The present thesis reviews the main results of studies carried out in Uzbekistan in the years of 1996-2000 under the project ' interrelations between Deep Lithospheric Structures and Metals Concentrations" The investigations have been carried out in two regions of Uzbekistan: in the Almalyk-Angren region , and in Central Kyzylkums. These regions provide nearly 100% of ore output of the Republic (gold, silver, copper, fluorite, uranium) and ensure the 7-8th place in world production. The main conclusions are: 1.The upper part (10-20km) of the earth's crust in the Almalyk-Angren and Central Kyzylkum ore regions has a stratified-block structure. The upper sedimentary stratum of Mesozoic-Cenozoic age, with a thickness of 0 to 2 km, is not developed in all places. The other part is composed of Paleozoic and pre-Paleozoic sedimentary and magmatic rocks of various composition. They were metamorphosed from greenschist to amphibolite facies. In addition, the Central Kyzylkum rocks were dynamo-metamorphosed as a result of elastic-viscous tectonic deformations. 2.Both the above regions are, at the present level, characterised by weak anomalies regional gravity and magnetic fields.The both regions are areas of present uplift (2-8mm/year), where endokinetic energy is produced. At the same time, large ore deposits are characterized by a reduced gravity field and lower velocities of seismic waves, indicative of high jointing (uncondensity) of ore-bearing blocks. 3. The anomalies of heat flow and electrical conductivity are connected with zones of deep-seated faults. The latter are, in places, marked by emissions of underground gases (hydrogen, methane, etc.). 4. Both regions are characterized with multiply prolonged (40-60 million years) development of tectonic and magmatic processes, with formation of large granitoid plutons and various (differing in form and composition) rocks of volcano-tectonic structures, differing in composition, in age, as well as in character and scale of mineralization. 5. On the base of revealed and formulated geological and geophysical parameters of local possibilities of origin of large and superlarge endogenic deposits. Purposeful carrying out of prospecting can be allowed to reveal some new deposits and increase resources of precious, base and rare metals, that will provide for a long time working of mines and establishing the new ones. On the other hand established and described new kinds of connections between deep structures and peculiarities of magmatism and metallogeny are of planetary character and general theoretical significance.

A PLUME BENEATH THE NORTHEASTERN AFRO-ARABIAN CONTINENT?

Michel J. CARA[1], Eric DEBAYLE[1], Georges HERQUEL[1], Jean Jacques LEVEQUE[1], Anne SIEMINSKI[1], Deborah SICILIA[2], Jean Paul MONTAGNER[2], Atalay AYELE[3], Jamal M. SHALAN[4] ([1]EOST, University of Strasbourg, [2]Institut de Physique du Globe de Paris, [3]Geophysical Observatory, University of Addis-Ababa, [4]National Seismological Observatory Center, Dhamar)

A cooperation program linking the University of Addis Ababa, theNational Seismological center of Dhamar and ˝Institut National desSciences de l´Univers˝- France, led us to install 5 broad-band STS2seismometers in Ethiopia and Yemen during the years 1999-2002. Thanks tothe records available at other permanent and temporary stations (GEOSCOPE,IRIS and PASSCAL), a large set of broad-band teleseismic data have beencollected and processed in the northeastern Afro-Arabian region. In this presentation, we review the results obtained by the differentgroups participating in the cooperation program, and we discuss inparticular the question of the origin at depth of the Afar hot spot. Surface-wave tomographic models based on two different waveforminversion techniques have been constructed, constraining the location ofa low shear-wave speed anomaly in the upper 250 km beneath the EthiopianPlateau, Afar, the Red Sea, the Gulf of Aden and southwestern Arabia.The waveform inversion technique of Cara an Lévêque (1987) allows us toget reasonable resolution down to the upper mantle transition zone. Theresult of this tomographic model suggests the presence of a deeplyrooted low velocity material beneath the South of the Red Sea and theArabian plate (Debayle et al., 2001). This result is discussed in thelight of observation of receiver function peaks related to the 410 and670 km depth discontinuities in the region. Other constraints on the shallower asthenospheric flow isprovided by azimuthal anisotropy coming from the inversion offundamental mode Rayleigh-waves. The directions of fast SV-wavesinferred from the Rayleigh-wave data is compared with the directions offpolarization of the fast SKS waves in the region, allowing us to putsome constraints on the upper-mantle flow beneath the region.

3-D RHEOLOGICAL STRUCTURE OF THE LITHOSPHERE FOR THE ORDOS BLOCK AND ITS ADJACENT AREA

Shao Xian ZANG, Rong Qiang WEI, Yong Gang LIU (Department of Geophysics, Peking University)

Ordos block is in the northern-central China. It connects with Tibet plateau, but it is an inactive block surrounded by active deformed zones so it causes a big attention from geoscientists. In this paper, we study the rheological structure of Ordos block and its surrounding area to study the reason for the special behavior and provide the necessary parameters for geodynamic study. It needs the velocity structure, composition and the thermal structure of the lithosphere for studying the rheological structure. The velocity structure of the crust was obtained from exploration seismology and seismic tomography. The lower boundary of the thermal structure is taken as the lower lithosphere boundary because there is no constraint from seismic exploration study. The thermal structure was obtained using the surface heat flow data. The composition are taken as granite in the upper crust, Anorthosite in the middle crust, felsic granulite in the lower crust, wet peridotite in the upper mantle part of the lithosphere. According to the results in the laboratory, three main rheological deformation mechanisms in the lithosphere, namely frictional sliding, brittle fracture and creep are considered. The state of stress deduced from earthquake mechanism in the Ordos area is that the maximum and minimum principle stresses are horizontal and the medium principal is vertical, so Byerlee's law in Anderson faulting system is used for strength of frictional sliding. The brittle fracture mechanism is usually ignored in some rheological studies because the strength of the brittle fracture obtained from small samples is too big when comparing it with other two mechanisms. We obtained the strength of the brittle fracture deduced from results on small-scale specimen and subjected to the constraint of a few existed data on large-scale specimen. The Dorn equation is used for the strength of creep. The rheological structure of the lithosphere is obtained by different constraint: constant strain rate, constant tectonic force, strain rate-dependent force and realistic strain rate constraint. The results show that the rheological structure changes with the different constraint and is vertical layering and horizontal variation. The influence factors and applications are discussed.

THE VRANCEA NATURAL LABORATORY OF GEODYNAMICS

Dorel ZUGRAVESCU, Vladimir Nicolaevich STRAKHOV, Alexander Olegovich GLIKO, Constantin Stefan SAVA, Vladimir Georgievich BOUDANOV (Institute of Geodynamics)

In the Romanian Carpathians bending zone the geotectonic conditions assured the constitution of a true natural geodynamics laboratory, which allows the survey of an ensemble of physical parameters causally linked with the complex phenomena that lead to

the cumulating/triggering of seismic energy. Its characteristic geodynamic features and its geographical position make this laboratory unique in the world, a laboratory offered by nature to researchers in particularly favorable conditions, allowing optimal circumstances for research, from the point of view of its structure (perfectly spatially delimited) and from the point of view of the socio-economic interests implied and its accessibility. Among the features that confer the seismogenic zone of Vrancea as a geodynamics laboratory its uniqueness, the following must be emphasized: the small, strictly delimited area of the epicentral zone, corresponding to an ellipse-shaped area having the large axis oriented North-East to South-West of about 70 km and the small axis of about 35 km; the situation of the hypocenters till depths that, exceptionally, may exceed 180 km, with a practically aseismic zone situated between 40 and 60 km; the high frequency of earthquake occurrence corresponding to the same epicentral area (small magnitude earthquakes occur, practically, daily); the fact that, several times per century, earthquakes with a magnitude significantly higher than 7.0 on the Richter scale are triggered; the extended area, situated in Romania, the Republic of Moldova, Bulgaria, Hungary, Yugoslavia, and even in Ukraine and Russia, affected by the strong earthquakes triggered in that zone, the area being intensely populated (the city of Bucharest has approximately 3 million inhabitants) and comprising edifices of highest socio-economic importance, including nuclear power stations; the presence of an ensemble of geodynamics observatories and observation points, grouped in a Polygon of Geodynamics, which benefit both from historical observations extending over more than a millennium, and from instrumental observations initiated approximately a century ago and improved continuously by the addition of new instrumentation; its accessibility: the Polygon of Geodynamics Căldăruşani - Tulnici includes the international airport Otopeni, the city of Bucharest - Romania's capital, and a dense network of roads and railways crisscrosses it. In order to give to the interested scientists the possibility to work together for enhancing the knowledge on this natural poligon, using all available modern means, in the frame of an internationol form of cooperation, the Institute of Geodynamics ˝Sabba S. Stefanescu˝ of the Romanian Academy and the United Institute of Earth Physics ˝O.Yu. Schmidt˝ of the Russian Academy of Sciences, founded the ˝International Virtual Laboratory of Geodynamics˝ in the year 2001. Other research units from Romania, France, Germany, Belgium and Republic of Moldova have already expressed their intention to participate in the activities of this Virtual Laboratory.

LITHOSPHERIC THERMAL AND MECHANICAL STRUCTURE OF EASTERN TIBETAN PLATEAU WITH TECTONIC IMPLICATION

Yong ZHENG[1], Xiong XIONG[2], Rongshan FU[1] ([1]Department of Earth and Space Sciences, University of Science and Technology of China, [2]Institute of Geodesy and Geophysics, Chinese Academy of Sciences)

The mass eastward flow of Tibetan Plateau is one of the most prominent tectonic features of the plateau. The mass move eastwards, and tend to run nearly southeastwards in front of the Sichuan Basin. On the other hand, the results from both the numerical simulation and subcrustal stress field induced by mantle flow suggest that the crustal deformation is strongly decoupled from that of the mantle in the eastern Tibetan Plateau. So, the questions are addressed: why the mass moving direction changes from the east to the nearly southeast, and what is the mechanical background of the decoupling between the deformation of the crust and the mantle. To clarify the questions, a two-dimensional algorithm is designed to determine the steady state lithospheric thermal and strength structure along two profiles crossing the main tectonic units of the eastern Tibetan Plateau. The temperature distribution within the lithosphere and at any material boundary is calculated by a finite element technique with the surface heat flow, heat generation and the thermal conductivity as the input data. With the given rheological parameters of crustal and mantle medium, the strength distribution and the total lithopheric strength is determined in the selected columns. The numerical results show significant variation of the lithospheric temperature and strength distribution of different tectonic units. The temperature is very high in the active tectonic regions, such as Kunming, Lijiang and Tengchong, while is low in the Sichuan Basin, a stable tectonic unit titled "cold basin" in China continent. The zone with the strongest lithosphere is the Sichuan Basin, while those with weakest lithosphere are Tengchong, Lijiang and Kunming. The brittle deformation zone is confined within the first 20km in most study areas except the Sichuan Basin. The result agrees with that obtained from studies on gravity and lithospheric flexure, which shows that the lithosphere is very weak in Tibetan Plateau, especially in the eastern plateau. In addition, our result shows very weak strength distribution within the lower crust, which is suggested to be one of the most important factors for the decoupling of deformation between the crust and mantle. As usual, the mass movement usually takes the weak zone as the preferential flowing direction. Since the Sichuan Basin, with a strong lithosphere, is a very stable tectonic unit in China continent, it may be a barrier for the mass eastwards flowing. When the mass flowing encounters the Sichuan Basin, it tends to take the zones with weak lithospheric strength as the preferential direction and move along them. So, the mass moving direction changes from east to nearly southeast in front of the Sichuan Basin. It is suggested that the lithospheric thermal and strength distribution in various tectonic units may play an important role for the crustal movement in the eastern Tibetan Plateau.

JSS06/10A/A04-008   1110

PN TOMOGRAPHIC IMAGING OF MANTLE LID VELOCITY AND ANISOTROPY AT THE JUNCTION OF THE ARABIAN, EURASIAN, AND AFRICAN PLATES

Ali I. AL-LAZKI[1], Eric SANDVOL[2], Dogan SEBER[2], Muawia BARAZANGI[3], Niyazi TURKELLI[4], Randa MOHAMAD[5] ([1]Department of Earth Sciences, Sultan Qaboos University, [2]Department of Geological Sciences, University of Missouri, [3]Institute for the Study of the Continents, Snee Hall, Cornell University, [4]Department of Geophysics, Kandilli Observatory and Earthquake Research Institute, [5]Syrian National Seismological Center, General Establishment of Geology and Mineral Resources)

The Arabian plate´s interaction with the Eurasian plate has played a major role in building the young mountain belts along the Zagros-Bitlis continent-continent collision zone. Arabia´s northward motion is considered to be the primary driving force behind the present-day westerly escape of the Anatolian plate along the North and East Anatolian fault zones as well as the formation of the Turkish and the Iranian plateaus. In this study we mapped Pn wave velocity and anisotropy structures at the junction of the Arabian, Eurasian, and African plates in order to elucidate the upper mantle dynamics in this region. Pn is a wave that propagates within the mantle lid of the lithosphere and is often used to infer the rheology and fabric of the mantle lithosphere. Using a strict selection criterion we used arrival times of 166,000 Pn phases to invert for velocity and anisotropy in the region. Using a least squares tomographic code, these data were analyzed to simultaneously solve for both velocity and azimuthal anisotropy in the mantle lithosphere. We found that most of the continental regions in our study area are underlain by low Pn velocity structures. Broad scale (~500 km) zones of low (< 8 km/s) Pn velocity anomalies underlie the Anatolian plate, the Anatolian plateau, the Caucasus region, northwestern Iran, and northwestern Arabia and smaller scale (~200 km), very low (< 7.8 km/s) Pn velocity zones underlie southern Syria, the Lesser Caucasus, the Isparta Angle, central Turkey, and the northern Aegean Sea. The broad scale low velocity regions are interpreted to be hot and unstable mantle lid zones, whereas very low Pn

velocity zones are interpreted to be regions of no mantle lid. The low and very low Pn velocity zones in eastern Turkey, northwestern Iran, and the Caucasus region may be associated with the latest stage of intense volcanism that has been active since the Late Miocene. The low Pn velocity zones beneath the Anatolian plate, eastern Turkey, and northwestern Iran may in part be a result of the subducted Tethyan oceanic lithosphere beneath Eurasia. We also found a major low velocity zone beneath northwestern Arabia and the Dead Sea fault system. We interpret this anomaly to be a possible extension of the hot and anomalous upper mantle of the Red Sea and East Africa rift system. High Pn velocities (8.1 - 8.4 km/s) are observed to underlie the Mediterranean Sea, the Black Sea, the Caspian Sea, and central and the eastern Arabian plate. Observed Pn anisotropy showed a higher degree of lateral variations in comparison to the Pn velocity structure. Though the Pn anisotropy varies even in a given tectonic region, in eastern Anatolia very low Pn velocity and Pn anisotropy structures appear to be coherent.

SIGNIFICANCE OF MANTLE DYNAMICS IN INTERACTION BETWEEN THE SUBMARINE INTERFACES

Xianglong JIN, Gao JINYAO (Second Institute of Oceanography and Key Lab of Submarine Geosciences, SOA)

The significance of mantle dynamics in interaction between the subseafloor interfaces is elaborated from the mantle dynamic features reflected by hotspots, mantle low-velocity zones and mantle-convection stress fields, the secular processes of submarine mineralization for hydrothermal mineral, polymetallic nodule and cobalt crust, and possible the short-term phenomena changing the Earth hydrology and climate system. Mid-Ocean ridges around the Earth are important channels for the substance and energy from mantle in interaction between the submarine interfaces. Hydrothermal vents with abundant polymetallic elements transported into oceanic basins by ocean currents are mineralization resources for polymetallic nodules. The hotspots have good correspondence to seamount chains distributed on low, middle latitudes, also being mineralization resources for seamount cobalt crusts. Now that mid-ocean ridge spreading, hotspot and hydrothermal activities of geological scale possess a long-term accumulation of mantle energy, and may causes the abrupt nonlinear events in a short time, such as earthquake, volcanism and tsunami, even oceanic and climate process. El Nino could be related with mantle dynamics. The El Nino occurs at the warm pool with high temperature and sea level in the western Pacific Equator, and migrates from western Pacific to eastern Pacific along the equatorial zone. The western Pacific warm pool is near by the highest uplift of the global geoid surface (New Guinea: 5°20.4'S,142°40.2'E), beneath which there are a broad magma province, a huge convergence of mantle substance and stress. The warm pool could be due to the mantle energy conveyed by magmatic process. Under the Equator and low latitude Pacific, there exists a low-velocity zone in mantle, which shrinks towards the Equator down to lower mantle. This indicates that upper mantle is highly melted and releases enormous energy along the Equator. Much thinner than continental crust, oceanic crust is relatively easy to release mantle energy through hydrothermal activities along various scales of fractures. Twenty-five main hotspots are all distributed in the seafloor of southern Hemisphere. Of them, eight hotspots between 0°-30° S in the middle and eastern Pacific, eleven hotspots in south of 30° S around Antarctica, with the tectonic and hydrothermal activities along the eastern Pacific ridge, are all probably provide enough substance and energy transported through the middle and deep oceanic currents for mineralizing process. Nowadays observation techniques and accumulated data are not enough to prove the processes impacting the transportation of mantle substance and energy, and the submarine mineralization. One of the most difficult problems is severe shortage of seabottom heat flow data along the Equator and low latitude Pacific. For this reason it is needed to establish a global or regional observatory network in the context of international cooperation, including middle and deep oceanic current observations.

MUTUAL INTERACTION BETWEEN MAGMATISM AND GEODYNAMICS IN THE CARPATHIAN-PANNONIAN REGION, EASTERN EUROPE

Ioan SEGHEDI[1], Hilary DOWNES[2], Alexandru SZAKÁCS[1], Zoltán PÉCSKAY[3] ([1]Institute of Geodynamics, [2]Birkbeck/UCL Research School of Geological and Geophysical Sciences,Birkbeck College, Malet St., London WC1E 7HX, UK, [3]Institute of Nuclear Research of the Hungarian Academy of Sciences, P.O. Box 51, Bem ter 18/c, H-4001 Debrecen, Hungary)

The Carpathian-Pannonian Region is a result of convergence between Africa and Europe and a good example of the link between magmatism and geodynamics. A complex spectrum of microplate motion and related geologic processes (subduction, collision and extension) are inferred. Kinematics of the Intracarpathian blocks (Alcapa, Tisia) up to the collision with European Plate were responsible for the generation of various kinds of magmas (calc-alkaline, alkaline). Relevant examples suggest that mantle dynamics is deduced from petrological features of the magmas, refining the existing geodynamic models: (1) In the Western Carpathians and Pannonian Basin felsic explosive volcanic activity occurred (21-18 Ma), then felsic and intermediate calc-alkaline volcanic activity was generated across a large area (18-12 Ma, sporadically between 12-8 Ma). In several small areas between 10-0.1 Ma alkali-mafic volcanism was generated. The age relationships and geochemical features suggest south toward north youngness and admit sediment and fluid decrease, initially a crustal source, then a mixing between crustal and mantle source and finally a mantle source This magmatism at its inception was subduction-related. Extrusion and counter-clockwise rotations of Alcapa, rollback and collision triggered partial melting either by delamination or straight asthenosphere upwelling. Finger-like asthenosphere upwelling likely generated younger alkali-mafic magmatism. (2) In the westernmost East Carpathians simultaneous (15-9 Ma) calc-alkaline volcanism is spread across ca. 100km in several parallel lineaments. The geochemical features reveal significant mantle-source variation in back-arc setting and larger fluid induced metasomatism, source-enrichment and assimilation toward the trench. This magmatism suggests subduction-related rollback triggered melting, since its generation was probably related to the rollback of a subducted slab and collision, followed by back-arc extension, asthenosphere rise and presumably breakoff processes. (3) In the Apuseni Mountains typical calc-alkaline and adakite-like magmas (15-9 Ma) do not show relationships with contemporaneous rollback processes in front of the orogen. OIB-like alkali-basaltic magmatism (2.5 Ma) and shoshonitic magmatism (1.6 Ma) ends the magmatic activity. The mechanism of magma genesis is lithosphere breakup during rotations (~60 degree) between 14-12 Ma, which generated decompressional melting of the lithospheric (early) and asthenospheric (later) sources. Transtension and rotation triggered melting processes are inferred. Alkali-basalts suggest decompressional melting of OIB-like rising asthenosphere. Such asthenospheric melts mixed with lithospheric melts to generate alkaline-shoshonitic rocks during the transtension and attenuation of the lithosphere along an east-west reactivated fault-system. (4) At the southeastern part of the Eastern Carpathians contemporaneous eruption (2-0.3 Ma) of adakite-like calc-alkaline, shoshonitic and alkali-basaltic magmas occurred following normal calc-alkaline magmas. Decompressional melting of an OIB-like asthenospheric mantle (producing alkali-basaltic magmas) coupled with fluid-dominated melting of the subducted slab (generating adakite-like magmas) and mixing between slab-derived melts and asthenospheric melts (generating shoshonites) is supposed.

IA

Breakoff and tearing of the subducted slab at shallow levels in the extreme southern part of the arc can explain this situation, as heat from the asthenosphere plume produced melting of the hydrated torn slab, as well as generating melt via decompression. This magmatism can be characterized as related to rollback, breakoff and tearing triggered melting processes.

JSS06/10A/A04-011 — 1210
SEISMIC ANISOTROPY AND PLATE-MANTLE INTERACTION

Götz BOKELMANN (Stanford University)

Seismic anisotropy is a powerful tool which allows us to constrain the degree of plate-mantle interaction. Some questions we are interested in are: How strong is the mechanical coupling between continental plates and underlying mantle? Is there an asthenosphere under continental plates, i.e. under shield regions? How important are the forces acting at the base of the plate for driving the plates? Are individual plates driven by ridge push and slab pull or rather by mantle convection? Are lithospheric deformation and surface tectonics do some degree caused by deeper motions? The answer to those questions may lie in observing the deformation state of the deep lithosphere, using seismic anisotropy. We may determine the direction of relative motion between plate and deeper mantle if finite grain rotation at the base of the lithosphere is incomplete and the fast anisotropic axes show a plunge angle different from horizontal. We have examined plunge angles for a large number of seismological stations on Earth, e.g. the Canadian Shield. For the latter we have found that fast axes under the shield dip to the west, roughly in the direction of absolute plate motion, and that the anisotropy is consistent with a simple-shear deformation of the deep lithosphere. This is consistent with basal tractions under the shield aiding the motion of the continent rather than resisting it (e.g., Bokelmann 2002, GJI 248, 2, 278-287; Geology 30, 11, 1027-1030). A similar result has been obtained recently by Lui and Bird (2002, GRL 29(24), 2164, doi:10.1029/2002GL016002) based on tectonic modeling. Clearly, seismic anisotropy may play an important role in the integration of seismology and geodynamics. A rheological continent model based on observed seismic anisotropy suggests that the level of stress is on the order of a few MPa (Bokelmann and Silver, 2002, GJI, 29(23), 2091, doi:10.1029/2002GL015925) which indicates that the coupling of continental plates to the deeper mantle can not be ignored. It also suggests that there is probably no well-developed zone of localized deformation (asthenosphere) under the central parts of stable continental areas. For pdf-files see my homepage http://pangea.stanford.edu/~goetz/home.html .

SEISMOTECTONICS OF THE LITHOSPHERE OF ACTIVE OCEANIC MARGINS

Serguey A. BOLDYREV (Institute of Physics of the Earth, Russian Academy of Sciences, B.Gruzinskaya 10 Moscow 123995 RUSSIA)

In the present work, using the Kamchatka sector of the Pacific Mobile Belt as an example, we discuss the results of a structural analysis of the earthquake focus distribution and a mechanism of elastic stress realization at the active oceanic margins. To describe the seismic field of the lithosphere in the studied region, we used data of the Kamchatka seismological survey (KAM) on shallow-focus (H $<$ 60 km) seismicity for the period from 1962 through 1998. The principal peculiarities of the shallow-focus seismicity in the Kamchatka region are the local, selective character of the origination of earthquakes and the spatial stability of areas with elevated seismic activity throughout the observation period. These stable areas are clustered into linear systems. The sites of intersections of such systems are distinguished for their high seismic activity. They are commonly associated with instrumental epicenters of the strongest (M $>$6.5) earthquakes. As was mentioned above, the character of seismotectonic processes and physical properties of the lithosphere within the study area are fundamentally dissimilar in segments situated north and south of the main lineament at 550 N. This lineament is traced from the central Kamchatka rift zone to the Bering Sea coast of the Komandorskie Islands. The volcanic ridge is displaced along this lineament by almost 70 km; however, the lineament is practically not expressed in the topography and principal geophysical fields. The near-surface seismicity (H $<$ 30 km) dominating northward of 550 N, is caused by nearly horizontal compressive stresses with azimuth of 170 100. It is represented by sublatitudinal lineaments spaced with a periodicity of 35-40 km. In the southern segment, the seismicity is governed by nearly horizontal compressive stresses (azimuth 123 70). The majority of the foci appear in the subcrustal lithosphere, and the block dimension governed by the seismotectonic processes is 120 x 80 km. The lineaments oriented along the SFZ are dominated by upthrow-type displacements, which results in thrusting of lithospheric blocks from the west and east over the central segment of the SFZ. As a result, the central part subsides, affecting the configuration of the crust--mantle interface. On the whole, a direct relation between the seismotectonics and geomorphology of active ocean margins is not observed. In transition zones, the shallow seismicity is likely to reflect the structural features of the crust--mantle interface.

SPATIAL VARIATION IN ISOSTATIC PARAMETERS REVEALED THROUGH THE CONTINUOUS WAVELET TRANSFORM

Jonathan KIRBY[1], Christopher SWAIN[2] ([1]WA Centre for Geodesy, Curtin University of Technology, [2]20 Bedwell Crescent, Booragoon, WA, Australia)

A new technique based on anisotropic admittance and coherence functions and the two-dimensional continuous wavelet transform (2D-CWT) will be presented in this paper. This approach is considered necessary because existing isostatic analyses tend to use the approximation of isotropic responses and the Fourier transform technique. It is argued here that the wavelet transform allows for a more regional analysis that preserves spatial structure and relationships. Some preliminary results of the new technique will be presented from a case study over central Australia, where there is a reasonably homogeneous coverage of gravity and terrain data. These results indicate that the technique does offer an advance upon existing methods. Comparisons of variations in effective elastic thickness estimated using the new technique, with those derived from teleseismic experiments, show good agreements, indicating that the new technique is effective.

