUSSELL[1], S. KELLOCK[1], E. SAWYER[2], B.C. STEWART[2], M.J. BATES[2], D.J. PARKER[2] ([1]Imperial College London, [2]Rutherford Appleton Laboratory)

Initial flight of the Geostationary Earth Radiation Budget instrument: from launch to operations Mission The Geostationary Earth Radiation Budget (GERB) instrument, launched in 2002 on the MeteoSat Second Generation satellite mission, provides a new perspective on the earth-atmosphere radiation system. This instrument is providing measurements of spectrally integrated radiation over a disk on the earth centred at 0°N, 10°W every 15 minutes. Such high temporal resolution allows us to study the evolution of the effects of clouds on the net radiation leaving the earth-atmosphere system. This is an area of major uncertainty in our current knowledge of the system and is potentially a very important climate feedback process. The instrument is also ideally positioned to study radiative properties of the site of origin and much of the subsequent pathway of atlantic hurricanes and Saharan dust storms. Instrument design Measurements are made over the total (0.3-30µm) and shortwave (0.3-4µm) wavelength ranges and the longwave channel is obtained by subtraction. As the satellite is spin-stabilised, GERB uses a despin mirror rotating in the opposite direction to the spacecraft to direct radiation into the optics. An array of 256 detectors records a N-S strip of the earth, building up full total and shortwave scans every 5 minutes, which is then averaged to produce a 15 minute level 1 product. Spatial resolution is 50km² at the sub-satellite point. On board calibration includes an internal blackbody for the longwave and an integrating sphere for the shortwave range. Post-launch results and initial data The commissioning period of the instrument was in late 2002 and early 2003. It was carried out by collaboration between the instrument team at Rutherford Appleton Laboratory, Oxford and the operations team at Imperial College, London. A number of tests were implemented during this time and data was acquired in different instrument modes, allowing different elements of the system and their operating status to be examined. The results of these show that in-flight operation of the instrument is as expected and is similar to operation during ground calibration even under the 18G environment imposed by the rotation of the satellite. The results of these analyses and further tests to determine data quality will be presented. Initial data product validation analysis is underway and preliminary results will be discussed.

ASTER: A NEW TOOL FOR ESTIMATING LAND SURFACE EMISSIVITY

Thomas SCHMUGGE[1], Kenta OGAWA[2], Frederic JACOB[1], Andrew N. FRENCH[1], Ann HSU[1], Jerry RITCHIE[1] ([1]USDA/ARS Hydrology & Remote Sensing Lab, [2]USDA/ARS Hydrology & Remote Sensing Lab and Hitachi Ltd. Tokyo, 101-8010, Japan, [3]Hydrological Sciences Branch, NASA/GSFC, Greenbelt, Maryland, USA.)

The multispectral thermal infrared data obtained from the Advanced Spaceborne Thermal Emission and Reflection (ASTER) radiometer on NASA´s Terra satellite have been shown to be of good quality and provide a unique new tool for studying the land surface. ASTER has 5 bands in the 8 to 12 micrometer waveband with 90 m spatial resolution, when the data are combined with the Temperature Emissivity Separation (TES) algorithm the surface emissivity over this wavelength region can be determined. This paper will present some quantitative emissivity results obtained over test sites in southern New Mexico, USA; the Jornada Experimental Range and the White Sands National Monument which are compared with ground measures. The Jornada site is typical of a desert grassland where the main vegetation components are grass and shrubs with a large fraction of exposed soil while the White Sands site is mainly dunes of gypsum sand which provides a good relatively homogenous emissivity target. More than a dozen ASTER scenes over these New Mexico test sites have been acquired since the launch of Terra in December 1999. There were simultaneous field campaigns in May of 2000, 2001 and 2002 and September/October 2001 and 2002. Also, MASTER (MODIS-ASTER airborne simulator) coverage was obtained for several of the dates. In spite of the 90 m resolution, the results appear to be in good quantitative agreement with laboratory measurements of the emissivity for the quartz rich soils of the Jornada with values $<$ 0.85 for the 8 - 9 micrometer channels. For the longest wavelength channels little spatial variation of the emissivity was observed with values of 0.96 +/- 0.005 over large areas. Emissivity values from the ASTER data for the gypsum at White Sands were in good agreement with values calculated from the lab spectra for gypsum and with each other. Gypsum has a strong emissivity minimum centered on the ASTER 8.63 micrometer band , and the satellite results for this band agree within 0.01 of the value calculated from the laboratory spectra.

AN END-TO-END MODELING STUDY TO GENERATESYNTHETIC DATA CUBES FOR IMAGINGSPECTRAL SENSING APPLICATIONS

Chih-Yue Jim KAO, William Scott SMITH, Jon M. REISNER (Applied Physics Division, Los Alamos National Lab)

An airborne IR hyperspectral imaging sensor based on the Fourier transform spectrometer technique has been used for studying atmospheric gaseous plumes under the auspice of US Department of Energy. Model generated synthetic data of spectral intensity associated with the plume and the surface background is useful in terms of performing trade studies as well as testing new algorithms. To cope with the highly turbulent and transient atmospheric boundary layer where plume emissions and evolution are embedded, we have used a high-resolution (at the scale of 1 m) time-dependent Navier-Stoke atmospheric hydrodynamic code, HIGRAD, to replace the Gaussian/multi-fractal approach in the original package of the Los Alamos End-to-End Modeling of Imaging Spectral Sensing Applications (EMISSA). The output from HIGRAD is then used for calculations of radiance reaching the sensor through the Fast Atmospheric Signature Code (FASCODE) with a spectral resolution of 1 cm-1 or less. The modeled plume structure in concentrations and associated plume images in radiance bear great resemblance to the commonly observed phenomenology. The 3-D data cubes of spectral intensity are used to test a plume contrast model for its capability in quantifying the column densities of chemical species. The synthetic data produced through our approach proves to be effective in evaluating our understanding of the thermal infrared imaging process.

COMBINING CROP GROWTH MODELS AND REMOTE SENSING DATA FOR CROP YIELD PREDICTON: FROM FIELD TO REGIONAL SCALES

Yanxia ZHAO (Research Center of Agrometeorology and Remote sensing Application,Chinese

Academy of Meteorological Sciences(CAMS),Chinese Meteorological Administration(CMA))

It has been widely recognized that global change on some extent are attributable to human activities; many human systems are sensitive to global change, and some are more vulnerable. Agriculture is one of the most vulnerable. Food security has been attracting more and more attentions. The studies on crop yield prediction are therefore very significant in providing information to policy makers and government and keeping sustainable development. There are many methods of crop yield estimation. Among them, the most promising method is combining crop growth models and remote sensing data to estimate crop yield. The different ways for integrating crop models with remote sensing data can be generally classified into two groups: the forcing strategy and the 're-initialization/re-parameterization strategy. The forcing strategy is to update at least one state variable in the crop model using remote sensing products as the values of some variables. The crop model runs at a constant time step (e.g., daily), but it is very difficult to acquire remote sensing imagery at such high-resolution temporal steps. The common practice is to fit an empirical curve to the estimate values from remote sensing observations and then carry out the interpolation according to the model time step. The 're-initialization/re-parameterization strategy minimizes the difference between the values from remote sensing and the predicted ones from crop models by adjusting model parameters or the initial conditions. One method is to use the derived variables from remote sensing data to recalibrate crop model by optimization procedures. Another method is to directly use the observed radiometric information directly re-parameterize or re-initialize a crop model, which needs to couple the radiative transfer models with crop models. This assimilation of remote sensing data leads to the retrieval of one initial condition, subsequently it allows to use the model more confidently over an area where no ground information is available. Some case studies have been conducted using the strategies such as combining SOYGRO, AFRCWHEAT2, SUCROS or WOFOST crop models and remote sensing data. The results show that the accuracy and scale of crop yield estimation are improved when remote sensing information is used in the crop models. I tried to couple DASSAT crop model and MODIS remote sensing data to predict China wheat yield and obtained a result which was much better than that without using remote sensing.

TM IMAGE CLASSIFICATION OF ZHALONG WETLAND (CHINA) USING NEURAL NETWORK

Min HAN[1], Lei CHENG[1], Qingyu ZHOU[2] ([1]Dalian University of Technology, [2]Songliao Water Resources Commission)

Remote sensing images usually distinguish land cover information by the brightness of pixels. Different brightness of pixels indicates the different information of spectrum. Therefore, an important application of remote sensing images is to understand the land cover state by classification techniques. Traditionally, the ways to classify land cover information are based on the Bayesian classifier. It is well known that the Bayesian classifier is theoretically optimal if the assumptions about the probability density functions (PDF's) are correct. A poor performance may be obtained if the true PDF's are different from those assumed by the model. This limits the application of the method. Maximum likelihood classification is one of examples based on the Bayesian classifier. Artificial neural network has already been applied in the field of classification of remote sensing images, especially back-propagation neural network classifier. Compared with traditional methods, neural networks do not need a probabilistic distribution pattern. They have strong adaptive learning ability. Owing to parallel processing, adaptive learning and nonlinear procedure, neural networks can classify TM Images more efficiently and successfully. This paper applies neural networks to classify land cover information from the TM images of Zhalong wetland. An adaptive back-propagation algorithm based on a robust error function is introduced to build a four-layer neural network. Zhalong wetland, one of important National Natural Reserves and Ramsar sites, is located in northeast of China , 70 km long and 40 km wide. The total area of the wetland is 2100 km2 and the water surface is about 800 km2. Considering the especial natural condition and the management demand, TM image analysis is expected to be useful technique in the water resources and ecosystem management of the wetland. In this paper, 7 categories of land cover information are classified, that is, water, marsh, farmland, woodland, grassland, residential area and salina. Comparing classification results of the four-layer neural network with three-layer neural network and the maximum likelihood classifier, conclusion can be summarized as follows: (1) the structure of the four-layer neural network and the adaptive back-propagation algorithm based on the robust error function is effective to classify TM image data; (2) the four-layer neural network adopted in this paper succeeded in building a complex model of TM image, and it avoided the great storage problem of remote sensing data, and (3) the adaptive back-propagation algorithm speeded up the descending of error. Above all, the four-layer neural network is superior to the three-layer neural network and the maximum likelihood classifier in the accuracy of the classification.

BALLOON-BORNE ALL SKY/ GROUND IMAGING OBSERVATION AND ITS APPLICATION TO THE VERIFICATION OF RADIATIVE-TRANSFER COMPUTATION

Daren LU, Wen xin ZHANG, Juan HUO (Institute of Atmospheric Physics, Chinese Academy of Sciences)

For validation of satellite remote sensing of surface reflectivity (albedo) and atmospheric aerosol characteristics, one of common procedures is to conduct ground truth observation for both surface and atmospheric observation. Since in optical wavelengths, multiple scattering and surface inhomogeneity as well as bi-directional reflectivity play important role, complete radiance measurements from both all sky and all direction of surface are ideal ground truth database. So far, separate observations of surface reflectance and sky radiance are used. Usually these measurements are not for all sky/ground. In this paper, we used a balloon-borne facility to simultaneously observe all-sky and all ground images. A pair of digital cameras with fish-eye lens is put on a specially designed tethered balloon with parallel opposite field-of views. With geometric and radiative calibration, we may have the all sky/ground directional radiance. Tethered balloon-borne facility makes the measurements at different height levels. Thus it is not just useful for "bulk" validation but for analyzing the difference and their causes. Also this kind of observation will be a useful database for strict verification of radiative transfer algorithm. The primary experimental results and the compassion with some RT algorithms will be introduced in this paper.*This work was supported by NSFC project No. 40027002 and Dept. of Science and Technology Project No 2001CCA02200

AESMIR: A NEW NASA AIRBORNE MICROWAVE IMAGER

Edward KIM (NASA Goddard Space Flight Center)

The NASA Airborne Earth Science Microwave Imaging Radiometer (AESMIR) is a versatile new airborne instrument. The AESMIR design is unique in that it will perform imaging at all standard passive microwave frequency bands (6--90 GHz) using a single mechanical package, providing an efficient solution for a wide variety of Earth science applications (snow, soil moisture/land parameters, precipitation, ocean winds, sea surface temperature, water vapor, sea ice, etc.). Using parallel filter banks, AESMIR provides simultaneous outputs matching the channel sets of AMSR-E, CMIS, Windsat, GPM, SSM/I, SSM/IS, and TMI. In addition, all bands except the 23-GHz sounding band incorporate fully-polarimetric (4-Stokes) receivers with parallel analog polarization combining as well as high-speed digital correlators, for a total of 54 output channels. The microwave radiometers themselves will incorporate state-of-the-art receivers, with particular attention given to instrument calibration for the best possible accuracy and sensitivity. The arbitrary 2-axis gimbal can perform conical and cross-track scanning, as well as fixed-beam staring. An L-band option is also feasible, again using the same scanner. Thus, simultaneous imaging from 1.4 to 90 GHz will be feasible. When paired with its millimeterwave sister instrument, CoSMIR, synchronized imaging up to 183 GHz is feasible. The single-package design of AESMIR makes it compatible with high-altitude aircraft platforms such as the ER-2 and the Proteus as well as lower-altitude aircraft such as the P-3, DC-8, C-130, and even ground-based deployments. Thus AESMIR can provide low-, mid-, and high-altitude microwave imaging while leaving maximum space for other instruments--optimizing opportunities for synergistic science and field campaign effectiveness.

NETWORK OF VECTOR ELECTRIC FIELDMILS FOR THUNDERSTORM WARNING AT ROCKET LAUNCHING STATIONS

Dattatraya B. JADHAV[1], R. VIJAYAKUMAR[1], D.R. JADHAV[1], G.V. RAMA[2] ([1]Physical Meteorology and Aerology Division, Indian Institute of Tropical Metorology, [2]SHAR Centre, Sriharikota, India)

Weather radar can not be used before and during launch operations, as field generated due to these radiations may trigger any accidental activity or may damage the important electronic systems. Also the electric fields due to charge clouds may introduce similar errors. Hence for taking precautionary measures for giving field warnings, a three-vector electric fieldmill system measuring Vertical, North-South and East-West component is developed. Four stations located ~10 km apart measuring the three vectors of electric field are utilized to locate the charge centers in 70 km diameter region. A single sensor is consists of two half-metallic cylindrical plates mounted on Fiberglass cylinder. The two metallic plate´s signal is collected through rotating condenser and amplified by the bridge amplifier. The field sensed by single sensor of two metallic plates is utilized to sense two vectors perpendicular to the direction of rotation of sensor plates using optointerrupters and phase sensitive detection system. These three vectors gives the direction of the charge centers in space due to charges in the cloud, which is indicator of thunderstorm development. Each station consists of two sensors mounted perpendicular to each other to measure the three vectors of electric fields, signal-conditioning system, Interfacing unit and PC based data acquisition and transmission system. The data is transmitted to the Central processing system via telephone lines. The data received is processed for locating charge centers in space and time for giving three different warning levels. The algorithm is developed to calculate the orientation of the charge canters in space and time. The central processing system displays information regarding the location of the charge centers on the map of rocket launching station in the diameter of 70 km. All the systems consisting of sensor, signal conditioning system, Microcontroler based data acquisition and instrument health monitoring system, software required for data acquisition, data display and data processing is developed indigenously. Similar systems can be utilised as thunderstorm warning system at airports, ships, power establishments ... etc. Preliminary results are presented in this paper.

CLIMATOLOGICAL CONDITION OVER THE WESTERN NORTH PACIFIC BASIN

Yoshio KURIHARA (Frontier Research System for Global Change)

Tropical cyclones that are observed in the Western North Pacific basin are called typhoons. This basin is defined as an area west of the date line of the North Pacific, including the South China Sea. A typhoon usually spends its entire life, from formation to decay, in this area. In the present talk, climatological condition of the atmosphere and ocean in this basin is described. Needless to say, the condition is strongly influenced by geographical features, including the global distribution of landmass. Relatively high sea surface temperature and strong conditional instability of the atmosphere in the tropics in this basin are conducive to typhoon genesis. The Pacific High pressure, monsoon trough and Tropical Upper Tropospheric Trough characterize the mass and wind field. Variability of these features at different time scales is an issue of importance. Formation of individual tropical disturbance can take place through combination of various factors. Increase above climatological mean in the low level vorticity and moisture in a broad area is certainly among them. It can be brought by transient features such as the Madden Julian Oscillation, mixed Rossby gravity waves, westerly wind burst along the equator, surge of southerly wind across the equator. The South China Sea is a loosely closed region, where formation and reintensification of typhoons are observed. The track of a typhoon is dependent on the large-scale wind surrounding the vortex as well as the flow associated with storm's structure. The so-called environmental wind at mid to high latitudes is strongly influenced by the behavior of synoptic scale systems in these latitudes. A typhoon may move westward and onto land to undergo structure change. If a typhoon moves northward, it may be transformed into an extratropical storm. The climatological condition in the northern part of the Western North Pacific basin is favorable for such transition. Specifically, it is featured by the existence of the jet stream at

upper levels, implying strong baroclinicity, large gradient of sea surface temperature, dry air over the land west of the basin, and so forth.

INTERANNUAL VARIABILITY OF TROPICAL CYCLONE FREQUENCY OVER THE WESTERN NORTH PACIFIC DURING THE LATTER HALF OF THE 20TH CENTURY

Michiaki YUMOTO, Tomonori MATSUURA (National Research Institute for Earth Science and Disaster Prevention)

Interannual variability of tropical cyclone (TC) frequency over the western North Pacific (WNP) during the latter half of the 20th century was investigated. Based on the time series of the TC frequency removed the interdecadal trend, nine years (1952, 1955, 1958, 1967, 1971, 1974, 1978, 1981, and 1994) are regarded as ″prolific years″ having on abundance of TCs. Six years (1963, 1969, 1973, 1987, 1995, and 1998) are recognized as ″infertile years″ in which the TC activity is low. Medians of TC frequencies in the prolific years and the infertile years were 32 and 21, respectively. The internal variability of TC frequency was related to the monthly frequencies in the boreal summer. Comparisons of atmospheric and oceanic summer conditions between the prolific years and the infertile years showed characteristics of the interannual variability of TC frequency. The atmospheric environments in prolific years were (1) westerly winds in the low-level troposphere, (2) low sea-level pressure, (3) divergent environments in the upper-level troposphere, and (4) high precipitation rate over the WNP, in comparison with the infertile years. Difference of the sea surface temperatures (SSTs) over the WNP showed the east-west contrast pattern. That is, the SSTs in the prolific years were warmer in the eastern part of the WNP and cooler in the western part than that in the infertile years. Finally, we will discuss the contributions of El Niño-Southern Oscillation and/or the Indian Ocean Dipole mode event, as the background of large-scale environmental changes, to the interannual variations of TC frequency.

MC02/07A/B20-003   1025

SEASONAL AND INTER-ANNUAL VARIATIONS OF TROPICAL CYCLONE APPROACHING INDOCHINA

Hideaki SHOJI, Jun MATSUMOTO (Department of Earth and Planetary Science, University of Tokyo)

The seasonal and inter-annual variations of the number of tropical cyclone approaching Indochina (TCIC) have been investigated for the period 1951-2000 by utilizing Typhoon track data analyzed by the Japan Meteorological Agency. In order to understand the mechanism of large inter-annual variabilities of the number and tracks of tropical cyclones (TCs), large-scale flow patterns in abundant tropical cyclones approaching Indochina (ATCIC) and in no tropical cyclones approaching Indochina (NTCIC) months have been compared by utilizing NCEP re-analysis wind data. Also analyzed is the state of the sea surface temperature (SST) fields.(BR)The results obtained in the present study are summarized as follows:(BR)1) The number of annual total TCIC shows no long-term trend. On the other hand, the number of TCIC in June and July, and that in October and November shows slight increasing trend.(BR)2) Clear differences of the birth places and major courses of tropical TCs are recognized between ATCIC and NTCIC months. Generally speaking, more TCs are generated in the SCS in ATCIC months, and the courses of TCs direct more northward in NTCIC months.(BR)3) When abundant TCs approach Indochina in June to September season, the anomalous easterly wind is observed at 500hPa over the South China Sea (SCS), which will favor the more westward tracks of TCs.(BR)4) In October and November at 850 hPa, the westerly monsoon flow from the Indian Ocean across the Malay Peninsula and the northeasterly monsoon flow over South China and the northern SCS are both stronger in ATCIC months. The effect of Asian monsoon activity on the TC genesis and courses in the western North Pacific may be more important in the post -monsoon season in October and November. At 500 hPa, northerly and easterly anomaly is apparent over the East China Sea and the SCS, respectively.(BR)5) In ATCIC months SST fields show El Nino pattern in August and September, while, they present La Nina pattern in October and November.