THE EFFECT OF NOISE ON ESTIMATES OF THE ELASTIC THICKNESS OF THE CONTINENTAL LITHOSPHERE BY THE COHERENCE METHOD

Christopher SWAIN[1], Jonathan KIRBY[2] ([1]20 Bedwell Crescent, Booragoon, WA, Australia, [2]WA Centre for Geodesy, Curtin University of Technology, Perth, Australia)

We model the lithosphere as a uniform elastic plate overlying a fluid and loaded with both surface and subsurface fractal loads to generate synthetic topography and gravity data. We simulate data having low (topographic) signal to (gravity) noise ratio by using an algebraically larger exponent for the subsurface load in the spectral synthesis fractal algorithm. The gravity power spectrum then decays less rapidly than that of topography, the spectra resembling those for central Australia. We then apply the coherence method to the synthetic data, using periodogram spectral estimation, and find that it correctly estimates the plate thickness. Using multitapers for either coherence or admittance spectra always yields significant underestimates unless the datawindow is larger than several times the flexural wavelength. We quantify this bias for the parameters used here for both low and normal signal-to-noise ratio data. We then apply the bias as a correction to an effective elastic thickness estimate, made using the multitaper coherence method, for central Australia: it yields 120 +/- 25 km.

ON THE INSTANTANEOUS MOTION OF THE SOUTH TASMAN SEA AND IT'S EFFECT ON THE ANTARCTIC PLATE

Atsuki KUBO[1], Yoshifumi NOGI[2], Tetsuzo SENO[3] ([1]Nat'l Res. Inst. for Earth Sci. and Disas. Prev., [2]National Institute of Polar Research, [3]Earthquake Research Institute, University of Tokyo)

Earthquake slip vectors deviate from the NUVEL-1 relative motions for both Pacific (PAC)-Australia (AUS) and AUS-Antarctic (ANT) plate boundaries near the Macquarie triple junction (Frohlich et al.,1997; DeMets et al.,1988). The South Tasman Sea, nominally part of AUS, plate might be a microplate or a diffuse deformation zone. However this idea has been denied based on one focal mechanism at its northern possible boundary by DeMets et al. (1988). A large earthquake (Mw8.1) occurred within ANT southwest of the triple junction on March 25, 1998. The microplate hypothesis including part of ANT did not explain the deviation of the slip vector of the 1998 earthquake (Condor and Forsyth, 2000). The stress-strain fields produced by the relative plate motions and/or topography forces did not explain the stress axes of the earthquake either (Kreemer and Holt, 2000). We propose the possibility of a rigid microplate in the South Tasman Sea based on the slip vector deviations, and examine its dynamical effect on the occurrence of the large earthquake. We estimate the WSW motion (~ 5 mm/yr) of the South Tasman Sea microplate with respect to AUS to satisfy the slip vector deviations. This motion is nearly normal to the AUS-ANT transform faults, and would produce the compression normal to the faults. This is similar to the fault-normal compression seen in the San Andreas fault (Zoback et al.,1991). This compressional stress field is consistent with the P-axis direction of the focal mechanism of the large 1998 earthquake, and we suppose that the collision of the South Tasman Sea to the Antarctica plate probably induced the large 1998 earthquake. *References* DeMets et al.(1988) JGR, 93,11877 Frohlich et al. HOW THICK IS THE LITHOSPHERE?

Irina M. ARTEMIEVA[1], Walter D. MOONEY[2] ([1]EOST, [2]USGS)

Seismic and thermal estimates suggest a highly variable thickness of Precambrian lithosphere (140-350 km), with a bimodal distribution for Archean cratons (~220 km and ~350 km). We discuss the origin of such large variations in lithospheric thickness and examine mechanisms of lithospheric erosion. Our analysis shows that the horizontal and vertical dimensions of Archean cratons are strongly correlated: larger cratons have thicker lithosphere. The basal drag model of lithosphere erosion (Sleep, 2001) is tested as a means of explaining the present-day bimodal distribution of lithospheric thicknesses of the Archean cratons. In agreement with theoretical predictions, we find that lithospheric thickness in Archean keels is proportional to the square root of the ratio of the craton length (along the direction of plate motion) to the plate velocity. These results show that the basal drag model provides a viable explanation for the variation in thickness of Archean cratonic roots. Basal drag may have varied in magnitude over the past 4 Ga. Higher mantle temperatures in the Archean would have resulted in lower mantle viscosity. This in turn would have reduced basal drag and basal erosion, and promoted the preservation of thick ($>$300 km) Archean keels, even if plate velocities were high during the Archean.

CONTINENT-CONTINENT COLLISION TECTONICS, REGIONAL UNDERPLATING AND ASSOCIATED KCR VOLCANISM IN CENTRAL INDIA

Saurabh Kumar VERMA (National Geophysical Research Institute, Hyderabad)

The central Indian region, comprising Son-Narmada-Tapti lineament and the Central Indian Mobile Belt (CIMB), represents a major geological setting that holds key to the evolution of Indian sub-continent. The CIMB separates the Bundelkhand-Aravalli cratonic block in the north from the southerly cratonic blocks of Dharwar and Bastar. It possibly represents the suturing of various cratonic blocks resulting from continent-continent collision tectonics during the Mesoproterozoic time. Recent studies considering Bouguer gravity, DSS and MT data reveal the presence of regional underplating all along the central Indian tectonic zone. High heat flow values and seismic tomography results further suggest the presence of a thin lithosphere which has interesting implications on the occurrence of diamondiferous kimberlite clan rocks in the region. It is now well established by geochronological studies that the volcanism associated with various kimberlite fields mentioned above was confined to a narrow window in time. Spatially widespread and coeval nature of these K/L's suggests a major thermo-magmatic activity of regional nature around1.1 Ga. In order to understand their origin, it is imperative to study the paleo-geographic distribution of various proto-cratonic blocks that evolved into present day Bundelkhand, Dharwar, Bastar, and Singhbhum Cratons. Based on available geochronological and paleomagnetic data, a reconstruction in time reveals that most of the proto-cratonic blocks were formed proximally around Paleoarchean time. Suturing of northern proto-cratonic (Bundelkhand) block with the southern (Dharwar, Bastar, and Singhbhum) blocks was completed along the central Indian tectonic zone (CITZ) by Late Archean/Paleoproterozoic time. Lithosphere(s) below these blocks grew steadily with time and by Mesoproterozoic time thickness of lithosphere below various cratonic blocks was sufficient to have P-T conditions suitable for the preservation of diamonds. Around 1.1 Ga, various Indian cratons; as well those from west Australia, central and southeast Africa, and Sao Francisco Craton in South America; were contiguous and formed part of the Rodinia supercontinent. It is interesting to note that most of the

Proterozoic kimberlites in the world are located in these regions and show an age around 1.1 Ga. Thus a common causative factor like a superplume seems to be able to explain the origin of such a large number of Proterozoic kimberlites in regions that are presently separated by thousands of miles. The proposed model also explains some of the deeper characteristics of the sub-cratonic lithosphere below CITZ deciphered by seismic sounding and tomography, heat flow, gravity, and MAGSAT studies.

HIGH RESOLUTION SURFACE WAVE TOMOGRAPHY IN EAST ASIA AND WEST PACIFIC MARGINAL SEA

Jieshou ZHU, Jia Min CAO, Xue Lin CAI, Zhong Qun YAN (Dept.Geophysics, Chengdu University of Technology)

According to approximately 12,000 long-period digital seismic waveforms from 704 events (7.0≥M≥5.0) recorded by 58 digital seismic stations from CDSN, GSN, GDSN, and GEOSCOPE network in Eurasia and west Pacific regions, 5,007 accurate surface wave dispersion curves with periods ranging from 8 to 250 seconds were selected and employed for inversion. The high resolution 3-D shear wave velocity images in this area were constructed by inversion of both dispersion and waveform showing a notable lateral variation in lithosphere and asthenosphere. The images of shear wave velocity indicate that from upper crust to the depth of 70 km, high velocities are displayed in the region of eastern part of East Asia and West Pacific marginal sea, in contrast, extremely low velocities illustrated in the Qinghai-Tibet Plateau and its surrounding areas. The low velocity anomaly chain is located along the convergence belt of Tethys from Mediterranean Sea, through Turkey, Iran, Himalayan orogens, Burma to Indonesian islands. In the depth of 85 km to 250 km a giant low velocity belt, which extends from north to south, about 2 500-4 000 km in width, 8 000 km in length, is strikingly located at the east part of East Asia and West Pacific marginal sea. In general it is divided by a boundary at 110ºE in lateral direction, and divided by depth of 70-85 km in vertical direction, the velocity images show striking differences. The western part mainly features an accumulated and thickened lithosphere caused by collision between India and Eurasia, and the eastern part displays mainly the extending and thinning lithosphere caused by asthenosphere upwelling. The lithosphere in the west part is 100 km thicker than in east part. The shear wave velocity of lithosphere in west is 0.2 km/s to 0.25 km/s higher than in east, the temperature in the bottom of lithosphere in eastern parts is 300°C-400°C higher than western parts. In Paleocene Indian lithospheric slab subducted beneath the Eurasian continent with low angle. A thick lithosphere root (140-180 km) is formed in Qinghai-Tibet Plateau. The lithospheric mantle has the characteristics of craton. In contrast it shows low velocity in crust because of the partial melt and flow motion of crustal material. The giant low velocity belt in East Asia and West Pacific marginal sea is similar with East Pacific ridge, Atlantic ridge and Indian ridge. The tectonic evolution may undergo the following stages. The lithosphere of east edge of Asia was broken up and the asthenosphere upwelling forming the giant rifts system in mid and late Mesozoic. The present trench-islands arc-basin system in West Pacific marginal sea is the results of interaction with Pacific plate, Australian plate and Eurasian plate in Cenozoic.

UPPER MANTLE HETEROGENEITIES BENEATH ANTARCTICA FROM MULTIMODE RAYLEIGH WAVEFORMS

Anne SIEMINSKI, Eric DEBAYLE, Jean-Jacques LEVEQUE (Institut de Physique du Globe de Strasbourg, CNRS and Universite Louis Pasteur)

We applied a waveform inversion method to about 3300 regional Rayleigh-wave seismograms to construct a 3D model of the shear velocity structure in the upper mantle beneath Antarctica. The fundamental mode and the first four overtones are modelled in the waveform analysis. The resulting model shows a good agreement with surface tectonics and the previous surface wave tomographic studies in the region for the uppermost 200 km. It also reveals broad, low-velocity anomalies at 200 km depth beneath the South Pacific Ocean extending in some locations down to at least 400 km depth. At these depths, the structure is mostly constrained by the overtones. We thus expect a resolution for depths beyond 200 km better than in the previous studies which were all based on inversion of the fudamental mode dispersion curves only. Synthetic experiments confirm that our dense coverage in fundamental mode and overtones allows to properly retrieve velocity anomalies in the uppermost 400 km of the mantle, so that the deep low-velocity anomalies we found should not be artefacts. We interpret them as the effects of upwelling material. This kind of structures support a model of a plume-fed asthenosphere as proposed by Phipps Morgan et al. (1999) although their locations do not directly correspond to any reported hotspot in the region.

CONTINENTAL SURFACE AREA AND THE ASSEMBLY TIME FOR SUPERCONTINENTS

Gary T. JARVIS (Department of Earth and Atmospheric Science, York University)

We employ a kinematic numerical model of circular continental blocks moving about randomly on a two-dimensional periodic model of the Earth's surface and monitor the time required for all of the blocks to assemble into a single model supercontinent. We examine the sensitivity of the assembly times of our modelsupercontinents to the size of individual continental blocks, the fraction of the model Earth's surface covered by the continents, the degree of continental deformation upon collision and the initial spatial distribution of the continents. Assembly times are found to be most sensitive to the total continental surface area. We show that in the absence of any dynamic effects due to deep mantle flow, continents of present-day scale moving randomly about the Earth's surface would naturally aggragate into a single mass in approximately 0.4 Gy. Although this is a purely geometrically imposed time scale, which would be modulated by the dynamic effects of convection in the mantle, it is comparable to the time scales of both mantle fluctuations and the time intervals between successive supercontinent formations. Consequently, continental surface area will be an important factor to include in future dynamic models of supercontinent formation.

CHAOTIC TOPOGRAPHY AND 'GODZILLA MULLION' IN THE PARECE VELA BASIN, IMPLICATIONS FOR COLD MANTLE AND DOMINANT AMAGMATIC EXTENSION

Kyoko OKINO[1], Yasuhiko OHARA[2], KR03-01 Shipboard Scientific party([1]Ocean Research Institute, University of Tokyo, [2]Hydrographic and Oceanographic Department of Japan)

The seafloor formed over the Miocene in the Parece Vela Basin (PVB) is characterized by chaotic topography and the well-developed mullion structures, indicating a weak magma supply and mantle exposure at the intermediate spreading rate (full rate = 8.8 to 7.0 cm/yr)

---

system due to an unusual cold underlying mantle. The recent studies by Ohara and others reported a large, 55*125 km giant megamullion and petrological characteristics of peridotite from the Parece Vela Rift (PVR), the extinct spreading center of the basin. During KR03-01 cruise in January 2003 (R/V Kairei), we conducted 18 dredge hauls and geophysical mapping in order to understand the amagmatic tectonics in the region. This poster presents the preliminary results of the geophysical mapping, in which we show the anomalous seafloor fabrics formed under the amagmatic backarc spreading. The mapped area consists of two parts, 1) chaotic terrain in the western PVB and 2) ridge-transform intersections of PVR including giant megamullion. Although the chaotic terrain is surrounded by «normal» well-organized north-south abyssal hills area, it is characterized by very deep depth, rugged bathymetry with isolated highs, and high Bouguer gravity anomaly, indicating thin crust. We found at least four new mullion structures, each consisting of domed highs with continuous corrugations. The most prominent mullion has two clear, large corrugations, which continue from the 1500 m domed high to the smaller, 600 m high to the west. The corrugated pattern stops at the N-S trending minor ridge at its west and also N-S trending, but gently eastward convex lineament at its east. These features can be interpreted as the breakaway zone and the termination, corresponding to the start and end of the amagmatic phase with mantle exposure. The giant megamullion structure in the central PVR is quite large, so we propose to name it «Godzilla Mullion». It has the following unique characteristics compared with other seafloor megamullions; 1) its exceptional magnitude, 2) development over an entire segment (not only the inside corner), 3) «high» intermediate spreading rate (7.0 cm/yr), and 4) moderate gravity anomalies. Peridotites were recovered over the whole mullion structure in the cruise. The ridge-transform intersections of the Godzilla Mullion area and northern PVR also show the anomalously deep rift, mullions, remnant inside corner highs and peculiar abyssal ridge bends. These features are compatible with the existence of cold mantle and dominant amagmatic extension.

TELESEISMIC BODY- AND SURFACE-WAVE STUDIES IN THE LITHOPROBEWESTERN SUPERIOR TRANSECT: GLIMPSES INTO THE DEEPER ARCHITECTUREOF AN ARCHEAN CRATON

Stephane SOL, Colin J. THOMSON, Michael KENDALL, Don WHITE, Isa ASUDEH (IASPEI)

The Archean Western Superior Province in northern Ontario, Canada, isinternally divided into a number of east-west trendingmetasedimentary, metaplutonic and granite-greenstone subprovinces which getprogressively younger from north to south.Recognition of this geologicalarchitecture played an importantrole in the formation of ideas about Archean tectonics, specificallythat modern-day accretionary processes could have operated in a broadly-similar manner in theearly Earth.In order to characterize the underlying upper mantle, broadband teleseismic data were recordedduring a 5-month deployment of 17 instrumentsin an array cross-cutting the subprovince boundaries, with two more stationsextending coverage further north into the trans-Hudson orogen (THO). SKS splitting results within the W. Superior are broadly consistent with those of earliernearby experiments. Large (up to 2.1s) splitting times can be seen and we believethat an evolution in fast shear-wave polarization directioncan be discerned as the subprovinces are traversed.One station is anomalous and we attribute that to lateral variations (see below).The two trans-Hudson stations show virtually no SKS splitting, in stark contrast with thelargest splitting seen in the closest (and oldest) part of the W. Superior just to the south. Travel-time tomography shows significant lateral variations deep into the upper-mantle,perhaps extending to 670km. Whilethe best-resolved structures are reminiscent of subduction with an appropriate orientation,we cannot be sure if this represents a paleo-slab, possibly recently delaminated from thecontinental root, or the signature of small-scale convection. Indeed, a break in the patternof the tomography images at around 300km may represent the bottom of the lithosphere.Results from a collinear refraction/wide-angle-reflection (R/WAR) surveyalso suggest dipping structures just below the Moho. Rayleigh and Love dispersion across the array indicates that (i) the NS profile is best treated inthree segments and (ii) there is a Rayleigh/Love discrepancy suggesting anisotropy is important.Analysis along an orthogonal EW path from permanent station ULM supports the latter idea, as doesa close inspection of the Rayleigh/Love particle motions in various frequency bands forsurface-waves arriving from all azimuths. Several thought-provoking observations arise from jointly considering all these observations.In the younger terranes, SKS fast orientation seems to coincide with apparent subductiondirection imaged in the tomography, an exception being anomalous station 5070.The divergent observations at this stationare consistent with the presence of `shallow´ lateral variations nearby. Similarities are also observedbetween the R/WAR velocity model and the one inferred from surface-wavedispersion. Both indicate crustal thinning moving northward and fasterupper-mantle velocity in the E-W direction.Lastly, although SKS indicates null splitting at the THOstation BPW, surface-wave polarizations provide evidence of significant anisotropy.

LATERAL VARIATIONS OF SHEAR-WAVE SPLITTING BENEATH THE BOHEMIAN MASSIF - FIRST RESULTS OF PASSIVE SEISMIC EXPERIMENT BOHEMA

Jaroslava PLOMEROVA[1], Ludek VECSEY[1], Vladislav BABUSKA[1], Ulrich ACHAUER[2], Michel GRANET[2], BOHEMAWorking Group ([1]Institute of Geophysics, Czech Academy of Sciences, Bocni II, 141 31 Prague 4, Czech Republic, [2]EOST- Institut de Physique du Globe Strasbourg, 5, rue R. Descartes, 67084 France)

A dense network of stations, consisting of 61 permanent and 84 temporary stations, has been deployed to operate during 2001-2003. The array is centered in the geodynamically active part of the Variscan Bohemian Massif (BM, central Europe) around the crossing of the Eger Graben (EG) with the Marianske Lazne Fault (MLF). The BOHEMA (BOhemian Massif Anisotropy and Heterogeneity) research team is formed by scientists from 10 institutions of the Czech Republic, Germany and France. The team will develop geodynamic model of the lithosphere-asthenosphere system beneath the western part of the BM. It will be based on all available geophysical, geological and petrological data. A three-dimensional anisotropic tomographic model will be one of major results of the experiment. A joint inversion of the shear-wave splitting parameters and P-residual spheres aims at finding a general 3D orientation of anisotropic structures. We present first results of the shear-wave splitting analysis which show lateral variations of anisotropy across and along the EG, and compare them with the near-surface tectonics. Mapping changes in anisotropic parameters delimits large-scale domains of mantle lithosphere - Saxothuringian to the north- west and Moldanubian and Tepla-Barrandian to the south-east - with divergent orientation of dipping anisotropic structures on both sides of the rift structure of the EG. The research will further concentrate on distinguishing between thermal anomalies and anisotropic structures and try to answer the question about a possible existence of a thermal plume in the mantle beneath the western EG. The resulting geodynamic model will shed light on possible causes of earthquake swarms, which periodically occur in the region.

CONSTRAINTS ON PALEOBOUNDARIES OF MICROCONTINENTS FROM LATERAL VARIATIONS OF SEISMIC ANISOTROPY IN THE MANTLE LITHOSPHERE

Vladislav BABUSKA, Jaroslava PLOMEROVA (Institute of Geophysics, Czech Academy of Sciences, Bocni II, 141 31 Prague 4, Czech Republic)

Systematic preferred orientation of olivine crystals is the dominant source of large-scale seismic anisotropy in the subcrustal lithosphere and asthenosphere. Both the surface waves and body waves indicate ″frozen-in″ dipping anisotropic structures in the mantle lithosphere and a mostly sub- horizontal anisotropy due to the present-day flow in the asthenosphere. From lateral variations and magnitude of the observed seismic anisotropy we deduce a ″frozen-in″ origin of the continental mantle fabric created most probably in a stress field acting during the formation of individual lithosphere domains. The dipping structures may represent remnants of accreted pieces of ancient oceanic lithosphere and paleosubductions inferred also from dipping seismic reflectors extending into the mantle. Joint analysis of shear-wave splitting parameters and patterns of teleseismic P- residual spheres provide a good resolution for identification of boundaries of lithospheric domains with different fabric orientations, e.g., in the Variscan massifs of central and western Europe and in the Baltic Shield. The domains characterised by consistent orientation of anisotropy may represent individual cycles of ″accretion″ process. Boundaries of these domains are zones of potential weakness for later processes like rifting, volcanism and intraplate earthquakes. While most methods of continental reconstructions study the uppermost crust, seismic anisotropy allows us to contribute to modelling of the structure and development of the mantle lithosphere, which plays in many aspects decisive role in crustal tectonics.

THE STRACTURE OF LITHOSPHERE AND ASTHENOSPHERE IN EAST ASIA AND WEST PACIFIC MARGINAL SEA

JJieshou ZHU, Jia Min CAO, Xue Lin CAI, Zhong Qun YAN (Dept.Geophysics, Chengdu University of Technology)

The continent of East Asia and West Pacific marginal sea was formed by convergence of a series of micro-plates and blocks in the late Paleozoic (about 250-220 Ma). Since Mesozoic (about 150 Ma) the asthenospheric material upwelling caused the lithosphere extension and thinning, and with strong activities of volcano and magma. In Cenozoic the continental margin continued to develop large scale rifts and marginal sea, a series of extending oceanic ridges and basins appeared. In Paleocene epoch the Indian sub-continent collided with the Eurasian continent causing the crust to be shortened and rapidly uplifted, forming the highest of Qinghai-Tibet plateau and the largest convergent region on the Earth. Consequently, reconstruction the 3-D structure of lithosphere and asthenosphere is significant to understand the relationships between the surface tectonics and the deep earth′s structures and dynamics in this region. We employed about 55,000 km high precision explosion deep seismic profiles and high resolution seismic tomographic images in the studied area (60°E-150°E, 0°S-60°N) to make 2º×2ºgrid point model. For each point the layered parameters of depth, density, velocities Vp and Vs in the crust, lithospheric mantle, asthenosphere to 410 transition zone are given. The thickness of lithosphere in East Asia and West Pacific marginal sea varies from 50 km to 200 km. The thinning lithosphere with thickness of 50-80 km is located in West Pacific marginal sea, eastern part of North China, and southeastern part of South China. The thickness of 80-100 km is located in transition region of eastern part of East Asia. The thickness of 100-130 km is located in transition region of middle part of East Asia. In the continental craton and accumulated thicken lithosphere regions, such as India, Tarim, Yangtze, Qinghai-Tibet, Siberia, Kazakhstan, the thickness of lithosphere can reach 130-200 km. There is tremendously thick lithosphere of 180-200 km in the eastern part of Qinghai-Tibet Plateau and in Pamir and northern India. The Pacific and Philippine plate show highest velocity that indicates the characteristics of lithosphere of these oceanic plates are remarkably different with the continent. There exists a giant low velocity belt in the asthenosphere with length of about 8,000 km, width of about 2,500-4,000 km from Sea of Okhotsk, Kuril basin, Sea of Japan, North China and South China, South China Sea to Philippine Sea. The characteristics of the low velocity belt is not same with subduction zone in East Pacific, however, it is the same with the Pacific Ocean rise, Atlantic Ocean ridge and Indian Ocean ridge. The tectonic evolution may undergo the following stages. The lithosphere of east edge of Asia was broken up and the asthenosphere upwelling forming the giant rifts in Mesozoic. The present trench-islands arc-basin system in West Pacific marginal sea is the results of interaction with Pacific plate, Australian plate and Eurasian plate in Cenozoic.

JSS06b/10P/D-015   Poster   1400-039

THE 3D STRUCTURE OF LITHOSPHERE AND AND ITS DYNAMIC IMPLICATIONS IN QINGHAI-TIBET PLATEAU

Jieshou ZHU, Zhong Qun YAN, Shen QU (Dept.Geophysics, Chengdu University of Technology)

The Qinghai-Tibet plateau and its surrounding areas including Indian subcontinent, Xinjiang, Mongolia, is a largest lithosphere convergence place in the world, which characterized by continent-continent collision with a thick lithosphere. The high resolution seismic surface wave tomographic inversion has been conducted for studying the 3D velocity structure of lithosphere and asthenosphere in those areas. About 1400 long period surface wave waveform recordings are available for both dispersion and waveform tomographic inversion. The block inversion by grid 1º×1ºin Qinghai-Tibet plateau show the high resolution 3D shear wave velocity variation from earth′s surface to 400km depth. The images of S-wave velocity at different depths show significant characteristics of lithosphere and asthenosphere structure in Qinghai-Tibet plateau and its surrounding areas. In depth of 16-32 km the Qiangtang terrane indicates extremely low velocity, in opposed, the surrounding areas show relative high velocity such as in Indian peninsula, Pamir and Hindu Kush region, Tarim basin. In depth of 40-70 km the low velocity areas are extended to the surrounding terranes. In depth of the 85-130 km the still shows low velocity, however, the Lahsa terrane has a relatively high velocity. It clearly shows the correlation between the S-wave velocity in the top of upper mantle and the Pn wave velocity (based on earthquake Pn phase tomographic image) with characteristics of low velocity in Qiangtang terrane. It is identified, for the first time, by seismic tomography that the high velocity blocks of both Indian and Eurasian plates occur in the lower part of lithosphere in plateau. The velocities of the Vs in the blocks are between 4.60 and 4.70km/s, and the two blocks were collided against each other. The bottom of lithosphere generally ranges 140 to 160 km and up to 185km in region of the southeast plateau where continent lithosphere roots existed. The asthenospere thickness is generally range 140 to 180km, and the Vs velocities from 4.35 to 4.45km/s within the asthenosphere. Since the collided of India and Eurasia in the beginning of Cenozoic (about 55 Ma), a continental root with the thickened lithosphere of 140 km-180 km thick was formed in Qinghai-Tibet Plateau and central Asia. The Indian lithospheric slabs subducted beneath the Qinghai-Tibet Plateau and the lithosphere shortened about 2,500 km. The manner of lithosphere shortening is delamination and accumulation. The lithospheric mantle of Qinghai-Tibet Plateau has the characteristics of craton (lower temperature and small deformation)

that shows high velocity. In contrast the crust in plateau shows low velocity that may be related with the higher temperature and strong deformation causing the crust partial molten and flow.   The velocity profiles of surface wave tomography in Qinghai-Tibet plateau indicate the subducted detached Indian lithospheric slab beneath the plateau. The location of collision of Indian lithospheric slab with Eurasian is along the Jinsajiang suture zone.

SUBDUCTION ZONE STRUCTURE BENEATH INDONESIA (REVISITED)

Sri WIDIYANTORO[1], Gede SUANTIKA[2], Wahyu TRIYOSO[1] ([1]Department of Geophysics and Meteorology, Institut Teknologi Bandung, [2]Volcanological Survey of Indonesia)

Seismic tomographic images of the Earth's mantle beneath the Indonesian island arcs presented in earlier publications depict the complex morphology of subducted oceanic lithospheric slabs. Slab penetration into the lower mantle with and without deflection, slab lying flat on the 660-km discontinuity, slabs subducted in two-opposing directions and slab detachment represent co-existence of slab styles within the study region.Recently, we have revisited the Indonesian subduction zone structure by means of a non-linear tomographic imaging technique in which 3-D ray tracing has been carefully implemented. We have used P- as well as S-wave arrival times from an updated version of the reprocessed global data set by Engdahl et al. The results provide some improvements in the positioning of heterogeneity. Intriguing slab morphologies are observed, for instance: (i) penetration into the lower mantle of the westward dipping slab of the two opposing subducted slabs of the Molucca Sea plate by taking the form of folded slab; (ii) southward subducted back-arc oceanic crust below Bali; and (iii) possible slab detachment below central Sumatra. The first two observations represent new features revealed by this revisit and the detachment below part of Sumatra to some extent supports our previous result. The inversion of travel-time residuals of direct S phases generally confirms the inferences from the P-wave information with comparable detail resolved. We present the new tomographic models for the Indonesian subduction zone in detail. Inspired by the nature of subduction processes that is closely related to volcanism, we have also applied the non-linear seismic tomographic imaging approach to a volcano tomographic investigation. This has been conducted in part under the encouragement of the IASPEI-IAVCEI Working Group on Subduction Zones Located in Developing Countries. Here, a preliminary result from tomographic investigation of Mount Guntur in West Java is also presented.

INTERMEDIATE DEPTH EARTHQUAKES DISTRIBUTION AND THEIR FOCAL MECHANISM IN VRANCEA SEISMOGENICZONE, ROMANIA

Andrei BALA, Mircea RADULIAN, Emilia POPESCU (NATIONAL INSTITUTE FOR EARTH PHYSICS, Bucharest, Romania)

The Carpathian Orogen is of Alpine age, composed of many Mesozoic and Cenozoic terranes. Back-arc volcanism, and back-arc extension in the Pannonian area, accompanied the Neogene subduction. A bent paleosubduction zone was recognized in the Eastern Carpathians, along which the original oceanic basement of flysch and the Subcarpathians nappes were consumed. A small portion of this zone is still seismically active in the Vrancea area. This prominent south-eastern zone of the Carpathian Orogen lies above a nest of strong recent earthquakes (1940, MW = 7.7; 1977, MW = 7.5; 1986, MW = 7.2; 1990, MW = 6.9) situated between 60 and 200 km depth. This is the only place in the entire Carpathians where folding and thrusting occurred during Pleistocene in the outermost zones between two deep faults in the Moesian Platform. These recent crustal movements recorded in the area are accompanied by moderate crustal seismic activity (between 10 - 50 km depth and Mmax = 5.5), which together with intermediate depth seismicity produce high seismic risk in a densely populated area. In Vrancea area, the original oceanic lithosphere descended to more than 200 km depth, as indicated by the intense intermediate depth seismic activity. Recent works in seismic tomography indicate that regional scale anomalies of the seismic velocities are appearing down to 350 km depth.The tectonic plate evolution of the whole Carpathian Arc and Pannonian back-arc Basin indicates that at least three tectonic units have been in contact and, at the same time, in relative motion : the East European Plate, the Moesian plate and the Intra-Alpine plate. There were represented 526 hypocenters of earthquakes from the period 1929 - 2000 which have computed focal mechanism. Most of the epicenters are situated in an area which includes Vrancea zone (25° - 28.5° E, 44.5° - 47° N).Because of the great number, they were found to describe well the limits of the tectonic plate (plate fragment ?) which is supposed to be subducted in this region. These limits were put in direct relations with the known geology and tectonics of the area. A conclusion to these observations is that at least one seismogenic zone is present in the crust and 2 zones are present in the domain of the intermediate earthquakes: the first from 60 - 100 km and the second from 100-110 km to 200 km depth. These 3 zones have clearly different characteristics both in the number of earthquakes occurred and also as the total released energy of the earthquakes occurred in each zone. They are also different in respect with the orientation angle of the blocks, which is changing at about the same depth. The ″transition zone″ (around 100 - 110 km depth) appears as a relatively low activity seismic zone. Available fault plane solutions for the intermediate depth earthquakes are analyzed in several depth intervals indicated by the seismic activity. Correlation of the focal parameters in connection with the depth of the hypocenters is discussed.

JSS06b/10P/D-018   Poster   1400-042

ANISOTROPIC VELOCITY STRUCTURE OF THE JAPAN ISLANDS

Motoko ISHISE[1], Hitoshi ODA[2] ([1]Graduate School of Natural Science and Technology, Okayama University, [2]Department of Earth Science, Okayama University)

Assuming that seismic anisotropy is attributable to hexagonal anisotropy of which the c-axes lie horizontally, we investigated the lateral variations of isotropic and anisotropic P-wave velocity beneath the Japan Islands composed of two island arcs, the southwest and northwest Japan arcs, under which the Philippine Sea plate and Pacific plate subduct, respectively. The P-wave velocity anisotropy is described by direction of the hexagonal c-axis and intensity of anisotropy at grid points that are spaced out 0.5° in the N-S and E-W directions and 10-30 km in depth under the study area. In the Tohoku district, northeast Japan, the tomographic image of the isotropic P-wave velocity reveals a high velocity slab corresponding to the descending Pacific plate and a low velocity region upwelling above the plate. The anisotropic velocity structure is found to be different between the eastern and western regions of the Tohoku district. The seismic anisotropy of the western region is characterized by the c-axes which are orientated in the east-west direction that is nearly parallel to the descending direction of the Pacific plate, whereas the c-axes in the eastern region are in the north-south direction that is nearly perpendicular to the geomagnetic lineation observed near the Japan trench. Comparison between the anisotropic and isotropic lateral structures shows that the east-west direction of the c-axes are dominant in the pronounced low velocity zone of the upper mantle and the north-south direction is conspicuous in the high velocity Pacific plate. In the Chugoku and Shikoku districts, southwest Japan, a clear difference is found in the P-wave anisotropy of the crust and upper

mantle. The crust exhibits the seismic anisotropy characterized by the c-axes orientated in the east-west direction. A systematic change of the axis distribution is found in the upper mantle, where the c-axes are in the north-south direction within the south side region of a boundary line located at 34° N and in the east-west direction within the north side region. The location of the boundary is coincident with that of leading edge of the seismic belt of the upper mantle earthquakes occurring in the Chugoku and Shikoku districts. The mantle anisotropy in the south side region of the boundary is attributed subduction of the Philippine Sea plate, while the regional stress field due to interaction between the Eurasia and Pacific plates arises the mantle anisotropy of the north side region and crustal anisotropy.

SELF-CONSISTENT DYNAMICAL MODELS OF THE SUBDUCTION IN THE MANTLE CONVECTION SYSTEM: ON THE DRIVING FORCE AND THE ROBUSTNESS OF GENERATION OF THE PLATE TECTONICS

Tomoeki NAKAKUKI, Chiho HAMADA (Department of Earth and Planetary Systems Science, Hiroshima University)

We have developed self-consistent dynamical models of the plate-mantle convection system to understand dynamics of initiation of the subduction. We utilize rheology depending on the hysteresis of the stress to realize the subduction-like descending flow of a cold thermal boundary layer with high viscosity (Honda et al., 2000). No external forces are applied to the surface boundary and the plate in the model. We introduce heterogeneity of the surface region, i.e., ˝oceanic˝ and ˝continental˝ region, which is treated as a horizontal heterogeneity of the yield stress and/or the composition at the surface. We here use realistic rheology including Arrhenius-type temperature and pressure dependence and maximum yield strength whose values are in the range of 200 to 600 MPa (400 to 1200 MPa in a deferential stress) as large as those reported by the experimental studies for the rheology of the lithosphere. We also examine effects of a preexisting weak zone at the oceanic-continental plate boundary.　Our results show that the subducted slab is formed when the strength of a fault zone at the plate boundary is small enough. This does not strongly depends on the maxmum strength of the lithosphere, namely, the subduction successfully occurs even at the highest value in the model (600 MPa). We also analyze forces working on the plate and the slab. At the initial condition, motion of the plate begins with compressive force induced by the shape of the plate (ridge push force) and plume (mantle-drag force). A negative buoyancy by the slab balanced with resistance by the overriding plate until the slab penetrates into the depth of 150 to 200 kilometers. This implies that the force continuously pushing the plate such as mantle-drag force to initiate the subduction until the slab reaches the depth at which the slab-pull force overcomes the resistance. When the weak zone is not set in the initial condition, the subducted plate is generated under the condition with the yield strength less than 200 MPa. This suggest that the other mechanism fracturing the plate may be required to generate the initial weak zone which develops the plate boundary.

FLUID DISTRIBUTION IN THE MANTLE WEDGE OF NE JAPAN INFERRED FROM SEISMIC VELOCITY AND ATTENUATION STRUCTURES

Junichi NAKAJIMA, Akira HASEGAWA (Tohoku University)

Our recent tomographic work [Nakajima et al., 2001] revealed detailed P- and S-wave velocity structures beneath the northeastern (NE) Japan arc. The results show that inclined seismic low-velocity zones are continuously distributed in the mantle wedge of the NE Japan arc in parallel to the down-dip direction of the subducting slab. They corresponded to the seismic high attenuation zones estimated by Tsumura et al. [2000]. These zones have been interpreted as the ascending flow from deeper portion of the back-arc side, which perhaps contains large amount of fluids.　In order to know the shape of fluid-filled pores and volume fraction of fluid in these low-velocity zones, we first estimated temperature distribution in the mantle wedge by applying experimental results of high-temperature and low-frequency internal friction in Peridotite [Kampfmann and Berckhemer, 1985] to the P-wave attenuation structure [Tsumura et al., 2000]. Estimated temperature in the mantle wedge ranges from 1000°C to 1200°C. We calculated values of dlnVs/dlnVp by using the results of Nakajima et al. [2001] after correcting P- and S-wave velocity variations caused by temperature heterogeneities, which enables us to know whether or not melt or aqueous fluid in the low-velocity zones is in the state of textural equilibrium [Takei, 2002]. As a result, it is found that fluid phase exists in the low-velocity zones of the mantle wedge in NE Japan. We infer that the fluid phase in the low velocity zones is not H_2O but melt, since the estimated temperature in the low velocity zones exceeds wet solidus of Peridotite [Kushiro et al., 1968]. Aspect ratios of melt-filled cracks and their volume fractions are approximately 0.01-0.1 and 0.1-1 %, respectively, which suggests that melt pockets are distributed in the low velocity zones. Aspect ratio of melt-filled cracks varies with depth. It is approximately 0.1 at a depth of 90 km or so and less than 0.1 at shallower depths. This shows that the melt existing in rocks is far from textural equilibrium at shallower depths (at least shallower than 65 km), which would suggests that melt migration through interconnected cracks is dominantly occurring in the shallow part of the ascending flow in the mantle wedge of NE Japan.

ON THE RELATIONSHIP BETWEEN ISOTOPE HETEROGENEITY AND CONVECTION IN THE EARTH'S MANTLE

Yury V. MIRONOV[1], Vladimir M. RYAKHOVSKY[1], Alexander A. PUSTOVOY[2] ([1]Department of Geoinformation Systems, Vernadsky State Geological Museum of RAS, Moscow, Russia, [2]Atlantic branch, Shirshov Institute of Oceanology of RAS, Kaliningrad, RUSSIA)

One of the topical questions of modern global geodynamics - how to coordinate chemical heterogeneity and convection in the Earth's mantle? We have tried to answer this question by comparison of the isotope and tomographic data on the Atlantic and Indian oceans, and also on adjacent continents. The Arctic (the spreading ridges of Northern Atlantic, Norvegian-Greenland sea and Arctic ocean, islands Iceland and Jan-Mayen, Iceland-Fareroe Rise, traps of Norway, Britain, and Greenland), Northern-Central (Mid-Atlantic Ridge from Reykjanes ridge up to 24ES, numerous islands and rises, located at the same latitudes, Cameroon Line, African and European rifts, Aden and Red sea spreading centers, and also Comores in Indian ocean), Southern (Gough, Tristan-da-Kunha, Walvis ridge, Rio Grande Plateau, Discovery, traps of Southern America and Africa, islands and mid-ocean ridges in Indian ocean), and Bouvet-Antarctic (the rises Spiss and Shona, the most southern part of Mid-Atlantic ridge, island Bouvet, an adjacent part of Southwest-Indian Ridge, and also traps and rifts on northern coast of Antarctic Continent) Sr-Nd-Pb isotope sublatitudinal provinces are chosen in this region. They include mid-ocean ridges, oceanic rises and islands, as well as Late Mesozoic-Cenozoic continental rifts and traps. The specificity of these provinces determine either end-members of Zindler-Hart's ˝mantle tetrahedron˝ HIMU (Northern-Central and Bouvet-Antarctic provinces) and EM1 (Southern province), or component ARCTIC. The latter locates outside ˝tetrahedron˝ and is widespread in the Arctic province. The common component in magmatic rocks from all provinces and types of structures is certain component F (' focal". It represents average characteristic of all known intratetrahedron components (FOZO, C, PREMA etc.), updated by methods of multidimensional statistics. In withinplate structures component F forms quasy-binary mixtures with specific component (for given province). Mid-ocean ridge basalts (MORB) from different provinces vary in stable admixture of the same specific components, but as a whole represent admixture between F and DM, DM+HIMU is less abundant. Basing on the newest Becker-Boschi's tomographic model two types of low velocity mantle area, which are considered as a place of superplum generating, was separated. Both low-mantle and mid-mantle plums are discordant to the isotopic provinces, but differ on depth, size and relation to riftogeneous structures and areas of modern magmatism. Probably, all mantle plums are originated in relatively homogeneous reservoir F and later reacted with heterogeneous the most upper part of mantle. The main components of the latter are DM, HIMU, EM, ARCTIC. As against the majority of researchers we count, that top border of F reservoir is on rather small depths as the component F is widely distributed in products of the least deep magmatism out of the plums (MORB). The offered model can remove the fundamental contradiction between the fact of mantle heterogeneity and necessity of convection in its basic volume. The work is supported by RFBR, and federal program ˝World Ocean˝.

LONG-TERM EVOLUTION OF THE GLOBAL WATER AND CARBON CYCLES

Siegfried A. FRANCK, Christine BOUNAMA, Werner VON BLOH (Potsdam Institute for Climate Impact Research)

We investigate the thermal and degassing history and future of the Earth with the help of a parameterised mantle convection model including the exchange of water and carbon between the mantle and the surface reservoirs. Both volatiles are of specific importance because they exert a major influence on a wide range of geological, biogeochemical and biological processes. Water and carbon dioxide provide the necessary conditions for the emergence and maintenance of photosynthetic-based life. Water is the most abundant volatile and is drawn from the surface reservoirs to the mantle by subduction of the ocean floor. Outgassing of water from the mantle occurs at mid-ocean ridges. The water content of the mantle is directly coupled with the thermal and degassing history via a water-dependent rheology of mantle material. Carbon dioxide is much less abundant than waterbut believed to have a main influence on the Earth´s climate. Our model for the global carbon cycle contains the reservoirs mantle, ocean floor, continental crust, biosphere, kerogen, as well as the aggregated reservoir ocean and atmosphere. Both global cycles (water and carbon) are mainly coupled via the process of volatile exchange between mantle and surface reservoirs (i.e. subduction and spreading).We calculate the evolution of all water and carbon reservoirs over Earth´s history and into the long-term future under a maturing Sun. We obtain reasonable values for the present distribution of carbon in the surface reservoirs. The water content in the surface reservoirs shows an outgassing eventat the beginning of planetary evolution followed by a subsiding process to end up in the recent situation of one ocean at the Earth´s surface. In thelong-term future only about 1/4 of the modern ocean will be subducted into the mantle. The life span of the photosynthesis-based biosphere will end upin about 1.2 billion years. This results from too low atmospheric carbon content and not from a lack of water in the surface reservoirs or from too high surface temperatures. At this time mean global surface temperatures will be in the order of about 40°C.

JSS07/09A/A02-001　　0900

THE NATIONAL TSUNAMI HAZARD MITIGATION PROGRAM

Eddie N. BERNARD (NOAA/PMEL)

The National Tsunami Hazard Mitigation Program is a state/Federal partnership that was created to reduce the impacts of tsunamis to U.S. Coastal areas. It is a coordinated effort between the states of Alaska, California, Hawaii, Oregon, and Washington and three Federal agencies: the National Oceanic and Atmospheric Administration (NOAA), the Federal Emergency Management Agency, and U.S. Geological Survey. Because of NOAA´s responsibility to provide tsunami warning services to the nation, NOAA has led the effort to forge a solid partnership between the states and the Federal government. The partnership has established a mitigation program in each state that is preparing coastal communities for the next tsunami. Inundation maps are now available for many of the coastal communities of Alaska, California, Hawaii, Oregon, and Washington. These maps are used to develop evacuation plans and, in the case of Oregon, for land use management. The partnership has successfully upgraded the warning capability in NOAA so that earthquakes can be detected within 5minutes and tsunamis can be detected in the open ocean in real time, paving the way for improved tsunami forecasts. An overview of the program will be given along with the results of a review of the program´s accomplishments.

SEISMIC ACTIVITY AND TSUNAMI ACTIVITY OF THE MAIN TSUNAMIGENIC REGIONS IN THE PACIFIC: A COMPARATIVE STUDY

Viatcheslav K. GUSIAKOV (Department of Geophysics, Institute of Computational Mathematics and Matematical Geophysics)

The historical tsunami catalog collected within the HTDB/PAC (Historical Tsunami Database for the Pacific) Project contains the most complete parametric tsunami data covering the whole Pacific and the full historical period of available observations (from 47 BC to present). As a supplementary part, the database contains the parametric earthquake catalog having more than 230 000 historical earthquakes occurred in the Pacific region. The collected data give us a possibility to study the variability of the tsunami potential of submarine earthquakes over the main tsunamigenic regions in the Pacific. For each region, the tsunamigenic potential is evaluated on the basis of the tsunami efficiency (TE) coefficient which is calculated as ratio between the number of tsunamis of tectonic, landslide and unknown origin and the total number of the coastal and the submarine earthquakes with magnitude Ms = 7.0 and depth h < 100 km. In this study, only the instrumental part of both catalogs (from 1901 to present) has been used. In the Pacific, the tsunami efficiency, calculated in the above manner, varies from 84% for the South America region to 36% for the New Zealand -

Tonga region. The comparison of the variation of the TE ratio with the position of the main sedimentation zones in the Pacific (Lisitsyn, 1974) shows that the regions located within the equatorial humid zone (New Guinea - Solomon, Indonesia, Philippines) have the increased number of tsunamigenic events as compared to the regions located in other zones. The circum-continental zonation in the sedimentation rate resulted in the highest TE ratio for the South America region where the tsunamigenic sources are located closest to land. The higher sedimentation rate results in a higher potential for the submarine slumping thus considerably increasing the efficiency of the tsunami generation mechanism. The earthquakes in the marginal seas (the Japan Sea, the Okhotsk Sea, the Bering Sea) have a higher tsunami efficiency as compared to the earthquakes in the Pacific ocean. For Hawaii, the TE ratio exceeds 100%, which shows that some events were generated by the earthquakes with magnitudes less than 7 or even had a non-seismic origin.

JSS07/09A/A02-003   0930

SOURCE MODELING OF HOLOCENE TSUNAMIS ALONG THE KURIL TRENCH

Kenji SATAKE[1], Futoshi NANAYAMA[2], Shigeru YAMAKI[3] ([1]Active Fault Research Center, GSJ/AIST, [2]Institute for Marine Resources and Environment, GSJ/AIST, [3]Seamus Corporation)

Numerical tsunami modeling along the Kuril trench indicate that unusual tsunami deposits in eastern Hokkaido were brought by large earthquakes with longer ruptures than those recorded in the region's 200 years of written history. Eastern Hokkaido's historical tsunamis are typically from interplate earthquakes, with rupture length of 100 - 200 km. Such events, occurred in 1952 (Mw 8.1) and 1973 (Mw 7.8) as well as 1843 (M 8.0) and 1894 (M 7.9), rarely produced tsunami heights more than 4 m. These earthquakes have been considered characteristic of the southern Kuril trench. Extensive tsunami deposits, recently found and mapped in eastern Hokkaido, indicate larger prehistoric tsunamis. At Kiritappu, for instance, sand sheets extend as much as 3 km inland, whereas the historic tsunami inundated no more than 1 km. Ten sheets of tsunami deposits indicate recurrence of such unusual tsunami with an average recurrence interval of about 500 years. The most recent event occurred in the 17th century. Geologic evidence of coastal uplift was also found for the 17th century, while historic documents in Honshu rules out unusual tsunamis that would cause damage along the Sanriku coast. We made numerical modeling of tsunamis by using finite-difference computations of the non-linear long-wave equation, to calculate coastal tsunami heights for the Hokkaido and Honshu coasts and inundation for selected sites where the tsunami deposits were mapped. For the inundation, moving boundary condition with the minimum grid interval of 25 m is adopted. We modeled various fault parameters. The fault widths are 50 km (tsunami earthquake), 100 and 150 km (typical interplate events), 200 and 250 km (wide faults that would uplift the coast). We also varied fault length along the trench axis as 100 - 200 km (single segment) and 300 km (multi-segment). On the Hokkaido coast, the largest tsunami heights are computed from multi-segment fault or tsunami earthquake. The wide faults produce smaller heights, because the coast is also uplifted. The computed heights from tsunami earthquake locally vary because of the shorter wavelength. The tsunami inundation is largest from the multi-segment fault, reproducing the extent of tsunami deposits. The wide faults produce less inundation, whereas the single-segment fault or tsunami earthquake does very little inundation. On the Sanriku coast, the tsunami heights from the wide faults are large enough to have caused damage. Other models produce smaller tsunami that can be escaped from historic documents. In summary, only multi-segment fault can explain the tsunami deposits and lack of documented damage on Sanriku coast. Geologic evidence of uplift can be explained by aseismic slip on deeper part of plate interface.

TSUNAMI WAVES GENERATED BY 1883 KRAKATAU ERUPTION: ANALYSIS, SOURCEDEFINITION AND NUMERICAL SIMULATION

Efim PELINOVSKY[1], Alexander STROMKOV[1], Irina DIDENKULOVA[1], ByungHo CHOI[2] ([1]Laboratory of Hydrophysics, Institute of Applied Physics, [2]Department of Civil and Environmental Engineering, Sungkyunkwan University, Suwon, 440-746, KOREA)

The 1883 Krakatau volcanic eruption has generated a destructivetsunami higher than 40 m on the Indonesian Coast where more than36,000 lives were lost. Sea level oscillations related with this eventhave been reported on significant distances from the source in theIndian, Atlantic and Pacific Oceans. Evidence of many manifestationsof the Krakatau tsunami was a subject of the intense discussion.Thirty-five tide-gauge records are collected by the Royal Society andpublished in the special report in 1886. All records are digitizedwith time sep 30 s and processed. First of all, the tide componentsare calculated and eliminated from the records. Then the Fourierspectra of the residual records are calculated and analyzed. Thecepstral analysis is applied to determine the generated wave in thetsunami source. It has the pulse form with characteristic durationabout 30 min. The form of generated wave is in agreement with tsunamirecords in near-epicentral zone (Sunda Strait) and genration mechanismby Nomanbhoy and Satake (1995). The results of given analysis arecompared with the results of the direct numerical simulation of thetsunami wave propagation in the framework of the linear shallow-watertheory using the ETOPE2 bathymetry. Data of witness reports are alsoused for comparison of the numerical results.

DISTRIBUTION OF CUMULATIVE TSUNAMI ENERGY FROM ALEUTIAN-ALASKA TO WEST CANADA

Tokutaro HATORI (Member of the Seism. Soc. Japan)

Large Aleutian-Alaska tsunamis have been recorded since 1788. The 1946 Aleutian tsunami associated with a moderate earthquake (Ms 7.4) hit the Hawaiian Islands. The 1964 Alaska tsunami was observed in the whole of the Pacific regions. Tsunami magnitude was the largest (Imamura-Iida scale: m=4). The source areas of large tsunamis in 1957, 1964 and 1965 extend 600-900km along the trench. In the present paper, the distribution of cumulative energy (square value of tsunami height, H^2, where H: the mean height in segment unit) for each 200km segment along the Aleutian-Alaska trench is investigated for the recent 103-year (1900-2002) and historical (1788-1899) periods. For the total tsunamigenic energy, ΣH^2, during 215-year period, percentages of the received energy in the 1,000km range were 39% in Central Alaska, 32% in the Alaska Peninsula and 11% in Central Aleutian Islands. During the recent 103-year, the energy value in Central Alaska is nearly comparable with those of the Kamchatka and South Chilean regions. If the tsunami energy is accumulated with the mean rate since 1788, the expected value in Central Alaska is small comparing with the observed value of the recent 103-year, because of the 1964 event. On the contrary, the expected value in the ranges of the Central Alaska Peninsula (400km length) and Yakutat regions is about twice larger than the observed value, suggesting high tsunami risk.