INTERANNUAL VARIABILITY OF TROPICAL CYCLONE FREQUENCIES FROM AN ENSEMBLE CLIMATE SIMULATION WITH THE NCAR CCM3

Junichi TSUTSUI, Hideyuki KITABATA (Central Research Institute of Electric Power Industry)

The western North Pacific and the North Atlantic are both majortropical cyclone (TC) basins, for which reliable TC records areavailable over a period of more than 50 years. Such long-term TCrecords show large variability with interannual and interdecadal timescales associated with naturally occurring climate changes, and thecharacteristics of the variability is different between the twobasins. El Nino and Southern Oscillation (ENSO) is one of thecontributory factors to affect the variability. In the North Atlantic,an anomalous increase in upper tropospheric westerlies during ENSOwarm events inhibits TC activity by increased tropospheric verticalwind shear, and less anticyclonic upper level winds. In the westernNorth Pacific, although the relationship between TC activity and ENSOis not as evident as in the North Atlantic in terms of the annualnumber of TC formations, ENSO events can modulate the location offormation area or seasonal activity. Considering this characteristic behavior of TCs in the two basins, we areinvestigating impacts of sea surface temperature (SST) variationsassociated with ENSO on TC activity by numerical experiments. Thepresent study adopted the National Center for Atmospheric Research(NCAR) Community Climate Model version 3 (CCM3) including amodification in the moist convection schemes. This modification is animplementation of an inhibition mechanism for the deep convectionscheme in the model, and allows the model to produce TC-likedisturbances with a realistic frequency. Since the model shows alarge interannual variability even with climatological SST data as aboundary condition, we´ve been conducting an ensemble climatesimulation to reduce such model-inherent variations. Currently, we have completed seven climate simulations using observedSST from 1979 through 1989. Time integrations will be extended to theend of the 1990s. In the 1980s, two ENSO warm eventsoccurred. Observed TC records show some responses to the events suchas decreased frequencies during the periods. In the western NorthPacific, it is remarkable that the observed response was delayed morethan several months. Although the simulated interannual variationsindicate some features of observed tendencies, the reproducibility inthe western North Pacific is not as good as in the North Atlantic. Inparticular, the model shows scattering results among the ensemblemembers regarding the observed delayed response. This result impliesthat SST variations associated with ENSO affect TC activity ratherdirectly in the North Atlantic, and that more climatological factorsare indirectly involved in the TC activity in the western NorthPacific.

A MECHANISM OF INTERDECADAL VARIABILITY OF TROPICAL CYCLONE ACTIVITY OVER THE WESTERN NORTH PACIFIC

Tomonori MATSUURA, Michiaki YUMOTO, Satoshi IIZUKA (National Research Institute for Earth

Science and Disaster Prevention)

Tropical cyclone (TC) activity in the western North Pacific (WNP) has changed interdecadally with an approximately 20-year period between 1951 and 1999 (Yumoto and Matsuura 2001). The cause and mechanism of interdecadal variability of TC frequency in the WNP is investigated using NCEP/NCAR reanalysis and the result obtained from a high-resolution coupled general circulation model (CGCM). The interdecadal variability of TC activity in the WNP correlates with long-term variations in sea surface temperatures (SSTs) in the tropical central Pacific and with those of westerly wind anomalies associated with the monsoon trough that appears over the tropical WNP during the typhoon season of July to October. The westerly wind anomalies at near 10°N show positive feedback with the SST anomalies in the central Pacific. Therefore, the interdecadal variability of TC frequency is related to long-term variations in atmosphere-ocean coupling phenomena in the tropical North Pacific. A 50-year long-run simulation using the high-resolution CGCM showed the robustness of interdecadal variability of TC frequency.

MC02/07A/B20-006   1145

DECADAL VARIABILITY OF TROPICAL CYCLONE ACTIVITY OVER THE WESTERN NORTH PACIFIC

Hsin Hsing CHIA[1], Pao-Shin CHU[2], Chet ROPELEWSKI[3] ([1]Central Weather Bureau, Taiwan, [2]University of Hawaii, U.S.A., [3]Columbia University, U.S.A.)

Time series of tropical cyclone (TC) counts over the Western North Pacific from1965 to 2001are analyzed by a statistical change-point analysis. This method isidentical to that used recently to identify decadal variations of tropical cyclone activity over the central North Pacific (Chu, 2002). For the western North Pacific, results revealtwo epochs of activity. The epoch during 1989-1997 is marked by high activity in contrast to the low activity during 1968-1988. Large-scale environmental conditions conducive to cyclone activity during the peaktyphoon season (July through October) for the active (1989-1997) and inactive (1968-1988) epochs are investigated. The parameters considered include sea surface temperatures, sea level pressures, relative vorticity at the lower troposphere, and vertical wind shears between the lower (850 hPa) and upper (200 hPa) troposphere. The source of the data comes from the NCEP/NCAR reanalysis product and the horizontal resolution of the reanalysis dataset is 2.5 deg latitude/longitude. Relative to the inactive epoch, a warmer ocean surface over the region where TCs are generally formed in the western North Pacific is found in the active epoch, althoughthis warming is rather small ($<.2$ deg C). The region bordered between 10N-20N and 130E-155E (Chia and Ropelewski, 2002) is referred to as the major genesis area (MGA). Lower sea level pressures are also found over the MGA in the active epochcompared to the inactive epoch. More interestingly, large anomalies of low-levelcyclonic vorticity are observed over the MGA during the active epoch in contrast tothe inactive epoch. Independently, streamline analysis reveals a huge anomalouslycyclonic circulation gyre, similar to the monsoon gyre, with strong equatorial westerly anomalies over the western North Pacific when the inactive period is subtracted from the active epoch. Weaker vertical wind shears over the MGA arefound during the active epoch as opposed to the inactive epoch. Although some ofthe aforementioned changes are small (e.g., sea level pressures), variations in eachindividual environmental field work in the proper sense and collectively favor more cyclone incidences as observed during the recent epoch. Research is underway todetermine whether the changes in environmental conditions during the active and inactive epochs are statistically significant and to explore variations in other key parameters (e.g., upper-level divergence). IMPACTS OF SST WARMING AND CO2 INCREASE ON TROPICAL CYCLONE FREQUENCY

Jun YOSHIMURA[1], Masato SUGI[2] ([1]Global Warming Research Program, Frontier Research System for Global Change, [2]Japan Meteorological Agency)

For realistic numerical simulation of tropical cyclones (TCs), it is generally thought that high-resolution models are required. Simulating greenhouse gas-induced warming with high-resolution atmospheric general circulation models (AGCMs), sea surface temperatures (SSTs) are usually prescribed (as ´time-slice experiments´). But it is difficult to predict global-mean SST warming exactly in response to given CO2 increase (such as doubling), based on current scientific understanding. Moreover, if global climate is in a transient state after rapid CO2 increase (due to human activity, for example), global-mean SST should be significantly lower than that of equilibrium value. We have studied about decrease in simulated TC frequency due to greenhouse warming, using high-resolution AGCMs (e.g. Sugi et al. 2002). In the present study, we investigate impacts of SST warming and CO2 increase separately, using a T106 atmospheric model (JMA-GSM8911) with prescribed SST. It is shown that, in response to CO2 increase without changing SST, TC frequency reduces globally. This change may be caused by decrease in convective precipitation in the tropics, and the change in convective heating is balanced with weakening of long-wave radiative cooling in the lower troposphere. On the other hand, SST warming without changing CO2 does not have large impacts on global TC frequency.

USE OF QUIKSCAT DATA IN STUDYING THE EVOLUTION OF TROPICAL CYCLONE STRUCTURE

Johnny C.L. CHAN, Cleo YIP (Laboratory for Atmospheric Research, Dept. of Physics & Mat. Sci., City University of Hong Kong)

Since the launch of the QuikSat in 1999, valuable ocean-surface wind data have been available for the study of tropical cyclone structure. In this paper, we will present results from detailed analyses of these data around tropical cyclones over the western North Pacific (WNP) for the period 1999-2002. Because of possible contamination near the center, the focus is on the outer-wind structure. Temporal evolutions of the size (radius of 15 m/s winds) and outer-wind strengths will be presented. The size variations are found to be consistent with those found in previous studies. An interesting finding is that the average size during this period over the WNP generally tends to be smaller than those from other years. This result is explained in terms of the environmental flow patterns (typical of La NiOa

conditions) in which the tropical cyclones were embedded. Such an observation further emphasizes the control of the environment on the size evolution of a tropical cyclone. The evolution of the outer-wind strength as well as the entire outer-wind structure for different tropical cyclones can be classified into several types, each of which can be explained in terms of the changes in the environmental flow patterns. In some cases, internal dynamics apparently also has an important contribution.

MC02/07P/B20-002   1420

ON THE FORMATION OF CONCENTRIC VORTICITY STRUCTURE IN TYPHOONS

Hung-Chi KUO[1], Lee-Yaw LIN[1], Chih-Pei CHANG[2], R. Terry WILLIAMS[2] ([1]Department of Atmospheric Sciences, National Taiwan University, [2]Department of Meteorology, Naval Postgraduate School)

During 25-26 September 2001, Typhoon Lekima moved northwestward near the southern tip of Taiwan. At 0900 local time 25 September, the typhoon possesses a small and strong central core vortex (of 10^{-3} to 10^{-2} s^{-1} vorticity field) with a huge area of convection southwest of the vortex. Subsequent revolution as indicated by radar reflectivity suggests that the huge area of convection stretched and wrapped around the central vortex to form a concentric eyewall structure in less than 10 hours. In this work we use a nondivergent barotropic model to test a hypothesis that the formation of the concentric eyewall in Typhoon Lekima may be in part due to the vorticity advective dynamics. In this hypothesis we postulate that the concentric eyewall is a result of the shearing out of the huge area of convection into a band surrounding the central vortex. We test the hypothesis by considering the interaction between a small and strong inner vortex (the tropical cyclone core) and a larger and weaker outer vortex (the vorticity induced by the moist convection outside the central vortex of a tropical cyclone). The formation of the concentric eyewall is studied in terms of the separation distance, the vorticity strength ratio, and the radius size ratio of the two vortices. In general, the formation of the concentric vorticity structure requires a very strong core vortex (at least 4 times stronger than the neighboring vorticity), a larger area of the weaker vorticity field (2 times larger in size), and a separation distance of 2 to 3 times of the inner vortex radius. The evolution in Typhoon Lekima appeared to meet these conditions. The negative vorticity anomaly between the two vortices serves as a shield to impose a barrier to the inward mixing of the outer vorticity field. If the separation distance is too close, the resultant evolution most likely leads to either a merger or a tripole vortex formation. The central core vortex has to be strong to maintain itself against any deformation field from the environment due to the outer vortex. In addition, the stronger vortex induces a differential rotation across the weaker vortex to strain out the latter into a vorticity band surrounding the former. The change of sign of vorticity gradient across the band satisfies the Rayleigh necessary condition for instability. However, the band is stabilized by the Fjortoft sufficient condition for stability because the strong inner vortex can cause the wind at the inner edge to be stronger than the outer edge, allowing the vorticity band and therefore the concentric structure to be sustained.

MC02/07P/B20-003   1440

DETECTABILITY OF TYPHOON EYES OVER OCEANS IN TRMM PR AND IR OBSERVATIONS

Yasu-Masa KODAMA, Takuya YAMADA (Department of Earth and Environmental Sci. Hirosaki University)

Satellite cloud images have been utilized for detecting typhoon centers and for evaluating typhoon intensity (e.g., Dvorak method). However, internal structure of typhoons, especially eyes, sometimes cannot be observed by cloud images, when typhoons are covered with upper cloud shields. TRMM (Tropical Rainfall Measuring Mission) launched in late 1997 realized space-bone precipitation-radar (PR) observations. PR of TRMM can observe the internal structure of typhoons under upper cloud canopy. Since TRMM also mounted IR imager in the atmospheric window, we can compare the internal structure of typhoons observed by PR and the configuration of typhoons shown in IR cloud images. In this study, we examined detectablity of typhoon eyes in PR observations (rainfall intensity at 3km ASL) and IR observations (TBB in 12μm channel) of TRMM and studied their statistical relation to the typhoon intensity and life-stage, for 71 cases between 1998 and 2000, when the central portion of typhoons fall into the PR observation swath (~ 220km). In 55% of the whole 71 cases, eyes were detected not in IR but only in PR observations. Eyes were detectable in both PR and IR for ~ 32% of the whole cases, while not detectable in nether PR nor IR for 13 % of the whole. There were no cases in which eyes were detected only in IR. Maximum wind speed of typhoons averaged for the cases when both IR and PR detected the eyes was ~ 20 knot larger than that for the cases when only PR detected. In the developing stage of typhoons, eyes were obscure in both IR and PR observations for 24% of the cases in this stage, and detectable in only PR for 62% of the cases. Eyes were detectable in IR only for 13% of the cases. In the mature stage, most of typhoons (97%) have eyes detected in PR observations, while only minor part of typhoons (35%) has eyes detected in both PR and IR. In the decaying stage, the detectability of typhoon eyes in IR is largest (detectable for 45% of the cases in this stage), while eyes were obscure in both IR and PR for 20% of the cases. We need remark that typhoon eyes cannot be observed in IR in many cases due to upper cloud shields extended over typhoon eyes. Typhoon eyes are obscure even in the PR observations in a small part (1/3~1/4) of the cases in developing and decaying stages. Detectability of typhoon eyes in IR observations increases larger in the later stage of typhoon life cycle.

MC02/07P/B20-004   1500

TEMPORAL AND SPATIAL VARIATIONS OF PRECIPITATION OF LANDFALLING TYPHOONS IN TAIWAN

JONG-DAO Ben JOU (DEPARTMENT OF ATMOSPHERIC SCIENCES, NATIONAL TAIWAN UNIVERSITY)

This study examines the temporal and spatial variations of precipitation structure within 300 km radius of the typhoon center by using reflectivity data taken by Doppler radars in Taiwan during landfall. Four typhoons with different tracks and intensity were analyzed. The gird-averaged reflectivity data in four quadrants were used to show the evolution of the eyewall, the rainbands in the annular area outside the eyewall, and area extended to 300 km from the center of the eye. More than 50 hours radar data with time interval of 6 minutes were analyzed in this study. The contraction of the eyewall, the outward propagating spiral rainbands, and the organized convective precipitation areas were identified. The asymmetric characteristic of the precipitation structure of typhoons was documented and the effect of Taiwan topography on the nature of these precipitation features was also discussed.

MC02/07P/B20-005   1540

DIURNAL VARIATION PATTERNS OF THE LOW TBB AREA OF TYPHOONS

Fumi UENOBE, Masaki ISHIWATARI, Atusi NUMAGUTI (Graduate School of Environmental Earth Science Hokkaido University)

Diurnal variation patterns of cloud area of 37 typhoons in 1999 and 2000 are observed. The percentage ratio of cloud area with Tbb < 203 K to the circular area whose radius is 10 degree from each typhoon center (hereafter referred to as low Tbb percentage coverage) is analyzed. All previous studies (eg. Muramatsu 1983) show that "one maximum peak and one minimum peak pattern (O-pattern)" dominates in higher Tbb area. In lower Tbb area, various patterns appear: O-pattern, double-peaked pattern (D-pattern), multiple pattern (M-pattern). As a cause of D-pattern, Muramatsu (1983) suggests ground heating in daytime. However, there are three problems in previous studies. Firstly, since the number of storms analyzed by previous studies is not large, whether the other kind of patterns exist or not is unclear. Moreover, the incidence of each pattern cannot be determined. Secondly, since the method of composite analysis is commonly used, the question which of the environment and the characteristic of each storm determines the diurnal pattern is not considered. The third problem is the effect of ground heating. Muramatsu (1983) finds that, for two cases, D-pattern appears when typhoons pass over an island. The analysis of much more cases is needed. In this study, diurnal pattern of cloud area of tropical storms is reconsidered. Tbb horizontal distribution is calculated from Visible and IR Spin Scan Radiometer data (VISSR) of the GMS-5. In order to determine the typhoon center, best track data in Weather chart published by Japan Meteorological Agency. NGDC ETOPO5 global gridded elevation data is also used in order to define land area in this study. Observation of time series of low Tbb percentage coverage shows that there exist 4 kinds of diurnal pattern. They are O-pattern, D-pattern, M-pattern, and one maximum peak and flat pattern. The last one is not shown in any previous studies, therefore, is a new kind of diurnal pattern. Variety of diurnal patterns is always recognized in each time series if typhoons are not in decaying phase. Even in one time series of particular typhoon, more than one pattern appear. O-pattern has the highest incidence. In order to reconsider the effect of ground heating, time series of low Tbb percentage coverage of typhoons which exist on the ocean and those which stay in land area for at least one day. In time series of low Tbb percentage coverage of both types of typhoons, there appear D-pattern and O-pattern. Therefore, contrary to the discussion of Muramatu (1983), it is suggested that the effect of ground heating is not necessary for occurrence of D-pattern.

TROPICAL CYCLONES WITH AN ELLIPTICAL EYE OBSERVED AROUND THE SOUTHWESTERN ISLANDS IN JAPAN

Toshihisa ITANO, Gen'ichi NAITO (Department of Earth and Ocean Sciences, National Defense Academy)

Tropical cyclones with an elliptical eye are occasionally observed around the Southwestern Islands in Japan.Such an elliptical eye was first reported in Typhoon Cora(T6618) during its passage around the Miyakojima Island.This typhoon is known as one of the hardest tropical cyclones which have ever hit Japan, and caused severe damages on that island.At this time, the maximum instantaneous wind of 85.3m/s, which is the historical record of a surface wind officially observed in Japan, was measured at the Miyakojima observatory under the tip of the longer axis of the elliptical eyewall.This implies the investigations of elliptical eyes of tropical cyclones are great importance from the view point of both meteorological interest and disaster prevention. One of the peculiar phenomenon analyzed in the elliptical eye of Typhoon Cora is that it followed the azimuthal wave number two structures of pressure, wind and other meteorological fields, which were quite similar to those observed in tornados taking a multiple vortex structure.This seems to indicate the phenomenon appeared with the elliptical eye is a multiple vortex phenomenon occurred in a typhoon-scale vortex.However, scarcity of the following studies prevents the further statement on this phenomenon. In the present study, we try to investigate several tropical cyclones with an elliptical eye which passed through the Southwestern Islands in 1990s.Results indicate the azimuthal wave number two structure as was observed in Typhoon Cora in all cases.This may confirms the reliability and reproducibility of the phenomenon, and also support the idea that the elliptical eyes are manifestation of the multiple structure observed in tropical cyclones.

COMPARISON OF THE SPATIAL DISTRIBUTION OF RAINFALL IN TROPICAL CYCLONES OF THE WEST PACIFIC AND OF OTHER OCEANIC BASINS

Manuel LONFAT[1], John A. KNAFF[2], Frank D. MARKS[3], Shuyi S. CHEN[1] ([1]RSMAS/MPO, University of Miami, [2]CIRA/Colorado State University, [3]NOAA/AOML/Hurricane Research Division)

The goal of this study is to characterize the spatial structure of rainfall in Tropical Cyclones (TC). We focus in particular on typhoons and on how their rainfall distribution differs from those of TCs in other areas. Surface estimates of rainfall are obtained from the Tropical Rainfall Measuring Mission (TRMM) passive microwave (TMI) instrument. Our database extends over the 3-year period from 1 January 1999 to 31 December 2001, and includes more than 2000 instantaneous observations of the TC rainfall. TRMM global coverage allows us to compare the distributions in various geographical areas, and the passive instrument has good enough resolution to derive significant information on the asymmetric structure of the rain. In this study, the rainfall asymmetry is constructed using a first order Fourier analysis on the rainfall estimates in four quadrants around the center. We compute the asymmetry in 50-km wide annuli, outward to 300 km. The analysis is conducted both in a reference system aligned with the storm motion direction and in a system based on the environmental wind shear vector. We define the vertical shear as the wind difference between the 200 and 850 mb levels. The shear information is obtained from the Statistical Hurricane Intensity Prediction Scheme (SHIPS). The asymmetry is located ahead of the storm center in motion-relative coordinates. The global analysis shows larger asymmetries in the shear-relative coordinate system. The asymmetry develops down-shear left in the North Hemisphere basins. The North West Pacific distribution, which includes all observations north-west of the dateline, shows a similar asymmetry location as the global average. The asymmetry is located down shear-left, but shifts cyclonically with radial distance. By 275 km, the asymmetry is along the shear direction. West Pacific storms however are the most symmetric storms, globally. Differences will be shown to relate to the intensity distribution of TCS in the West Pacific as well as to the general environmental wind conditions that prevail. Our study provides insights on the physical mechanisms that may alter the TC rainfall structure. By addressing differences among various basin TC distributions, the relative importance of processes such as associated to the vertical shear can be addressed.

EFFECTS OF ROLL VORTICES ON THE STRUCTURE OF THE MARINE BOUNDARY LAYER IN TROPICAL CYCLONES

Isaac GINIS[1] ([1]University of Rhode Island, USA)

Recent observations in tropical cyclones using high-resolution synthetic aperture radars clearly demonstrate secondary circulations in the atmospheric boundary layer (roll vortices)

M

in the region between the main rainbands. These roll vortices with the horizontal scale of 2-4 kilometers are not resolved by present tropical cyclone models, either research or operational. Nevertheless, they may contribute significantly to the vertical exchange of momentum, heat, and moisture in the boundary layer. We investigate here the mechanisms of their formation and effects on the structure and dynamics of the marine boundary layer in high wind conditions typical for tropical cyclones. A non-hydrostatic model of the marine boundary layer with the horizontal resolution of 50 m is presented that explicitly calculates the two-way interaction of convective motions and background flow. The model simulations indicate the development of roll vortices in the boundary layer on a time scale of a few hours and a spatial scale of ~2-3 km that are superimposed on the mean wind field. They are generated mainly by dynamic instability in the boundary layer induced by the strong wind shear and air-sea heat and moisture fluxes. The roll layer is coincided with the depth of the boundary layer. The associated convective fluxes affect greatly the vertical profiles in the boundary layer and air-sea fluxes.

THE GENERATION MECHANISM OF THE MESOSCALE PRESSURE DIP WITHIN THE TROPICAL CYCLONE

Hironori FUDEYASU[1], Taiich HAYASHI[2] ([1]Department of National Research Institute for Earth Science and Disaster Prevention, [2]kyoto Univercity, Japan)

One of the interesting phenomena within the tropical cyclones (hereafter denoted by TC), which are approaching the Japan Islands, is the low-pressure area occurring away from the TC center called as Pressure dip (hereafter denoted by PD). This PD has been recognized as a meso-β-scale disturbance with the horizontal scale of more than 100 km and the duration of more than 10 hours. The barographs during the passage of the TC sometimes show the sudden pressure drop in several stations during the passage of the PD. In this present study, the numerical simulation using the PSU/NCAR MM5 was performed to reveal the details of the spatial structure of the PD. The mesoscale trough (hereafter denoted by MT) was detected in the northwest quadrant of the TC, similar to the observed PD. Above the MT, the local strong downward wind was recognized in the whole troposphere. The dry air-intrusion was generated by this strong downward wind, and the warm-air anomaly was formed corresponding to the dry-air intrusion. The generation mechanism of the warm-air anomaly region above the MT was investigated by the backward trajectory analysis. The warm air came from the upper-troposphere of the northwest of the TC. The dry air was advected to the west of the TC by the upper-level westerly wind at the slope of the isentropic surface. When the TC moved northward, the dry air was brought to lower-troposphere by this strong downward wind. The descending dry air formed the warm-air anomaly through the adiabatic and diabatic warming process. The warm-air anomaly causes the pressure drop. Using the theoretical equation assuming the hydrostatic balance, the amount of the pressure drop was estimated using the temperature and depth of anomaly layer. The calculated amount of the pressure drop (-5 hPa) by theoretical equation was roughly reasonable with amounts of observed PD. The present study on the PD suggested the structure change of the TC in the mid-latitude baroclinic zone around the Japan Island.

THE EFFECT OF ENTRAINMENT IN A CUMULUS PARAMETERIZATION ON THE SIZE OF A SIMULATED TROPICAL CYCLONE

Akihiko MURATA, Mitsuru UENO (Typhoon Reserch Department, Meteorological Research Institute)

The effect of cumulus parameterization on the size of a tropical cyclone is investigated using the Meteorological Research Institute / Numerical Prediction Division unified Nonhydrostatic Model (MRI/NPD-NHM) with 20 km horizontal resolution. The model includes the Arakawa-Schubert cumulus scheme with a prognostic closure assumption. Sensitivity experiments are conducted with varying the degree of entrainment in the scheme. First of all, the scheme is modified so that fractional entrainment rate can vary with height instead of being set constant, which is based on recent observational and numerical studies. The magnitude of the cloud-base entrainment rate, which is the closure of the modified scheme, is changed ranging from two to ten times of that of the original scheme. The size of the simulated tropical cyclone, defined as the radius of 15m/s azimuth-averaged surface wind, decreases with increases in the cloud-base entrainment rate. The size difference between the cases manifests itself in the form of the difference in the radial profile of axisymmetric tangential velocity on the surface. The tangential velocity profile seems to be linked to the radial profile of precipitation, which also depends on the entrainment rate; the rainfall amount over the radii outside the 200 km radius, measured from the storm center, drops with increasing the entrainment rate. The less rainfall in the larger entrainment rate cases are accounted for by relatively little mass flux in the scheme, suggesting that vertical static instability over the outer radii is not eliminated so much as those of the smaller entrainment rate cases. In fact, vertical static stability over the outer radii decreases as the entrainment rate increases. In order to clarify the mechanism that regulates the size of the simulated tropical cyclone, an equation for axisymmetric tangential wind tendency is used. The temporal and vertically mass-weighted average of the tendency over the outer radii decreases with increases in the cloud-base entrainment rate, which is consistent with the result mentioned above that the storm size shrinks with increasing the entrainment rate. Over the outer radii, the difference in axisymmetric inflow and updrafts are mainly responsible for that in the axisymmetric tangential wind tendency. Since the inflow in lower and middle troposphere, where the absolute vorticity is positive, is stronger in the smaller entrainment cases, the flux of the vorticity due to the inflow is larger, which brings larger tangential wind tendency. As for the axisymmetric updrafts, the magnitude in the smaller entrainment cases are greater in middle and upper troposphere under the condition of the negative vertical shear in the tangential wind. The situation leads to greater vertical advection of the tangential wind by the updrafts, thereby more rapidly intensifying the tangential wind.

TRMM SCIENTIFIC DATA AT THE GES DAAC AND THEIR APPLICATIONS TO MONITORING TROPICAL CYCLONES

Hualan RUI[1], Bill TENG[1], Long CHIU[2], Zhong LIU[2] ([1]GES DAAC, GSFC, NASA, [2]George Mason University)

More than five years of data from the Tropical Rainfall Measuring Mission (TRMM), an US-Japan joint mission, are available at the Goddard Earth Sciences Distributed Active Archive Center (GES DAAC). These data have been used for a variety of applications throughout the world, including monitoring tropical cyclones. These tropical cyclones, particularly the strong ones such as hurricanes or typhoons, bring strong winds and heavy rainfall along their paths and, when over land, cause tremendous human and economic loss and damage. For tropical cyclones initiated over the oceans, it is difficult to monitor them and to forecast their intensity change, since there are not sufficient observations over the oceans. TRMM has yielded invaluable information on rain intensity and distribution, rain type, and storm depth. With the first space-borne Precipitation Radar, TRMM has provided dramatic three-dimensional views of storm structures of many past tropical cyclones, including typhoons Phanphone, Sinlaku, and others. With the use of TRMM data, tropical cyclone forecasts and tracks are likely to continually improve, leading to better preparation for hurricanes/typhoons and a reduction in unnecessary evacuations during hurricane/typhoon season. Since TRMM´s launch in November 1997, its standard products have been processed by the TRMM Science Data and Information System (TSDIS) and archived and distributed to general users by the GES DAAC. These standard data products, discussed in this paper, are available at http://lake.nascom.nasa.gov/data/dataset/TRMM/. The TRMM Online Visualization and Analysis System (TOVAS), http://daac.gsfc.nasa.gov/hydrology/TRMM_analysis.html, developed by the GES DAAC, provides users with a friendly web-based interface for quick exploration, analysis, and visualization of TRMM gridded rainfall products for tropical cyclone and other features. A new Experimental TRMM Real-time Multi-satellite Precipitation Data Set, created by G.J. Huffman et al. of the GSFC Laboratory for Atmospheres and the TSDIS, recently became available to the general public via the TOVAS. The real-time aspect of this data set could significantly increase the capability of TRMM real-time applications, such as monitoring tropical cyclones and forecast modeling.

TYPHOON SPIRAL BAND STRUCTURES OBSERVED WITH A WIND PROFILER NETWORK

Michihiro TESHIBA[1], Manabu D. YAMANAKA[2], Hiroyuki HASHIGUCHI[1], Yoshiaki SHIBAGAKI[3], Yuichi OHNO[4], Shoichiro FUKAO[1] ([1]Radio Science Center for Space and Atmosphere, Kyoto University, [2]Graduate School of Science and Technology, Kobe University / Frontier Observational Research System for Global Change, Japan, [3]Osaka Electro-Communication University, Japan, [4]Communications Research Laboratory, Japan)

We have investigated the characteristics of the wind behavior associated with Typhoon 0221 (Higos), which was observed with the wind profiler network and data acquisition system (WINDAS), which consists of 25 L-band boundary layer radars (BLRs), of Japan Meteorological Agency (JMA) and a L-band BLR of Communications Research Laboratory, simultaneously.This typhoon passed from the south of Japan to the north along the east side of Japan islands, and landed at 20 LST (11 UTC) on October 1, 2002.The central pressure of this typhoon was about 960 hPa at the typhoon´s landing.So the typhoon remained strongly while the typhoon passed. We found from the averaged horizontal winds obtained by 6 BLRs that there were inflow and outflow below and above 2 km in height during the typhoon center´s approaching, and there existed outflow below 6 km in height and strong counter-clockwise winds within 300 km in distance from the typhoon center after the center´s passing, whose features are similar to the previous results obtained by a VHF wind profiler, the MU radar.We also found that the fluctuating component of the radial wind was nearly strong around the rainbands, and the fluctuation of the wind was coming to the typhoon center with a counter-clockwise rotation. We will discuss the relationship between this fluctuation and the rainbands and/or the moving speed of the typhoon.We could reveal these characteristics for the first time by using the data of the wind profiler network.

RADAR OBSERVATIONS OF TYPHOON 9807(VICKI)

Noriyuki KAWANO[1], Yoshiaki SHIBAGAKI[2], Shoichiro FUKAO[1] ([1]Radio Science Center for space and atmosphere, Kyoto University, [2]Osaka Electro-Communication University)

In east Asia, tropical cyclones are called Typhoon.We conducted the Doppler radar observation during the passage of Typhoon 9807(Vicki) on Sep. 1998 with the middle and upper atmosphere (MU) radar located in the central region of the Japan Islands (at Shigaraki). The center of T9807 passed about 40 km northwest of the MU site. T9807 caused much damage by strong wind, and MU radar observation was also interrupted due to power cut by strong surface wind.A remarkable downdraft exceeding 6 m/s was found at the low level just before power cut, at which time also a rainband was observed by a meteorological radar operated by Japan Meteorological Agency (JMA). Global objective analysis produced by JMA shows that cool-dried air advected in the tail of the Typhoon on the middle troposphere, we also confirmed this cool-dried air by means of a radiosonde launched at the MU observatory, and the rainband was located in front of this cool-dried air. In our presentation, we will show a case study observation for the Typhoon at mid-latitude in east Asia, and discuss the relations among the cool-dried air, the rainband, and the strong wind.

WINDSTORM CATASTROPHES IN EUROPE AND JAPAN - CURRENT LOSS ANALYSES IN THE PERIOD 1990 - 2002

Peter MIESEN (GeoRiskDepartment, Munich Re)

Vulnerability is a crucial parameter in the windstorm risk (= hazard x vulnerability x exposed values). For this reason it has been the subject of repeated analyses performed in the past 25 years by Munich Re´s Geo Risks Research Dept. on the basis of empirical loss data from major windstorm catastrophes and is one of the essential quantities in studies for estimating loss potentials. The identification of possible changes in the vulnerability of insured objects – for example on account of new construction materials and architectural developments – is essential for risk carriers. On the one hand, it is necessary to have as realistic picture as possible of future losses when allocating risk capital in order to avoid being hit by unexpected accumulation losses should a catastrophe event occur. But fairness towards insurance clients also requires that any changes that may occur in loss expectancy are considered too when calculating prices that are commensurate with the risk. The studies presented here compare the behaviour of buildings during the winter storms in Europe in 1990 and 1999 and during the typhoons in Japan in 1991 und 2002. During this period, the loss ratios were subject to changes that were in some cases quite considerable, for which an initial explanation is suggested.

EXTRATROPICAL TRANSITION OF TROPICAL CYCLONES IN THE WESTERN NORTH PACIFIC: THEIR FRONTAL EVOLUTION

Naoko KITABATAKE (Typhoon Research Department, Meteorological Research Institute)

The major islands of Japan, which is located in the mid-latitude, are hit by several tropical cyclones (TCs) every year. These TCs are often at the extratropical transition (ET) stage. According to the Best Track data of the RSMC Tokyo-Typhoon Center, 21 TCs out of 57 were transformed to extratropical cyclones in the western North Pacific in 2001-2002. Particularly, 25 TC translated northward beyond the 30N, and the 20 cases out of them transformed into extratropical cyclones. Sometimes the frontal rainband associated with a TC at the ET stage brings a torrential rainfall and the subsequent flood. The variation of the translation speed may contribute to a forecast track error and disasters due to the strong winds. We examined the frontal structure of the 21 ET cases in 2001-2002 using the objective analysis dataset of JMA. The fronts are defined by the thermal front parameter of Renard and Clarke (1965), although the 925-hPa equivalent potential temperature was used as a thermal variable. Three types of the ET were found: 1) the warm seclusion pattern, 2) the cold advection pattern, and 3) the open wave pattern. Nine cases out of 21 ETs were classified as the warm seclusion pattern. When a TC moved northward and approached to the mid-latitude baroclinic zone, a warm front became obvious, extending eastward from the cyclone center. A rather weak cold front was formed 12-24 hours later south of, but not in the vicinity of, the cyclone center. This frontal structure included some features similar to the frontal fracture of Shapiro and Keyser (1990). Although the horizontal temperature gradients increased near the cyclone center in the lower troposphere, the cyclone still had the warm core structure. The warm-core structure and the shear deformation contributed to the warm frontogenesis and the cold frontolysis in the vicinity of the cyclone center. The TC followed a northward track and increased its translation speed, and subsequently organized into an occluded extratropical cyclone, decreasing the translation speed. These cyclones dissipated in 48 hours after the transformation. The cold-advection pattern was such that a TC moving ENE-ward approached to a preexisting cold front. Two cases out of 21 were classified as this type. They transformed into weak frontal cyclones in an environment of strong cold advection, and subsequently dissipated. In the other 10 cases, the TCs transformed into open-wave extratropical cyclones. Most of them were not well organizedand dissipated in 36 hours, whereas three cases began reintensification as a extratropical cyclone in 24 hours after the transformation. As the aforementioned warm-seclusion pattern, a warm frontogenesis preceded the cold frontogenesis, although the cold frontogenesis occurred also in the vicinity of the cyclone center. Moreover the TCs did not lose their translation speed.

APPLICATION OF STEERING WEIGHT CONCEPT TO TYPHOON SAOMAI IN 2000

Mitsuru UENO, Akihiko MURATA (Typhoon Research Department, Meteorological Research Institute)

In an attempt to diagnose the mechanism by which a typhoon moves through vertically sheared environmental flows with keeping its vertical coherency, a series of idealized numerical simulations of typhoon are carried out and eventually a new approach termed ˝steering weight concept˝ is proposed based on the numerical results. The steering weight is a set of weighting factors mathematically derived from the surface pressure tendency equation and can be a measure of how much sensitive the storm motion is to the steering flow at each vertical level. The overall movements of simulated typhoons are well explained by taking into consideration not only so called ˝steering flow˝ but also the steering weight. The new concept is also applied to real typhoon cases such as Typhoon Saomai in 2000 to see the validity of the concept in real situations. The experiments are performed using a 20km version of MRI/NPD nonhydrostatic model which includes an Arakawa-Schubert cumulus parameterization scheme. It is found from the experiment that the simulated motion of Saomai is sensitive to and systematically changed with the tuning parameters of the scheme such as entrainment rate and relaxation time in a consistent manner with the foregoing idealized simulations, suggesting a strong correlation between steering weight and storm motion in real situations. The steering weight concept will be outlined at the conference putting stress on the results from real typhoon cases now in process.

TROPICAL CYCLONE ASSIMILATION AND PREDICTION. PART II: COMPARISON BETWEEN THE NORTHWEST PACIFIC AND OTHER TROPICAL CYCLONE BASINS

Lance M. LESLIE[1], Seon Ki PARK[2] ([1]School of Meteorology, The University of Oklahoma, [2]Ewha Womans University, Seoul, South Korea)

In this study a comparison is made of the performance of a tropical cyclone assimilation and prediction system applied to the northwest Pacific basin, compared with its performance in four other tropical cyclone basins. The assimilation and prediction system used in the study is the HIRES (from High RESolution) system developed over the past decade at The University of New South Wales, Sydney, Australia and presently at The University of Oklahoma, USA. The four other tropical cyclone basins to which the HIRES system is applied include the north Atlantic, southwest Pacific, southeast and north Indian Ocean basins. The HIRES system was run at a horizontal resolution of 10km and employed several assimilation technique including 4D-Var, I3D-Var or intermittent cycled assimilation. Each assimilation procedure was applied over the 24 hour period leading up to the commencement of the forecast period.A total of 20 northwest Pacific cases (see the companion conference paper by Park and Leslie) were selected, together with a total of 30 cases from the other four tropical cyclone basins. The performance assessment focused on mean absolute and rms errors in track and intensity predictions. The forecasts were evaluated at 12 hour intervals out to 96 hours. Error statistics for the northwest Pacific basin were compared with those from the other basins. It was found that although a total of 50 tropical cyclones were used for the comparison, most of the storms investigated followed regular tracks, being either 'straight runnersAEor tropical cyclones recurving in a classical path, such as around a sub-tropical ridge. Tests of statistical significant difference revealed no difference between the error statistics for the northwest Pacific and the other regions at the 5% confidence level. It was therefore decided to focus only on tropical cyclones that exhibited unusual behavior and, as a consequence, are regarded as difficult storms to forecast accurately. A total of five cases were chosen from the northwest Pacific and five from the other basins. Detailed case studies were carried out on all these ten tropical cyclones. It is well-known that each of the tropical cyclone basins investigated here has different characteristics, both for genesis and for the factors dictating the subsequent motion and intensity of the tropical cyclone. The results of these case studies therefore will be described in the context of the impact of these differing basin characteristics on the performance of the HIRES system.

DEVELOPMENT OF A TWO-WAY MULTIPLY-NESTED MOVABLE MESH TYPHOON MODEL

Wataru MASHIKO, Chiashi MUROI (Meteorological Research Institute)

In order to get better prediction of typhoon track, intensity, heavy rainfall and strong wind distribution, and inner structure, we are on the way to develop a two-way multiply-nested movable mesh typhoon model based on Meteorological Research Institute/Numerical Prediction Division unified nonhydrostatic model of the Japan Meteorological Agency (MRI/NPD-NHM; Saito et al., 2001). MRI/NPD-NHM has been used to simulate various cases of mesoscale phenomena. However, numerical experiments of typhoon in high resolution have rarely been conducted due to the limited computer resources. For the precise prediction of typhoon, enormous computer resources are needed because environment fields around a typhoon largely affect the typhoon evolution and therefore a large model domain is needed. Moreover, since each convective cloud plays an important role to a typhoon, fine mesh (horizontal grid size; less than 1-2km) that represents convection is desirable especially near the typhoon center. The major advantage of the two-way nested model is that it can effectively reduce computational time and memory requirements because both the large domain and high resolution can be accomplished together by arranging fine mesh over the typhoon area and coarse mesh over the environment. The main procedures of the two-way interactive mesh refinement scheme are (1)construction of an interface between coarse mesh and fine mesh, (2)interpolation that is used to provide initial and boundary values of fine mesh, (3)feedback from fine mesh to coarse mesh, and (4)boundaries conditions for fine mesh. We employed monotone advection algorithms for the interpolation procedure(2) and one point feedback with a smoother-desmoother for the feedback procedure(3) used in Penn State/NCAR Mesoscale Model (MM5). As for boundaries conditions(4), we adopted the radiative-nesting boundary conditions considering the difference between coarse and fine mesh´s values (Chen 1991). Some Fortran90 modules concerning two-way nesting were added to MRI/NPD-NHM in such a way that minimizes the change of its original source code. To check the dynamical core of the model, we performed three-dimensional numerical simulations of a mountain flow with the model. The two-way nested model that covers the near-mountain area with fine mesh and elsewhere with coarse mesh produced almost the same results as those from the model with fine mesh all over the model domain and no erroneous wave reflection was excited near the boundaries. And computational time could be reduced, compared with the model covered with all area fine mesh. The impact of the two-way nesting and the case study of typhoons in the Western North Pacific will be shown at the symposium.