JSS07/09A/A02-006   1015

DAMAGES TO HOUSES BY THE 1964 TSUNAMI IN CRESCENT CITY, CALIFORNIA

Nobuo SHUTO (Faculty of Policy Studies, Iwate Prefectural University)

To remind the 1964 tsunami in Crescent City, California, on March 28, a book ˝Dark Disaster 64/84˝ was published by W.H. Griffin in 1984. Articles in this book are analyzed to give threshold of damage to houses, by locating the houses and buildings and estimating the tsunami in the city area. The 1964 tsunami hit Crescent City, as a far-field tsunami after travelling over 3,000 km. It began with rather gentle and small inundation of the first and second waves that inundated only small, shoreline parts of the city. Before the biggest fourth wave came, the seawater receded to show the bottom of Crescent bay, and most of ships and boats got aground. Then the forth wave came and showed the spilling breaking near the shoreline. The seawater, however, entered the city area as a gentle current, except the area of I and J streets where the wave front formed a wall of water 5 feet high. The largest water depth was about 8 feet above ground. This inundation height was lower than the ceiling of the first story of houses and shops. Many wooden houses were floated, moved and damaged. The major cause of the damage was not impact of water flow near the wave front nor floated materials such as cars, lumbers and debris, but buoyancy due to seawater. Typical examples are as follows. In case of a one-story house, ˝Hearing a strange noise, I got out of bed and throwing a light weight bedspread over my shoulders, went to investigate. As I did my house was torn loose from its foundation and floated for about 50 feet˝. The water depth was estimated as deep as 4 to 7 feet. In case of a two-storied building with a large attic, built of redwood, it was lifted completely from its foundation and moved some 30 feet or more. The estimated water depth was about 4 feet. Fourteen examples of wooden houses showed that a wooden house not connected with foundation would be lifted by seawater of 4 feet high. Other nineteen examples showed that non-wooden buildings were not moved by seawater less than 8 feet deep, even though windows and doors were completely broken by seawater or floated materials. The tsunami- related fire in Crescent City should not be forgotten in the coastal development in any country. An extremely small possibility to ignite brought a big fire because of oil tanks.

JSS07/09A/A02-007   1030

THE SEARCH FOR TSUNAMI SOURCE DISCRIMINANTS IN THE NEAR AND FAR FIELDS

Emile OKAL[1], Costas E. SYNAOLAKIS[2] ([1]Department of Geological Sciences, Northwestern University, [2]Department of Civil Engineering, University of Southern California)

We seek to identify observables of tsunami waves, both in the near and farfield, which could be used to discriminate between dislocation and landslidesources. In the far field, we deriveasymptotic expressions for the energy, spectral amplitude and directivityof tsunami waves generated by double-couples obeying universal scaling laws,and by landslides modeled as single forces.We discuss the influence of Dahlen´s [1993] quadrupolar corrections forthe latter, which we find crucially important in the case of tsunami waves.We show that the spectrum of landslide tsunami waves issignificantly offset to high frequencies (10 mHz), where dispersion becomesimportant thus diminishing far-field amplitudes. We reproduce the resultsof Kajiura [1981] on the growth of the energy of earthquake tsunamisas the power 4/3 of the seismic moment. We show thatthe total energy generated into a tsunami wave by a landslide of acceptable sizeremains dwarfed by that generated by a mega-thrust dislocation. Wediscuss the far-field directivity pattern due to source finitenessfor both dislocation and landslide models, and conclude that strong directivity,i.e., a narrow azimuthal lobe of maximal amplitudes, requires generation bya dislocation source in the case of tsunami waves, and can thus be useda source discriminant.In the near field, we use numerical simulations to explore the influence ofearthquake source parameters on observable properties of tsunami run-upamplitudes. These include earthquakegeometry (source depth, strike, dip, slip angles), size (seismic moment),location (distance from shore and centroid depth), as well as beach geometry(water depth and beach slope). We focus both on maximum run-up and on thedistribution of computed run-up along the beach, which leads to twodimensionless parameters, namely (i) the ratio of maximum run-up tothe amount of slip on the fault; and (ii) the aspect ratio of abell curve fitted to the lateral distribution of run-up.We find that the first parameter remains oforder 1, while the second one remains smaller that the maximum strainreleased during the earthquake, itself an invariant.By contrast, in the case of landslidesources, the aspect ratio of the lateral distribution of run-up along the beachcan be 1 to 2 orders of magnitude greater, suggesting its use asa potential discriminant in the near field.We apply these discriminants to the case of the 1946 Aleutian tsunami,and suggest that its source must haveinvolved both a large slow earthquake (to explain the far field tsunami)and a coeval landslide (responsible for the near field tsunami).

INTEGRATED WEB-BASED ORACLE AND GIS ACCESS TO TSUNAMI AND EARTHQUAKE DATA FOR QUALITY CONTROL AND ANALYSIS

Paula Kay DUNBAR[1], John C. CARTWRIGHT[2], Daniel KOWAL[2], Thomas GAINES[2] ([1]National Geophysical Data Center, [2]Cooperative Institute for Research in Environmental Sciences)

The National Geophysical Data Center (NGDC) catalogs information on tsunamis and significant earthquakes, including effects such as fatalities and damage. NGDC also maintains a large collection of geologic hazards photos. All of these databases are now stored in an Oracle relational database management system (RDBMS) and accessible over the Web as tables, reports, and interactive maps. Storing the data in a RDBMS facilitates the search for earthquake and tsunami data related to a specific event. For example, a user might be interested in all of the tsunami events near Japan. The user could then directly access related information from the tsunami tables such as tsunami runups, additional comments, and references. If the event is in the significant earthquake database, the user could access related information from the earthquake tables without having to run a separate search of the significant earthquake database. Users could also first access the significant earthquake database and then obtain related tsunami information. The ArcIMS-based interactive maps provide integrated Web-based GIS access to these databases as well as additional auxiliary geospatial data. The first interactive map provides access to individual GIS layers of tsunami sources, tsunami effects, significant earthquakes, volcano locations, and various spatial reference layers including topography, population density, and political boundaries. The map service also provides ftp links and hyperlinks to additional hazards information such as NGDC's extensive collection of geologic hazards photos. For example, a user could display all of the tsunamis that have caused damage in Alaska and then by using a hyperlinks tool, display images showing damage from a specific event such as the 1946 Aleutian Islands event. The second interactive map allows users to display related natural hazards GIS layers. For example, a user might first display tsunami source locations and select tsunami effects as the related feature. Using a tool developed at NGDC, the user could then select a specific tsunami event and automatically display the tsunami effect locations related to that event. The user could also select significant earthquake events and display tsunami events related to specific quakes. These tools improve data access and are being used to quality control the data. These capabilities also help coastal communities

assess their risks, identify hazards, and promote public awareness of tsunamis and earthquakes.

JSS07/09A/A02-009   1115
VULNERABILITY ASSESSMENT AND PREVENTION MEASURES FOR TSUNAMI FLOODING OF URBAN AREAS AND INDUSTRIAL PORTS OF MEXICO

Salvador F. FARRERAS, Modesto F. ORTIZ (Oceanology Division, CICESE Research Center of Mexico)

The Middle-America Trench subduction zone adjacent to the southwestern coast of Mexico accounts for a consistent and regular history of locally destructive tsunamis generated by large earthquakes. The 19 September 1985, 9 October 1995 and 22 January 2003 are the most recent events, with maximum wave heights from 2.5 to 5.0 meters. This coast is the site of two major industrial ports and an approximately 1000 km corridor of tourist resorts and urban communities. Among them, the heavy industrialized port of Lázaro Cárdenas with two steel mill plants, a fertilizer factory, a container port, metal and mineral docks, grain storage silos, and a fuel oil terminal, located on the sand shoals of a river delta. An important element for the vulnerability assessment is the determination of probable tsunami wave elevations and expected inundation limits at each location. The best alternative to determine these parameters is through numerical simulation of wave generation and propagation from the source to the shoreline and inland areas. Three and five meters are the maximum wave heights representative of the low and middle risk tsunamis most frequently arriving to this coast. These two cases were simulated in a computer. An ocean water disturbance produced by a sea-floor earthquake was assumed. Earthquake fault parameters were derived from the Harvard centroid moment tensor of two past events. Deep-water linear wave theory for the far ocean, and shallow water non-linear one for the near shore and interaction with the coast, were considered. Non-fixed boundaries with discharges conditioned to the state of the water level at the borders, were used to model the flooding and recession at the coast. The equations were solved through an explicit central finite-difference ″leap-frog″ algorithm for interconnected grids of different sizes. The model was validated comparing the results with recorded sea level data and run-up and flooding extension measurements from the two past tsunamis. Results of the numerical simulations show the maximum computed water levels and the boundaries of the inundation areas under threat. Inundation maps showing this information were produced. The tsunami vulnerability assessment for two cases, an urban settlement and an industrial port, is described in detail. For the industrial port: a low risk event will produce slight damage, railroad tracks destroyed, access bridges washed out, and ledges of sand removed or deposited on the beaches; and a middle risk event will produce major and extensive property damage to the installations and danger to life. With the exception of the steel factory which is located adjacent to the hills, escape routes through the single access bridge and road to other facilities will be useless. Recommendations include the relocation of urban settlements, installations and services, and the establishment of evacuation routes and emergency shelters.

JSS07/09A/A02-010   1130
PROGRESSES IN THE ASSESSMENT OF TSUNAMI GENESIS AND IMPACTS AROUND THE PORTUGUESE COASTS

Luis MENDES-VICTOR[1], Antonio RIBEIRO[2], Luis MATIAS[3], Maria Ana BAPTISTA[3], J.Miguel MIRANDA[3], Pedro MIRANDA[3], Nevio ZITELLINI[4], Eulalia GARCIA[5], Carlos CORELA[1], Pedro TERRINHA[2] ([1]Instituto Geofisico da Universidade de Lisboa, [2]LATTEX, Portugal, [3]CGUL, Portugal, [4]IGM, Italy, [5]UTM-CSIC, Spain)

The tsunami generated by the 1755.11.01 earthquake was probably the major event of this kind felt all over the North Atlantic well reported by coeval sources. The coasts of the Iberian Peninsula, Northwest Morocco were deeply affected by that phenomenon which tremendous impacts on the city of Lisbon and several other ones have been well documented. The last 20 years, the scientific european community, thanks to the support received from EU (Projects DETWS, IAM, GITEC, GITEC-TWO and BIGSETS) and from FCT (Projects MATESPRO and RIMAR) was able to develop successive steps improving considerable knowledge on the parameters and functions of sources and tsunami propagation. In order to evaluate the tsunami hazard, comprehensive studies were developed recognizing the importance of the inter-disciplinary approach for this kind of phenomena. Tsunami propagation models were designed being the simulations controlled by real data deducted from historical report or instrumental data. In order to assess the considerable impacts along the Portuguese coasts different run-up models have been use and tested. The location of the 1755.11.01 source has been a key question, motivating intensive marine research in the southern area of Portugal looking for unquestionable morphological or geological evidence of fault rupture and local source area present-day seismic activity.

SOUTH AMERICAN TSUNAMI IMPACT IN NEW ZEALAND

Gaye L. DOWNES (Institute of Geological & Nuclear Sciences)

Documenting the effects of historical events is crucial for understanding tsunami hazards and risks and for use in persuading public authorities and the public that tsunami are a real threat. The data are also useful for identifying, for paleotsunami studies, sites suitable for preserving in the geological record a known event and possibly a succession of previous events. Further, good run-up data are essential for the calibration and validation of numerical tsunami propagation and inundation modelling. Historically, New Zealand has been particularly vulnerable to tsunami from South America. The 1868, 1877 and 1960 tsunami had significant impact along the east coast of the North and South Islands, and at outlying islands. The damage was limited by the sparseness of coastal settlement and by the near coincidence of the largest waves with low tide at several of the most affected locations in all three events. Nevertheless, houses, bridges, boats, and harbour facilities were damaged with wave heights of up to 4 m (peak to trough, over 7 m) on the two main islands. On the outlying Chatham Islands, 800 km to the east of the main islands, the 1868 tsunami was devastating, causing one death, and destroying an entire Maori village and several European houses with run-up of 6-6.3 m. This height is documented in a recently-found inundation map and reconnaissance report produced within a month or so of the tsunami. This and other recently found data as well as re-evaluation of previously known information on the 1868 and 1877 tsunami now provide an excellent picture of inundation at more than thirty New Zealand sites, and at several other Pacific island sites. Of the hundred or so observations of these two tsunami in the ' Tsunamis in the Pacific 47BC 2000AD database, over one third come from New Zealand. These observations and that of other tsunami that have affected New Zealand should prove invaluable in future numerical modelling of tsunami from sources around the Pacific Rim, the results of which will benefit many island nations of the South Pacific as well as New Zealand.

TSUNAMI SIMULATION FOR THE SOUTHWESTERN COAST OF ANATOLIA

Ahmet Cevdet YALCINER[1], Baris HABOGLU[1], Efim PELINOVSKY[2], Fumihiko IMAMURA[4], Costas SYNOLAKIS[3] ([1]Dept. of Civil Engineering, Ocean Engineering Research Center, Middle East Technical University, [2]Department of Applied Mathematics, Nizhny Novgorod State Technical University, Nizhny Novgorod, Russia, [3]Dept. of Civil Engineering, University of Southern California, Los Angeles, CA, USA, [4]Disaster Control Research Center, Graduate School of Eng.,, Tohoku University, Aoba 06, Sendai, Japan)

The deepest region of the Mediterranean sea lies as a trench more than 4000m depth, at the coordinates 28.7°E, 35.7°N, with the size of 80km in E-W direction and 60 km in S-N direction. This trench expands towards North to Dalaman coast at South of Anatolia in Turkey. The coastal environment around this trench at southwestern Anatolia is very attractive and densely used by all kinds of tourist affairs. There are numerous earthquakes and tsunamis that occurred in this region are documented in historical records. The paleotsunami studies could provide valuable information and detected the traces of historical tsunamis at the Dalaman and Fethiye coasts. The well know fault zone Hellenic Arc lies from South of island Crete in W-E direction, bends towards NE at East of Rhodes and enters Anatolia near Dalaman town. This fault zone is directly dependant on the subduction zone in the region and have significant normal component which is one of the important mechanism to cause tsunamis. The slopes of this deep trench are steep enough to cause probable slope failures or submarine landslides which are another important sources of tsunami generation mechanism. There have not been made the detailed marine surveys to identify the sediment characteristics and slope stability in the region. But the importance of tsunami generation and coastal amplification still remain an unanswered question. There are 293 significant earthquakes and 13 tsunamis in the region have been documented in between the years 0-1900. There are 403 earthquakes with magnitude greater than 5, and 5 tsunamis in the region occured in between1900-2002. As seen from this simple information, the reliability of the databecomes higher with the years coming to present time. Using this data 28 different tsunami scenarios related to the generation by fault break is selected. 12 different tsunami scenarios related to the generation by submarine landslides are determined for the tsunami effect on the coastal environment in the region. The model applications to understand the tsunami behavior and coastal amplification related to various source mechanisms in the region are performed for this problem. The two different models using shallow water equations for solving the tsunami generation, propagation and coastal amplification are used. These models are TUNAMI-N2 (for fault generated tsunamis) and TWO LAYER (for underwater landslide generated tsunamis) written in Tohoku University, Japan. The distribution of maximum positive tsunami amplitudes at 50 different coastal stations are determined for totally 40 different tsunami scenarios and the results are discussed.

JSS07/09A/A02-013   1215
DB DRIVEN QUICK TSUNAMI FORECASTING IN KOREA

Ho Jun LEE[1], Yong Sik CHO[2] ([1]Senior Researcher, National Institute for Disaster Prevention, Seoul 121-719, Korea, [2]Associate Professor, Department of Civil Engineering, Hanyang University, Seoul 133-791,Korea)

Theoretical and numerical researches including survey of past tsunamis have been studied in Korea. These include tsunami generation, propagation and run-up in the East Sea. The results show complicated characteristics in the East Sea. Especially, in case of Korean Eastern Coast, it is convinced that energy divergence from the Yamato Rise which located at the center of sea causes unusual tsunami height in specific region. Therefore, we should compute tsunami accurately using fine spatial grid size in numerical model. To use a numerical model covering entire region of Korean eastern coast with finer grid meshes, it needed high performance computer and large time computation. However we have about two hours from its generation to arrival in Korea, maintenance of an effective forecasting system is important for tsunami disasters countermeasure. This research presents a way to predict tsunami in a few minutes with high accuracy on PC. To solve linear long wave equation which explains tsunami propagation, superposition of its sub-solution as Eq. (1) could be used. $F(x,y,z,t)=\sum_i f_i(x,y,z,t)$ (1) Where, F is a solution of linear long wave equation, f_i is the sub-solution of equation when we divide initial sea surface profile of tsunami into number of elements, and is the number of partitions. Generally, in tsunami computation, we simplify the fault plane as a single or number of rectangle as its shapes. If the fault is simplified as two planes, summation of independently computed result for each fault would be equal to the real tsunami event in linear computation. Then the function is equivalent to a solution of independent tsunami event, and the F is to the solution of real tsunami. In advance, we can compute using unit event having 5 X 5 km area and 1m height unit event located along the entire active faults in the East Sea. Through the tsunami computation for every unit event, time series of sea water levels at certain locations along the Korean Eastern Coast are gathered for each computation. Finally, these are multiplied by real initial sea surface displacement at every location of unit event in real tsunami event. Then, summations of the each value on time axis will gives sea water levels in real tsunami computation. Consequently, only simple computation of the initial tsunami waves and manipulation of pre-computed data set, makes it possible to deduce tsunami heights and arrival time along the coast in a few minutes on PC. Using this method, the 1983 tsunamis are deduced and compared with the results which computed from the tsunami numerical model, and it shows good agreement each other. This study has accomplished for the quick estimation of detail tsunami heights along the Korean Eastern Coast. We are now computing the unit events using SX-5 super computer of KMA. After the establishment of DB, quick estimation of tsunami will be used for its forecasting and diminishing its damages. This research was financially supported by the Korea Meteorological Administration.

STUDY ON THE TSUNAMI BEHAVIORS NEAR THE ULCHIN NUCLEAR POWER PLANT SITE

Sobeom JIN[1], Fumihiko IMAMURA[2] ([1]Structural systems and site evaluation Dept. KINS, [2]Disaster Control Research Center, Graduate School of Engineering, Tohoku University)

When a nuclear power plant is to be located at an area which is subjected to tsunamis, a comprehensive analysis to estimate the potential effects of tsunamis should be carried out and the design code based on historical as well as probable maximum tsunamis should be obtained to protect all potentials of tsunamis. We have three main issues in this subject; (1) what kind of damage caused by a tsunami can be expected, (2) what code or numerical model can be applied to estimate such damage, (3) how we can evaluate the probable maximum tsunami to ensure that the plant will be adequately protected against all potential tsunami effects. All nuclear power plants in Korea are located along the coastline for taking

cooling water. As typical example, the nuclear power plant site at Ulchin is located along the eastern coast of the Korean Peninsula, which has been effected by tsunami historically (1741, 1964, 1983 and 1993 events). Recently, it is reported that many undersea earthquakes have occurred around the Korean Peninsula, and its occurrences would increase. And seismic gaps that could affect huge tsunami attacks at the Ulchin site have been pointed out. Numerical analyses at Ulchin were performed for three recent tsunami events (1964, 1983 and 1993 tsunami events) and a virtual/possible tsunami event along the eastern coastline of the Korean Peninsula. The maximum run-up and draw-down heights are numerically estimated by using a combined numerical model based on the shallow-water theory. On the historical tsunamis, calculated run-up and draw-down heights are compared with field measurements. Although a slight discrepancy is observed, we obtain the overall agreement reasonably. The maximum run-up and draw-down heights at Ulchin site should be predicted to evaluate the safety of plants. Those of 1983 tsunami event; 3.30m and (-)3.10m on the still water level are selected as maximum value. As the result, it is concluded that the plants of Ulchin site might be safe against the four tsunami events. Hereafter, as the other effects of tsunamis, the integrity assessment of cooling water structure against tsunami attacks should be reviewed. And the sand sediment by tsunamis could affect the safety features of the plant should be taken into account. Furthermore, for more conservative condition as the probable maximum tsunami, the parameter study on the seismic gaps should be carried out.

JSS07/09P/A02-002   1415
ESTIMATION OF AN EFFECT OF HETEROGENOUS TSUNAMI SOURCES IN A SEISMIC GAP OFF SAKATA COAST FOR A TSUNAMI HEIGHT DISTRIBUTION

Tomoyuki TAKAHASHI (Faculty of Engineering and Resource Science, Akita University)

The 1983 Japan Sea Earthquake Tsunami and the 1993 Hokkaido Nansei-Oki Earthquake Tsunami (Okushiri Tsunami) occurred along the Eastern Margin of the Japan Sea. In a plate boundary along the margin, there are other seismic gaps. A seismic gap off Sakata coast is one of them, and it locates on the south of the Japan Sea Earthquake. If an earthquake will occur there, a huge tsunami will be generated. A damage of the tsunami would happen along the Japan Sea coastal zone not only in Japan but also in the Korea Peninsula and Russia. Especially, Yamagata Prefecture and Akita Prefecture in the Tohoku district in Japan face to the tsunami source, so the tsunami will attack there directly. Furthermore, because distances between the tsunami source and these prefectures are very short, the damage due to the tsunami depends on a heterogenous dislocation of tsunami source. In this study, an effect of the heterogeneity of tsunami source in the seismic gap off Sakata coast for a distribution of tsunami height along shore is estimated with the tsunami numerical simulation. The heterogeneity of tsunami source, however, has not been studied well as compared with the asperity of fault. We can find one example in a study on the Nankai Trough. Many earthquakes as large as magnitude 8 class had occurred along the Trough at an interval of 100 to 150 years. The giant tsunamis generated by these earthquakes gave huge damages to Japan and they propagated toward some countries along the Pacific Rim. Many studies on the earthquakes and the tsunamis along the Nankai Trough has been conducted and Japanese government released the assumed models for the disasters and their estimated damages based on those research results. Because the earthquake model has taken in the asperity of fault, it is improved as compared with past models. The tsunami model, however, reproduces the 1707 Houei event which was largest tsunami along the Trough, and the heterogeneity of tsunami source has not been discussed. The tsunami sources in the seismic gap off Sakata coast are close to land, therefore tsunami heights along coasts would be affected by the heterogeneity of tsunami source strongly. If an estimation of tsunami damage is carried out without the heterogeneity source, it is possible that there are underestimated areas. In this study, as a first step of research about the effect of the heterogenous tsunami source, I have estimated a variance of tsunami height distribution along shore due to some parameters which are a magnitude of heterogeneity, distance between tsunami source and coast, strike of fault, depth of fault, water depth where tsunami generated and bathymetry.

JSS07/09P/A02-003   1430
ON THE REFLECTION OF AN OBLIQUELY INCIDENT BORE FROM AN INCLINED WALL

Hideo MATSUTOMI, Kentaro IMAI (Department of Civil and Environmental Engineeing, Akita University)

Edge bores were witnessed, photographed and videotaped on the north Akita coast in Japan at the time of the 1983 Nihonkai-Chubu earthquake tsunami, and the necessity of studying them from a viewpoint of tsunami disaster prevention was pointed out. In relation to the edge bores, physical experiments are carried out to examine a few fundamental characteristics of the reflection of an obliquely incident bore from an inclined plain wall. The experimental flume is 100 cm wide, 10 cm high and 350 cm long with a horizontal bed. Incident bores are generated by rapidly pulling up a gate, installed 1 m from one end of the flume. The experimental conditions are that the initial water depth h1 in the upstream region of the gate is three cases of 7, 8 and 9 cm, the constant water depth h0 in the downstream region of the gate is 2 cm, the inclined angle θ of the wall is three cases of 10°, 20° and 90° (vertical), and the incident angle α of the bore is three cases of 60°, 70° and 80° (nearly parallel to the wall). Wave gauges are arranged at about 30 locations to measure time histories of the incident and reflected bore surface elevations. In addition, the state of the incident and reflected bores are videotaped to grasp their features and to model the reflected bore. A simplified model is presented for the case of the vertical wall, which can estimate the bore heights ΔH and ΔH3 of the reflected bores propagating upstream and downstream respectively, the propagation velocities ω and ω3 of the reflected bores propagating in the respective directions, and the angle β between the reflected bore front line in the upstream region of the incident bore and the installed direction of the vertical wall. Through examinations and comparisons of the experimental results and the solutions of the model, it is concluded that the developed model is useful, the propagation velocity ω is not zero, the angle β is not so affected by the intensity of the incident bore and so on.

JSS07/09P/A02-004   1445
A STUDY OF THE GENERATION MODEL OF TSUNAMI CAUSED BY A COLLAPSE OF VOLCANIC ISLAND- A CASE OF THE 1741 OSHIMA-OSHIMA TSUNAMI -

Kei KAWAMATA[1], Kazuaki TAKAOKA[1], Kazuhiko BAN[1], Fumihiko IMAMURA[2], Shigeru YAMAKI[3], Eiji KOBAYASHI[4] ([1]Nuclear Power Dept., Electric Power Development Co.,Ltd., [2]Disaster Control Research Center, Tohoku University, [3]Seamus Ltd., [4]Kaihatsu Computing Service Center,Ltd.)

Although the frequency of tsunamis generated by a volcanic eruption including debris, lava flow, failure, and collapse is less than those generated by an earthquake under the sea, the former tsunamis are reported to cause more damage than the latter. Because the wave height is locally amplified and attacked the surrounding area. The 1741 Oshima-Oshima tsunami is a representative tsunami documented in the Japan Sea, which would be caused

by the sector collapse of the Oshima-Oshima. So far it is not exactly clear about the detailed mechanism of the sector collapse and the tsunami generation. A landslide induced tsunami can be modeled in several ways. The first is to model the water disturbance caused by landslide, which is calculated by the motion of fault with horizontal and vertical movement (Satake, 2001). The second is to model motion of landslide as a fluid flow and solve the equations for multi-phase fluid flow. The authors selected the second and introduced a two-layers model (Imamura & Imteaz, 1999), A calculation in the whole Japan Sea including the Korean Peninsula was performed to reproduce the 1741 Oshima-Oshima tsunami. The main features of tsunami caused by the volcanic eruption with major collapse could be clarified by the observation in the hydraulic experimental study. The 1st is that the wave height of forward-wash and back-wash nearby wave source is higher. The 2nd is that the period of tsunami is short, suggesting the importance of wave frequency dispersion. Based on the hydraulic study, the authors improved the two-layers model which was developed by Matsumoto et al.(1998) through estimating proper coefficients and introduce the interface stress model, and applied the improved two-layers model to the 1741 Oshima-Oshima tsunami in order to reproduce the tsunami heights from the Hokkaido coast to the Korean Peninsula in the Japan Sea. The topographic data before and after the sector collapse was given by Satake (2001). A propagation of tsunami was based on the linear Boussinesq equation considering the wave transformation in addition to the nonlinear long wave equation. It was found from the calculation results that the computed tsunami was much not decayed in spite of short-period wave about five minutes, the computed tsunami heights well reproduced the observed tsunami heights in distant places such as Noto, Shimane, the Korean Peninsula. But a question of reproducibility remains unsettled that is related to a directivity of tsunami energy in the north and south flank of the Oshima-Oshima.