DEVELOPMENT OF TYPHOON-OCEAN COUPLED MODEL AT METEOROLOGICAL RESEARCH INSTITUTE IN JAPAN METEOROLOGICAL AGENCY

Akiyoshi WADA (Department of Typhoon, Meteorological Research Institute)

For the purpose of one of the attempts to improve typhoon prediction, 'Typhoon-ocean coupled model' has been developed at Meteorological Research Institute (MRI) in Japan Meteorological Agency (JMA). As an ocean part of the coupled model, a mixed layer model with turbulent mixing processes has been constructed using reference from Bender et al. (1993) (Wada 2002). The ocean model with global analysis data every 6 hours and Rankin vortex from JMA best track data could successfully reproduce about 3°C cooling of sea surface temperature (SST) observed by R/V Keifu Maru after the passage of Typhoon REX on August 29, 1998. As an atmospheric part of the coupled model, the typhoon model (TYM) routinely used in JMA was transferred to MRI. The horizontal resolution in the typhoon center has been revised from 24km to 20km in the present work. A numerical prediction using Typhoon-Ocean coupled model was conducted for Typhoon BILIS of which the initial time was at 12UTC on August 20, 2000. Computed SST cooling by Typhoon BILIS can be found on the right of the running typhoon. The maximum SST cooling during 72 hours reaches to 2.8°C after 36 hours from the initial time, while minimum sea level pressure (MSLP) of the coupled model, 936.hPa, rises to nearly 17hPa compared with that of TYM, 920.0hPa at that time. The maximum wind speed of the coupled model decreases and its region moves outside compared with the original typhoon model. The coupling effects are confirmed in horizontal distributions of sensible plus latent heat fluxes and precipitation. We should note that it is difficult to compare directly the best track MLSP of Typhoon BILIS in JMA with computed MSLP because the initial observed MSLP is not always equal to the initial bogus MSLP. Nonetheless, correlation coefficients of 6-hour MLSP tendency over 27 samples during 2000-2002 seasons indicate that MLSP tendency of the coupled model agrees better with that of JMA best track MSLP than with that of TYM MSLP. However, SST cooling after the passage of Typhoon BILIS by the coupled model is indeed insufficient compared with about 5°C observed SST cooling by TRMM/TMI. This is because TYM and the coupled model tends to estimate the intensity weaker than that in JMA best track data so that forcing from the atmosphere and the ocean by models becomes weaker. The fundamental problem may exist in the atmospheric boundary processes or cumulus parameterization as well as in the oceanic processes.

TROPICAL CYCLONE ENERGY DISPERSION AND CYCLOGENESIS IN THE WESTERN NORTH PACIFIC:OBSERVATIONS AND SIMULATIONS

Tim LI, Yongti ZHU, Yuqing WANG, Bing FU, Xuyang GE, Bin WANG (University of Hawaii)

Using the QuikSCAT and TRMM satellite data, we identified tropical cyclone (TC) genesis processes during the western North Pacific (WNP) typhoon seasons in 2000 and 2001. Our particular focus is on the processes associated with the TC energy dispersion and easterly wave forcing. Among 34 TCs generated in the WNP during the two seasons, there are 7 TC genesis cases associated with easterly wave forcing and 6 cases associated with TC energy dispersion. It is noted that not all TCs have a clear Rossby wavetrain pattern in their wake. The wavetrain is more likely to appear in the wake of intense TCs. The TC induced Rossby

M

wavetrain is well simulated in a 3-D high-resolution model. While a TC moves northwestward in a beta plane, its energy propagates southeastward, forming a synoptic-scale wavetrain of alternating regions of anticyclonic and cyclonic vorticity perturbations. The maximum strength of the TC energy dispersion is found in the lower troposphere at 850 hPa. Experiments with both explicit and mass-flux convective heating schemes showed that a new TC could not be generated in the Rossby wavetrain of a preexisting TC in the resting environment. An anomaly baroclinic model was developed to understand the role of the WNP mean monsoon flow on the TC genesis. In the model an idealized or realistic basic-state field is specified, which does not change with time. Under the basic-state patterns similar to the monsoon gyre and the monsoon shear line, the model successfully simulates the TC formation associated with the Rossby wave energy dispersion of a preexisting TC. The physical mechanism responsible for the TC genesis is argued to be associated with the scale contraction of the synoptic-scale wave due to the concentration of the perturbation vorticity by convergent mean monsoon flows. Because of this scale contraction, the synoptic-scale wavetrain with a large meridional wavelength is organized into vortex-scale circulation and convection, leading to the formation of a new TC. The generated new TC has realistic dynamic and thermodynamic structures such as spiral cloud bands, asymmetric maximum winds and the warm core/eye wall structure. Further sensitivity experiments indicate that anomalous warm SST may greatly enhance the cyclogenesis process.

A STUDY OF TROPICAL CYCLONE FORMATION IN THE WESTERN NORTH PACIFIC

Cheng-shang LEE (Dept of Atmospheric Sciences, National Taiwan University, Taipei, Taiwan)

Observations have shown that significant changes in the environmentalcirculation pattern often occurred during the formation of a tropicalcyclone. This study attempted to investigate the evolution of the circulationpattern during tropical cyclone formation in the western North Pacific usingthe EC grid point data and the QuikSCAT data. Results showed that about 40% ofall tropical cyclones might be affected by the trade wind surges or the cross-equatorial surges during their formation stage. The PSU/NCAR MM5 was used tosimulate the formation process of four cases. Model results were analyzed toexamine the structure evolution and to address the important physicalprocesses responsible for the formation of these systems. The role of tradewind surges and the cross-equatorial surges on tropical cyclone formation inthe western North Pacific will be discussed.Results also showed that during 1950-2001, there were about 4.1 tropicalcyclones formed in South China Sea (SCS) each year (about 27 for the wholewestern North Pacific basin). Among these systems, 17.3% formed in early season(May-June). This percentage was much higher than the 9.5% for the rest of thewestern North Pacific basin (east of 120E). In this study, the environmentalcirculation pattern during tropical cyclone formation in SCS during differentseasons will also be examined. In the early season of 2002, there were twotropical cyclones formed on stationary fronts located at the northern part ofSCS. One system formed in late May and only maintained as a tropical depression(TD06). The other formed in early June and reached tropical storm (TyphoonNoguri) intensity. In this study, the formation process of these two systemswill be examined and tropical cyclone formation under the baroclinicenvironment will be discussed.

TYPHOON VAMEI: AN EQUATORIAL TROPICAL CYCLONE FORMATION

Chih-Pei CHANG[1], Ching-Hwang LIU[2], Hung-Chi KUO[3] ([1]Naval Postgraduate School, [2]Chinese Culture University, [3]National Taiwan University)

Due to the diminishing Coriolis effect, the belt 300 km either side of the equator has been considered tropical cyclone-free. Typhoon Vamei, which developed near Singapore on 27 December 2001, was the first recorded tropical cyclone formation within 1.5 degrees of the equator. It caused damages to the carrier USS Carl Vinson and an accompanying ship. The development was the result of two interacting systems, a weak Borneo vortex that drifted into the southern tip of the South China Sea and remained there for four days, and a strong and persistent cold surge that created the large background cyclonic vorticity at the equator. The development process is similar to the spinning of a top played by a child. The probability of a similar equatorial development is estimated to be once every 100-400 years.

MC02/08A/B20-004	1000

RECENT OBSERVATIONAL STUDIES ON TROPICAL CYCLONE FORMATION IN THE WESTERN NORTH PACIFIC

Kevin K.W. CHEUNG, Russell L. ELSBERRY (Department of Meteorology, Naval Postgraduate School, Monterey, California, U.S.A.)

Since a tropical cyclone (TC) may form and reach a mature stage within five days, an understanding and ability to predict TC formation is necessary to make skillful five-day forecasts. The goal of the observational study is to understand the physical processes during TC formation, and possible interactions with environmental systems with different spatial scales. Through examination of historical TC cases, detailed values and distributions of the environmental parameters such as relative humidity, convective instability and vertical wind shear associated with formations may be identified, that can be used as the basic reference in operational forecast situations. However, the character as well as the environment of the TC seedling (monsoon depression, waves, etc.) and the presence of mesoscale convective systems (MCSs) might also play an important role in TC formation. Therefore, the statistical properties and evolution processes of MCSs are also studied using both analyses and satellite data. The focus will be on how MCSs are controlled by tropical circulations of different time scales (from those with period less than one month to the longer-period Madden-Julian oscillation that are both correlated with TC formation to certain degree), and whether there are specific MCS configurations during the early-stage intensification of TCs. Much can also be learned from verifying the skill of operational global numerical weather prediction (NWP) models in predicting TC formation since many of these models are capable of spinning up circulations that have quite realistic TC structures. In particular, knowledge on the physical conditions in determining a TC formation (certainly limited by the finite resolution of the models and their physical parameterizations) can be obtained in comparing the real TCs generated in the NWP models and the spurious vortices (false alarms). Some effort along this idea on the U.S. Navy Operational Global Atmospheric Prediction System (NOGAPS) has already been finished. Verifications will be extended to the NCEP Aviation model, Taiwan's CWB global forecast system, German Meteorological Institute's global model, and Japan's global spectral model. Progress from the above observational studies will be presented during the Symposium.

MC02/08A/B20-005	1100

MESOSCALE ANALYSYS OF FORMATION PROCESS OF TYPHOON OVER THE WESTERN NORTH PACIFIC

Kazumasa MORI (Meteorological Research Institute)

Mesoscale features of convection organized in the formation process of typhoon (TY) Rex (T9804) on 21 August 1998 and around low-latitude lowpressure area (L) on 4 November 1999 over the western north Pacific were investigated using mainly research vessel Keifu Maru(I) radar data. Two MCSs were formed successively in a mesoscale (400 km) low-level cycloniccirculation (LLCC) around the central area of the forming TY Rex. Mesoscaleconvection organized as the first MCS once decayed. However, the mesoscaleLLCC which appeared to have been intensified corresponding to the formationof the first MCS remained. After the decay of the first MCS, near the centerof the residual mesoscale LLCC, meso-γ-scale intense convection was newlyinitiated. The meso-γ-scale intense convection evolved into the second MCSassociated with further intensification of the mesoscale LLCC, which wasa kernel structure of the pre-TY Rex evolving from tropical depression(TD)to tropical storm (TS) stage. The low pressure area (L) was a pre-disturbance which developed to TD. A low-level confluent line made by west-northwesterly and west-southwesterlyflow was detected by tracking of cell echoes. Several MCSs organized withinthe L. Among the MCSs, an eastward moving squall-line like MCS formed to thenorth of the confluent line (CL) and a east-northeastward moving squall-linelike MCS formed to the south of the CL merged each other around the CL.On the process of the MCSs merger, individual two intense convective lines ofthe leading edges of MCSs were also merged sustaining their intensity andchanged from line to area of about 30km horizontal scale. By about threehours after the merger, large stratiform echo with horizontal scale about 500 kmformed and spread to the southwest of the mesoscale intense convective area andLLCC appeared to be initiated around the area. The first case of TY Rex formation is one example of mesoscale process of typhoon formation by successive and mutual intensification of MCSs and LLCCchained through an implied release of latent heat and consequent decrease ofsurface pressure on mesoscale associated with the intense convection within the MCSs. The second case of low-latitude L implies the role of MCSs merger for formation of intense mesoscale convection on the process of TY formation.

MC02/08A/B20-006	1120

TYPHOON GENESIS IN GLOBAL HIGH-RESOLUTION SIMULATIONS ON THE EARTH SIMULATOR

Mayumi K. YOSHIOKA[1], Takeshi ENOMOTO[2], Yoshio KURIHARA[2] ([1]Earth Simulator Center, Japan Marine Science and Technology Center, [2]Frontier Research System for Global Change)

Cumulus clusters in the tropics sometimes evolve into tropical depressions, which can eventually develop to typhoons. While such a process may be autonomous, it has also been argued that it is necessarily associated with the presence of favorable background conditions. Utilizing simulation results from aAFES (Atmospheric global circulation model For the Earth Simulator), we attempt to study formation mechanism of tropical mesoscale systems. The effect of cumulus convection is treated in the model by the simplified Arakawa-Schubert parameterization scheme. Two different resolutions are used: one with horizontal resolution T1279 and 96 vertical levels (T1279L96) and the other with T319 and 24 levels (T319L24). In the case for June situation, a tropical cyclone is generated over the Warm Pool at both resolutions in the surf region of westward propagating equatorial waves. However, the one in the T1279L96 simulation becomes much more intense, apparently due to enhanced convections associated with a westerly burst. This wind burst is not found in the T319L24 simulation. In the case for September situation, four typhoons are simulated during the integration period in the T1279L96 simulation, but three in the T319L24 simulation. An investigation for this case will also be shown focusing on the differences of the background fields in two resolutions.

MC02/08A/B20-007	1140

RECENT MESOSCALE MODELING STUDIES ON TROPICAL CYCLONE FORMATION IN THE WESTERN NORTH PACIFIC

Kevin K.W. CHEUNG, Russell L. ELSBERRY (Department of Meteorology, Naval Postgraduate School, Monterey, California, U.S.A.)

To complement the observational studies being carried out in our research group, modeling studies are also performed following two strategies. One is to simulate historical TC formation cases to further our understanding of the physical mechanisms during formation. For example, the NCAR/PSU MM5 model has been used to simulate the formation of Typhoon Robyn (1993) that occurred during the Tropical Cyclone Motion (TCM-93) field experiment. Observations during the intensive observational periods of TCM-93 are nudged into the model fields and high-resolution analyses are used to evaluate the simulations. The essential features associated with Robyn's formation can be realized in the 27-km resolution fine grid using the Betts-Miller cumulus parameterization. However, the intensification of the tropical cyclone is found to be highly sensitive to the model configurations, such as choice of cumulus scheme, boundary layer parameterization, number of model levels, and size of the nested domain. Diagnostic studies are being performed to understand these model sensitivities and to find a better model configuration for TC formation prediction. Future efforts will include a high-resolution simulation (with 9-km fine grid resolution or less) of the same case, so that the structure of the associated mesoscale convective systems is better predicted in the model. The second strategy is to study near real-time predictions of TC formations in the western North Pacific (WNP). To truly measure the skill of dynamical predictions of TC formations after the model is tuned specifically for the WNP, U.S. Navy Coupled Ocean/Atmosphere Mesoscale Prediction System (COAMPS) is used. Since TCs may form over a large domain in the WNP, a single grid with 27-km resolution is being tested with cases during the 2002 season. After the preliminary set up work is completed, forecasts of up to 144 h will be obtained. After verifications and evaluations of the results from the 2002 cases are done, modifications to the model configuration and/or model physics will be made. Focus will be paid on the effects of assimilation of various kinds of satellite products on the skill of predicting TC formation.

MC02/08A/B20-008	1200

NUMERICAL STUDY OF THE EVOLUTION OF A BAY OF BENGAL TROPICAL CYCLONE AND THE IMPACT ASSESSMENT

Bhaskar Rao Venkata DODLA (Department of Meteorology and Oceanography, Andhra University)

 A tropical cyclone crossed the East Coast of India at around 20 N latitude between 0430-0630 UTC on 29th October 1999 causing enormous damage to the coastal region of Orissa State. The India Meteorological Department has named this cyclone as ´super cyclone´ as the estimated minimum central surface pressure attained was 912 hPa and associated maximum sustained winds of 155 knots. In this study an attempt has been made to simulate

the evolution of this cyclone using a NCAR MM5 mesoscale model. The evolution has been simulated using a two way nested two-domain model integration with horizontal resolutions of 30 km and 10 km. The model has been integrated for five days using the initial and boundary conditions taken from NCEP 1-degree daily data from 25th October 1999. The model could successfully simulate the evolution satisfactorily with the intensification and movement agreeing with the observations. The evolution of mesoscale convective features associated with the developing cyclone has been analysed. The model could produce the rainbands agreeing with the observations. The locations of the maxima of convection as the cyclone is evolving are well obtained by the model. The rainfall intensity and distribution at different stages of the cyclone are also well predicted. This study shows the usefulness of NCAR MM5 for the study of tropical cyclones over the north Indian Ocean and to understand the physical mechanisms associated with the mesoscale convective systems associated with tropical cyclones. However, the model underpredicted the ultimate strength with a minimum central surface pressure of 960 hPa which may be due to the limitations of horizontal resolution and sensitivity to physical parameterization schemes of convection and boundary layer. An impact assessment of the above cyclone is made in terms of the loss of life and damage to property. The collected data indicates the loss of 10,000 human lives and 400,000 cattle and nearly a million of other live stocks. The total estimated loss to the agriculture sector alone is about 2000 crores of Indian rupees or 400 million US dollars. Added to this there has been extensive damage to telecommunication network, power supply, building structures and the roadways. A storm surge of 5-6 meters above the astronomical tide of 2.5 meters has been reported which lead to tidal inundation up to 35 km inland from the coast of Paradeep. Some preliminary results of the impact assessment of the tropical cyclones along the East Coast of India will be presented. A statistical analysis of all the available cyclone data that crossed the coastal region of Andhra Pradesh along the East Coast of India is made. The damage associated with these cyclones is discussed in terms of the loss of life and property. The damage due to different. aspects such as high winds, torrential rainfall and storm surge will be discussed. The study emphasises the usefulness of numerical modeling studies to predict the strength and movement of the cyclones and to assess their impact.

EFFECTS OF ENVIRONMENT, TYPHOON MODELING

MC02/08P/B20-001   1400
INTERACTION OF POTENTIAL VORTICITY ANOMALIES IN EXTRATROPICAL TRANSITION OF TYPHOON BART (1999)

Jun YOSHINO, Hirohiko ISHIKAWA, Hiromasa UEDA (Disaster Prevention Research Institute, Kyoto University)

In recent years, considerable concern has been raised about *extratropical transition of tropical cyclones*. Once a tropical cyclone reaches at the mid-latitude baroclinic zone, it drastically changes its structure and strength. Mid-latitude tropical cyclones are expected to be influenced by surrounding systems (e.g. synoptic troughs, ridges and jet stream). Typhoon Bart (1999) has undergone a rapid weakening (a central pressure change of +50hPa/day) around Japan Islands and, after that, an unexpected re-intensification (-15hPa/day) over the Sea of Okhotsk. The purpose of this study is to investigate the detailed structure, dynamics and transitional process of mid-latitudinal Typhoon Bart using the mesoscale modeling system PSU/NCAR MM5. Furthermore, employing the gridded datasets from the successful simulation, a piecewise potential vorticity (PV) inversion is performed to determine the relative contributions of discrete pieces of the PV to the Bart's decaying and intensification. Bart simulated by MM5 shows good agreements with the JMA best track for Bart and GMS-5 images. The cloud field of Bart has changed from axisymmetric pattern to asymmetry in its transitional process. Although Bart in the cyclolysis phase was far from an upstream synoptic trough composed of a high PV anomaly at upper levels, it began to come under the influence of the lower-level dry and cold air mass and upper-level negative PV anomaly. The cold air mass intrusion in Bart led to contribute to the large positive value of frontogenesis along the cold front. According to the results of the piecewise PV inversion, the upper-level negative PV anomaly, which would be generated by the diabatic heating in cloud, caused a rapid surface cyclolysis. The cloud activity associated with Bart resulted in the self-decaying with the generation of the negative PV anomaly aloft. However, a low-level positive PV anomaly associated with the Bart's warm core remnant was the most significant contribution to the deepening rate, despite of the development of the negative PV anomaly. In the re-cyclogenesis stage, the simulated Bart wrapped typhoon cloud bands spirally and became an axisymmetric pattern again like its mature stage. The simulated PV field indicates that the upper-level high PV anomaly originating in high-latitudinal stratosphere, was vertically coupling with the low-level positive PV anomaly formed in the remnant of Bart. The spiral cloud bands in Bart produced the strong ascending motion resulting from the lifting of the tropopause, and accomplished the vortex stretching of Bart, and developed the divergent flow near the tropopause. The static piecewise PV inversion analyses showed that the upper-level dry positive PV anomaly with the synoptic perturbation was a minor contribution to the surface cyclogenesis, but it was essential factor to act on a positive feedback of cyclogenesis. The negative PV anomaly aloft, to the north of Bart, that had decreased its surface cyclonic activity in the weakening stage, played in an important role in evolving the outflowing jet streak and accelerating the positive feedback of cyclogenesis, resulting from the steeper PV gradient near the tropopause.

MC02/08P/B20-002   1420
SEA SURFACE COOLING WITH THE PASSAGE OF TYPHOONS IN THE NORTHWESTERN PACIFIC OCEAN

Chul-hoon HONG (Pukyong National University)

The ocean response to typhoons in the Northwestern Pacific Ocean is studied using the Buoy Data from Japan Meteorological Agency during 1982 to 2000 and a three-dimensional primitive model (POM). Sea Surface Cooling (SSC) response is emphasized, analyzing 27 typhoons. SSC at Buoy 21004 (29°00 N, 135°00 E)is observed in all cases, ranging from –6 to -3 °C.The amplitude of SSC is correlated with typhoon strength, track, and translation velocity. SSC after the passage of strong typhoons preserves more than about 10 days. The intense SSC occurs well in the cases of typhoon-tracks leftward from the Buoy 21004 (when viewing the typhoon from behind). A three-dimensional numerical model of which domain covers most of the Northwestern Pacific Ocean (24°N to 52°N) including the East China Sea, the Yellow Sea, and the East (Japan) Sea is implemented to simulate Typhoon Abby, August in 1983, and identifies well SSC with about ~-4 °C. The model suggests that a cyclonic eddy with a diameter of a few hundred kilometers occurs behind the typhoon, and SSC is greatly influenced by the eddy behavior.