JSS07/09P/A02-005   1500
TSUNAMI SIMULATION CONSIDERING DYNAMIC OCEAN-BOTTOM DISPLACEMENT DUE TO SEISMIC FAULTING

Hiroyuki MATSUMOTO[1], Tatsuo OHMACHI[2], Hiroshi TSUKIYAMA[3] ([1]Deep Sea Research Department, Japan Marine Science and Technology Center, [2]Department of Built Environmanet, Tokyo Institute of Technology, [3]Tsukiyama Research Inc.)

A new technique of tsunami numerical computation that includes the dynamic motion of ocean-bottom is conducted. The traditional tsunami computations assume long-wave (or shallow water) approximation, i.e., the initial water surface displacement is the same as the static displacement of ocean-bottom. In this study, the dynamic motion of ocean-bottom is used as the boundary condition and 3-D numerical computations are carried out. Dynamic displacements of the ocean-bottom caused by the seismic faulting are simulated first by a 3-D boundary element method (BEM). Then, by applying velocity associated with the displacement at the ocean-bottom, water waves are simulated by a 3-D finite difference method (FDM) taking into account acoustic effects. As a result, the acoustic (or Rayleigh) waves that propagate through water could be reproduced in addition to tsunamis. It should be noted that the simulated tsunami is found to be remarkably larger in the wave height especially in the near-field where the acoustic effects are significantly appeared. In the far-field, however, as compared with the traditional computation, there is a little difference in the wave height. Finally, the present technique is applied to actual tsunamis caused by the 1983 Nihonkai-Chubu earthquake and the 1993 Hokkaido-Nansei-Oki earthquake. These simulated tsunamis are found to agree well with the observations.

JSS07/09P/A02-006   1515
HYDRODYNAMIC INVERSION OF THE SOURCE PARAMETERS OF TSUNAMIGENIC EARTHQUAKES

Pedro M. MIRANDA, Carlos A. PIRES (Dep Physics, Centro de Geofisica, University of Lisbon)

Tsunamis produced by large submarine earthquakes contain information on the location and geometry of the earthquake source that may, in some cases, be successfully inverted providing an independent contribution to the general problem of earthquake inversion. Tide gauge series from near-shore tsunamis are potentially richer in information content, as their signals are less distorted by propagation effects. Even in those cases, it is not easy to deal with a number of difficulties, arising from observational errors at the tide gauges, from insufficient knowledge of the small scale bathymetry and from many model uncertainties. In this study we use the adjoint method as an inversion tool for tsunami data, incorporating both the hydrodynamic propagation and the earthquake source parameterization. The method is designed to perform the direct optimization of the tsunami fault parameters, from tide-gauge data, imposing strong geophysical constrains to the inverted solutions, leading to a substantial enhancement of the signal-to-noise ratio, when compared with the classical technique based on Green's functions of the linear long-wave model. A 4-step inversion procedure, which can be fully automated, consists (i) in the source area delimitation by adjoint backward ray-tracing, (ii) adjoint optimization of the initial sea state, from a vanishing first-guess, (iii) non-linear adjustment of the fault model and (iv) final adjoint optimization in the fault parameter space. Results with a set of idealized and real bathymetries, show that the method works well in the present of reasonable amounts of error and it provides, as a by-product, a resolution matrix that contains information on the inversion error, identifying the combinations of source parameters that are best and worst resolved by the inversion.

JSS07/09P/A02-007   1530
A PROPERTIES OF THE CARRIER-GREENSPAN MAPPING APPLICATED TO WAVE RUN-UP ON A SLOPING BEACH

Victor M. KAISTRENKO (Institute of Marine Geology and Geophysics, Russian Academy of Sciences)

Carrier and Greenspan (1958) found a representation for variables of the non-linear shallow water system on a sloping beach by the scalar potential satisfying the linear wave equation. This approach is used for wave run-up description. It is important that the exact solutions received in frames of this approach can be used for testing of the numerical models. There is a simple modification of this mapping which transforms non-linear shallow water system into similar linear shallow water system. This mapping hasseveral interesting properties: 1. Each equation of the initial non-linear system after multiplication by Jacobian of transformation (x,t) → (x´,t´) gives the corresponding equation of the linear system. The new parameters (x´,t´) of the linear system are likewise to space and time variablesof the initial system. There are an integral equalities tieing the non-linear and corresponding linear expressions. 2. Jacobian of transformation (x,t) → (x´,t´) written using new variables is a product of two linear expressions. This fact simplifies investigation of zeroes of Jacobian corresponding to wave breaking. 3. Considered mapping is asymptotically equal because it is an initial partof the Taylor expansion. 4. The non-linear and corresponding linear shallow water systems have its own simple invariant group of scale transformations. Basing on it's a non-trivial two-parameter invariant group of transformations of non-linear system was created. These transformations allow to get a set of solutions from the one solution of the non-linear shallow water system. 5. Under several conditions a wave field descripted by the non-linear shallow water system on sloping beach in the full domain can be gotten from the run-up height

depending from the time. 6. Several examples are considered. The work was supported by the Russian Foundation for Basic Research. References. Carrier G.F., Greenspan H.P. Water waves of finite amplitude on a sloping beach. J.Fluid Mech., 1958, v.4, N 1, pp.97-109

CONSTRUCTING LANDSLIDE TSUNAMI SOURCES

Philip WATTS[1], Stephan T. GRILLI[2], Francois ENET[2], Joseph S. WALDER[3], Andrea PANIZZO[4], Christopher F. WAYTHOMAS[5] ([1]Applied Fluids Engineering, Inc., [2]University of Rhode Island, [3]USGS, Cascade Volcano Observatory, [4]Universite degli Studi dell' Aquila, [5]USGS, Alaska Volcano Observatory)

A considerable amount of experimental work has been performed in order to characterize the mechanics of tsunami generation by landslides of both subaerial- and subaqueous origin. This work has proceeded along with significant advances in numerical simulations of landslide tsunamis, using complete and accurate fluid dynamic models. These efforts, carried out in tandem, have provided considerable insight into the mechanics of landslide tsunamis. However, both laboratory experiments and numerical simulations are often costly, time-consuming activities that many tsunami researchers do not have the means to access or perform. Fortunately, because many of the tsunami features documented in the experimental and numerical work are coherent structures of predictable scale, much of the experimental and numerical results can be generalized. While further experimental and numerical work will certainly refine our understanding of tsunami generation, sufficient information currently exists with which to construct reliable initial conditions, or tsunami sources, as inputs to a tsunami propagation and inundation model. A tsunami source comprises a statement of the initial free surface shape and velocity distribution. We demonstrate in detail a general technique of constructing tsunami sources for underwater landslides, subaerial landslides, and pyroclastic flows. We evaluate the time scale of tsunami generation and perform scaling analyses for each type of mass failure, following the same procedure yet finding different results. With these different time, amplitude, and wavelength scales in hand, we interpret the available experimental and numerical results with accurate curve fits using dimensionless quantities. These curve fits allow us to construct tsunami sources. We compare the resulting tsunami sources with the original experimental and numerical results on which they are based, in order to test the accuracy of the complicated fitting techniques. However, tsunami sources can also be constructed, through interpolation, away from the original tsunami data. We find that underwater landslides are most sensitive to landslide volume and depth, that subaerial landslides are most sensitive to volume flux and duration of motion in the water, and that pyroclastic flows behave effectively as a subaerial landslide with respect to tsunami generation. We finish our presentation with demonstrations of tsunami source calculations, performed in real time, and we summarize the numerous successful case studies already carried out to date with such tsunami sources.

JSS07/09P/A02-009 1615
WAVES AND RUN-UP GENERATED BY ATHREE-DIMENSIONAL SLIDING MASS

Costas Emmanuel SYNOLAKIS[1], Fred RAICHLEN[2], Jose BORRERO[1], Burak USLU[1] ([1]department of civil engineering, university of southern california, [2]departmenf of civil engineering, california institute of technology)

We report results from small and large scale laboratory experiments with the objective tounderstand the basic fluid mechanics of water waves generated by partially aerial and submarine landslides. We use two both wedge and hemispherical shaped bodies. We have conducted ، small-scale three-dimensional experiments in a wave tank 38cm wide with a slope (1:2.08) constructed at one end to represent the near-shoreregion. A triangular shaped lead block with a horizontal length of 18 cm, a 9 cmhigh front-face and a width of 5 cm was used to represent a landslide. The blockwas released from rest abruptly moving down-slope by gravity. Water surface-timehistories were obtained in front of and to the side of the at-rest position of the wedge.While the data weree useful, it is only with an investigation conducted at a large enough size so as to reduce scale effects that reliable data can be obtained to confirm numericalmodels as used to establish coastal inundation limits and to define the run-up. Large scale experiments were conducted in a wave tank with a length 104 m, width3.7 m, and depth 4.6 m and with a plane slope (1:2) located at one end. A freely slidingwedge with a horizontal length of 91 cm, a vertical face 46 cm high and a width of61 cm was used to represent the landslide. A hemisphere of 46cm radius was also used.Both bodies were instrumented with an accelerometer and a position indicator, and their initial position (with varied mass and two different orientations) ranged from totally aerial to fully submerged. The surrounding water surface variation and the run-up time histories were measured electronically.The results provide a carefully obtained set of data conducted at a scale whichminimizes viscous and capillary effects. These experimental data are compared tonumerical models which define the runup.

JSS07/09P/A02-010 1630
TSUNAMI GENERATION BY NON-LINEAR PHENOMENA IN SOURCE

Mikhail A. NOSOV, Sergey V. KOLESOV, Sergey N. SKACHKO (Physics Faculty, M.V.Lomonosov Moscow State University)

This study is focused on tsunami generation mechanism due to non-linear energy transfer from high-frequency oscillations of water layer to low-frequency gravitational surface waves. The non-linear tsunami generation mechanism is related to seismic bottom motions; however the mechanism differs from a simple water displacement by bottom deformations. During bottom earthquake water layer can be considered as incompressible or as compressible fluid. These two cases can be distinguished taking into account the position of the bottom displacement frequency spectrum relatively the lowest normal acoustic frequency 4H/c, where H is ocean depth, c is sound velocity in water. Thus in case of "shallow water", the incompressible fluid theory can be applied, whereas "deep ocean" ought to be considered as a compressible fluid. The main response of a compressible water layer from bottom deformation is elastic oscillations, which are caused by repeated reflections of an acoustic impulse from bottom and top surfaces. In case of incompressible fluid a periodic bottom motions are assumed. Mathematical description of the non-linear tsunami generation mechanism is based on the non-linear Euler equations. It is assumed that fluid velocity, density and pressure can be expressed as a sum of variable (fast) and time averaged (slow) terms. The fast components are calculated as a linear response of water layer (compressible or incompressible) to bottom motions. Averaging the Euler equations in time we obtain equations to describe the time-averaged flow (surface gravitational waves). The non-linearity of the Euler equations introduces additional terms in the time-averaged flow equations which can be interpreted as external mass force and distributed mass source. The time-averaged flow equations are solved within framework of the linear shallow water theory. The amplitude of the surface gravitational wave generated by the non-linear mechanism is estimated as a function of ocean depth and of duration and velocity of bottom displacement. It is shown that this mechanism can provide a noticeable contribution to tsunami amplitude.

A SHARED-USE, LARGE-SCALE, MULTIDIRECTIONAL WAVE BASIN FOR TSUNAMI RESEARCH

Solomon YIM, Daniel COX, Charles SOLLITT, Cherri PANCAKE, Harry YEH

Under the Network for Earthquake Engineering Simulation (NEES) program, the US National Science Foundation is funding the expansion of Oregon State University's multidirectional wave basin to create a shared-use next-generation experimental facility for tsunami research and engineering practice. The new facility addresses the unique requirements posed by tsunami research, with basin dimensions and wave generation capabilities closely matching the community's vision of the ideal basin." When completed in 2004, the basin will support high resolution, unprecedented-scale experiments with very dense instrumentation. Researchers will be able to test and validate advanced analytical and numerical models of tsunami phenomena induced by sub-sea earthquakes, spanning a full range of ocean, coastal, and harbor studies. An integral part of the project is the exploitation of advanced network technologies to allow researchers located at distant sites to play active roles in experiments at the facility, viewing data and images in real time and participating in decision-making. The broader research community will benefit from this large tsunami experiment facility, a comprehensive experiment databank, with specialized interfaces for experiment re-play, searching and browsing archives of past experiments, extraction of experimental data for use in validating numerical models, and a community repository for numerical simulation codes.

MODELING THE 1741 TSUNAMI FROM OSHIMA-OSHIMA ERUPTION IN JAPAN SEA

Kenji SATAKE[1], Stefano TINTI[2] ([1]Active Fault Research Center, GSJ/AIST, [2]Dipartimento di Fisica, Universit di Bologna)

The 1741 Oshima-Oshima tsunami, the most destructive historical tsunami in Japan Sea, was generated by submarine landslide associated with the eruption of Oshima-Oshima volcano. The small island is located between the source regions of the 1983 Japan Sea (M 7.7) and 1993 Southwest Hokkaido (M 7.8) earthquakes, both caused extensive tsunami damage. The 1741 tsunami caused 2,000 casualties along the Hokkaido coast and damage as far as along the Korean Peninsula. The estimated tsunami heights are 3-13 m on Hokkaido coast, 3-6 m on Tsugaru peninsula, 1-5 m on other coasts of Honshu, and 3-4 m on the Korean peninsula. There was no record documenting ground shaking from an earthquake in 1741. In contrast, a large-scale sector collapse occurred on Oshima-Oshima volcano, but the volume change associated with the subaerial landslide was too small to explain the observed tsunami heights. Recent swath bathymetry surveys indicate that the landslide extended to ocean bottom with the volume change of about 2.5 km³, nearly an order of magnitude larger than the subaerial slide. We computed the tsunami generation from landslide, both subaerial and submarine, by using two different models: a block model and a simple kinematic landslide model. The mapped bathymetry change is used as initial conditions. The tsunami propagation is computed in two different grids, 6˝ around the source and 1´ grid for the entire Japan Sea. The computed heights from the block model well reproduced the estimated tsunami heights. For the kinematic landslide model, we searched parameters that best match the observed and computed tsunami heights. They are the horizontal slide velocity of 40 m/s and rise time of 2 min.

JSS07a/09P/D-002 Poster 1700-103
HOLOCENE TSUNAMI DEPOSITS FROM LARGE EARTHQUAKES ALONG THE KURIL SUBDUCTION ZONE, EASTERN HOKKAIDO

Futoshi NANAYAMA[1], Kenji SATAKE[2], Ryuta FURUKAWA[3], Koichi SHIMOKAWA[2], Kiyoyuki SHIGENO[4] ([1]Institute for Marine Resources and Environment, Geological Survey of Japan, [2]Active Fault Research Center, Geological Survey of Japan, [3]Institute of Geoscience, Geological Survey of Japan, [4]Meiji Consultant Co. Ltd.)

Holocene tsunami deposits in eastern Hokkaido between Nemuro and Hiroo show that the Kuril subduction zone repeatedly produced earthquakes and tsunamis larger than those recorded since AD 1804. Twenty-two postulated tsunami sand layers from the past 9500 years are preserved in lake bottom near Kushiro City, and almost ten postulated tsunami sand layers from the past 3000 years are preserved in peat layers on the coastal marsh of eastern Hokkaido. We dated these ten tsunami deposits (named Ts1 to Ts10 from shallower to deeper) in peat layers by radiocarbon and tephrochronology, correlated them with historical earthquakes/tsunamis, and surveyed their spatial distribution to estimate the tsunamis inland inundation limits. Ts1 is inferred 20th century and may correspond to the tsunami from the AD 1960 Chilean earthquake (M 9.5) or the AD 1952 Tokachi-oki earthquake (Mt 8.2). Ts2 is inferred 19th century (Edo era) and is correlated with the AD 1843 Tempo Tokachi-oki earthquake (Mt 8.0) recorded in a regional document Nikkanki of Kokutai-ji temple at Akkeshi. Ts3 is located just below 17th century tephra, Us-b and Ta-b (AD 1667-1663), so it is also dated as 17th century (Edo era). Ts4 is dated around 13th century (Kamakura era). Ts5 to Ts8 are between two regional tephra layers, B-Tm (Ca 9th century) and Ta-c2 (ca 2.5 ka). In particular, Ts5 is found just below B-Tm tephra, so it is dated 9th century (Heian era). Ts9 and Ts10 are under the regional tephra Ta-c2 (ca. 2.5 ka) and represent prehistorical events. Our detailed surveys indicate that Ts3 and Ts4 can be traced more than 3 km from the present coast line in Kirittapu marsh, much longer than the limits (< 1 km) of recent deposits Ts1 and Ts2 or documented inundation of the 20th century tsunami events. The recurrence intervals of great tsunami inundation are about 100 to 500 years, longer than that of typical interplate earthquakes along the Kuril subduction zone. The longer interval and the apparent large tsunami inundation indicate unusual origin of these tsunamis.

TSUNAMI FLUID FORCE ON VEGETATION

Kentaro IMAI, Hideo MATSUTOMI (Department of Civil and Environmental Engineeing, Akita University)

One of the features of the 1998 Papua New Guinea tsunami is that the maximum tsunami height of 14.8 m was observed on the sand spit with vegetation of Sissano lagoon faced the tsunami source, which caused a large number and high rate of human casualties. In countries of the western Pacific Ocean area, the coastal vegetation attracts their attention as a means of tsunami countermeasures from the economical and environmental reasons. In the light of these situations, physical experiments are carried out to examine a few fundamental characteristics of the tsunami fluid force acting on vegetation. The experimental flume is 0.3 m wide, 0.5 m high and 11.0 m long with a horizontal bed. Tsunamis are modeled by bores and generated by rapidly pulling up a gate, installed 5 m from one end of the flume. The bores propagate, in order, in the regions of the constant water depth, a uniformly sloping beach, the sand spit with vegetation, and a lagoon with a constant water depth. Model tree consists of the trunk with the diameter d of 0.24 cm and the foliage with the void ratio of 0.7. The model trees are arranged in both the staggered and grid patterns on the sand spit. The vegetation density κ (= total cross section area of trunks/vegetation area = $\pi(d/L) \cdot dn/4$) is four cases of 0, 0.5, 1.0, 1.5%, where L is the depth length of the vegetation area and n is the number of trees per unit width along the shore. These conditions make Shuto´s 'vegetation thickness dn´ 0 ~ 400 and are realistic. Through analyses of the experimental data using Morison´s equation added a linear wave making resistance term (caused by the trembling of the foliage), it is clarified that (1) the drug coefficient CD is 0.5 ~ 1.4, the added mass coefficient CM 1.1 ~ 1.4 and the coefficient θ´ of the linear wave making resistance 0.2 ~ 0.6, (2) these coefficients decrease as κ increases, (3) CD and CM change with the same tendency as those of group of piles in open channel flows, (4) the inertia force FI reaches 20 % of the maximum drag force FDmax at the early stage, and after that the drag force FD and the linear wave making resistance force FA become dominant, (5) as the ratio of FA to FDmax is about 0.2, FA can not be ignored.

TIMING AND SCALE OF TSUNAMIS CAUSED BY THE 1994 RABAUL ERUPTION, EAST NEW BRITAIN, PAPUA NEW GUINEA

Yuichi NISHIMURA[1], Mitsuhiro NAKAGAWA[2], Jonathan KUDUON[3], Joseph WUKAWA[3] ([1]Institute of Seismology and Volcanology, Hokkaido University, JAPAN, [2]Graduate School of Science, Hokkaido University, JAPAN, [3]Rabaul Volcanological Observatory, Geological Survey of Papua New Guinea, PNG)

The 1994 Rabaul eruption series is one of the most recent eruptive events which accompanied significant tsunamis. On September 19, 1994, Vulcan and Tavurvur Volcanoes erupted almost at the same time. These volcanoes are located at the eastern and western side of Simpson Harbour, respectively. During the main stage of the Vulcan eruption, small tsunamis were recorded on tide gage installed at the township of Rabaul. According to the eyewitness accounts and reported damages, tsunamis occurred several times at Matupit Island, south of Rabaul (with the largest wave invading 100-200 m inland) and also on the southern part of Rabaul. In order to investigate the timing and scale of the 1994 Rabaul tsunamis, we conducted reconnaissance geological mapping of the 1994 tsunami deposits. Around Rabaul, the tsunami deposits are identified as sand layers or characteristic pumiceous sand (mixes pumice and sand) layers sandwiched by tephras from both Vulcan and Tavurvur Volcanoes. The tephra might play an important roll to preserve the original structures of the tsunami deposits. According to the chronological studies of both tephra and tsunami deposits, we infer that the tsunami was not generated by the first small eruption from Vulcan Volcano although this eruption occurred close to the coast. The tsunamis were excited several times or continuously by larger pyroclastic flows and base surges during the climactic stage of the volcano. Tsunami run-up heights estimated from distribution of tsunami deposits are ca. 5 meter around western to southern shore of Matupit Island.

CHARACTERISTICS OF HISTORICAL TSUNAMI EVENTS OF EASTERN HOKKAIDO, JAPAN, REVEALED BY SEDIMENTARY FACES OF THE TSUNAMI DEPOSITS

Yuichi NISHIMURA[1], Kazuomi HIRAKAWA[2], Yugo NAKAMURA[2], Naomichi MIYAJI[3], Masayoshi KOMATSU[3] ([1]Institute of Seismology and Volcanology, Hokkaido University, JAPAN, [2]Graduate School of Environmental Earth Science, Hokkaido University, JAPAN, [3]Department of Geosystem Sciences, Nihon University, JAPAN)

Based on resent works on tsunami deposits, eastern Hokkaido was known to be affected by large tsunamis more than 10 times during the last 5000 years (Hirakawa et al. 2002, Nanayama et al., 2002). Most these tsunamis are thought to be caused by large earthquakes along the Kuril Trench. Earthquake recurrence along the trench has been estimated by dating these tsunami deposits. The sizes of the events were also estimated for the case if their invaded areas are well traced. Here, we investigated sedimentary characteristics of these tsunami deposits to consider whether these historical tsunamis are all similar or not. This consideration is necessary to re-evaluate the earthquake and tsunami recurrence along the Kuril trench. We found some fields where plural tsunami deposits lie between peat deposits and are traced inland by hand excavation. For example, near the mouth of Tokachi River, eastern Hokkaido, we could identify six tsunami layers in a ca. 1 meter thick peat deposit. We traced them along a small channel in a glass field up to 1500 meter inland from the beach. The tsunami deposits were identified as continuous sand layers that consist of very coarse to fine sand. The sand layers show the typical characteristics of reported tsunami deposits: thickness and mean grain size of the deposits decrease with the distance from the sea (Nishimura and Miyaji, 1995). However, grain size analyses of the sand deposits indicate that the size-decreasing patterns are significantly different among the tsunami deposits. We speculate that these sedimentary faces of the tsunami deposits are mostly linked to the wave height, wavelength and invaded direction of each tsunami, because there are no evidence for critical environmental change in the peat deposit.

RUN-UP CALCULATION OF HOKKAIDO SOUTHWEST EARTHQUAKE TSUNAMI WITH DISPERSION EFFECT

Masafumi YOSHINO[1], Toshifumi MIKAMI[1], Takahiro AKITA[1], Hiroyuki IWASE[2] ([1]Engineering Department, Alpha Hydraulic Engineering Consultants Co.,Ltd., [2]Ecoh Co.,Ltd.)

1.Introduction Hokkaido Southwest earthquake tsunami occurred on July 12th 1993 (M 7.8). During this tsunami disaster, Okushiri island suffered serious damages (casualties: 230 dead and missing persons), and run-up height of more than 30m was recorded at Monai coast, face to tsunami source. In the recent years computation model becomes an important and decisive tool for planning tsunami counter-measures. Shallow water theory models were used in many cases, but for this particular event some improvement was needed. In order to reproduce accurately the tsunami propagation, it is not possible to ignore dispersion effect in shallow sea. Consideration of soliton fission of tsunami, wave profile curvature effect and breaking are necessary. In this study, we reproduced the 1993 tsunami by the use of non-linear dispersive long wave theory model with two-step mixed finite difference scheme, and compared results accuracy versus non-linear long wave theory model and observed run-up height. 2.Numerical model We used depth-integrated Madsen-Sørensen equations which includes dispersive terms. The computation model is based on two-step mixed finite difference scheme, alternating implicit and explicit scheme. Initial surface elevation was calculated by the use of Mansinha and Smylie method from fault model of DCRC. Computation area consists in a set of nested grids. Maximum grid size is 1800m, and minimum is 12.5m. Time step is 0.2sec. Calculation period is 60 minutes. 3.Conclusion As a key result of this study, tsunami height was amplified in the shallow sea by soliton fission effect, and accuracy of wave height distribution was improved versus non-linear long wave model. Maximum run-up height and flooding area was similar to observed value.

EVALUATION FOR TSUNAMI SOURCE AREA BASED ON A PRECISE ANALYSIS OF CRUSTAL DEFORMATION--VERIFICATION ON TSUNAMI RUN-UP HEIGHTS BY THE 1993 HOKKAIDO-NANSEI-OKI EARTHQUAKE --

Masafumi MATSUYAMA, Yasuhira AOYAGI, Hiroyoshi TANAKA, Shintaro ABE (Central Research Institute of Electric Power Industry)

The purpose of this study is to confirm that a new tsunami source model, constructed by Aoyagi et.al(another presentation), can give an evaluation of tsunami run-up heights on the safe side. Targeted area is a source of Hokkaidonansei-oki Earthquake tsunami. The model is intended to be applied to safe design basis against tsunamifor important coastal facilities. In the source model, crustal deformation, that is tsunami initial condition, is calculated by a 3D finite element model with fault parameters re-examined by the distribution of aftershock hypocenters etc. The calculation is carried out on the assumption that only hanging side of reverse faults is displaced. As a result of numerical simulation based on shallow water theory with dynamic fault parameters, the model gives reasonable results around Okushiri Island. Especially, along the southwest coast of Okushiri Island, where the run-up heights over 20m were recorded, tsunami heights obtained by the model, can envelop measured run-up heights, while previous models caused underestimation along southwest coast. Consequently, these results demonstrate that the new source model can evaluate the tsunami run-up heights on the safe side.

CAUSE OF THE TSUNAMI OF THE AITAPE EARTHQUAKE OF 17TH JULY, 1998, PAPUA NEW GUINEA

Yoshinobu TSUJI (Earthquake Research Institute, University of Tokyo)

The Aitape Earthquake (Mw 7.1) occurred in the sea area off the north coast of Sissano Lagoon at 8h49min, 17th July, 1998 (UT). After the earthquake a huge tsunami hit the several villages near the mouth of Sissano Lagoon, and about 2000 people were killed. We made a field survey on the damaged coast and gathered eyewitnesses' accounts of survivors living in the villages around the lagoon. Survivors of Warapu and Arop, villages on the western and the eastern sandspits of the lagoon testified that they felt eminent shakings three times, the second one was the strongest, and that the huge tsunami came just after (or at the same time of) the third shaking. The board band seismograph at Jayapura, about 155km west of the hypocenter of the main shock, recorded the main shock (M7.1) at 8h 49min and the maximum aftershock at 20.3 minutes after it (9h 09min). No another eminent shock was recorded, but a shock of not a seismic origin was recorded between 8.6 and 9.5 minutes after the main shock (around 8h 57min). We also made an aftershock observation at three points (Aitape, Vanimo, and Lumi) on the coastal region from the beginning of August to the end of September, 1998. Locations of hypocenters of 49 aftershocks were decided. The distribution of those aftershocks shows that the location of the main shock is distributed in the sea area just in front of Sissano Lagoon between the coastline to the trench axis (depth: about 4000m) which runs about 50 km apart from the coastline in parallel to it. Running time of a long water wave (tsunami) is estimated to be 12 minutes from trench area to the coast. JAMSTEC made marine survey researchs for four times by the vessels Natsushima and Kairei from December 1998 to February 2001, and detailed sea bottom topography was clarified, sea bottom observations, and echo-sounding profiling were made. We found out a round shaped crater, called 'mphitheater' with diameter 7-8km in the sea area just the front of the lagoon, 25km apart from the shoreline. We found out several fresh cracks on the south slope of the crater, and folding on the foot of the slope, and a trace of a slumping with debris. Many traces of surface layer sliding were found out on the sound profiling charts generally at almost all slopes including those in the Amphitheater. Considering all those results, together with eyewitnesses' accounts, the following scenario could be assumed; 1.The tsunami, which hit the coastal villages was not caused by the main shock. 2.The tsunami was supposed to be formed by a sliding of surface sediment layer on a slope in or near the Amphitheater. It occurred at 9 minutes after the main shock.

BAY ON TROUBLED WATERS:MODELLING TSUNAMI HEIGHTS ALONG THE COASTS OF SOUTHWESTERN LUZON AND MANILA BAY FROM EARTHQUAKES ALONG THE MANILA TRENCH AND MANILA BAY AREA

Ishmael C. NARAG[1], Erlinton B. OLAVERE[1], Bartolome C. BAUTISTA[1], Ma. Leonila P. BAUTISTA[1], Yuichiro TANIOKA[2] ([1]Seismological Observation and Earthquake Prediction Division, Philippine Institute of Volcanology and Seismoloy, [2]Hokkaido University, Hokkaido, JAPAN)

Tsunami hazard along the Manila Bay is one of the least studied earthquake-related hazards. The tsunami threat comes from earthquakes originating from the Manila Trench located west of the bay as well as from a source region in the bay area. Meanwhile, a previous study on earthquake hazards in Metro Manila had suggested that the metropolis has a low vulnerability to tsunami hazards due to the narrow configuration of the mouth of Manila Bay, the presence of Corregidor Island near the mouth of the bay which has an abating effect on any tsunami wave and the relatively deep slab of the Manila Trench beneath the bay. However, historical records show that there were accounts of at least two earthquakes that mentioned occurrence of unusual sea waves after a felt earthquake that affected Manila shores and its nearby vicinity. For the past ten years, the coastline population and industries along Manila Bay has significantly increased which warrants the need to verify whether the tsunami hazard in the study area is indeed low. In order to do this, a modelling study was conducted in order to determine possible tsunami heights that may result from an earthquake along the Manila Trench and a source zone in Manila Bay. The present modelling effort uses bathymetric grids generally interpolated from available digital bathymetry data and corrected from available bathymetric maps. Source parameters for representative earthquakes were inferred from available seismic data and estimated magnitudes of historical events occurring in the study region. Tsunami waveforms were

numerically computed by a finite-difference computation of the linear long-wave equations. Model runs were made for earthquakes with various magnitude sizes for the Manila Trench as well as for the 1863 Manila Bay Earthquake. Risks and vulnerability analyses could be done effectively if we could consider effects of variations of tsunami heights for different earthquakes especially in areas with existing communities and industries in the bay. In order to determine whether the configuration of the Manila Bay will have an effect on the ensuing tsunami, finer bathymetric data will be gathered and further modelling will be done to determine better tsunami heights.

STUDY OF DIATOM FLORA FOR PALEO-TSUNAMI EVENTS IDENTIFICATION

Nadezhda G. RAZJIGAEVA[1], Tatiana A. GREBENNIKOVA[1], Larissa A. GANZEI[1], Alexander Ya. ILYEV[2] ([1]Pacific Institute of Geography, Russian Academy of Sciences, [2]Institute of Marine Geology and Geophysics, Russian Academy of Scie)

The presence of marine diatoms in the deposits show marine influence, that may resulted by different causes: marine transgression, strong storm surges and tsunami. Diatoms was studied in 16 key sections of Kunashir island from sand layers of peat bogs and barrier palaeo-lake deposits and from overlying and underlying deposits. The studied sections are located on different distance fromcoastal line (up to 2.5 km). Diatoms analysis can provide valuable evidence forthe validity of proposed tsunami deposits. Presence of marine and brackish species in sandy layers suggest a seaward source for the sand, as opposed to a downriver flood deposits and reflect configuration of ancient coastal line. Diatom analysis suggests that the tsunami may have deposited finer-graned sediments and diatoms at last distance farther upland where sand layers have notbeen observed. Content of marine species and their diversity depend as by distance from sea coast as sand layer thickness that possibly is connected with tsunami intensity.Content of neritic and oceanic species is higher in tsunami layers compare to marine deposits of Holocene transgressice phases. Appearance and high percent content of deep-sea species is connected to strong marine water flow, penetratedfar landward and brought large amount these forms as compared with storm-induced surge. Possibly this fact can serve as informative sign of palaeo-tsunami. It should be noted that some of the marine taxa found under thesand layers may be due to infiltration of marine water into peat. The rarity andpoor preservation of diatom valves indicate long-distance transport during a high-energy event. The most palaeo-tsunami deposits are late Holocene that explains predominance of south- and north-boreal diatoms, typical for modern sublittoral environment of this region. Warm-water species were found in middle-Holocene palaeo-tsunami deposits that was connected with Kuroshio current system shift northward. The results of this study show the usefulness of diatom palaeoeclogy as a tool for reconstructing the ecological effect of tsunami on swamp geosystems. Freshwater diatom assemblage from tsunami layers and overlaying deposits indicates that palaeo-tsunami had an influence on environment pH. After tsunamidiatom assemblage common for acid swamp environments (acidophilous and acidobiontic) changed by diatom flora of neutral and alkaline environments. Thus, palaeo-tsunami influence to environment results in changes of development tendency of swamp system, that could have effect to landscape development. The work was supported by the Russian Foundation for Basic Research, grants01-05-79184, 01-05-79024, 02-05-65409 and Far Eastern Division of the Russian Academy of Sciences.

REGIONAL AND LOCAL TRIGGERING OF THE AUGUST 17, 1999 TSUNAMI IN THE IZMIT BAY (TURKEY)

Stefano TINTI, Anna MANUCCI, Gianluca PAGNONI, Filippo ZANIBONI, Alberto ARMIGLIATO (Department of Physics, Sector of Geophysics, University of Bologna, Italy)

We present the main results of a set of numerical simulations of the tsunamioccurred on August 17, 1999 along the coasts of north-western Turkey, and inparticular of the Gulf of Izmit. The tsunami followed a devastatingM_w=7.4 earthquake which affected mainly the easternmost part of theSea of Marmara. The earthquake supposedly broke at least five long right-lateralstrike-slip segments of the North Anatolian Fault: a very relevant part of theseismic energy was released along fault segments placed partly or completelyoffshore. The rupture scenario is further complicated by the slipping ofdip-slip ancillary faults connecting the main strike-slip segments, and byliquefaction and subsidence phenomena, reported to have occurred in a largenumber of coastal places. Concerning the dip-slip faults, they are mainly foundin the central and eastern basins of the Izmit bay and were identified on thebasis of both bathymetric and geological data analysis. Numerous field surveys,performed soon after the event, allowed to identify and measure the effects ofthe tsunami in the Gulf of Izmit. The run-up measurements range typically in theinterval 1-3.5 m along the entire coastline of the Izmit Bay. A significantexception is represented by the small town of Degirmendere, where a local slumpwas accompanied by the collapse of some buildings along the shoreline: here,some eye-witnesses reported water waves exceeding 10 m. In the present study,we investigate numerically the August 17, 1999 tsunami trying to reproduce thewater wave heights both along the entire Izmit Bay coastline and locally inDegirmendere. For this purpose, our analysis is carried out through two mainexperiments. In the first, we utilise the most recent hypotheses on the rupturedfaults and simulate the tsunami propagation in the Izmit Bay and its impactalong the coast, comparing the numerical results with the experimentalmeasurements. In the second experiment, we study the triggering and theevolution of the local slump occurred in Degirmendere, and the consequent watermovement generation. The main result of our approach is that, on the scale ofthe entire Izmit Bay, it is possible to reproduce the observed tsunami effectsonly by considering the rupture occurred on the secondary dip-slip faults:moreover, the local effects seen in Degirmendere must be considered theconsequence of the local slump alone and not of the earthquake-induced tsunamithat affected the Izmit Gulf.

RESTORATION OF A TSUNAMI SOURCE BY INVERSION OF THE COASTAL TIDE-GAUGE RECORDS

Tatjana A. VORONINA[1], Viacheslav K. GUSIAKOV[1], Vladimir A. TCHEVERDA[2] ([1]. Institute of Computational Mathematics and Mathematical Geophysics, SD RAS, [2] Institute of Geophysics, SD RAS)

The inversion of the tsunami wave records obtained on the coastal tide-gaugesis widely used to determine the initial water displacement in a tsunami source area.Mathematically, this problem is formulated as inverse problem of mathematical physics for restoration of the initial water displacement in the source area by the water level oscillations observed on the number of points distributed along the coastline. As it was shown by Kaistrenko (1972), in a general case of an arbitrary source, this inverse problem does not have a unique solution. Its solvability depends on a number of a priori assumptions, one of which is that the source function can be presented as product of space- and time-dependent functions, where the time-dependent function is supposed to be known. Even under this assumption, the problem remains to be an ill-posed problem whose solvability depends on the number and length of

waveforms used in the inversion, their spatial distribution and the signal-to-noise ratio. As a mathematical model of the problem, we use the linear shallow water equations numerically solved (by finite difference method) on the model bottom relief having some basic morphological features typical for the island arc regions. The inverse problem is solved by least square inversion using a truncated SVD approach. The quality of the solution obtained is evaluated as relative errors (in L2-norm) in restoration of the source function. As a model of the initial water displacement we used a dipolar displacement representing the surface deformation due to the typical tsunamigenic earthquakes with the reverse dip-slip or the low-angle thrust mechanisms. On the basis of a series of numerical experiments made we conclude that (1) the quality of the source restoration strongly depends on the number of waveforms used and their azimutal coverage; (2) to obtain a reasonable quality of source restoration we need to use at least 5 records smoothly distributed over the space domain that is comparative in size to the projection of the source area onto the coast line; (3) complexity of a source function and the presence of the background noise imply serious limitations on the accuracy of the restoration procedure, more complex sources require larger number of wave records and finer computational grid used for the calculation of synthetic waveforms.

POST-EVENT SURVEY OF THE DISASTROUS TSUNAMI OF 30 DECEMBER 2002 HITTING STROMBOLI ISLAND, ITALY

Stefano TINTI[1], Alberto ARMIGLIATO[1], Laura GRAZIANI[2], Alessandra MARAMAI[2], Anna MANUCCI[1], Gianluca PAGNONI[1], Filippo ZANIBONI[1] ([1]Department of Physics-Geophysics, University of Bologna, Italy, [2]Istituto Nazionale di Geofisica e Vulcanologia, INGV, Rome, Italy)

Stromboli volcano is located in south Tyrrhenian sea, Italy and is known to have been affected by several tsunamis during its recent eruption history. Following a period of intense volcanic activity, on December 30, 2002 a series of landslides occurred in the NW flank of the volcano, called Sciara del Fuoco. The two largest ones took place with a time separation of about 7 minutes according to the seismic signals, and involved tens of cubic meters of material. The totalmass failure affected the subaerial as well the submarine flank of the volcano. Both slides produced a tsunami, but the first one was by far the most violent. The post-event survey was conducted in a number of campaigns under the control of the civil protection authorities that were limiting the access to the island owing to the persistent danger of tsunamigenic collapses and explosions. The tsunami was observed in the whole south Tyrrhenian sea. It was disastrous in Stromboli and hit severely the neighbouring island of Panarea. Waves as high as 7-10 m attacked especially the northern coast of Stromboli and destroyed most of the houses on the water front. Severe damage was also caused to houses and structures on the north-eastern coast of Stromboli. The physical effects of the waves were spectacular: erosion channels, deposition of large sheets of sediments, transport of large breakwaters blocks, of boats and trailers, uprooting of trees, destruction of brick and stone walls, production of local coastal slumps, etc. The tsunami caused no fatalities and injured only a small number of people since it occurred in winter: all the houses destroyed were uninhabited, but are usually full of tourists in peak season. The occurrence of the tsunami has shown the inadequacy of the recording system of long sea waves in Italy and has posed dramatically the issue of the implementation of an early alert and warning system for tsunamis.

MODELLING OF THE HOLOCENIC MEGATSUNAMI INDUCED BY THE SECTOR COLLAPSE OF STROMBOLI IN THE TYRRHENIAN SEA, ITALY

Stefano TINTI[1], Kenji SATAKE[2], Gianluca PAGNONI[1], Filippo ZANIBONI[1] ([1]Department of Physics-Geophysics, University of Bologna, Italy, [2]Active Fault Research Center, AIST, Japan)

Stromboli is one of the most active volcanoes in the Aeolian Islands arc in south Tyrrhenian sea, Italy. Flank collappses have occurred frequently in the history of the volcano. In the last 13 ka at least four such episodes have taken place, involving volumes in the order of 1 cubic kilometer. The last collapse occurred presumably less than 5 ky BP. It was responsible for the formation of the Sciara del Fuoco (SdF), a huge scar in the NW flank of the volcano that is now almost completely refilled by the eruption products of the volcano which is characterised by persistent activity. The SdF extends underwater down to 800 m bsl and deposits associated with the collapse have been probably identified in the Stromboli channel at depths larger than 2000 m. The collapse generated likely a megatsunami that hit Stromboli with powerful waves and that radiated in the whole Tyrrhenian sea. Following previous studies that were centered on the tsunami evolution in the generation region and in the near-field, here the propagation of the waves in the Tyrrhenian sea is studied in order to identified the coastal segments of the Tyrrhenian coasts that were most affected by the tsunami. The collapse is simulated by means of a block model that subdivides the sliding volume into 2D matrix of adjacent blocks and computes their motion under a Lagrangian approach. The tsunami is modelled by means of a shallow water finite-difference technique over a grid covering the Tyrrhenian sea.

SEISMICITY OFFSHORE IBERIA: THE 1761 IBERIAN EARTHQUAKE AND TSUNAMI

Maria Ana BAPTISTA[1] ([1]ISEL, CGUL, [2]CGUL, FCUL, Portugal, [3]CIMA, UA, Portugal)

Earthquake catalogues for the Iberian Peninsula report several moderate to strong magnitude events. In the 18th Century three major earthquakes, of magnitude greater than 7, are reported: 27.12.1722, 1.11.1755, 31.03.1761. Their source area is controversial due to the lack of detailed and coherent descriptions. Any attempt to shed new light on the source location contributes to the evaluation of seismic and tsunami risk in Iberia. The 31 March 1761 earthquake was felt in Lisbon at noon, alarming the inhabitants and throwing down ruins of the past 1st November 1755 earthquake. According to coeval sources the earthquake was followed by a tsunami that was observed in Cornwall (United Kingdom), Cork (Ireland). The Portuguese catalogues locate this event on the Horse Shoe Abyssal Plain, south of Gorringe Bank and 7.5 magnitude, while the Caribbean tsunami catalogue (Lander et al., 2002), locates the event further north 37N 10W and the estimate of the epicentral intensity MMI is IX. In this study we present: a reappraisal of the available historical reports, concerning the 1761 event, a revision of the macroseismic intensities along Iberia and the tsunami observations along the western Portuguese and Galicia coasts, England, Ireland and West Indies. With this dataset we use backward ray tracing techniques to discuss the location of the event and its integration with one of the major tsunami generation areas in the western Portuguese margin.

HUGE TSUNAMIS BASED ON TSUNAMI DEPOSITS ALONG THE PACIFIC COAST OF EAST HOKKAIDO, NORTHERN JAPAN

Kazuomi HIRAKAWA[1], Yugo NAKAMURA[1], Yuichi NISHIMURA[2] ([1]Graduate School of Env.

Earth Sci.,Hokkaido Univ., [2] Graduate School of Natural Sciences, Hokkaido Univ.)

It is well known that large earthquakes have occurred every several tens of years along the Kuril Trench off the coast of East Hokkaico, Japan. This study aims at first to examine huge tsunamis and their recurrence interval since last 6,500 years ,based on the tsunami deposits along the pacific coast of Tokachi to Nemuro region, secondly to show the significance of some types of lamdforms for such discussion and thirdly to consider the erthquakes which have generated those Tsunamis. Major results are as follows: 1. We have so far identified 6 sand (gravel) layers with tsunami deposits along the Tokachi coast since last 2.5 ~3.0 ka.They are distributed not only in the alluvial lowland (at least 2.5 km inlandward from the present coast), but also on the terrace with sea cliff up to ca. 15 m in height. 2. On the basis of dated marker tephras and C-14 dates, occurrence age of the tsunami should be AD 16/17th Century, 13th C., 6~7th C., 3rd C., BC3 rd ~4th C. in descending order respectively. Thus the recurrence interval of these tsunamis must be 400~600 years. 3. Another 9 marine sand layers are intercalated in the peat and muddy sediments filling the former lagoon. They might show the Tsunami occurrence ca 3.2, 3.7, 3.9 , 4.2 , 4.6 , 4.9, 5.0, 5.6 and 6.0 ka BP, referring to the C-14 dates. 4. Although large earthquakes (Magnitude 8.0 +-), ex. 1843-, 1894-, and 1952-earthquakes had occurrred with the recurrence interval less than 100 years also since the last huge Tsunami of AD 16/17 C., they are not recorded as the tsunami sand layer indicated above. Sand bar landform closing lagoons from the Pacific Ocean, 5~6 m above sea level is wholly covered with a volcanic ash Ta-b erupted in AD 1667. This fact means that the Tsunami higher than 5 m in wave height had not occurred since then. The landforms such as the sand bar and coastal coastal terraces with adequate height of cliff might be significant for the evaluation of magnitude of tsunami. 5. Thus we should expect that tsunami sand layers on the sea cliff had been supplied by extraordinarily huge Tsunamis which had attacked the coastal area of Pacific Ocean in Hokkaido every 400 to 600 years. 6. Source areas of such Huge Tsunami off the coast of Tokachi region and Nemuro region seems to have been mostly same. The erthquake which had caused such huge Tsunamis might have occurred in the intraplate relatively near the coast.

JSS07a/09P/D-017 Poster **1700-118**

AN FEM MODELING FOR THE TSUNAMI SOURCE AREA OF THE 1993 HOKKAIDO NANSEI-OKI EARTHQUAKE, JAPAN

Yasuhira AOYAGI[1], Shintaro ABE[1], Masafumi MATSUYAMA[2], Hiroyoshi TANAKA[2] ([1]Geosphere Environmental Science Department, Central Research Institute of Electric Power Industry, [2]Fluid Science Department, Central Research Institute of Electric Power Industry)

We propose a modeling method of tsunami source area to evaluate tsunami run-up height on the safe side. This method should be applied to the design of important coastal structures, which combines safety and economical efficiency against tsunami. We choose the 1993 Hokkaido Nansei-oki earthquake tsunami as a case study, because large tsunami run-up heights were measured at the coasts of the Okushiri Island close to the source area and further we can acquire good geophysical datasets for model parameters. First, to decide the fault dimension, we relocated the first 1-day aftershock hypocenters determined by JMA (Japan Meteorological Agency), by referring to the hypocenters determined by an OBS-network later installed at the source area. The relocated hypocenters are concentrated onto some clusters correlating well with the en-echolen oceanic ridges with N-S strike over 100km long. We classified them to six fault segments. Secondly, we constructed a 3-D FEM crustal model including the shape of the faults and displaced those hanging wall sides upward as reverse faults in order of the source process for about 70 seconds. The amount of displacement on each fault was estimated from fault area, seismic moment and rigidity. The calculated vertical deformation of seafloor finally shows subsidence in northwest, uplift in northeast, very large uplift in southwest and subtle subsidence in southeast of the source area. As a result of following numerical simulation based on shallow water theory using the dynamic tsunami source model, the calculated tsunami run-up heights became equal or more than observed ones all around the Okushiri Island. Since we didn´t revise the source model with trial and error to fit the observed tsunami run-up heights, the method can be an advantage to evaluate tsunami run-up height on the safe side. See Matsuyama´s abstract to know tsunami calculation in detail.

FIELD SURVEY AND PRELIMINARY MODELING OF THE SEPTEMBER 9, 2002 WEWAK, PNG EARTQUAKE AND TSUNAMI

Jose C. BORRERO[1], Jose BORRERO[1], James BU[2], Christine SAIANG[2], Burak USLU[1], John FRECKMAN[4], Brandon GOMER[3], Hugh DAVIES[2], Emile OKAL[3], Costas SYNOLAKIS[1] ([1]Department of Civil Engineering, University of Southern California, [2](2) Department of Geology, University of Papua New Guinea, [3](4) Department of Geological Sciences, Northwestern University, [4](3) Marine Facilities Division, California State Lands Commission)

We report the results of field surveys and tsunami modeling effortsconducted in the aftermath of the Papua New Guinea earthquake and tsunamiof September 9, 2002. The 2002 earthquake generated a moderate tsunamiand occurred only 120 km ESE of the infamous 1998 event, which caused acatastrophic tsunami that killed over 2000 people. The 2002 earthquake hada larger seismic source and contributed more destruction (reaching MMIntensity IX and causing 5 fatalities) than the 1998 seismic event. On theother hand, its tsunami was relatively benign, with maximum runup heightsof 5 m in the offshore islands, and 2.5 m on the mainland. Thedistribution of runup along the coast from the 2002 tsunami also featuresan aspect ratio representative of standard dislocation sources. Thedisparity between the 1998 and 2002 tsunamis is a direct consequence ofthe generation of the former by a massive underwater landslide, which wasnot the case in 2002. Detailed modeling results from the two events arepresented which highlight the differences in the runup signatures of thetwo tsunami generation sources.

TSUNAMIS: THEIR SCIENCE, ENGINEERING AND HAZARD MITIGATION (IASPEI, IAVCEI, IAPSO)
Location: Site A, Room 2

SS07/10A/A02-001 **0830**

TSUNAMI DEPOSITS AND THEIR SEDIMENTARY PROCESS OF THE 1993 HOKKAIDO-NANSEI-OKI EARTHQUAKE AND 1741 OSHIMA-OSHIMA ERUPTION, SOUTHWESTERN HOKKAIDO

Futoshi NANAYAMA[1], Kenji SATAKE[2], Koichi SHIMOKAWA[2], Kiyoyuki SHIGENO[3] ([1]Institute for Marine Resources and Environment, Geological Survey of Japan, [2]Active Fault Research Center, Geological Survey of Japan, [3]Meiji Consultant Co. Ltd.)

We examined sedimentary facies, structure and grain size distribution of tsunami deposits from the 1993 Hokkaido-Nansei-Oki earthquake and the 1741 Oshima-Oshima eruption, southwestern Hokkaido. The 1993 tsunami of July 12th , 1993, left continuous onshore sand deposits along the west coast of the peninsula. Tsunami deposits along the estuary of Usubetsu River at Taisei consist of mainly medium to fine grained marine sands with gravels. The thickness decreases with landward distance from the shoreline, and finally they pinch out like a lenticular shape at the most upper limit of tsunami run-up. The deposits can be grouped into four sedimentary units. Each of these units is bounded by erosional bases, and interpreted as deposited by up flow of first run-up (Unit 1), return flow of first run-up (Unit 2), up flow of second run-up (Unit 3) and return flow of second run-up (Unit 4), respectively, by current directions. The upper unit (Unit 4) is more widely distributed and associated with coarser grains than the lower units (Units 1-3), because the second run-up was larger than the first run-up. Grain size distributions of up flow and return flow deposits are clearly different. Namely, Unit 4 deposits have a peak at 2.5 phi (Pu-1). In contrast, Unit 3 deposits have bimodal peaks at -0.5 to 1.5 phi (Pu-2) and 2.5phi (Pu-1). While the Pu-1 population is constant regardless of distance from the shoreline, the P-2 population clearly varies with the distance. The different sources account for the difference; the Pu-1 population was originated from the sea bottom and Pu-2 was provided from river bottom during the tsunami run-up process. On Oshima-Oshima, a small volcanic island southwest off Hokkaido, a violent eruption and sector collapse occurred on August 29th, 1741, and very destructive tsunami was also documented in this region. The 1741 tsunami deposits were found by Nishimura et al. (2000) along the Ayukawa Coast in Kumaishi. We tried new trench survey on a sand dune and studied sedimentary structures in detail. The deposits can be grouped into two sedimentary units, Unit I (lower unit) and Unit II (upper units). Each unit show sedimentary features, such as grain size or thickness variation, very similar to those of the 1993 tsunami. Grain size distributions of up flow (Unit I) deposits have bimodal peaks at -0.5 phi (Pa-2) and 2.0 phi (Pa-1), while the return flow deposits (Unit II) have a peak at 2.0 phi (Pa-1). Again, the different sources account for the difference: the Pa-1 population was originated from the sea bottom and Pa-2 was provided from gravel coat during the tsunami run-up process.