MC02/08P/B20-003   1440
A CLIMATOLOGICAL STUDY OF BINARY TROPICAL CYCLONES IN THE WESTERN NORTH PACIFIC BASIN

Suguru ISHIJIMA (NPO Okinawa Typhoon Center)

A climatological study was made on the occurrences of the binary tropical cyclones in the western North Pacific and the feature in their relative and actual tracks was investigated. The analysis of JMA meteorological observation data covering for the period of 45 years(1952-1996) indicates that the binary tropical cyclone system(BTS) occurs at the rate of nearly twice a year in the months of May through November with thetotal of 90 cases . Their occurrences are most abundant from their initial center-positions orienting in the E-W direction in the open oceanic region south of Japanand east of the Philippines. The relative rotation sense of the binary tropical cyclones and the separation distance between them in the period of analysis were featured with CyclonicApproaching(CA), Cyclonic Approaching and anticyclonic Departing(CAD), primarilyAnticyclonic rotating(aC), nearly Stationary (ST) and Compound(CM) modes. The CA mode only occupies 22% of the whole number of BTS with its nearly half merged into one tropical cyclone and the majority belongs to CAD mode. The aC mode exists only by 10% . The averaged separation distance between the binary tropical cyclones of CA modes which merged into one cyclone is as short as 430kmwhile those CA modes which showed no merging could only approach as close as 700km.The CAD modes featured with the anticylonic rotation in the later stage could only approach upto 830km. The averaged intensity ratio defined as a ratio of the intensity of one weaker pair against the other stronger pair is 0.65. The intensity and the size ratios are discussed as the effective parameter in determining a critical merging separation distance and the mutual interaction behavior. Some unique features found in thetracks of individual pairs of BTS will be presented.

MC02/08P/B20-004   1500
A NEW LOOK AT THE BINARY INTERACTION: POTENTIAL VORTICITY DIAGNOSIS OF THE UNUSUAL SOUTHWARD MOTION OF TROPICAL STORM BOPHA (2000) AND ITS INTERACTION WITH SUPERTYPHOON SAOMAI (2000)

Chun-Chieh WU, Treng-Shi HUANG, Wei-Peng HUANG, Kun-Hsuan CHOU (Department of Atmospheric Sciences, National Taiwan University)

Tropical Storm Bopha (2000) showed a very unusual southward course parallel to the east coast of Taiwan, mainly steered by the circulation associated with Supertyphoon Saomai (2000) to Bopha's east. The binary interaction between the two typhoons is well demonstrated by the potential vorticity (PV) diagnosis. With the use of the piecewise PV inversion, this paper quantitatively evaluates how Bopha moved southward due to the binary interaction with Saomai. A newly proposed centroid-relative track, with the position weighting based on the steering flow inducded by the PV anomaly associated with the other storm, is plotted to highlight such binary interaction processes. Note that the above analysis can be well used to understand the more complicated vortex merging and interacting processes between tropical cyclones either from observational data or numerical experiments. The results also shed some light on the prediction of nearby tropical cyclones.

MC02/08P/B20-005   1550
ASSIMILATION AND PREDICTION OF TROPICAL CYCLONES. PART I: PERFORMANCE IN THE NORTHWEST PACIFIC

Seon K. PARK[1], Lance M. LESLIE[2] ([1]Department of Environmental Science and Enginnering, Ewha Womans University, South Korea, [2]School of Meteorology, University of Oklahoma, U.S.A.)

The northwest Pacific basin is one of the most active tropical cyclone (TC) regions in the world. It also is one of the most populous regions, so the accurate prediction of tropical cyclone tracks is of great importance. Almost all east Asian countries are affected by TCs, and active research programs are part of weather centers in many countries including Japan, PRC, South Korea and Taiwan. In this study, we present numerical results obtained for TCs over the northwest Pacific based on a high resolution limited-area assimilation and prediction system, called HIRES (HIgh RESolution model), which is developed at Univ. of New South Wales, Australia and Univ. of Oklahoma, U.S.A. Numerical experiments for a total of over 20 TC cases have been performed by employing advanced assimilation techniques such as four-dimensional variational analysis (4D-Var) and inverse 3D-Var (I3D-Var), followed by high resolution (10 km) predictions of track, intensity and precipitation. The cases focused on landfalling TCs affecting Hong Kong, Japan, PRC, the Philippines, South Korea, Taiwan, and Vietnam. The assimilation used all available data, including satellite and radar observations for three TCs that hit Hong Kong in 1999. Additional focus has been on the 2002 season, especially TCs affecting Japan and South Korea in both the Pacific and the East/Japan Sea regions. Results will be presented concentrating on a number of aspects of the numerical experiments. The impact of assimilating nonconventional data using both 4D-Var and I3D-Var methods will be discussed. In addition, a comparison made of the two approaches, relative to control forecasts using no assimilation will be described. Other aspects of the forecasts that are assessed include tracks, intensity and quantitative precipitation forecasting for several storms that produced flooding after nearing or making landfall. Planned future work includes the hybrid application of I3D-Var and 4D-Var techniques, given the large gains in efficiency provided by the I3D-Var approach.

MC02/08P/B20-006   1610
IMPROVING TROPICAL CYCLONE INITIALIZATION WITH APPLICATION OF QUIKSCAT DATA

Chi-Sann E. LIOU[1], Yi JIN[2] ([1]Naval Research Laboratory, [2]Science Applications International Corporation)

Due to lack of observations, tropical cyclone initialization for numerical model forecast remains a difficult problem. For Pacific Ocean region, the initialization is even more difficult since there is no reconnaissant flight and the majority of available observations near typhoon centers are single-level, remote-sensed satellite observations. At Naval Research Laboratory, we initialize tropical cyclones for operational model forecast through the use of synthetic observations. The synthetic observations are generated according to the latest observed position, structure, and intensity of tropical cyclones. These observed parameters reported in warning messages are, in general, determined by forecasters using available observations. We have developed a method to enhance the accuracy of the observed structure parameters by objectively retrieving these structure parameters from Quikscat satellite data. The method gathers Quikscat data within 600 km radius of a tropical cyclone, screens out poor quality data, and computes azimuthally averaged wind speed in every 15 km at 4 quadrants. Radii of 34 and 50 knot wind are then retrieved from the averaged wind speed at each quadrant by least square fitting the wind speed to a fifth-order polynomial. The retrieved 34 and 50 knot radii are weightly averaged with the radii included in the warning message to become the structure parameters used in constructing the synthetic

M

observations. Numerical experiments have been conducted to evaluate high-resolution tropical cyclone forecast in the Coupled Ocean/Atmosphere Mesoscale Prediction System (COAMPS™) with and without the application of Quikscat data. Preliminary results show that the cyclone track and structure forecast are improved with the application of Quikscat data, and for some cases the improvement is quite significant. The paper presented at the symposium will discuss the retrieval method as well as the evaluation results from the numerical experiments.

MC02/08P/B20-007 1630

A PILOT STUDY ON THE SURVEILLANCE OF TYPHOONS NEAR TAIWAN USING GPS DROPSONDE

Chun-Chieh WU[1], Po-Hsiung LIN[1], Tien-Chiang YEH[2] ([1]Department of Atmospheric Sciences, National Taiwan University, [2]Central Weather Bureau, Taipei, Taiwan)

Due to the important potential value of the GPS dropsonde data, a pilot study will be conducted on the aircraft surveillance of typhoons near Taiwan using GPS dropsonde. This work will not only improve the atmospheric data surrounding typhoons, but (also) promote the research on data assimilation and adaptive observation. This is a pioneering research work led by scientists in Tawain to conduct typhoon surveillance experiments in the western Pacific, with international participants from the NCEP, HRD, FNMOS of U.S., and the MRI of Japan. The project will use aircrafts to perform experiments on typhoons in the northwestern Pacific Ocean for the first time in up to 15 years. Researchers will fly above typhoons approaching Taiwan and release GPS dropsondes to obtain environmental data from areas of interest around the typhoon periphery. Data will be transmitted to the Central Weather Bureau in real time and compared with the results of numerical prediction models. Apart from increasing our understanding of the typhoon structure, the project will improve forecasting of typhoon track, intensity, and wind and rainfall distribution. The typhoon surveillance experiments will be conducted when the first typhoons of the 2003 season threaten Taiwan. The project is expected to yield impressive breakthroughs in typhoon research, forecasting, and observation when it is completed.

MC03/09A/A07-001 Invited 0900

SEASONALLY VARYING AIR-SEA INTERACTION IN THE AUSTRALIAN-INDONESIAN MONSOON

Harry HENDON (BMRC)

Dry season rainfall anomalies across Indonesia are spatiallycoherent, strongly correlated with local SST, and tightly coupled toEl Nino/Southern Oscillation (ENSO). Broad-scale Indonesian rainfalland SST anomalies tend not to persist from the dry season into the wetseason and rainfall in the heart of the wet season tends to beuncorrelated with SST and spatially incoherent. Seasonally varyingfeedback between Indonesian SST, winds and rainfall explains thegrowth, persistence and coherence of the local anomalies during thedry season and their decay or change in sign once the wet seasoncommences. During the dry season anomalous surface easterlies,remotely driven by warm SSTs in the central Pacific during El Nino,act to increase local wind speed, cooling the ocean surrounding and tothe east of Indonesia and thereby increasing the anomalous SSTgradient across the Pacific. Hence, local rainfall and the Walkercirculation are further reduced. Once the climatological surfacewinds across Indonesia shift from southeasterly to northwesterlyassociated with onset of the Australian summer monsoon, the anomaloussurface easterlies act to reduce the wind speed. The initial cold SSTanomaly is damped, reducing the negative rainfall anomalies andsurface easterlies. These eastern Indian Ocean SST changes are drivenlargely by induced surface heat flux variations (primarily changes inlatent heat flux and net short wave radiation). Biennial variationsin the Indonesian region may also be induced by this seasonallyvarying air-sea interaction associated with ENSO.

MC03/09A/A07-002 0930

MECHANISMS BY WHICH SEA SURFACE TEMPERATURE ANOMALIES PERTURB THE WEST AFRICAN MONSOON SYSTEM

Kerry Harrison COOK, Edward Kalman VIZY (Dept. Earth and Atmospheric Sciences, Cornell University)

Statistical analyses of observations demonstrate that the West African monsoon is sensitive to anomalies in sea surface temperature (SST), and that this sensitivity is related to the interannual variability of the system. An analysis of model simulations (GCM and mesoscale climate model) and the NCEP/NCAR reanalysis is used to understand how this sensitivity comes about when the SST anomalies are relatively close to the African continent. In general, the West African monsoon is more sensitive to SSTAs in the Gulf of Guinea than in the eastern Atlantic off the west coast of Africa. The reason for this difference is the background atmospheric state. In response to a warm SST anomaly, for example, the presence of large meridional temperature gradients at higher latitudes allows the atmosphere to advect cold air to balance the heating. In the tropics, however, with much smaller horizontal temperature gradients, anomalous heating is balanced in large part by adiabatic cooling, i.e., rising air. As the air rises, water vapor condenses heating the air more and amplifying the response. Because of this feedback, the sensitivity to warm SSTs is greater than the sensitivity to cold SSTs.Anomalous precipitation maxima associated with warm SST anomalies in the Gulf of Guinea do not occur over the warm SST anomalies, and they do not weaken the monsoon even though they reduce the land/seas temperature contrast. Rather, they tend to enhance the monsoon precipitation over West Africa by the introduction of higher water vapor amounts into the on-shore flow. Large-scale sinking in the middle-troposphere over the Gulf suppresses convection over the ocean and allows the moisture to accumulate in the atmosphere and be transported into the monsoons system over the land surface

---

MC03/09A/A07-003 0950

TROPICAL PRECIPITATION PATTERNS IN RESPONSE TO A LOCAL WARM SST AREAPLACED AT THE EQUATOR OF AN AQUA PLANET: AN ENSEMBLE STUDY

Kensuke NAKAJIMA[1], Yukiko YAMADA[3], Masaki ISHIWATARI[2], Yoshi-Yuki HAYASHI[3] ([1]Department of Earth and Planetary Science, Faculty of Sciences, Kyushu University, [2]Graduate School of Environmental Earth Science, Hokkaido University, [3]Division of Earth and Planetary Sciences, Graduate School of Science, Hokkaido University)

For the purpose of examining the initial development of the atmospheric response to a warm SST anomaly placed at the equator, anensemble switch-on experiment is conducted with an aqua planet GCM. Anensemble average of the size of 128 satisfactory reduces the transientnoise caused by both small scale convective activity and large scaleintraseasonal variability. A convection center develops on the SST anomaly within three daysafter the switch-on. As a barotropic (or Lamb-wave like) response tothe warming, pressure increases globally outside the low pressureregion around the warm SST area. The response after this initialglobal pressure rise is just as expected from Gill (1980); a warmKelvin wave-like anomaly is emitted to the east of the convectioncenter, and a warm Rossby wave-like anomaly is emitted to thewest. The Kelvin wave-like signal propagates at a speed quite slowerthan that expected from its vertical wavelength, suggesting that thesignal is a "moist" Kelvin wave. Transient decrease of precipitationoccurs at the front of the signal; the coupling of convection andvertical motion is consistent with its slow propagation. After several days, precipitation to the east of the warm SSTbegins to recover because of the surface frictional convergenceassociated with the Kelvin wave-like equatorial low pressure anomaly. On the other hand, precipitation to the west decreases monotonically.It seems that the continuous reduction of precipitation in the westernarea is caused by the equatorial surface frictional divergence associated with the relatively high pressure anomaly at the equator ofthe Rossby wave structure. Throughout the duration of the integration period, 50 days afterthe switch-on, zonally averaged surface pressure in the tropicscontinues to rise. At the same time, zonal mean flow in the uppertroposphere in the tropics is accelerated to become westerly. Thismass redistribution, presumably related to the wave momentum fluxcaused by planetary wave emission toward the mid-latitudes generatedat the heat source on the SST anomaly, contributes about a half of theamount of time-mean positive pressure anomaly to the west of the warm SST area.

MC03/09A/A07-004 1030

DOES THE ANOMALOUS SST LEAD TO THE CONTRASTING CHARACTERISTICS OF THE 1993 AND 1994 EASM?

Huang-Hsiung HSU, Wen-Shung KAU, Ren-Tzeng CHEN (Department of Atmospheric Sciences, National Taiwan University)

East Asian summer monsoon (EASM) in 1993 and 1994 exhibits contrasting characteristics, which resulted in the 1993 drought in Taiwan and the 1994 drought in Japan, respectively. During July and August 1993, an anomalous anticyclonic circulation and below-normal precipitation appeared over Taiwan andthe Philippine Sea, while an anomalous cyclonic circulation and above-normal precipitation appeared over Japan. The reversed situation was observed in 1994. The most contrasting sea surface temperature anomalies (SSTA) were observed in the extratropical Pacific in a zonally elongated area extending from the Japan Sea to the dateline. The relationship between the SSTA and circulation anomaliesdiffers from that often observed in the tropics. For example, the cyclonic (anticyclonic) circulation anomaly was located above the negative (positive) SSTA in 1993 (1994). The anomalous atmospheric circulation and surface heat fluxes several months before the appearance of the extratropical SSTA were in a distribution that could result in the increase and drop of the SST in 1993 and 1994, respectively. The anomalous atmospheric circulation in the extratropical Pacific during the spring and early summer might have led to the changes in SST. Two General circulation models (i.e., NTUGCM and ECHAM4) were used to simulate the contrasting 1993 and 1994 EASM by prescribing the observed SSTA. The NTUGCM was able to simulate the contrast to some extend. However, the significant difference between the ten ensemble members indicate that the different initial conditions can result in larger fluctuations than those forced by the anomalous SST. Interestingly, the ECAHM4 produced precipitation and circulation anomalies that were in opposite phase to the observed. These results suggest that the anomalous SSTA in the extratropics was more like a response than a forcing. It follows that the AMIP-type climate simulation may produce incorrect results when and where the effect of SSTA forcing is relatively insignificant. Mechanisms other than the oceanic effect seem to be responsible for the contrasting 1993 and 1994 EASM. Our recent study indicates that the anomalous circulation may be related to the anomalous heating over the Tibetan Plateau instead of over the ocean.

INTERANNUAL INDIAN RAINFALL VARIABILITY AND INDIAN OCEAN SST

Gabriel Andres VECCHI, D.E. HARRISON (JISAO, University of Washington)

Understanding and predicting interannual variability of Indian rainfall during the southwest monsoon has potential social and economic benefits, and is also a topic of scientific interest; much effort has been made to understand and predict nation-wide measures of Indian monsoon variability (e.g. All-India Rainfall). We suggest that a two-regional approach offers a useful alternative framework for understanding the interannual variability of the Indian monsoon. Indian rainfall is concentrated in two regions, each with strong area-average mean and variance in precipitation: the Western Ghats and the Ganges-Mahanadi Basin region. Over the past 23 years, rainfall over these two regions together explains 90% of the interannual variance of All-India rainfall, and interannual rainfall anomalies in each region are significantly correlated with All-India Rainfall. However, the time series of rainfall anomaly averaged over each region are uncorrelated with each other, suggesting that the interannual variability in each region is controlled by different mechanisms. We also explore statistical relationships between Indian Ocean sea surface temperature anomalies (SSTA) and precipitation anomaly over these two regions. We find strong simultaneous and leading correlations involving distinct Indian Ocean SSTA patterns, with the SSTA patterns preceding the southwest monsoon by up to nine months. Enhanced southwest monsoon precipitation in the Western Ghats is associated with warm SSTA in the Arabian Sea at the onset of the monsoon, while enhanced Ganges-Mahanadi Basin precipitation is associated with cool SSTA off the coasts of Sumatra and Java at the onset of the monsoon. Both regions are associated with leading SSTA patterns in the southern Indian Ocean, with the Western Ghats (Ganges-Mahanadi Basin) associated with warm (cool) SSTA patterns. The correlations with Western Ghats rainfall anomaly are generally robust; these relationships may contribute useful statistical forecast skill for rainfall in this region. The six and nine month lead correlations with Ganges-Mahanadi Basin rainfall are also generally robust. However, the zero-lag correlations with Ganges-Mahanadi Basin rainfall anomalies result primarily from one year with very strong SSTA and rainfall anomaly - this is not a robust statistical connection. The regional rainfall anomaly/SSTA connections are much stronger than those of All-India rainfall anomaly/SSTA. The mechanisms behind the connection at zero lag between warm Arabian Sea SSTA and enhanced Western Ghats precipitation have

been explored in the literature, but it still remains to explain the other observed relationships between SSTA and rainfall variability in these two centers of action.

OCEAN ROLES IN THE TRANSITION PHASES OF THE BIENNIAL INDIAN-AUSTRALIAN MONSOON TENDENCY

Jin-Yi YU[1], Shu-Ping WENG[2], John D. FARRARA[3] ([1]University of California, Irvine, [2]Central Weather Bureau, Taiwan, [3]University of California, Los Angeles)

This study uses a series of CGCM (coupled atmosphere-ocean generalcirculation model) experiments to examine the roles of the Indian andPacific Oceans in the transition phases of the biennialIndian-Australian monsoon tendency. In each of the three CGCMexperiments, air-sea interactions are restricted to a certain portionof the Indo-Pacific Ocean by including only that portion of the oceanin the ocean model component of the CGCM.The results show that the in-phase transition from a strong (weak)Indian summer monsoon to a strong (weak) Australian summer monsoonoccurs more often in the CGCM experiments that include an interactivePacific Ocean. The out-of-phase transition from a strong (weak)Australian summer monsoon to a weak (strong) Indian summer monsoonoccurs more often in the CGCM experiments that include an interactiveIndian Ocean. The associated sea surface temperature (SST) anomaliesare characterized by an ENSO-type pattern in the Pacific Ocean andbasin-wide warming/cooling in the Indian Ocean. The Pacific SSTanomalies maintain large amplitude during the in-phase monsoontransition in the northern autumn and reverse their sign during theout-of-phase monsoon transition in the northern spring. On the otherhand, the Indian Ocean SST anomalies maintain large amplitude duringthe out-of-phase monsoon transition and reverse their sign during thein-phase monsoon transition.These seasonally dependent evolutions of Indian and Pacific Ocean SSTanomalies allow these two oceans to play different roles in thetransition phases of the biennial tendency in the Indian-Australianmonsoon system.

CAN THE SST IN THE WESTERN NORTH PACIFIC AFFECT THE INTENSITY OF BAIU PRECIPITATION?