TRACES OF TSUNAMIS OF MAJOR NANKAI EARTHQUAKES IN THE BOTTOM SEDIMENTARY LAYERS OF TADASUGA-IKE AND KIRIMA-IKE LAGOONS, SUSAKI CITY, KOCHI PREFECTURE, SHIKOKU ISLAND

Yoshinobu TSUJI[1], Makoto OKAMURA[2], Yumi MATSUOKA[2], Yuichi NAMEGAYA[1] ([1]Earthquake Research Institute, University of Tokyo, [2]Kochi University)

A series of gigantic earthquakes accompanied with huge tsunamis occurred in the sea region off Nankai District, the Pacific side of Shikoku Island and the western part of Honshu Island periodically in the intervals of about one hundred years. Lagoons Tadasuga-Ike and Kirima —Ike are located on the south-east coast of Shikoku, separated from the Pacific ocean by sand dunes. Whenever a gigantic earthquake occurred in the open ocean area, sea water rushed into these lagoons by tsunami waves, and thin sand layers were formed. We gathered piston core sampling at several points for the bottom sedimentary layers of both of the lagoons, and found out more than ten thin sand layers formed by historical and pre-historical tsunamis. We made dating for several layers by the carbon 14 method. We found out three historical tsunami traces of the 684 Hakuho, the 887 Nin-na, and 1099 Kowa Nankai Earthquakes, and in addition that, we obtained more than ten pre-historical tsunami traces. The oldest trace of Tadasuga-Ike lagoon shows the year of about 20-th century BC.

PALEOTSUNAMI DEPOSITS INVESTIGATIONS ON THE KUNASHIR ISLAND

Alexander Ya. ILYEV[1], Nadezhda G. RAZJIGAEVA[2], Victor M. KAISTRENKO[1], Elena V. GRETSKAYA[1], Larisa A. GANZEY[2], Elena A. TIKHONCHUK[1], Andrey A. KHARLAMOV[3] ([1]Institute of Marine Geology and Geophysics, Russian Academy of Sciences, [2]Pacific Institute of Geography, Russian Academy of Sciences, [3]P.P.Shirshov Institute of Oceanology, Russian Academy of Sciences)

During the 2001-2002 years many tsunami traces were found on the Pacific coast of the Kunashir Island which is located in the region with very high tsunami activity. Upper tsunami traces were related to October 4, 1994 event and many others were related to old events having Holocene age. As main the tsunami traces are the layers of well sorted sand between peat and lacustrine silt-pelitic sediments and diatom oozes on the terraces near the sandy coast. Several tsunami traces are pumice layers. To evaluate the paleotsunami height the geomorphologic profiles were created for all examples of the tsunami traces. More than 150 sections (excavated trenches or outcrops) in the peat areas and paleo-lakes along the Kunashir Island coast were investigated, and the found examples were used for the following analysis (radiocarbon dating, chemical analysis of tephra, grain-size and mineralogial analysis of tsunami sands, biostatigraphy). At times inside these layers we found a wood scraps which wereanalysed by radiocarbon method to evaluate the layer age. Many tephra examples were used to estimate the tsunami layers age too. The time period related to thefound tsunami deposits is about 6000-7000 years. The reconstructions of tsunami heights and inundation were based on the present configuration of the coastal line because in the late Holocene it was similar to the modern one. Most of the studied sections are located on the coastal plain and low marineterrace sequences. Tsunami deposits are represented by very thin sandy sheets (thickness 1-5 mm, rare up to 3 cm) found beyond storm-wave influence with penetration in land up to 2.5 km. This sand from such sheets is well sorted (So = 2-3) and distribution of the size of particles generally is two-modal whose peaks are locating in the range 0.07-0.12 mm. This testifies to a single deposition of found sandy layers. Good age correlation of such sandy layers from the sites located in different places of the coasts is one of the criteria for tsunami origin of thedeposits. These events can be correlated with historical and prehistorical tsunamis of the Eastern Hokkaido and Iturup Island. One of the partial problems of the field investigation was the looking for tsunami traces on the Okhotsk sea coast related to the possible tsunami generated by explosion of the underwater volcanoes locating in the Okhotsk sea.Possibly, one sandy layer of 10 cm thick found at the height about 10 m near Tretyakovo settlement and having marine origin is related to volcanogenic tsunami because Pacific tsunamis penetrating into Okhotsk sea have no such amplitudes. The work was supported by the Russian Foundation for Basic

ESTIMATES OF TSUNAMI RUN-UP HEIGHTS FROM TSUNAMI DATA FOR THE COAST OF PERU

Evgueni A. KULIKOV, Alexander B. RABINOVICH (Shirshov Institute of Oceanology, Russian Academy of Sciences)

We have used data from the World Data Center-A (Boulder, Colorado) to estimatetsunami statistics and heights for the coasts of Peru and northern Chile. Two types of database search were conducted: ˝Tsunami Event˝ and ˝Tsunami Run-up.˝ For each search, we selected all data for the Pacific coast from 0°S to 35°S, including Peru, northern Chile, and Ecuador. From the ˝Tsunami Event˝ search, we selected 180 events for the period 1562 to 1996. From the ˝Tsunami Run-up˝ search, we found more than 400 run-up values for different coastal sites. Instrumental recording of sea level variations began systematically only in the20th century, so that the quality of the recently acquired historical data is markedly different. Basically, we have statistics for ˝small˝ tsunami events (wave heights less than 1-2 m) for the last 80-90 years. Despite the irregular spatial distribution of historically reported tsunami run-up for the coasts of Peru and northern Chile, the tsunami risk for the whole coast seems to be quasi-uniform in that it does not appear to depend on latitude. This can be explainedby the almost uniform spatial distribution of tsunami sources (earthquake epicenters) and the relatively uniform structure of seafloor topography along the coast. Run-up heights cannot be expected to be uniformly distributed along the coast for a single tsunami source. Maximum run-up heights are normally observed near the source. Statistically, tsunami heights decrease away from thesource region according to sqrt(R), where R is the distance from the source. However, for purposes of this analysis, the statistical distribution of tsunamirun-up heights is treated as uniform from 5° to 35° latitude. The spatial distribution of tsunami heights along the coast may be significantlymodified by local topography, shoreline irregularities, shelf resonance effects, and other topographic factors. Thus, to correctly estimate tsunami heights for a selected coastal site, the above effects need to be examined overa broad neighboring segment of the coast. Due to differences in data quality forthe recent and historical periods, we provide separately: (1) A statistical analysis of all data from 1562 to 1996; and (2) a statistical analysis of recentdata from 1906 to 1996. According to these analyses, the historical data from1562 to 1900 are devoid of small tsunamis with run-up heights less than 1 m. In the 20th century, coinciding with the beginning of sea level surveys and instrumental recording, the number of observed small tsunamis increases dramatically, similar to the numbers of earthquakes. For this reason, the distribution for the full data set falls below the distribution for recent data for small heights (less than 2-3 m). However, for large run-up (greater than 3-4 m), both graphs merge. We find that for large tsunami run-up, the tsunami run-up height h is given by the function h ~ T^p, where T is the return period is typical of lognormal distributions (Gumbel, 1962). This approximation has been used to estimate tsunami run-up heights for the basic return periods of 5,10, 20, 50, and 100 years.

JSS07/10A/A02-005　　　　　　　　　0930

THE COMPARISON BETWEEN THE 1936 AND 1978 MIYAGI-OKI EARTHQUAKES

Yuichiro TANIOKA (Hokkaido University)

On June 12, 1978, a large earthquake (M=7.4) occurred off the Pacific coast of Miyagi prefecture, northeastern Japan. The earthquake killed 28 persons and caused extensive damage in Miyagi prefecture. The previous large earthquake occurred in this region was the 1936 Miyagi-oki earthquake which also caused extensive damage. Therefore, a next large earthquake is expected in this region in near future. It is important to estimate the slip distribution of both the 1978 and 1936 events in order to discuss a possible rupture area of the next event. We estimate the slip distribution of the 1978 Miyagi-oki event using the tsunami waveforms observed at 14 tide gauge stations along the Pacific coast of northeastern Japan. We also analyze a tsunami waveform generated by the 1936 earthquake. Previously, the rupture process of the 1978 Miyagi-oki earthquake was estimated using the seismological data (ex. Seno (1980)). Seno (1980) show that the focal mechanism of the earthquake is a thrust type and the seismic moment is 3.1×10^{20} Nm. The event was separated into two subevents, one ruptured the eastern (trench-ward) part and the other ruptured the western (landward) part of the aftershock area. We numerically compute the tsunami waveforms using the finite-difference computation. The grid size is basically 20 sec of arc (about 600m), but finer grids (4 sec of arc) are nested near the tide gauge stations. Tsunami waveforms at 14 stations are computed for 6 subfaults with a unit amount of slip, and use as the Green's function for the inversion. The subfault size is 30km X 30km. The result of the inversion shows that the largest slip of 1.3 m was found in the western (landward) part of the fault area. The total seismic moment is calculated as 1.7 X 10^{20} Nm (Mw=7.5) assuming that the rigidity is 5×10^{10} N/m². The slip pattern of our study is consistent with the previous study by Seno (1980). Next, an original tsunami waveform observed at Hachinohe for the 1936 Miyagi-oki earthquake was found in Hachinohe observatory of JMA. A detail bathymetry map of Hachinohe port in 1936 was also found. Using those data, we compute the tsunami waveforms at Hachinohe from the fault model estimated for the 1978 earthquake. The result shows that the computed tsunami amplitude was about three times larger than the observed amplitude but the computed waveform pattern is consistent with the observed one. This suggests that the moment magnitude (Mw) of the 1936 earthquake is about 7.1. More data are necessary to estimate a slip distribution of the 1936 earthquake.

JSS07/10A/A02-006　　　　　　　　　0945

THE LATER PHASE OF THE TSUNAMI OF THE NEMURO-HANTO-OKI EARTHQUAKE OF JULY 17, 1973

Yuichi NAMEGAYA, Yoshinobu TSUJI (Earthquake Resarch Institute, University of Tokyo)

A large earthquake (M 7.4) occurred in the sea region eastern off Nemuro peninsula, Hokkaido on 17 June 1973 and was accompanied with a small tsunami. Tidal stations on the Pacific coasts in east of the Japanese Islands recorded the tsunami. The tsunami height of more than 150 [cm] was recorded at Hanasaki, Nemuro city. On the tsunami records at the several stations on the Pacific coasts of Hokkaido and the north part of Honshu, an obvious later phase waves were recorded independently at 2 to 2.5 hours after the arrival of the initial wave. The later phase waves appeared in such way that after the initial wave train was once attenuated, suddenly another eminent train of the later phase waves appeared. At several stations the wave height of the later phase exceeded the initial one. In order to clarify the reason why such an eminent phase waves appear about 2 hours later than the arrival of the initial wave, we made a numerical calculation of the propagation of the tsunami. We assumed the length, width of the fault to be 100 [km] and 100 [km]. The dip angle and the amount of dislocation were assumed to be 27 [deg] and 0.96 [m]. In addition, we use the calculation grid of the spherical coordinate system with the intervals of 1 [min] both in EW and NS directions. The influence of the rotation of the earth and the fluid viscosity were

neglected. We introduced bottom friction of the amount to be 0.05 to 0.1, for giving the equivalent energy dissipation to the effect of the reflection of the waves at the coastline. The calculated time length was 6 hours with using the leap frog method, and time interval of one step was 1.5 [second]. We found out that a large reflective wave was generated on the southern coast line of Kunashiri Island and it reached the Pacific coasts of Hokkaido and North Honshu about 2.5 hours later after the arrival of the initial wave train, and it is supposed to be the later phase wave train.

SOURCE AREA AND RUPTURE PARAMETERS OF THE 31 DEC. 1881 MW=7.9 CAR NICOBAR EARTHQUAKE ESTIMATED FROM TSUNAMIS RECORDED IN THE BAY OF BENGAL

Modesto ORTIZ[1], Roger BILHAM[2] ([1]Department of Oceanography, CICESE, [2]CIRES and Geological Sciences, University of Colorado)

On the morning of 31 December 1881 a submarine earthquake beneath the AndamanIslands generated a tsunami with a maximum crest height of 0.8 m that wasrecorded by eight tide gauges surrounding the Bay of Bengal. Since theearthquake occurred 8 years before the construction of the world´s firstteleseismic-recording seismometer, little has been known about its ruptureparameters or location. Waveform and amplitude modeling of the tsunami indicatethat it was generated by a Mw=7.9+0.1 rupture on the India/Andaman plateboundary resulting in 10-60 cm of uplift of the island of Car Nicobar. Therupture consisted of two segments: the northern 40-km-long segment is separatedfrom the southern 150-km-long segment by a 100 km region corresponding to thewestward projection of the West Andaman spreading center. The main ruptureoccurred between 8.5°N and 10°N with a total area of 150 km x 60 km dipping20°E with a mean slip of 2.7 m. The recurrence time for 1881-type events isestimated to be 114-200 years based on inferred GPS convergence rates andinferred plate closure vectors, although slip partitioning in the region mayextend this estimate by as much as 30%.

JSS07/10A/A02-008　　　　　　　　　1015

TSUNAMI RESONANCE CURVE OF BAYS BASED ON THE OBSERVED NATURAL PERIODS

Kuniaki ABE (Niigata Junior College, Nippon Dental University)

Sea level oscillations were observed using a portable pressure gauge at heads of 36 bays in Sanriku district, Japan and the natural periods were obtained from the most predominant periods in the spectra. The natural periods obtained vary from 7 to 60 minutes and the average was 25 minutes. On the other hand amplification factors of tsunami as the ratio of the maximum inundation level observed at the head to one observed at the mouth were calculated at each bay for large tsunamis of 1896 Sanriku, 1933 Sanriku, 1960 Chile and 1968 Tokachi-oki. The maximum inundation levels were taken from survey data after the tsunami invasions. The ones at the mouth were taken to be half of the maximum inundation levels averaged at open coast. They are 5 m (north coast), 2.0 m (south coast) for the 1896 tsunami, 2.5 m for the 1933 tsunami, 1.3 m for the 1960 tsunami and 1.5 m (north coast), 0.75 m (south coast) for the 1968 tsunami, respectively. Plotting the factors as a function of the natural period for each tsunami we obtained a tsunami resonance curve of bays. Assuming the representative period of tsunamis as 10 minutes for 1896 tsunami, 9.4 minutes for the 1933 tsunami, 49 minutes for 1960 tsunami and 22 minutes for 1968 tsunami, we summarized the result as a resonance curve of tsunami using the natural period normalized by the tsunami periods. The assumed periods were determined from the most predominant periods of the tsunamis observed at Ayukawa tide station except for the 1960 tsunami, in which it was determined as average of the most predominant periods in many tide stations. All the data fit the resonance curve having maximums at unit value of the normalized natural period. Thus, it is clarified that a bay has a role of resonator to tsunami. At the same time it is emphasized that most predominant periods in a usual sea level oscillation and tsunami are important factors to understand the amplification.

STUDY ON THE EFFECT OF TSUNAMI REDUCING BY COASTAL CONTROL FOREST

Kenji HARADA, Fumihiko IMAMURA (Graduate School of Engineering, Tohoku University)

The artificial coastal barrier such as seawalls and break waters have been constructed in Japan and have played an important role in protecting the city and coastal area from natural hazards such as tsunamis, tidal waves, high waves. However, these barriers need high cost of construction and maintenance, and change the present environment and have forced inconvenient in ordinal life along coastal area. Therefore, new countermeasures considering combination with artificial and natural functions such as coastal forest and strengthen such natural one are necessary for reducing natural disaster and keeping good environment. However, concrete functions of coastal forest to reduce tsunamis are not established and formulated. It is time to provide with technical information and guideline for coastal barrier by using natural and artificial functions for more appropriate management. In order to use a coastal control forest positively and effectively as countermeasures against tsunamis, evaluation of the hydrodynamic effect by a tsunami control forest and clarification of a disaster prevention function are further required. Therefore, the present paper aims to find and compile functions of tsunami disaster prevention by a control forest from old tsunami reports and other studies, and to obtain results on tsunami reduction effect estimated by the numerical simulation including the resistance of tsunami control forest. From old tsunami reports and other studies, the function of control forest for tsunami disaster prevention can be summarized as follows; 1) to stop driftwoods and other drifts moved by tsunamis, and to prevent the secondary disaster of house damage by attack of drifts. 2) to reduce tsunami energy, inundation depth, inundation area, tsunami current and hydraulic force at behind of a forest by reflection and resistance of trees. 3) to provide a life-saving means by catching persons carried by tsunamis. 4) to form dunes which act as barrier against tsunamis, and to reduce inflow of tsunamis toward inland. In order to evaluate these reduction effects quantitatively, the tsunami numerical simulation with the resistance of forest were carried out. The forest conditions selected from general coastal forests are 10,30,50 trees per 100 square meters in forest density and 50,100,200,400m in forest width. The drag coefficient of the coastal forest is estimated by the hydraulic experiment with the model of branches and leaves by changes of inundation depth. The inertia coefficient is determined to be 1.7. From the calculated results, the spatial distribution of the maximum inundation depth, current and hydraulic forces can be shown and compared. It is found that increasing of forest width at behind of coastal forest can reduce not only inundation depth but also current and hydraulic force. A strong current in coastal forest can be possible to scour roots. And effects of tsunami reducing become more effective by increasing of forest density. By use these results, effects of reducing tsunamis can be evaluated quantitatively related to the tsunami and forest conditions.

JSS07/10A/A02-010   1100

NUMERICAL SIMULATIONS OF THE 2002 STROMBOLI ISLAND TSUNAMI, ITALY

Stefano TINTI, Alberto ARMIGLIATO, Gianluca PAGNONI, Filippo ZANIBONI (Department of Physics-Geophysics, University of Bologna, Italy)

Stromboli is a volcanic island in southern Tyrrhenian sea, Italy, that is known to have unstable flanks. The Sciara del Fuoco (SdF) on its NW flank is a deep scar produced by a huge sector collapse in the order of 1 Km cubic meters that very likely originated a large tsunami in Holocenic time. Since that collapse, the SdF was progressively refilled by eruption products, and is nowadays a steep sector mostly formed by poorly consolidated heterogeneous rocks. On 30 December 2002 two large slides with a total volume of tens of millions cubic meters detached from the SdF slope. Probably both slides generated a tsunami, but the first was much larger. It caused severe destruction in Stromboli, produced some damage in the archipelago, and was seen in several coastal places in the south-Tyrrhenian sea. Here the numerical simulations of the event are shown. The mass failure is simulated by means of a block model, implying that the mass is subdivided into a number of interacting blocks sliding down the volcanic flank. In the simulation the block gain soon very high velocities, owing to the large steepness of the slope. The tsunami is simulated through a finite-element model in the near-field over a domain covering Stromboli and Panarea. The results of the simulations are in satisfactory agreement with the observations collected after the event. Within a few minutes time, the entire coast of Stromboli is attacked by the tsunami, and it takes only 5 minutes to the tsunami to attack the neighbour island of Panarea. The wave train travels around the island radiating from the source. The computed wave height decreases in moving away from the source (SdF), but in many places of the northern coasts it exceeds 7-9 m in agreement with the data.

JSS07/10A/A02-011   1115

DEVELOPMENT OF A TSUNAMI CATALOGUE FOR THE PACIFIC COAST OF CANADA

Fred E. STEPHENSON[1], Olga N. SOLOVIEVA[2], Sydney O. WIGEN[1], Boris W. LEVIN[2], Alexander B. RABINOVICH[2], Evgueni A. KULIKOV[2], Olga I. YAKOVENKO[2] ([1]Institute of Ocean Sciences, [2]Tsunami Laboratory, P.P. Shirshov Institute of Oceanology, 36 Nakhimovsky Prosp., Moscow, 117851, RUSSIA)

The Canadian coast is the only segment on the west coast of North America for which no comprehensive tsunami catalogue exists. The ˝Catalogue of Tsunamis on the Eastern Shore of the Pacific Ocean˝ (Soloviev and Go, 1975) lists 61 tsunamis that have affected the region of ˝The United States, Canada, and Southeast Alaska˝, with cited Canadian observations or measurements for only 5 of these events. The ˝Historical Tsunami Database for the Pacific Region˝ (Gusiakov, 2001) contains 9 tsunamis (events or runups) observed on the Pacific coast of Canada, including the recent Queen Charlotte tsunami of October 12, 2001. These catalogues do not include any Canadian information on many other tsunami events, in particular the Alaska tsunami of March 28, 1964 (several million dollars damage in Port Alberni, British Columbia) and the Chile tsunami of May 22, 1960, both of which were well documented in Canada. Sydney Wigen inspected the analogue records of tide stations on the west coast of Canada looking for possible wave action associated with 1451 events occurring over a 75 year period (1906-1980) and collected other data on tsunami manifestation for the Canadian coast. But he summarized and published the results of his work only for one station - Tofino, a long-term station on the west coast of Vancouver Island with 43 recorded tsunami of 6 cm or more (Wigen, 1983). The results of the searches carried out by Wigen at the other tide stations existed only in the form of hand-written tabulations. Several measurable tsunami have been recorded on the Canadian coast in the last twenty years, but no attempt has been made until now to continue to the work of Wigen and to incorporate this information with the earlier work to produce a comprehensive catalogue of tsunami observations and measurements. The development of a tsunami catalogue was undertaken as a joint project between the Institute of Ocean Sciences and the Tsunami Laboratory of the P.P. Shirshov Institute of Oceanology. The preparation of this catalogue provides an opportunity to review and update the Canadian information included in the ˝Tsunami Database˝ and to capture through scanning or other means data sets not previously available to tsunami researchers. The prepared list of tsunamis includes 57 events from 1891 to 2001 observed on the Pacific coast of Canada.

JSS07/10A/A02-012   1130

TSUNAMIS AND METEOROLOGICAL TSUNAMIS NEAR THE KURIL ISLANDS: INFLUENCE OF SOURCE AND TOPOGRAPHY

Alexander B. RABINOVICH (P.P. Shirshov Institute of Oceanology, Moscow, Russia)

The Kuril Islands are a region of high seismic and atmospheric activity. The Pacific coast of these islands is highly exposed to the threat of tsunami waves that arrive from the open ocean and amplified due to resonance on the shelf and/or in the local bays, inlets and harbors. Pronanced long-wave oscillations in the region are also generated by atmospheric disturbances, in particular by typhoons and atmospheric fronts. These "meteorological tsunamis" significantly affect coastal areas and may be of high danger for coastal population. Despite the different origin of tsunamis and meteotsunamis, both are modified and amplified by topography in a similar way, so it is often difficult to distinguish between these two phenomena without knowing the exact source characteristics. Recognition and separation of these phenomena are important for the revision/improvement of existing tsunami catalogues but also to better understand the generation mechanisms for destructive waves and to mitigate their catastrophic effects. To investigate this problem and to compare seismic and meteorological tsunamis, we used historical tsunami records from coastal tide gauges collected for the coast of the South Kuril Islands, in particular those associated with tsunamis in 1960, 1963, 1975, 1991, and 1994. We also used long-term series of 1-min data from a number of bottom pressure stations deployed in 1990-1992 in various bays and inlets of Shikotan Island and three precise microbarographs working simultaneously on the coast. Our analysis was based on the assumption that both tsunamis and meteotsunamis are formed by the combined effects of external forcing and topography. So, for different events recorded at the same site, similarities are because of the topography while differences arise from the forcing. In contrast, for the same event recorded at different stations, similarities are mainly associated with the forcing while differences are related to local topographic features. Analysis of the spectral distributions and comparison with background noise enabled us to reconstruct the topographic transfer functions for all sites on the Kuril Islands and to estimate the sources. The estimated source functions for long waves associated with seismic events were found to have typical periods of approximately 8 to 40 min, while those generated by a storm had shorter periods and energy pumping from high-frequencies due to non-linear interaction of wind waves and swell.

JSS07/10A/A02-013   1145

POST-DISASTER TECHNICAL CLEARINGHOUSES: AN OPERATIONAL MODEL FOR TSUNAMIS AND EARTHQUAKES IN HAWAII

Laura S. L. KONG[1], Brian YANAGI[2], Stan GOOSBY[3], Ray ISAWA[3] ([1]International Tsunami Information Center, and Hawaii State Tsunami Advisor, [2]Hawaii State Civil Defense, [3]Pacific Disaster Center)

A disaster, whether a damaging tsunami or earthquake, can attract a large number of local, national, and international professionals interested in investigating its scientific, economic, and social impact on affected communities. At the same time, scientists, structural engineers, and social scientists are wanting to document the phenomenological data and obtain eyewitness observations from those directly affected, emergency responders and government officials must focus their highest priorities on public safety, field damage reconnaissance, and integrity evaluation of critical support lifelines and infrastructure. Without a data management system that is integrated into government emergency operations, perishable data collection may be logistically difficult to acquire before erosion or bulldozers eliminate the evidence, and in all likelihood, could interfere with emergency responder activities. The establishment of an electronic Post-Disaster Technical Clearinghouse (PDTC) can provide a modern framework for the coordination of activities, and integration of scientific and engineering investigations with emergency operations. The Hawaii Post-Disaster Technical Clearinghouse is an initiative of the Hawaii State Civil Defense Tsunami Technical Review Committee (TTRC) and Hawaii State Earthquake Advisory Committee, and the Pacific Disaster Center, to develop a web-based, electronic technical clearinghouse for archiving and displaying information in a Geographical Information System (GIS) database. The PDTC is envisioned as a multi-hazard system for disaster intelligence gathering to collect, report and store information following a disaster. The PDTC web site, activated immediately following a damaging earthquake or tsunami, will provide users with a central shared repository for efficiently accessing, managing, and viewing all data, surveys, and reports, and provide a single resource point for widespread information exchange among researchers, emergency managers, and practitioners, and for sharing with the media and public. Trusted users may post and access data or damage reports, or may utilize the web-based GIS tools to select map layers to plot for use in emergency operations or as reports to the media or other interested parties. The PDTC implementation strategy highlights a four-phase approach in which user requirements are identified, system design architecture developed, system implementation and maintenance resources and costs identified, and finally a prototype PDTC created for user evaluation. Data to be archived at the PDTC includes the following: seismological information, including seismicity, shaking intensity, and earthquake source characteristics; tsunami information, including maregrams, runup and inundation, tsunami damage, and eyewitness accounts; geotechnical information, including ground deformation and failure; structural and non-structural impacts to building, structures, lifelines, and critical facilities; and social and economic impacts. In Hawaii, the tsunami PDTC coordinators will be the State and County Tsunami Advisors. The International Tsunami Information Center can provide coordination assistance for national and international tsunami scientists seeking participation. In order to collect perishable tsunami data, TTRC scientists have written the Hawaii Post-Tsunami Scientific Survey Plan, which upon activation will deploy trained local volunteers to record tsunami arrivals and impacts on significant coastlines; the tsunami observers will be pre-cleared to allow them access into restricted, but safe areas.