Sophie FUKUTOME, Christoph FREI, Christoph SCHÄR (Atmospheric and Climate Science, ETH)

Precipitation during the Japanese rainy season, named Baiu, undergoes large interannual fluctuations that justify the search for physical and dynamical processes regulating its intensity. The purpose of the present study is to examine the role played by the sea surface temperature (SST) in the Western North Pacific (WNP; 120-160°E, 20-60°N) in the interannual variability of Japan´s summer precipitation, with particular regard to its influence on lower tropospheric dynamics. To this end, numerical experiments are carried out with a regional climate model forced at its lower boundary by sea surface temperature anomalies corresponding to opposite regimes (wet or dry) of the interannual variability. Two pairs of summers with opposite behavior on the interannual scale are simulated, and subsequently repeated with exchanged SST evolutions. To assess the significance of the response signal with respect to the chaotic variability of the model, each experiment consists of a three-member ensemble with slightly modified initial atmospheric conditions. It is found that the response to SST forcing is non-linear. A wet summer forced by the SST of a dry summer experiences a decrease in precipitation over Japan of up to nearly 30%, while the opposite experiment yields no significant increase. This study demonstrates that the effect depends upon the relative position of the SST anomalies with respect to the low-level jet. While the SST distribution is unable to alter the course of the low-level jet, it can, if adequately placed, greatly affect the precipitation rate by influencing the jet´s baroclinicity, and the moisture convergence into the Baiu frontal zone. Thus, a wet summer, during which the Baiu front is located above Japan, reacts sensitively to the underlying SST, while a modification of the large-scale circulation would be necessary to bring about an equivalent response in dry years.

MC03/09A/A07-008   1150

IMPACT OF INDIAN OCEAN DIPOLE AND MONSOON VARIABILITY OVER SOUTH AND EAST ASIA : OBSERVATIONAL AND MODELING ASPECTS

Jai Ho OH, R.H. KRIPALANI, J.H. KANG (Dept. of Env, & Atmos. Sci., Pukyong National Univ., Busan, Korea)

The influence of the Indian Ocean Dipole on the summer monsoon rainfall over South Asia (India) and East Asia (China, Korea, Japan and Mongolia) has been investigated using simple statistical procedures. Long period data varying from 1869 to 2000 have been used applying correlation and composite techniques. While the observed rainfall data are used as a measure of rainfall activity, the NCEP-NCAR Reanalysis data are used to examine the circulation features associated with the extreme Dipole and the Monsoon phases over the India subcontinent, the East Asian-North Pacific sector and over Eurasia. Results reveal that the positive phase of the Dipole is favorable for following year's rainfall activity over India, China and Mongolia, but is unfavorable for the following year's monsoon activity over Korea and Japan. The relationships are more consistent and stronger for the remote Korean and Japan regions, rather than for the near Indian Ocean region.The positive (negative) phase intensifies (weakens) the monsoon circulation over the India subcontinent. Further the positive phase is associated with the weakening of the Tibetan High during the same year and the North Pacific Subtropical High in the following year. The circulation and snow distribution over Eurasia are also affected following an extreme dipole event. It is proposed to examine the physical and dynamical processes associated with the above observed tele-connections through a General Circulation Model. The model will examine the impact of the extreme phases of the Indian Ocean Dipole and the El Nino Southern Oscillation phenomenon on monsoon variability.

THE INDIAN SUMMER MONSOON-MEDITERRANEAN DYNAMICAL CONNECTION: THE CAUSE OF EUROPEAN FLOODS IN 2002?

Mike BLACKBURN, Brian HOSKINS (Department of Meteorology, University of Reading)

Our previous research has suggested that the ambient descent and lack of rain in the summer in the Mediterranean region is a dynamic response to the diabatic heating occurring in the Indian Monsoon. In the summer of 2002, the Indian Monsoon rainfall was much below normal and there was anomalous rain in Europe, with some occurring where it is normally suppressed and exceptionally heavy rain in many parts of southern and central Europe. Historical data does indeed show a correlation between summer Indian rainfall and the

intensity of the descent over southern Europe. However the correlation with southern European rainfall is less apparent. The latter is strongly correlated with North European blocking. The Indian Monsoon - Mediterranean relation will be assessed further using experimentation with idealised models.

MAINTENANCE OF SUMMER MONSOON CIRCULATIONS:A PLANETARY-SCALE PERSPECTIVE

Tsing-Chang (Mike) CHEN (Professor of Meteorology, Iowa State University)

The monsoon circulation, which is generally considered to be driven by the landmass-ocean thermal contrast, like a gigantic land-sea breeze circulation, exhibits a phase reversal in its vertical structure; a monsoon high aloft over a continental thermal low are juxtaposed with a mid-oceanic trough underlaid by an oceanic anticyclone. This classic monsoon circulation model is well matched by the monsoon circulation depicted with the observational data prior to the First GARP Global Experiment (FGGE). However, synthesizing findings of the global circulation portrayed with the post-FGGE data, we found that some basic features of major monsoon circulations in Asia, North America, South America, and Australia differ from those of the classic monsoon circulation model. Therefore, a revision of the classic monsoon theory is suggested. With four different wave regimes selected to fit the horizontal dimensions of these monsoon circulations, basic features common to all four major monsoons are illustrated in terms of diagnostic analyses of the velocity potential maintenance equation (which relates diabatic heating and velocity potential) and the streamfunction budget (which links velocity potential and streamfunction) in these wave regimes. It is shown that a monsoon circulation is actually driven by the east-west differential heating and maintained dynamically by a balance between a vorticity source and advection. This dynamic balance is reflected by a spatial quadrature relationship between the monsoon divergent circulation and the monsoon high (low) at upper (lower) levels.

DYNAMICS OF THE ATMOSPHERIC CIRCULATION ANOMALIES ASSOCIATED WITH THE NORTH AMERICAN MONSOON VARIABILITY

Mingfang TING, Renu JOSEPH (Department of Atmospheric Sciences, University of Illinois at Urbana-Champaign)

The year-to-year fluctuations of the Arizona/New Mexico (AZNM) precipitation during the month of July are examined in this study to identify the North American monsoon variability. Using the AZNM precipitation index for the years 1979 to 1998, we identified three wet (1984, 88, 90) and three dry (1994, 95, 97) monsoon years for analysis in this study. The atmospheric circulation anomalies for the wet (dry) monsoon years contain an anticyclonic (cyclonic) anomaly over the western United States at the upper troposphere. For the divergence field, there is a distinctive low level convergence (divergence) anomaly over the AZNM region associated with the wet (dry) monsoon years and opposite polarity anomalies over the central US. The maintenance mechanisms of these anomaly fields are further examined using a linear and nonlinear stationary wave model. The relative importance of the orographic forcings and the diabatic effect will be examined within the stationary wave model framework. The analysis will be extended to earlier years to increase the sample size and statistical significance.

RESPONSE OF THE ASIAN SUMMER TO CHANGES IN ENSO PROPERTIES

H. ANNAMALAI, P. LIU (IPRC/SOEST)

Of all the boundary forcings, the SST anomalies associated with ENSO have been the most dominant forcing of ASM variability. In comparison to the period 1950-75, despite the occurrence of prolonged El Nino conditions during 1991-95 and the two very strong El Ninos (1982 and 1997), the period 1977-2001 experienced weak ENSO-ASM relationship. We hypothesize that ENSO forced regional air-sea interaction in the Indian Ocean counteracts the suppressing effect of El Nino and therefore results in a weak ENSO-ASM association. The hypothesis is verified by diagnosing atmospheric reanalysis products and conducting sensitivity experiments with an Atmospheric General Circulation Model (AGCM). We show that during 1950-75 El Nino induced subsidence weakens the ASM for the entire monsoon season (May through October) but in sharp contrast during 1977-2001, El Nino induced air-sea interaction in the eastern equatorial Indian Ocean favors a stronger ASM during July-August while El Nino induced subsidence weakens it during May-June and September-October. We argue that the ENSO-ASM linkage is returning based on response of the ASM during the developing phase of the 2002 El Nino.

THE ROLE OF THE ATMOSPHERIC HEATING OVER THE TIBETAN PLATEAU IN THE FORMATION OF THE MONSOON WESTERLY

Kenji TANIGUCHI, Toshio KOIKE (Department of Civil Engineering, University of Tokyo)

This study focuses on the role of the atmospheric heating over the Tibetan plateau especially in early summer (this period is supposed to be the onset season of the Asian summer monsoon). The daily atmospheric temperature averaged from 500hPa to 300hPa layer is derived from the NCEP/NCAR reanalysis dataset. Lag correlation analysis between the time series of the air temperature over the western part of the Tibetan plateau and 850hPa p-velocity during the period of 16th march to 31st may for 1981-2000(20years) were conducted. Those results showed that there is a strong positive correlation over the Indian sub-continent and negative areas over the Arabian Sea and the Bay of Bengal. These areas with significant correlation values evidently emerge in case of positive lag, or the air temperature changes in advance of the p-velocity. These results indicatethat downward flow is formed in the positive area after the heating of the Tibetan plateau and downward flow in the negative correlation areas. The same analysis were applied between the air temperature over the western part of the Tibetan plateau and 850hPa geopotential height. The results showed that strong negative correlation region is formed in the northwestern part of the Indian subcontinent after the heating of the plateau. There is a strong atmospheric low in the monsoon season (called Monsoon trough) and the above-mentioned result indicatesthat the heating in the upper atmosphere over the Tibetan plateau can induce the formation of the monsoon trough. This low pressure region can affect the strength of the monsoon circulation and, in consequence, monsoon rainfall. At the same time, the vertical and horizontal flow were investigated by using NCEP/NCAR long term mean wind data. The seasonal progression of the Latitude-Altitude cross section averaged between 80-85E showed that a subregional circulationis formed over the Indian subcontinent, an upward flow related to the monsoon troughin the north(just below the Himaraya), and the subsidence in the south during the heating period. After the heating, this subsidence disappears. The Longitude-Altitude cross section along 15N showed that the monsoon circulation, low level westerly, is

formed in the lower atmosphere after the disappearance of the downward flow over the southern India. These results give a speculation about the formation of the monsoon westerly as follows; 1) the heating of the Tibetan plateau occurs, 2) the monsoon trough and a locally vertical small circulation (like Hadley circulation) are formed, there is a downward flow over the southern India, 3) the subsidence disappears, 4) the monsoon westerly emerges. But how the Hadley-like circulation is formed and the subsidence disappears have to be investigated in more detail.

THE ROLE OF MONSOON CIRCULATIONS IN THE DYNAMICS AND TRANSPORT OF THE TROPICAL UPPER TROPOSPHERE AND LOWER STRATOSPHERE IN NORTHERN HEMISPHERE SUMMER

Timothy J. DUNKERTON[1], Andrew GETTELMAN[2] ([1]NorthWest Research Associates, [2]National Center for Atmospheric Research)

Rotational circulations associated with convective heating in the Asian and North American summer monsoons maximize near the tropopause and are evident in stratospheric velocities and constituent transport to at least 30 hPa. Monsoon circulations also transport stratospheric air into the tropical upper troposphere owing to a relatively weak jet stream and PV gradient in NH summer. These unique circulation features are due, in part, to the large off-equatorial displacement of convective heating, and contrast sharply with the more equatorially symmetric circulation response in SH summer. While the North American monsoon in some ways is a microcosm of the Asian summer monsoon, the latter is stronger and more extensive in horizontal scale, resulting in deeper stratospheric penetration. Interesting (and provocative) differences in the distribution of water vapor and ozone are observed in connection with the two monsoon systems. Over South Asia, the monsoon creates a large pool of ozone-poor air and a moist anomaly slightly downstream. Over North America, a similar moist anomaly is observed, but ozone appears to be controlled by potential vorticity as the latter is influenced by a large-scale wave. The NH summer's unique combination of off-equatorial displacement of heating, warm ambient environment, vigorous deep convection of continental type, and forced evanescent planetary waves in creating the observed water vapor and ozone anomalies is examined with observations and a realistic CTM. Implications of these results for the water vapor tape recorder signal, upper tropospheric composition, climate and long-terms trends are discussed.

MC03/09P/A07-007   **1700**

INTERACTIONS AMONG HADLEY, WALKER AND MONSOON CIRCULATIONS OVER THE INDONESIAN MARITIME CONTINENT

Manabu D. YAMANAKA[1], Noriko OKAMOTO[2], Jun-Ichi HAMADA[3], Tien SRIBIMAWATI[4] ([1]Graduate School of Science and Technology, Kobe University, Japan / Frontier Observational Research System for Global Change, Japan, [2]Graduate School of Science and Technology, Kobe University, Japan, [3]Frontier Observational Research System for Global Change, Japan, [4]Agency for Assessment and Application of Technology, Indonesia)

The Indonesian 'maritime continent' has two climatologicalaspects. One is that this region itself plays a role of themajor heat source due to equatorial strong solar radiation(sensible heat) and high humidity from the Indo-Pacific warmwater pool (latent heat). The convection center generated thereinduces both meridional (Hadley-like) and zonal (Walker-like)circulations. The other aspect is that the region is located inthe middle of the annually-oscillating Asia-Australian monsooncirculation induced between the both hemispheres. The totalthree-types of circulations mentioned above are interacted witheach other. The convection center is shifted north-southwardpursuing the subsolar latitude, and the winter-hemisphericHadley-like cell is intensified by the monsoon circulation withthe same direction. The monsoon circulation is intensified with a Walker-type cell induced in the western side of the convection center in the summer hemisphere.The activity of the convection center (or the updraft region of the Hadley- and Walker-like circulations mentioned above) varies highly due to intraseasonal variations (ISV) propagating eastward by about 1000 km/day. The monsoon blows from the west in the backward (western) side of the first super cluster generated in southern-hemispheric summer, which opens the rainy season inthe Sunda Archipelago (Jawa, Bali and Nusa Tenggara). From the viewpoint of these interactions among the Hadley-like, Walker-like and monsoon circulations through ISVs, interannual variations such as the El Nino southern oscillation (ENSO) in the Pacific, the so-called dipole mode events (DME) in the Indian Ocean and some quasi-biennial-oscillation (QBO) like variations are discussed.

MC03/09P/A07-008   **1720**

A COUPLED GCM STUDY ON THE EFFECT OF MOUNTAIN UPLIFT ON ASIAN MONSOONS

Akio KITOH (Climate Research Department, Meteorological Research Institute)

Asian monsoon is greatly affected by the existence of mountain. To study the effect of progressive mountain uplift on East Asian climate, a series of coupled GCM experiments were performed. We used eight different mountain heights: 0% (no mountain), 20%, 40%, 60%, 80%, 100% (control run), 120%, and 140%. The MRI-CGCM2 has been integrated without flux adjustments for 50 years for each run, for which the last 40 years data are analyzed. Systematic changes in precipitation pattern and circulation fields as well as sea surface temperature (SST) appeared with progressive mountain uplift. In the summertime, precipitation area moves inland of Asian continent with mountain uplift, while the Pacific subtropical anticyclone and associated trade winds become stronger. The June mean precipitation in Japan was most close to the observations at the 80% mountain height case. The model has reproduced a reasonable Baiu rain band at the 60% case and higher. There was saturation in precipitable water amount over the Asian monsoon region at the 80% case. This is associated with the maximum western Pacific warm pool SST at the 80% case due to compensating effects of ocean dynamics and evaporative heat loss, thus warranting an importance of air-sea coupling and a need for use of coupled models for such sensitivity studies.

MC03/09P/A07-009   **1740**

RELATIONSHIPS BETWEEN WINTER AND SUMMER MONSOONS OVER EAST ASIA

Man Chi WU, Johnny C.L. CHAN (Laboratory for Atmospheric Research, Dept. of Physics & Mat. Sci., City University of Hong Kong)

The relationship between winter and summer monsoons over East Asia is examined using 40 years of NCEP/NCAR reanalysis data as well as station data of rainfall. The intensity of the winter monsoon is labelled as strong, normal or weak based on the unified monsoon index defined by an earlier study while the summer monsoon is classified into one of three patterns. Beginning with each winter, the summer patterns before and after are then identified so that a number of groups can be established. In general, a strong winter

---

monsoon is preceded (followed) by a summer pattern in which rainfall is generally more abundant over southern and northern China (the Type I pattern used by Chinese meteorologists). However, for a weak winter monsoon, the preceding summer pattern is not unique. After a strong winter monsoon, the following summer is likely to be one in which rainfall is above normal in central China or south China Type II or III). On the other hand, the summer following a weak winter monsoon is likely to have the Type I pattern, and thus a quasi two-year cycle. However, this cycle can be modified by the occurrence of the El NiOo or La NiOa.

POTENTIAL PREDICTABILITY OF THE SOUTH AMERICA SUMMER MONSOON

William K. LAU, Kyu-Myong KIM (Laboratory for Atmospheres, NASA/GSFC, Code 910)

We have developed a canonical ensemble correlation (CEC) methodology to maximizes potential predictability from various predictors based on hindcast skills. In this paper, we use CEC to estimate and to explore the We have developed a canonical ensemble correlation (CEC) methodology to maximizes potential predictability from various predictors based on hindcast skills. In this paper, we use CEC to estimate and to explore the dynamical controls of potential predictability of seasonal rainfall over South America, with particular emphasis on the South American Summer Monsoon (SASM) It is found that the tropical eastern Pacific and the tropical Atlantic contribute by far the largest fractions of the potential predictability in the tropical land regions (north of 20o S). Potential predictability is highest over the northeastern region during MAM, with the dominant contribution coming from the tropical Atlantic associated with meridional SST across the equator. The second highest potential predictability is found in the northwestern region including Columbia, Venezuela and northern Brazil in DJF with most of the contribution from the tropical Pacific, associated with El Nino. In the La Plata Basin (LPB), potential predictability is derived from the tropical Pacific in NDJ, associated with the onset of the SASM. Interestingly, during DJF and JFM, the dominant influence on LPB rainfall switches to the South Pacific, suggesting the influence of teleconnection wavetrains associated with the fluctuation of the SACZ. Compared to aforementioned continental scale regions, much reduced potential predictability in seasonal rainfall is found in the interior of the Amazon in all seasons, and along the west coast region of Chile in the subtropics and extratropics for all seasons. The dynamical controls on potential predictability for the SASM, including remote forcing, as well as interactions with and among regional feedback processes will be discussed.

REGIONAL MODULATIONS OF THE SOUTH AMERICAN MONSOON PRECIPITATION

Ernesto Hugo BERBERY[1], Estela A. COLLINI[2] ([1]Department of Meteorology, University of Maryland, [2]Servicio de Meteorologia de la Armada Argentina)

The South American monsoon precipitation is part of a complex climate system that affects large portions of southeastern South America. A second precipitation regime further south tends to show an inverse relation with the core monsoon, so that an increase of precipitation in one implies a reduction of precipitation in the other. This out-of-phase variability or dipolar behavior has been observed in a broad range of frequencies, from daily to interannual. Moreover, it has important consequences for the hydrology of La Plata, a basin in southeastern South America, since the location and character of the floods depends on whether one or the other regime is more active. A multiyear data set of Eta model short-term forecasts is employed as a proxy of regional analyses to investigate the mesoscale processes contributing to the functioning of the dipole and its seasonality. The Low-level Jet (LLJ) east of the Andes has a significant role in this pattern modulation as it experiments lateral shifts during the warm season. When the LLJ has an eastward shift, it can supply moisture directly to the monsoon region, and increased precipitation is detected over the northern part of the La Plata basin. Meanwhile, the moisture supply to the center of the basin becomes weaker and a simultaneous decrease of precipitation is found. When the jet shifts west, its core acquires a southward direction, effectively reducing the moisture supply to the monsoon but increasing it to the other center of the dipole with the corresponding changes in precipitation. Land surface-atmosphere interactions that modulate the precipitation dipole are inspected using short and long term simulations of the Eta model. On time scales of about two weeks and longer, increased soil moisture is associated with a decrease of the sensible heat and an increase of the latent heat, which results in a lower Bowen ratio (increased evaporative fraction) and increased precipitation. The above sequence suggests a positive feedback between soil moisture and precipitation.

MC03/10A/A07-003   **0930**

SALLJEX-BRASIL: THE BRAZILIAN COMPONENT OF THE SOUTH AMERICAN LOW LEVEL JET (SALLJEX) FIELD EXPERIMENT DURING DECEMBER 2002-FEBRUARY 2003

Jose A. MARENGO[1], Tercio AMBRIZZI[2], Iracema Fonseca CAVALCANTI[1], Manoel Alonso GN[1], Gilberto Fernando FISCH[3], Luiz Augusto MACHADO[3], Marcelo Enrique SELUCHI[1], Maria Assuncao SILVA DIAS[2], Pedro Leite SILVA DIAS[2], Javier TOMASELLA[1] ([1]CPTEC/INPE, [2]IAG/USP, [3]IAE/CTA)

The SALLLJEX-Brasil field experiment is part of a broader international research agenda of the Variability of American Monsoon Systems (VAMOS) and its component Monsoon Experiment in South America (MESA), wich are sponsored by the Climate Variability and Predictability (CLIVAR). The field experiment is also relevant to the observational and scientific activities in the continental scale experiment basins of the hydrographic basins that includes the Amazon and La Plata River basins. In the context of VAMOS and MESA, the regional experiment on South American Low Level Jet East of the Andes (SALLJEX) is basically dedicated to field observations and modeling studies of moisture transport between the Amazon and La Plata basins. There are some observational evidences as well as modeling studies that show that the Low Level Jet East of the Andes (hereafter, LLJ) is responsible for most of the moisture and energy transport between these two basins. The SALLJEX field experiment has regional components in each country involved (Argentina, Bolivia, Chile, Paraguay, Peru, Uruguay and United States). This abstract describes SALLJEX-Brasil, and the observational and modeling studies developed during the December 2002-February 2003 campaign. A science team involving scientists from Brazil, USA, Bolivia, Argentina, Paraguay and Peru is working on the analysis of series of detailed and high resolution surface, upper-air and remote sensing observation, in order to answer this science question: What is the role of the LLJ on the moisture transport from the Amazon to the La Plata basins? More specific science issues include: the synoptic variability of the:LLJ; the spatial structure and time variability from diurnal to intraseasonal time scales; the role of the of the LLJ in the intraseasonal variability of precipitation along the South Atlantic Convergence Zone; the role of the LLJ in the dynamics of the Mesoscale Convective

Complexes over the La Plata Basin; the interuannual variability of the LLJ; the dependence of the LLJ in relation to SST anomalies in the Pacific and Atlantic; the representation of the LLJ in atmospheric models; and the coupling between the occurrence or not of LLJ episodes and rainfall in the Andean region, east of the Andes, and southern Brazil-northern Argentina. The extension and upgrading of the current observational network will allow for better and more frequent surface and upper-air directed towards a better understanding of the LLJ, based on a combination of observation and monitoring of circulation and fluxes associated to the LLJ, complemented by regional and global models.

MC03/10A/A07-004   0950

LA NINA IMPACT ON SUMMER MONSOON IN BRAZIL: LARGE-SCALE INFLUENCES, REGIONAL PROCESSES AND ATLANTIC SST VARIATIONS

Alice Marlene GRIMM (Department of Physics, Federal University of Parana)

The rainy season in most of Brazil is associated with the summer monsoon regime in South America. The quality of this season is important because it rains little during the rest of the year over most of the country. In this study, the influence of La Nina events on the summer monsoon circulation, rainfall and temperature is analyzed with seasonal and monthly resolution, using data from a dense network of stations, giving a comprehensive view of the impact of these events. The expected precipitation percentiles during the monsoon season of La Nina events are calculated, as well as anomalies of surface temperature and thermodynamic parameters. This information is analyzed jointly with anomaly composites of several circulation parameters. There are abrupt changes of anomalies within the summer monsoon season, suggesting the prevalence of regional processes over remote influences during part of the season. In spring there are positive precipitation anomalies in north and central-east Brazil and negative ones in south Brazil. These precipitation anomalies are favored by the perturbation in the Walker and Hadley circulation over the eastern Pacific and SA, and by a Rossby wave-train over southern South America. Northerly moisture inflow from the Atlantic is favored into northern South America, and diverted towards the mouth of the Amazon by the low-level cyclonic anomaly north of the equator. In December (0) and January (+), probably triggered by anomalous surface cooling during the spring, there is an anomalous low-level divergence and an anticyclonic anomaly over southeast Brazil. This anomalous circulation directs moisture flux towards south Brazil, causing moisture convergence in part of this region and part of central-west Brazil. The thermodynamic structure in central-east Brazil does not favor precipitation over this region, and the wet anomalies in north Brazil are displaced northward. The dry anomalies in south Brazil almost disappear and even turn positive. In February (+), after the strongly below normal precipitation of January, the surface temperature anomalies turn positive over southeast. The low-level anticyclonic anomaly is much weaker than in January (+). There are positive rainfall anomalies in north Brazil and in the SACZ, and negative ones return to south Brazil. The intraseasonal variations of the La Nina impact are accompanied by SST variations off the southeastern coast of Brazil. It is not clear whether surface-atmosphere and land-ocean interactions favor the predominance of regional circulation anomalies over large scale perturbations in January or whether the atmospheric basic state in January is conducive to perturbations different from the other months in summer, leading to enhanced rainfall in Central-East Brazil.

INFLUENCE OF LAND SURFACE ON TRANSITIONFROM DRY TO WET SEASON OVER SOUTH AMERICA

Rong FU, Wenhong LI (Earth & Atmospheric Sciences, Georgia Institute of Technology)

Our analysis of the fifteen years of European Center for Medium Range Forecast (ECMWF) reanalyses suggests that the transition from dry to wet season in the Southern Amazon is mainly driven by increases of surface latent flux and consequently local thermal-driven precipitation. The latter triggers the reversal of the cross-equatorial flow, leading to large-scale net moisture convergence to the Southern Amazon. The analysis of early and late wet season onsets on an interannual scale shows that a longer dry season with a lower rainfall causes lower surface latent flux in the dry and earlier transition periods, compared to those observed before a normal wet season onset. This results in a higher Convective Inhibition Energy (CINE) and a lower Convective Available Energy (CAPE). These delay the increase of local thermal-driven rainfall in the initiating phase of the transition and consequently wet season onset. Conversely, a wetter dry season leads to a higher surface latent flux and weaker CINE. These promote an earlier increase of local thermal-driven rainfall and thus an earlier wet season onset. Our results imply that removal of the Amazon rainforest, which probably leads to a much drier surface during dry and transition seasons, could significantly delay the wet season onset and prolong the dry season.

DYNAMICS AND VARIABILITY OF THE SOUTH AMERICAN MONSOON SYSTEM

Carlos Roberto MECHOSO (Department of Atmospheric Sciences, University of California, Los Angeles, USA)

The warm season circulation over South America includes the second largest monsoon system in the world. This South American monsoon (SAM) affects large parts of the continent over which it develops, their population, agriculture, and economies. As in all monsoons, ocean-continent contrasts are of fundamental importance. This presentation starts with SAM's climatology. The evolution during spring and summer of the region of intense convection over South America, establishment of the monsoon high over Bolivia, and development of the South Atlantic Convergence Zone (SACZ) are described. A strong low-level jet along the eastern slopes of the Andes is introduced and shown to be a key contributor to the moisture flux from the tropics to the mid-latitudes. The role of South American orography on the dynamics of outstanding monsoon components is discussed. Next the presentation focuses on SAM's variability. There is compelling evidence that ocean-atmosphere interactions involving the Pacific and Atlantic oceans play a major role in determining the variability of SAM in several time scales, particularly the interannual but also in the interdecadal. In reference to the SACZ, its variability is linked to sea surface temperature anomalies in the tropical Pacific and North Atlantic, and in the southern subtropics of this ocean.

MC03/10A/A07-007   1110

A POSITIVE FEEDBACK PROCESS FOR MAINTAINING THE PRECIPITAION OF THE SACZ

Yasu-Masa KODAMA (Department of Earth and Environmental Sci. Hirosaki University)

The SACZ (South Atlantic convergence zone) is a significant precipitation zone which stretches from the active rainfall area developed over the Amazon Basin in summer. The SACZ is one of the elementary features of the South American monsoon system (Zhou and Lau, 1998). The rainfall over the Amazon, which is a strong atmospheric heat source, largely contributes to maintaining the SACZ (Kodama, 1993; Figueroa et al., 1995; Mattews, 1996). In this paper, we´d like to remark that the SACZ is not a simple slave of the Amazonian rainfall, but the rainfall along the SACZ also may play as a heat source to maintain the SACZ. Low-level northerly along the western edge of the subtropical high over the South Atlantic is important for maintaining the SACZ, because the northerly supplies much moisture and forms low-level convergence (Kodama, 1993). The northerly is considered as a part of monsoon circulation surrounding the monsoon heat low over the South America (Kodama, 1992). We performed vorticity budget analysis using the NCEP reanalysis data. The results suggest that the strong atmospheric heating along the SACZ also may intensify the low-level northerly. The heating maingtained by the rainfall along the SACZ forms an updraft along the SACZ. This updraft intensifies the cyclonic vorticity in the lower troposphere by the stretching process. Actually a low-level weak trough is observed along the southwestern side of the SACZ. SLP gradient, and combined northerly, are then intensified along the northeastern side of the SACZ. Note that the low-level trough is not strong in spite of the strong heating. This is because the vorticity generation by the stretching is canceled out by southward advection of lower absolute vorticity from the tropics by the northerly. This suggests that the northerly is partly maintained by the updraft along the SACZ, as a result of vorticity balance between the stretching and the poleward vorticity advection. A positive feedback may exist in rainfall activity of the SACZ, because the moisture supply by the northerly intensifies the rainfall, and the combined updraft, which may intensify the northerly. We will also show some results of AGCM experiments to reinforce this idea.

MC03/10A/A07-008   1130

ANALYSIS AND FORECAST OF THE MONSOON SYSTEM DURING A PERIOD OF THE SOUTH AMERICA LOW LEVEL JET EXPERIMENT IN JANUARY 2003

Iracema Fonseca CAVALCANTI[1], Pedro Leite SILVA DIAS[2], Maria Assuncao SILVA DIAS[2], Celeste SAULO[3], Matilde NICOLINI[3], Jose Antonio MARENGO[1] ([1]CPTEC/INPE, [2]IAG/USP, [3]UBA)

The monsoon system over South America is analyzed for January 2003, mainly for the period of 22-29 January 2003, during the South America Low Level Jet Experiment (SALLJEX). During this period there were several typical events, such as development of a CCM associated with LLJ over northern Argentina and with the passage of a frontal system; occurrence of the SACZ; occurrence of the Upper Level Cyclonic Vortex (ULCV) over Northeast Brazil; and prediction for a LLJ in the beginning of February. The synoptic situation during the period and the model forecasts are discussed based on results of several global and regional models (ETA, RAMS, LAM-CIMA, NCEP, NASA, UK MetOffice and CPTEC). The variability of the monsoon system can be seen, alternating cases of SACZ and LLJ as part of the intrasazonal cycle. In the beginning of the period a CCM developed ahead of a frontal system over Argentina. A LLJ case could be detected in the analysis. The ULCV started the development over Northeast and the frontal system moved toward southeastern Brazil, when strong southerlies developed over Argentina and Bolivia, reaching the Amazon Region. Another period of SACZ occurred, after a cyclogenesis development over Southern Brazil. The cloudiness band was well organized over central South America and the southern region had clear skies. This is consistent with several studies which show the opposite sign between central-east and southern South America. At the end of the period, there was a strong amplified trough over South America, and the Bolivia High continued displaced westward over the Pacific Ocean. The models were predicting the occurrence of a LLJ in the beginning of February, when the SACZ dissipates. Forecast models in general were able to forecast the general characteristics of the systems. However, there are significant differences in timing and intensity which are described and analysed.

MC03/10A/A07-009   1150

MODEL SIMULATION OF MOISTURE CONVERGENCE IN THE NORTH AMERICAN MONSOON

David A. SALSTEIN (Atmospheric and Environmental Research, Inc.)

From simulations over North America, we examine the ability of atmospheric general circulation models, principally those participating in the second phase of the Atmospheric Model Intercomparison Project, to reproduce observed moisture patterns in the regions of interest to the North American Monsoon Experiment (NAME): Precipitation, as well as overall moisture convergence start in the spring in low latitudes, and advance northward through western Mexico and reaching part of the southwest United States, with a maximum northward extent in August. This moisture convergence pattern then retreats back to its original location by the middle of the autumn. The AMIP models under consideration have mixed success in simulating this monsoon circulation, and the ability of a model to simulate the intensity and extent of the advance/retreat of the monsoon appears to be tied at least in part to its land surface scheme. Over a broader region, that is the conterminous United States, the summer season is instead a period when it is a moisture source region, and moisture divergence then is well captured by the ensemble of AMIP models there. In the NAME regions, the interannual variability of the moisture divergence simulation is of comparable magnitude to that of the observed but the phase is difficult to capture; the broader US area appears related to the phase of the El Nino-Southern Oscillation, and easier to simulate by the general circulation models, which react more successfully to large-scale forcing. Higher resolution models when available will be compared to additional observational data sets with the goal of establishing a relationship between resolution and success in capturing details of moisture divergence patterns of the monsoon circulation.

SUBTROPICAL MONSOONS IN EASTERN NORTH AMERICA AND EAST ASIA

Brian E. MAPES (Climate Diagnostics Center)

East Asian monsoon rains in late spring (known as Mei-Yu, Baiu, and Changma in China, Japan, and Korea) have a little-known analogue in southeastern North America. Both monsoon systems extend offshore many thousands of kilometers, but the western end of the east Asian monsoon system affects east Asian landsand hence has been extensively studied. The corresponding North American monsoon system is almost totally located offshore, affecting only Caribbean islands and the southern half of Florida. A comparative depiction of these two eastern-continent monsoon systems is presented. The subtropical circulation systems associated with the rains involve a complex blend of tropical and extratropical dynamics. The relative roles of circulationfeatures at upper levels (jets and their secondary circulations) and lower levels (subtropical highs in the western oceans) arestill unclear. We attempt to deduce more about the dynamics of these subtropical monsoons from the mean annual cycle in observations and 13 GCMs, as well as from observed interannual variability.

DATA ARCHIVES TO SUPPORT MONSOON SYSTEMS RESEARCH

Scot M. LOEHRER[1], Steven F. WILLIAMS[1], Jose G. MEITIN[2] ([1]Joint Office for Science Support, University Corporation for Atmospheric Research, [2]National Oceanic and Atmopsheric Administration/National Severe Storms Laboratory)

The University Corporation for Atmospheric Research/Joint Office for ScienceSupport (UCAR/JOSS) supports data management activities for a variety ofmonsoon related field projects around the globe. These include the Pan American ClimateStudies (PACS), Variability of the American Monsoon Systems (VAMOS), East Pacific Investigation of Climate Processes in the CoupledOcean-Atmosphere System 2001 (EPIC2001), and the proposed North American Monsoon Experiment (NAME). To support these projects UCAR/JOSS conducts a variety of datamanagement activities ranging from the planning and preparation of datamanagement plans, to the data collection, processing, quality assurance, archival and dissemination to support projectresearchers. In addition UCAR/JOSS is providing support to the World Climate ResearchProgramme (WCRP) Coordinated Enhanced Observing Period (CEOP) project. One of CEOP´s scientific objectives is to document the seasonal march ofthe monsoon systems, assess their driving mechanisms, and investigatetheir possible physical connections. To support this objective CEOP hasidentified a number of well instrumented ˝reference sites˝ in tropicalregions. UCAR/JOSS takes the data from each of these reference sitesand develops a quality assured hourly resolution ˝composite˝ data setin a uniform format. The initial data set for CEOP covers the periodfrom 1 July to 30 September 2001 and three additional annual cycledata sets are planned to follow over the period from October 2001 toSeptember 2004. This presentation will summarize these activities andprovide an overview of these various project databases.

MC03/10P/A07-003   1440

NORTH AMERICA MONSOON WINDS AS SEEN FROM QUICKSCAT

Simona BORDONI[1], Bjorn STEVENS[1], Timothy LIU[2] ([1]Department of Atmospheric Sciences, University of California Los Angeles, Los Angeles California, USA, [2]Jet Propulsion Laboratory, Pasadena California, USA)

Northward surges of relatively cool, moist maritime air from the Tropical Pacific into the Southwestern United States occur along the Gulf of California every summer during the North America monsoon season. These surges are believed to be strongly connected to the amount of convective activity in Arizona and northwestern Mexico. Lack of adequate lower tropospheric observations over northern Mexico and southwestern Arizona has hampered a definitive assessment of the role that gulf surges play in controlling the onset, the intensity and the variability of the NAM. In this paper, we use three year High Resolution Quickscat Data to study surface winds over the Gulf of California, to identify surge events and to study their relationship to monsoon activity. The 12.5-km resolution data set used in this study, derived from range compressed backscatter measurements, using the Direction Interval Retrieval with Threshold Nudging (DIRTH) method, have better spatial resolution and are more conducive to coastal studies than the standard QuickScat wind products (25 km resolution). Previous observations mainly collected during the SWAMP campaign havesuggested the existence of a persistent time-mean southerly wind over the Gulf of California, believed to be the primary means of moisture transport to the arid southwest deserts. At odds with these observations, high resolution QuickScat data reveal a weak mean northerly flow over the Gulf of California during the monsoon months, with an up-slope component to the Western Flank of the Sierra Madre Occidental. Gulf Surges are identified with abrupt wind reversals from northerly to southerly flow. This result seems to suggest that the primary mechanisms by which moisture is transported into the monsoon region is through transient processes rather than through the average mean flow and supports the hypothesis that gulf surges are strongly related to the beginning of monsoon bursts periods. Given such predominant role of transient effects, we propose a new Monsoon Index, based on the frequency and intensity of gulf surge occurrences from QuickScat data. Such index can be viewed as a measure of the overall strength of the North America Monsoon and can be used to identify the monsoon onset and to highlight the monsoonal variability, both on intraseasonal and inter-annual time scales.

MC03/10P/A07-004   1520

VARIABILITY IN EAST PACIFIC MONSOONAL CONVECTION OBSERVED IN EPIC2001

David J. RAYMOND[1], G.B. RAGA[2], Christopher S. BRETHERTON[3], Simon DESZOEKE[3], John E. MOLINARI[4] ([1]Physics Department, New Mexico Tech, [2]Centro de Ciencias de la Atmosfera, Universidad Nacional Autonoma de Mexico, [3]Dept. of Atmospheric Sciences, Univ. of Washington, [4]Dept. of Earth and Atmospheric Sciences, SUNY Albany)

A strong cross-equatorial sea surface temperature (SST) gradientoccurs in the east Pacific during the northern summer and fall, withwarmer SSTs north of the equator. During the late winter and earlyspring this gradient relaxes to near-zero, but does not reverse. Theresult is a cross-equatorial atmospheric circulation which variesseasonally, giving it a monsoon-like character, but not a completereversal on a seasonal basis. In other words, there is a strong SWmonsoon, but little or no NE monsoon. The low-level cross-equatorialflow up the SST gradient is remarkably steady in the northern summer.However, the convection observed over the Mexican warm pool in themonsoonal region is quite unsteady. One of the goals of the EPIC2001field program was to understand the origin of this variability.Intensive observations were made of convection in a 4 degree by 4degree box centered on 95 W, 10 N in September and October of 2001.Under normal circumstances this region is shielded from the NEtradewinds by the high terrain of southern Mexico and Central America,resulting in light surface winds. Little deep convection occurs underthese conditions, even though SSTs can be 28 C or greater. However,EPIC2001 observed two situations in which ample deep convection canoccur: (1) Under certain conditions strong flows through gaps in thehigh terrain to the north and east can impinge on warm pool. Suchevents have been studied extensively by Joe Zehnder and colleagues. (2) Westerly winds above the boundary layer are associated with thenorthward extension of the southwesterly monsoon flow, which resultsin stronger than normal winds over the Mexican warm pool. Thisapparently occurs because the geostrophic pressure gradient associatedwith these westerlies adds to the SST-induced pressure gradient whichdrives the climatological cross-equatorial flow -- easterlies have theopposite effect of suppressing the southwesterlies over the warm pool.Both of these situations result in stronger than normal total surfaceheat flux, which has been shown to be the primary forcing mechanismfor deep convection in this region. Examination of time series ofzonal winds near 850 mb at 95 W, 10 N shows that westerly wind pulsesat 5-6 day intervals are associated with westward-moving tropical wavedisturbances, many of which intensify into tropical storms. However,such tropical wave activity appears to be modulated at longer timescales by episodes of easterly and westerly winds, possibly associatedwith the MJO or other eastward-moving disturbances, as noted byMolinari and colleagues and by Maloney and Hartmann. EPIC2001 wasable to observe both easterly and westerly phases of this modulation.During the easterly phase, the low-level southwesterlies terminatedfurther south than normal and little tropical wave activity occurred.

MC03/10P/A07-005   Invited   1600

ROLE OF LAND SURFACE PROCESSES IN MONSOON DEVELOPMENT: EVIDENCE FROM EAST ASIAN AND SOUTH AMERICAN MONSOON SIMULATIONS

Yongkang XUE[1], Hann-Ming JUANG[4], Weiping LI[2], Fernando DE SALES[2], C. Roberto MECHOSO[3], Stephen D. PRINCE[5], Ruth DEFRIES[5], Carlos NOBRE[6] ([1]Department of Geography, Department of Atmospheric Sciences, University of California, Los Angeles, [2]Department of Geography, UCLA, USA, [3]Department of Atmospheric Sciences, UCLA, USA, [4]NCEP, NOAA, Camp Springs, USA, [5]Department of Geography, University of Maryland, USA, [6]CPTEC/INPE, Brazil)

Monsoonal systems provide the water for agriculture in the world´s most populous regions, yet an understanding of the mechanisms that govern the development of monsoons has been elusive. We present evidence for the importance of exchanges of water and energy between the land surface and the atmosphere for simulations of precipitation and circulation for the 1987 East Asian (EA) and South American monsoon systems (SAMS). We compare simulations by a NCEP general circulation model (GCM) coupled with two different land surface parameterizations, a two-layer soil model with no explicit vegetation representation (Referred to as SOIL), and a more comprehensive biophysical model (SSiB). The results show that feedbacks between vegetation and the atmosphere are crucially important for proper simulation of intra-seasonal monsoon evolution, including its intensity, the spatial distribution of precipitation, and associated circulation at the continental scale. In the EA monsoon simulations with the NCEP GCM/SOIL model, the moisture transport and precipitation at the monsoon onset were too strong. During the monsoon evolution, although its simulation generally produced a wet season, an important EA monsoon feature, the abrupt monsoon northward jump, was missing. With the coupled GCM/SSiB model, the monsoon evolution process, including the abrupt northward jump, was correctly simulated. SSiB produced very different surface thermal heating than SOIL. The longitudinal gradients of sensible heat flux at surface and temperature at low atmospheric levels were much stronger in GCM/SSiB simulations than in GCM/SOIL, which caused differences in moisture transport and may have triggered the jump. SAMS starts developing in Central America and then moves southeast towards the Amazons in South America. Afterwards, the largest precipitation moves northward and eventually retreats northwest. NCEP GCM/SOIL and NCEP GCM/SSiB also produced substantially different evolution and spatial distributions of SAMS. In the SAMS simulation, the GCM/SOIL model did not produce a clear southward movement of the precipitation in pre-monsoon season. Instead, it produced a very strong and early northward SAMS movement. The precipitation in the wet season monsoon was also too intense. The coupled GCM/SSiB model correctly simulated the monsoon evolution. To understand the mechanisms that contributed to the differences in the SAMS simulations, the surface energy and water balances were analyzed. The NCEP/SSiB produced different spatial distributions of surface sensible and latent heat fluxes than the NCEP GCM/SOIL. These differences were consistent with changes in the circulation and the improvements in the simulation of SAMS. In the pre-monsoon stage, land surface processes influenced the flow divergence over Central America. In the monsoon maturation stage, they also influenced the simulations in South Atlantic Convergence Zone. The results reveal that in addition to low frequency mean forcings, such as the monthly mean albedo, from the land surface that affect the atmosphere, the perturbation processes of vegetation forcing that have much shorter time scales, which are described by a biophysical model, are also important to the simulation of the monsoon system. The results suggest that processes affecting these feedbacks such as land cover change can, in turn, alter the timing and spatial patterns of monsoons.

MC03/10P/A07-006   1640

THE DIURNAL CYCLE OF CONVECTION OVER THE NORTHERN SOUTH CHINA SEA DURING SCSMEX

Richard H. JOHNSON, Steven L. AVES (Department of Atmospheric Science)

During May and June 1998, the South China Sea Monsoon Experiment (SCSMEX) was conducted tostudy the onset of the East Asian monsoon. As part of SCSMEX, a special radar and soundingnetwork was established over the South China Sea (SCS) to document characteristics ofconvection and changes in the circulation accompanying the monsoon onset. There were tworainy periods during SCSMEX, each approximately ten days long, one in mid-to-late Mayat the time of onset and the other in early June. Data from the BMRC C-POL radarwere available for all of the first of these periods, but only for a portion of thesecond. Six-hourly soundings taken at a number of sounding sites in the northern SCS havebeen used to determine the kinematic fields, apparent heat source, and apparent moisturesink over the northern SCS during the monsoon onset as well as to partially resolve thediurnal cycle of convection.Preliminary analyses of SCSMEX data over a large area in the northern SCS reveal amorning maximum in rainfall, consistent with findings for other tropical oceanicregions. The findings show good agreement between estimates of rainfall rate fromthe moisture budget and those from NASA´s Tropical Rainfall Measuring Mission (TRMM)precipitation radar (PR) and microwave imager (TMI). However, further analysis reveals that this diurnal cycle is not so simple. Specifically,there is a variation in the phase from an early-morning maximum near the South China coastto a mid-day maximum near Dongsha Island about 200 km to the south (as observed by C-POLand rain gauge data). Thus, there is a propagation of convection southward away fromshoreline, as has been observed over the Bay of Bengal by Yang and Slingo (2001) andZuidema (2002). This propagation is seen in both the radar and Japanese GMS satellitedatasets. We will explore whether this propagation is consistent with the idea recentlyput forth by Mapes et al. (2002) that offshore convection is a response to a diurnalgravity wave generated by the diurnally oscillating heat source of the daytime mixed layerover the land of south China, a wave which propagates offshore at 15--20 m /s. Thermodynamic and wind data from the six-hourly soundings along the south China coast andDongsha Island should help analysis of the wave structure, if it exists. Alternatively, itis possible that the propagation is a result of downdraft outflows from deep convection,i.e., gravity current dynamics. Changes in the structure of the convective systems as the propagateoffshore will be explored using the radar dataset.

MC03/10P/A07-007   1700

CASE STUDY OF THE BAY OF BENGAL MONSOON CONVECTION ON THE ONSET OF THE SOUTHERN CHINA SEA SUMMER MONSOON

Yimin LIU[1], JOHNNY C.L. CHAN[2], Jiangyu MAO[1], Guoxiong WU[1] ([1]LASG, Institute of Atmospheric Physics, [2]Laboratory for Atmospheric Research, Department of Physics and Materials Science, City University of Hong Kong)

Assimilated analysis fields from the South China Sea Monsoon Experiment and the outgoing longwave radiation data from the National Center for Atmospheric Research (NCAR) have been employed to describe the large-scale and synoptic features of the subtropical circulation during the Bay of Bengal (BOB, 6-20°N, 80-100°E) and South China Sea (SCS, 7-20°N, 110-120°E) monsoon onsets in 1998. The results show that the Asian monsoon onset during May 1998 exhibited a typical eastward development from the BOB region to the SCS domain. The weakening and retreat of the subtropical anticyclone from SCS were preceded by the intrusion of westerlies and the development of convective activities over the northern

part of the SCS (NSCS, 15-20°N, 110-120°E). As the vertical shear of zonal wind changes in sign, the ridge surface of the subtropical anticyclone tilted northward and the summer pattern was established over the SCS. Based on these observational results, version 4 of the NCAR climate model (CCM3) is used to investigate the physical link between the convection associated with BOB monsoon vortex and the SCS summer monsoon onset, as well as the mechanism of the evolution of the low-level subtropical anticyclone over the SCS.Introduction of heating over the BOB results in vigorous convection over the BOB, and the BOB monsoon onset, as well as the development of westerlies and vertical ascent over the NSCS region due to an asymmetric Rossby-wave response. Together with the low-level moisture advection, convection is induced over the NSCS. It is the condensation heating over the NSCS that causes the overturning of the meridional gradient of temperature over the SCS. Consequently the subtropical anticyclone in the lower troposphere over the SCS weakened gradually. Eventually as convection develops over the entire SCS domain, the subtropical anticyclone moves out of the region.

MC03/10P/A07-008   1720

DIURNAL CYCLE OF MOVEMENT OF CONVECTIVE CLOUD SYSTEMS OVER SUMATERA ISLAND

Namiko SAKURAI[1], Fumie MURATA[1], Manabu D. YAMANAKA[6], Hiroyuki HASHIGUCHI[3], Syuichi MORI[2], Jun-Ichi HAMADA[2], Yudi Iman TAUHID[2], Tien SRIBIMAWATI[4], Budi SUHARDI[5] ([1]Graduate School of Science and Technology, Kobe University, Japan, [2]Frontier Observational Research System for Global Change, Japan, [3]Radio Science Center for Space and Atmosphere, Kyoto University, Japan, [4]Agency for the assessment and application of technology, Indonesia, [5]Indonesian Meteorological and Geophysical Agency, Indonesia, [6]Graduate School of Science and Technology, Kobe University, and Frontier Observational Research System for Global Change, Japan)

Diurnal cycles are especially dominant in the tropics. This presentation introduces a diurnal cycle of movement of convective cloudsystems over Sumatera Island in Indonesia and surroundings analyzed with GMS IR data from May 2001 to April 2002. Sumatera Island is about 1,500km in length in the northwest-southeast direction across the equator,and there are mountainous districts in the western part and plains inthe eastern part. Convective activities start getting active in thewestern part of Sumatera Island in the afternoon, and the areas whereconvections are active migrate westward and/or eastward at a distance ofseveral hundreds kilometers from midnight to morning. Such diurnal cycle of migration in both directions is different from diurnal cycles, system travels in either direction, observed in other areas, such as Indochina peninsula (Satomura, 2000), the east of Tibet Plateau (Asai et al., 1998), and north and south America continents (Wallace, 1974, Riley et al., 1986, Carbone et al., 2002, Mapes et al., 2002). The westward migration is found almost every month except for August. The eastward migration is found mainly near the ITCZ, which is shifted northward and southward with an annual cycle.

Friday, July 11 AM

MC03/11A/A07-001   Invited   0830

UNDERSTANDING AND PREDICTION OF THE ASIAN MONSOON ONSET

Guoxiong WU, Jiangyu MAO, Anmin DUAN, Yimin LIU, Xin LIU (LASG, Institute of Atmospheric Physics)

Monsoon onset is characterized by the reversal in the direction of prevailing wind and the abrupt intensification of precipitation. As seasons evolve from winter to summer, the thermal contrast between ocean and land is changed, the aloft atmospheric temperature gradient between land and ocean is reversed, the atmospheric circulation pattern is transformed from winter type to summer type, and the monsoon onset occurs.In the boreal winter, the ridgeline of the subtropical anticyclone at 500 hPa is zonal located by 12oN, and the ridge surface tilts southward with increasing height. In summer while its tilting keeps unchanged over other longitudes, it tilts northward over the Asian monsoon area because the air over Asian Continent is warmer than over Indian Ocean. Therefore the ridgelines of the subtropical anticyclone in the lower troposphere are broken over the monsoon area. During the seasonal transition the tilting of the ridge surface of the subtropical anticyclone changes from southward to northward. At the time when the ridge surface becomes perpendicular to the surface, the meridional temperature gradient vanishes, implying the replacement of the wintertime gradient by the summertime gradient, and the occurrence of monsoon onset. A "monsoon onset axis" (MOA) is then defined as the axis at the ridge surface of the subtropical anticyclone that is perpendicular to the earth's surface. Based on the NCEP/NCAR analysis data, it is shown that the MOA appears firstly over the eastern Bay of Bengal (BOB) in early May, which indicates the start of the Asian monsoon onset process, then propagates gradually eastward. It passes South China Sea (SCS) few days before May 20, and reaches the western Pacific in early June. The severe deep condensation heating accompanied with the SCS monsoon onset extends northward quickly and contributes to the development of the South Asian High (SAH) over the south of the Tibetan Plateau. The westerly jet in the upper troposphere then retreats to the north of the Plateau, and strong divergence appears to the southwest of SAH. These help the development of convection over the region of Arabian Sea and India and the monsoon onset over South Asia in early June. To this end, the whole process of the Asian monsoon onset is completed, and the general circulation has transformed to its summer pattern.Based on these, the time series of the Asian monsoon onset are constructed and correlated with meteorological variables. Particular efforts are made in understanding the impacts of the Tibetan Plateau on the seasonal transition in the area. Results show that the BOB monsoon onset is well correlated with the ENSO events and the springtime thermal status over the Tibetan Plateau. The possibility in qualitative prediction of the BOB monsoon onset is then discussed.

MC03/11A/A07-002   0910

PREDICTABILITY ANALYSIS OF THE BAY OF BENGAL SUMMER MONSOON ONSET

Anmin DUAN, Guoxiong WU, Jiangyu MAO, Yimin LIU (LASG, Institute of Atmospheric Physics)

Based on thermal-wind relation and the fact that the essence of summer monsoon onset is a result of the change in land-sea thermal contrast, the relation between monsoon onset and the variation of the subtropical anticyclone is studied, and the concept "monsoon onset axis" is defined. The axis appears firstly over the eastern Bay of Bengal (BOB), then propagates regularly eastwards to the western Pacific by early June. Whenever the axis arrives at a region, the in situ lower-layer wind direction and the sign of meridional temperature gradient (MTG) in the upper-layer are changed, and monsoon onset occurs. Furthermore, the time required to overturn the MTG depends on the initial MTG as well as the averaged meridional differential heating before the monsoon onset. Based on these results, the daily and monthly NCEP/NCAR reanalysis data during March to May from 1980 to 1999 were used to explore the predictability of the BOB monsoon onset. Results show that qualitative prediction of the BOB monsoon onset is possible by using the initial MTG and the climate mean meridional differential temperature variations. Moreover, there is significant correlation between the

spring-time monthly-mean air temperature over the Tibetan Plateau and the BOB summer monsoon onset. This provides additional clue for predicting the monsoon onset. These two methods have been utilized to predict the qualitative BOB monsoon onset in 2000 and 2001 correctly. However, detailed examination reveals that a satisfactory prediction of the BOB monsoon onset requires the consideration of the low-frequency variability of the atmospheric circulation.

MC03/11A/A07-003   0930

THE SIGNIFICANCE AND THE PERSISTENCE OFPRECURSORY SIGNALS OF THE ASIAN SUMMERMONSOON

Kuniko EGAWA, Masaki ISHIWATARI (Graduate School of Environmental Earth Science, Hokkaido University)

The significance and the persistence of precursory signals associated with theAsian summer monsoon circulation are examined with NCEP (National Center forEnvironmental Prediction) reanalysis data set of 1948 to 1999. These precursory signals are defined as anomalies appearing over the Asian region during several seasons prior to summer of strong or weak monsoon years. The patterns of anomalies reverse according to the intensity of the summer circulation. The mostdiscussed precursory signal is zonal wind anomaly at the level of 200 hPa. Composite anomalies of zonal wind, temperature, geopotential height,surface temperature, surface pressure, soil moisture and outgoing long radiation (OLR) are analyzed for strong and weak summer monsoon years which are defined based on Webster-Yang index (Webster and Yang, 1992). In 200 hPa zonal wind, the significant signals emerge in winter of strong monsoon years and in spring of weak monsoon years. The persistent anomaly patterns are found in 200 hPazonal wind from winter to spring, though they are insignificant.For both strongmonsoon years and weak monsoon years, anomaly patterns persist from winter to spring in some years but not in other years. For OLR and 850 hPa temperature, the significant signals appear in winterand spring of strong and weak monsoon years. In these composite fields, anomaly patterns persist from winter to spring, but regional shifts of significantanomalies are observed. In all strong and weak monsoon years, similar anomalypatterns generally persist over the most Asian regions from winter to spring. In other fields, anomaly patterns in winter often differ from those in spring. Anomaly patterns in strong years don´t show opposite patterns to thosein weak years. The correlations between Webster-Yang index and each field during theperiod 1948 to 1999 are also examined. The correlation coefficient with 200 hPazonal wind in spring is -0.48. The largest value of correlation coefficient,-0.66, is given by OLR in spring. The correlation coefficient of other fields are close to or less than that of 200 hPa zonal wind. Above results suggest that, contrary to discussions of previous studies, the precursory signals does not always persist during several seasons. There remains difficulty in predicting the Asian summer monsoon by use of theseprecursory signals.

GLOBAL WIND PATTERNS AND ASSOCIATED SNOW ANOMALIES OVER EURASIA: PREDICTABILITY AND INFLUENCE ON LARGE SCALE MONSOON CIRCULATION

Susanna CORTI[1], Franco MOLTENI[2], Cedo BRANKOVIC[2] ([1]ISAC Institute of Atmospheric Sciences and Climate, CNR National Research Council, [2]ICTP International Centre for Theoretical Physics)

In this study we focus on (the relationship between):(i) the global long-lasting (persisting from winter to the early summer) upper tropospheric anomalous circulation;(ii) the tropical SST anomalies (which can determine the kind of flow (i))(iii) the snow depth anomalies over Eurasia (which can be determined by (ii) through (i)); (iv) and the large scale monsoon circulation in the following summer (related to (i), (ii) and (iii)).The dataset is the 40-year record (1958-98) of NCEP/NCAR re-analyses for sea surface temperatures and upper air fields, while, for snow depth fields, the Historical Soviet Daily Snow Depth dataset (based on observations at a series of 284 World Meteorological Organization (WMO) stations throughout the Former Soviet Union) is used.First the leading variability patterns of the atmospheric flow are searched for by calculating empirical orthogonal functions (EOFs) of seasonal anomalies. The Eurasian snow depth anomalies and SST anomalies associated with the leading circulation patterns are then identified by computing, for each season, the covariance between the principal components (associated with the EOFs) and the snow/SST anomaly time series. The relationship with the large scale monsoon circulation is evaluated through (lagged) correlations with the Webster and Yang index.

STRUCTURE AND EVOLUTION OF SOUTHERLY SURGES ON THE SUBMONTHLY TIMESCALE OVER THE EASTERN INDIAN OCEAN DURING AUSTRAL WINTER

Yoshiki FUKUTOMI[1], Tetsuzo YASUNARI[2] ([1]Frontier Research System for Global Change, JAMSTEC Yokohama Institute for Earth Sciences, [2]Hydrospheric Atmospheric Research Center, Nagoya University and Frontier Research System for Global Change, JAMSTEC Yokohama Institute for Earth Sciences)

Meridional wind surges from extratropics to tropics have been recognized as one of major regulators of tropical convective activity in many observational studies. The aim of this study is to confirm that the southern hemisphere (SH) meridional surge which is a form of extra-tropical forcing play a considerable role in modulating the tropical atmospheric and oceanic variability in the equatorial Indian Ocean neighboring the South Asian monsoon region.We explore the low-level surges on the submonthly (6-25 day) timescale occurring over the eastern Indian Ocean and associated tropical convection and large-scale atmospheric fields during the SH winter (June-August) season. For this study, the NCEP-2 reanalysis and NOAA/CDC OLR data on the daily basis for the 23-yr period from 1979-2001 are used, and composite analysis is carried out. A low-level surge index has been calculated using the 850hPa meridional component of wind over a key region where a local maximum of submonthly scale variance locates (17.5-2.5S, 87.5-97.5E). A total of 54 surge events are selected from the 6-25-day band-pass filtered index. Then, composites of various atmospheric and surface elements are generated based on this index to establish the relationships between the surge events and the large-scale fields.From the composites, the low-level meridional wind surges appear to be initiated by the mid-latitude Rossby wave passages along the mean westerly flow over the southern Indian Ocean and South Pacific. As the mid-latitude wave propagates eastward and develops in the entrance of the mean subtropical jet to the east of Australia, the low-level southerly surge blows through the subtropics into the equatorial region. The amplified wave and surge signals lead to a cold dry air incursion from the extratropics to the tropics. 2 to 4 days later with the surge peak, negative OLR anomalies develop near the key region, which is indicative of the local flare up of convection in the SH side equatorial region.This occurrence of convection can be explained by the influence of the incursion of cold and dry air accompanied by the southerly surge event. The enhanced southerly cold dry air flows from the mid-latitude into the tropics increase latent and sensible heat flux from the sea surface, which charges the low-level moist static energy in the near equatorial region. As a result of these processes, local unstable condition is set up in the lower troposphere, and subsequent convective motion is triggered. The potential roles of such surge events produced by the SH mid-latitude wave

M

passages on preconditioning the atmosphere for convection will be discussed in terms of the extratropical forcing and air-sea interaction.

THE 10-20-DAY VARIATION OVER THE SOUTHEAST ASIA IN 1998 RAINY SEASON

Satoru YOKOI, Takehiko SATOMURA (Department of Geophysics, Graduate School of Science, Kyoto University)

Intraseasonal variations (the 30-60-day variation and the 10-20-day variation) of convective activity and circulation pattern over Southeast Asia in 1998 rainy season are investigated using TMD rain gauge data, GMS5 IR1 data and GAME reanalysis data. Wavelet analysis of precipitation data in 1998 shows that the 30-60-day variation had its maximum amplitude in late June while the 10-20-day variation in middle August. Using IR1 data, it is shown that the latter variation had westward phase speed of about 5.6m/s. The circulation pattern with this 10-20-day variation is investigated using GAME reanalysis data. Lag correlation method shows that the horizontal circulation pattern in the lower troposphere resembled that of the equatorial Rossby wave of the gravest meridional mode very well. Namely, in the maximum rainfall stage of the 10-20-day variation over Indochina Peninsula, two cyclonic vortices were found whose centers were at 95E,10N and 85E,15S. These positions were about 10 degrees south of the positions that previous studies pointed out. This difference is probably due to one of the peculiarities in 1998 that the distribution of convection was south of climatological one. Besides, low height anomalies existed at the almost same positions as these cyclonic vortices. The westward phase speed and period are estimated to be 6.4 m/s and 12 days, respectively. From these two values, it is calculated that the equivalent depth is 64 m, which is consistent with the latitudinal scale of these vortices estimated by the linear theory. The vertical structures of this mode were as follows. Height anomalies in the upper troposphere were out of phase with that in the lower troposphere and a node existed at 300 hPa level. In the upper troposphere, the maximum amplitude was observed at 200 hPa level, while in the lower troposphere, it was at 700 hPa or 850 hPa level. These characteristics of vertical structures were also found in stream function anomalies. Lag correlation analysis also shows that anomalies of height and stream function in the lower troposphere were larger than that in the upper in the west of 120E, while anomalies in the upper were larger than that in the lower in the east. This fact indicates that as this wave moved west, its vertical structure changed such that the layer in which the maximum amplitude was observed changed from the upper troposphere to the lower troposphere. The background vertical shear of zonal wind is westerly (easterly) over the Western Pacific (the Bay of Bengal). Possibly this east-west distribution of the background vertical shear is important for this vertical structure change.