THE PUERTO RICO TSUNAMI WARNING AND MITIGATION PROGRAM AND RELATED TSUNAMI RESEARCH IN THE CARIBBEAN

Aurelio MERCADO[1], Ms. Christa VON HILLEBRANDT[2], Victor HUERFANO[2], Harry JUSTINIANO[1] ([1]Department of Marine Sciences, University of Puerto Rico, [2]Puerto Rico Seismic Network, University of Puerto Rico)

The Caribbean Sea region is well known for the hurricane hazard. But recent history has shown that in its northeast region, where the islands of Hispaniola, Puerto Rico, and the US Virgin Islands are located, the tsunami threat is another natural hazard that must be considered. Since 1867 three big, destructive, and local tsunamis have occurred in this region: the 1867 Virgin Islands tsunami, the 1918 Puerto Rico tsunami, and the 1946 Dominican Republic tsunami. Because of this ˝forgotten hazard˝, local and federal agencies have funded a series of applied research studies, and public outreach programs, with the purpose of quantifying the threat, and of public education. In addition, it is in NOAA´s plans to have a local tsunami warning system in Puerto Rico involving both the San Juan National Weather Office and the Puerto Rico Seismic Network. Here we will present the work involved in the several tasks of the Puerto Rico Tsunami Warning and Mitigation Program, including coastal flood mapping and development of algorithms for local and regional near real time characterization of seismic fault characteristics.

JSS07/10A/A02-015   1215

REDUCING TSUNAMI CASUALTIES: MITIGATION LESSONS FROM RECENT TSUNAMIS

Lori A. DENGLER (Humboldt State University)

Since 1990, 56 tsunamis have been observed or recorded, 22 of which were damaging. 13 events caused deaths contributing to at least 4000 tsunami fatalities in this time period. Only 3 of these events were recorded in the far field and produced no damage or casualties outside of the source region. At present, the primary focus of international tsunami mitigation efforts is the Tsunami Warning System in the Pacific. This system is designed to issue warnings for distant-source events and warnings played no direct role in reducing the impact of the tsunamis of the past 12 years. While recognizing that distant-source tsunamis pose a credible threat and the Warning System must be maintained and improved, significant reduction of tsunami casualties will only come by addressing the near-field vulnerability. During the past 12 years, International Tsunami Survey Teams (ITST) have studied 15 tsunami events. While the primary focus of these teams has been inundation, they have also gathered information on the human response to tsunamis and identifying factors that exacerbate or reduce impact. This paper summarizes the mitigation lessons from ITST reconnaissance studies.- The major cause of life loss is exposed populations coupled with a lack of awareness of the tsunami hazard. - Tsunami awareness can significantly reduce casualties. However, past experience in some cases can lead to increased vulnerability - The media can play a major role in education and awareness. - Lack of 24 hour emergency communications significantly slows response and increases morbidity.- ITST can play an important role in encouraging local tsunami mitigation efforts.The scientific tsunami community needs to bolster tsunami awareness by - Identifying and working with curriculum providers such as Non-Governmental Organizations - Supporting 24 hour emergency contact points in developing countries- Developing inexpensive, easily reproducible tsunami information materials available on-line in many languages- Improving and maintaining media contacts to provide consistent information when tsunami events occur.

CHANGES TO PACIFIC TSUNAMI WARNING CENTER PROCEDURES AND CRITERIA

Charles S. MCCREERY (Pacific Tsunami Warning Center)

The Richard H. Hagemeyer Pacific Tsunami Warning Center (PTWC) in Ewa Beach, Hawaii, is the operational center for the Tsunami Warning System in the Pacific, alerting most countries in the Pacific Basin to the threat of destructive teletsunamis. It will soon implement new procedures and criteria for issuing its tsunami warnings. Magnitude criteria will be based on moment magnitude, Mw, rather than the Richter surface-wave magnitude, Ms. While correlations of tsunami magnitude with Mw are not necessarily better than with Ms, Mw more accurately measures the very largest earthquakes that have the most potential to generate widespread destructive tsunamis. Mw, in combination with Ms or other more high-frequency measures of earthquake size, should also provide a better measure of the tsunami potential of anomalous ˝slow˝ or ˝tsunami˝ earthquakes, or events such as the April 1, 1946 Aleutians earthquake, with an Mw greater than 8 but an Ms of only around 7, that produced one of the most destructive tsunamis of the last century. Lastly, Mw can be estimated from broadband P-wave energy using Mwp, providing a quicker magnitude than Ms that requires much later surface wave arrivals. Consequently, PTWC should be able to disseminate initial warnings based on Mw in about 20 minutes on average in comparison to the current 30-40 minutes. PTWC will simultaneously raise its magnitude threshold for an expanding regional tsunami warning and watch from Ms greater than 7.5 to Mw greater than 7.8. A non-expanding regional warning will be issued for Mw greater than 7.5 but less than or equal to 7.8. These changes should help reduce the number of unnecessary warnings while still affording sufficient protection for all major destructive teletsunamis.

U.S. NTHMP EFFORTS TO DEVELOP FAR-FIELD TSUNAMI FORECAST GUIDANCE TOOLS

Frank I. GONZALEZ[1], Paul M. WHITMORE[2], Charles S. MCCREERY[3], David C. BURWELL[3], Vasily V. TITOV[1], Kwok Fai CHEUNG[4], Harold O. MOFJELD[1], Stanley GOOSBY[5] ([1]NOAA/Pacific Marine Environmental Laboratory, [2]NOAA/West Coast and Alaska Tsunami Warning Center, [3]NOAA/Pacific Tsunami Warning Center, [4]University of Hawaii at Manoa, Department of Ocean Resources and Engineering, [5]Pacific Disaster Center , Applications Development Division)

The U.S. National Tsunami Hazard Mitigation Program (NTHMP) is led by the National Oceanic and Atmospheric Agency (NOAA), in partnership with the U.S. Geological Survey (USGS), the Federal Emergency Management Agency (FEMA) and State agencies of Alaska, California, Hawaii, Oregon and Washington. A primary goal of the NTHMP is improvement in the speed, reliability and utility of tsunami warnings. NOAA´s Pacific Marine Environmental Laboratory (PMEL) conducts R&D in support of this goal, in collaboration with NOAA´S Tsunami Warning Centers (TWCs), emergency managers in the five partner states, academic researchers, and national and international institutions focused on disaster mitigation and management. Tools to provide operational forecasts of shoreline tsunami height and inland inundation are currently under development, as are methodologies for interpreting this information into the impact of the tsunami on humans and structures. The overall strategy is to combine tsunami model simulations with real-time seismic data and tsunami observations acquired by NOAA´s coastal tide gages and DART (Deep-ocean Assessment and Reporting of Tsunamis) network through data assimilation and inversion methodologies. Predicted tsunami wave height and currents can then be used as input to methodologies to estimate the impact. We will discuss the issues and challenges in meeting TWC operational requirements -- speed, accuracy, and user interfaces that provide guidance that is easy to interpret -- and the current status and plans of this effort.

JSS07/10P/A02-003   1430

TSUNAMI AMPLITUDE PREDICTION DURING EVENTS: A TEST BASED ON PREVIOUS TSUNAMIS

Paul Michael WHITMORE (NOAA/NWS/West Coast-Alaska Tsunami Warning Center)

The U.S. West Coast/Alaska Tsunami Warning Center´s far-field tsunami amplitude prediction method is tested by applying the technique to nine previous, well-recorded tsunamigenic events. The technique bases far-field amplitude predictions on pre-computed tsunami models and observed tsunami amplitudes (Whitmore and Sokolowski, 1996). Maximum modeled tsunami amplitudes are saved at 99 different locations along the Pacific coast of North America, Hawaii, and at the NOAA DART tsunami buoys for each of 204 hypothetical earthquakes. The earthquake locations range throughout the main ocean-wide tsunami generating zones of the Pacific basin; that is, Japan, Kuril Is., Kamchatka, Aleutian Is., Alaska, Cascadia, and Chile. Earthquakes of several different magnitudes are modeled at each location. Earthquake hypocentral parameters are based on previous earthquakes in the region and tectonic considerations. Vertical sea floor deformation is computed from the hypocentral parameters using static dislocation formulae (Okada, 1985). This deformation is the initial condition to a non-linear, shallow-water tsunami model. The equations of motion and continuity are solved using a finite difference technique (Kowalik and Whitmore, 1991) employing nested grids to accommodate areas which require higher spatial resolution. During an event, the most appropriate model, based on earthquake location and moment magnitude, is chosen from the 204 previously computed models. The pre-computed amplitudes outside the source zone are scaled based on the observed tsunami amplitude at nearby tide gages or DART buoys versus modeled tsunami amplitude. As the tsunami propagates further, the scaling factor is averaged with each new recording. Using this technique, predicted tsunami amplitudes outside the source area are shown to be sufficiently accurate to guide warning cancellation/ restriction/ expansion decisions. The technique is tested on the 1946, 1952, 1957, 1960, 1964, 1965, 1986, 1994, and 2001 tsunamis. Average error per event ranged from 0.04m to 0.29m with error defined as the absolute value of the difference between the recorded amplitude and the predicted amplitude. Had this technique been available during the 1986 Aleutian Is. and the 1994 Kuril Is. tsunami warnings, the warned areas likely would not have been expanded to include the U.S. West Coast, Canada, and Alaska east of Kodiak Island.

JSS07/10P/A02-004   1445

ASSESSING TSUNAMI MAGNITUDE FOR INUNDATION FORECAST

VASILY V. TITOV[1], Frank I. GONZALEZ[1], Mikhail LAVRENTIEV[2], Anatolii BEJAEV[3], Andrey MARCHUK[3], Alexander AVDEEV[3] ([1]NOAA/PMEL, [2]Institute of Mathematics, Novosibirsk, Russia, [3]Institute of Computational Mathematics and Mathematical Geophysics, Novosibirsk, Russia)

Forecast of tsunami inundation is one of the main goals of applied tsunami research. As part of the U.S. National Tsunami Hazard Mitigation Program (NTHMP), an effort is underway to develop practical tsunami modeling tools for real-time inundation forecast guidance. Quality of the model-based tsunami inundation estimates directly depends on the accuracy of the tsunami source evaluation. Tsunami sources are rarely available for direct observation. Instead, the source mechanism is usually inferred from various indirect measurements, mostly seismic and water-level data. Studies have shown that good inundation predictions are possible when comprehensive set of data is used for tsunami source estimates. However, very few of the measurements are routinely available in real-time (i.e. before a tsunami hit the forecasted shoreline): preliminary epicenter and magnitude of the earthquake are inferred from the seismic data (for earthquake-induced tsunamis); some of the water-level data from real-time reporting gages become available during tsunami propagation. Many modeling studies have demonstrated that the seismic data alone are often insufficient for estimating magnitude of tsunamis. Models provide adequate inundation estimates only when constrained by direct tsunami measurement (water-level data, runup measurement). The water level data can be inverted to determine source of the wave. At the same time, traditional tsunami inversion techniques may not be effective in real-time, when very limited data are available. The present study evaluates feasibility of determining tsunami magnitude (as oppose to earthquake magnitude) from real-time measurements and its use for practical inundation forecast. In particular, the potential of the Deep-ocean Assessment and Reporting of Tsunamis (DART) system is evaluated for real-time tsunami source evaluation. Tsunami scenarios are examined using available deep-ocean and coastal water-level data of historical events.

JSS07/10P/A02-005   1500

THE CHILEAN TSUNAMI WARNING SYSTEM AND APPLICATION OF THE TIME PROJECT TO THE CHILEAN COAST

Dante Gutierrez BESA (SERVICIO HIDROGRAFICO Y OCEANOGRAFICO DE LA ARMADA DE CHILE)

The Chilean coast is frequently exposed to the effects of near and far field tsunamis generated in the Pacific Ocean. For instance, the catastrophic events of 1868 and 1877 overwhelmed the coast of the northern region of the country. During this century, the most important disaster was the 1960 earthquake and tsunami of Valdivia. It is well known that this event had a great impact on thecoasts of most of the coastal states in the Pacific Ocean, mostly in Hawaii andJapan. The most recent event (Camana, Peru) recorded in the Chilean coast was the tsunami occurred at june 23, 2001.This historic situation has contributed to an awareness of the tsunami threat and therefore to the development of the research on several aspects of this phenomenon in Chile. In the last few years, new developments in technology have made it possible to improve the quality of the information to assess the potential risk of a tsunami event off Chilean coast. Starting from the year 2003, shoa will be operating a bouy system DART(Deep-ocean Assessment and Reporting of Tsunami),that will be installed in the north coast of Chile, in the proximities of Arica. The DART Proyect was conceived as part of the National Tsunami Hazard Mitigation Program of the United States (NTHMP), in a continuous effort to develop and to implement the capacity of early detection and report in real time of tsunamis in the deep ocean. As a very important complement to the operative work, inundation maps by tsunamis for the Chilean coast, following the techniques of the TIME project have been developed. The first maps for the four largest port cities in the northern part of Chile, namely Arica, Iquique, Antofagasta and Mejillones have been completed during 1997 and 1998. Arica and Iquique are located in a "seismic gap" zone. These inundation maps are being used for tsunami hazard planning by the national civil protection agency (ONEMI) and other government institutions. During the last years have been elaborated 20 maps for the rest ofthe ports and bays of the central area and south of the country. This paper provides information on the Chilean Tsunami Warning System and also reproduces the log of all actions taken in relation to the last event of Peru, June 23, 2001, considering both, internal and external information. On the lightof the flow of information gathered, the System was ready to generate a warning message on a ˝real tsunami˝. Fortunately, at the very last moment this message was not sent to the national authorities in charge of the evacuation plan, as new information collected, recommended not to do so. On the contrary, a message of ˝no tsunami threat ˝ was issued, providing relief to the mentioned authorities.

JSS07/10P/A02-006   1515

TSUNAMI OBSERVATION FROM SATELITE BY DATA TOPEX_POSEIDON MISSION

Vladimir V. IVANOV (Institute of Marine Geology and Geophysics Far Eastern Branch of Russian Academy of Science)

1. The Topex-Poseidon mission provides the information, which can be used for tsunami wave observation. It is possible to observe the wave with delay several hours (from the main shock of the Earthquake) on the distance several hundreds of kilometers (from the epicenter). In the case of tsunami July 12, 1993 at Japan Sea we have the records with delay 2 hours 40 minutes on the distance 400 kilometers. The data are recorded reliable on the depth more 200 m. 2. In the case of tsunami July 12, 1993 the records has the next parameters. The amplitude of wave was 1 - 3 cm, the characteristical distance was 100 – 200 km. Its corresponded to the low frequency component of the wave recorded by the tidal stations. 3. The high frequency component of the wave , which was observed on the tidal stations as a sequence of the intensive peaks, was observed on the satelite data as a small variations which contained several digital points with amplitude less than cm. 4. It is necessary to refine satelite data by using the special software for separating the tsunami wave. This separation is possible due to the next peculiarities of the backgroud signal. The first peculiarity is that the main part of observed variations were not changed from one cycle to another. The second peculiarity is that the main part of the variable part of signal caused by the variations of the satelite orbit from cycle to cycle. After refining the level variations can be observed with random noise with amplitude less than cm.

JSS07/10P/A02-007   1530

OPTIMAL PLACING OF THE TWS SEA LEVEL STATIONS FROM POINT OF VIEW OF TIMELY TSUNAMI WARNING

Alexander A. POPLAVSKY (Institute of Marine Geology and Geophysics, Russian Academy of Sciences)

The real water basins have very complicated, contrasting bottom relief. This circumstance allows us to find near the coasts a few points possessed the next property. Tsunami wave from arbitrary source will arrive in these points earlier than the rest coastal spots in the most of cases. So, these points are the best points for placing of the TWS sea level stations near the coast, because they have the minimal tsunami expected time. These points are the end-points of the main-high speed tracks for tsunami propagation. The open sea level stations placing near such tracks will detect the tsunami earlier than near-coastal stations. Known extreme properties of the differences of the tsunami expected times in two points allow us to find the optimal placing of the TWS sea level stations. We have found such placing for regions: to the East from Kamchatka and Kurile Islans and Japan Sea.

LOCAL TSUNAMI WARNING PROBLEM AND HYDRO-ACOUSTICAL SIGNAL DETECTION FOR EARLY LOCATION OF THE SEISMIC SOURCE PREPARATION

Boris W. LEVIN, Elena V. SASSOROVA, Victor E. MOROZOV (Tsunami laboratory, Shirshov Unstitute of Oceanology of RAS)

The problem of local tsunami warning remains up to now unsolved problem. The local tsunamis are generated within waterside no far than 100 km from coastal line and their propagation time from a source to coast is less than 1 hour. It makes these tsunamis extremely dangerous. The locations of tsunamigenic earthquake epicenters (earthquakes with magnitudes MS > 6.0) near the Kamchatka Peninsula over a period of 50 years (from 1950 to 2000) was analyzed. All earthquake epicenters are located in the near-shore zone. Mean distance between EQ source and coastal line for all selected events is less than 18 km. It makes impossible to prepare the warning message both theoretically and practically for near-shore seismic events. We have the same situation for the Pacific coast of the Kuril Islands. A possible way to solve this problem is to pick up the acoustic signals preceding underwater near-shore earthquakes, which appear in the critical state of the earthquake preparation. It is well known that the natural seismic noise pulses in the form of the acoustic signals with the frequency 0.01-1 kHz may forego large earthquake occurrence. In case of an oceanic earthquake, an acoustic and seismic emission radiation from the crust quake source must generate an acoustic signal in a water layer where this signal may propagate far because of a weak attenuation of the signal in the incompressible water. Now we have received the possibility to analyze the observation data from the long-term records of high-quality hydro-acoustic receiving array. A joint analysis of the local Kamchatka earthquake catalogue data and hydro-acoustic measurements was carried out. Two types of signals were detected from the zones of a bottom earthquake preparation: the micro-earthquakes (MEQ) whose focuses were located in the same area as the seismic focus of main earthquake and the seismic noise, which appears just before the main shock. The duration of MEQs was about 3-4 seconds, frequency - 40-75 Hz. If the time interval between the hydro-acoustic record and earthquake exceeded 4 hours no micro-earthquakes were observed. We conclude that the hydro-acoustic monitoring of the ocean noise opens the possibility to receive new information about the peculiarities of the earthquake preparation process and may be used for local tsunami warning system development.

JSS07/10P/A02-009 — 1615

CAN MICRO-TSUNAMI ANALYSIS BE USED A NEW ADDITIONAL TOOL FOR EARTHQUAKE LOCATION AND SOURCE PARAMETER STUDY?

Kenji HIRATA[1], Eric L. GEIST[2], Kenji SATAKE[3], Yuichiro TANIOKA[4], Hiroaki TAKAHASHI[4] ([1]Japan Marine Science and Technology Center, [2]U.S.Geological Survey, [3]Active Fault Research Center, National Institute of Advanced Industrial Science and Technology, [4]Institute of Seismology and Volcanology, Hookaido University)

The sensitivity of micro-tsunami waveforms on hypocenter location, fault size, and amount of slip as well as the high accuracy of ocean-bottom pressure gauges to detect micro-tsunamis makes it possible to locate hypocenter and source parameters for moderate-sized subduction earthquakes. We demonstrate this through analysis of micro-tsunami data from the January 28, 2000 earthquake (Mw 6.8) off Nemuro Peninsula, Hokkaido, Japan. The data was recorded on a cabled seafloor observatory south of Hokkaido that was deployed by JAMSTEC (Japan Marine Science and Technology Center) in 1999. Regional seismic networks provide the best estimates of hypocenter location of small to moderate earthquakes. Regional networks are, however, usually distributed on land and have a narrow station coverage for subduction zone earthquakes, resulting in a systematic location errors. Ocean-bottom seismographic (OBS) studies have suggested that the epicenters located by land-based regional seismic data alone tend to shift hypocenters a few tens of kilometers toward the trench. The focal-depth determination for subduction zone earthquakes is also less accurate if only land-based seismic network data are used. The cause of this systematic deviation is (1) narrow source-to-station coverage and (2) insufficient knowledge on the crustal and uppermost mantle structures in subduction zones. Tsunami generation depends upon earthquake source parameters such as source depth, fault size, and amount of slip along the fault. In other words, earthquake source information is retained by the tsunami waveform. Furthermore, tsunami propagation is controlled by bathymetry only and the first arrival times of tsunamis are closely related to their epicenter location. Therefore, analysis of small tsunamis from moderate-sized subduction zone earthquakes may constrain the hypocenter, as well as other source parameters. Standard tide gauges on the coast, however, cannot usually record small tsunamis because of ambient noise from wind waves and harbor resonance. Ocean-bottom pressure measurements, which are free from the complicated non-linear effects of the nearshore bathymetry on the tsunami wavefield, provide precise tsunami data with a high signal-to-noise ratio. To locate the earthquake hypocenter and to investigate source parameters from the micro-tsunami of the January 28, 2000 earthquake, we compare observed and theoretical micro-tsunami waveforms calculated assuming rectangular faults. The best-fit solution is obtained at (N43.0593°, E146.6407°, h=45 km), as the center of the fault, using a least-squares, grid-searching algorithm. This location is approximately 20 km to the WNW (toward the Kuril Islands) from a previous estimate of the fault center defined by regional seismic networks. The best-fit fault length and width are estimated to be 15 km and 30 km, respectively. The average amount of slip on the fault is estimated to be 0.80 m. The seismic moment is estimated at 2.42 x 10^19 Nm. This estimate is only 20% larger than 1.98 x 10^19 Nm obtained from the Harvard CMT inversion, and therefore micro-tsunami analysis can give a good estimation for scalar seismic moment. As demonstrated by these results, micro-tsunami waveform analysis provides improved accuracy of source parameters for studying small tsunamigenic earthquakes occurring along subduction zones.

JSS07/10P/A02-010 — 1630

DETECTING AND STUDYING TSUNAMI FROM IONOSPHERIC MONITORING

Juliette ARTRU[1], Vesna DUCIC[2], Victor TSAI[1], Hiroo KANAMORI[1], Philippe LOGNONNE[2], Makoto MURAKAMI[3] ([1]California Institute of Technology, [2]Institut de Physique du Globe de Paris, [3]Geographical Survey Institute)

GPS ionospheric monitoring performed with high-resolution data from dense networks allowed detection of ionospheric signals induced by tsunamiand seismic waves, through dynamic coupling between the Earth and the atmosphere. In both cases, what we observe is the ionosphere response to an atmospheric acoustic-gravity wave induced by the verticaldisplacement of the surface. Observation of tsunami waves using thistechnique presents a very good signal-to-noise ratio, as signal fromocean surface waves is filtered out through the atmosphere. This typeof measurements could open a new era for tsunami studies, as it can beperformed above the open ocean, and possibly in real-time.We will present here a study of the signal observed on GEONET data fora tsunami wave triggered by a Mw 7.6 earthquake in the Volcano Islandregion in March 2000, with an emphasis of the possible interpretationin terms of wave height at the surface. Both propagation properties ofatmospheric waves and geometry of measurement have to be taken intoaccount. We use

for that purpose TriNet seismic network data and from SCIGN network GPS ionospheric monitoring to compare the wavefield at the surface to the corresponding ionosephric perturbation. We presents results from a study of (1) Rayleigh-acoustic waves after the Mw 8.2 Alaska earthquake in Nov 2002, (2) Atmospheric solitary gravity waves detected at the ground level on TriNet seismic records and barographs.In a second part we will address how GPS measurements could be used toperform systematic studies of tsunamis, in terms of sampling, spatialresolution and sensitivity.

FORECASTS OF TSUNAMIS FROM THE ALASKA-ALEUTIAN AND JAPAN-KURIL-KAMCHATKA SOURCE REGIONS

Kwok Fai CHEUNG, Yong WEI, Yoshiki YAMAZAKI (Dept. of Ocean and Resources Engineering, University of Hawaii at Manoa)

A methodology is developed to assess the severity of a tsunami in progress based on real-time water-level data near the source. The inverse method, which uses tsunami signals in water-level data to infer seismic source parameters, is extended to predict the tsunami waveforms away from the source. This study focuses on the Alaska-Aleutian and Japan-Kuril-Kamchatka source regions and their potential threats to Hawaii. The algorithm divides each source region into a number of subfaults based on analyses of major historical tsunamigenic earthquakes. For unit slip of the subfaults, a linear long-wave model generates a database of synthetic mareograms at selected water-level stations near the source and at locations where the tsunami waveforms need to be predicted. When a tsunami occurs, regression of recorded tsunami signals near the source using the mareograms provides the slip distribution as well as the expected waveforms near Hawaii and at strategic locations in the Pacific basin. A jackknife resampling scheme provides the confidence interval bounds of the predictions. The algorithm along with the database has been tested and verified using numerically simulated and actual water-level data of past tsunami events.

ESTABLISHMENT OF A TSUNAMI ASSESSMENT MANUAL FOR NUCLEAR POWER FACILITIES

Hiroyoshi TANAKA[1], Makoto TAKAO[2], Tadashi ANNAKA[3] ([1]Fluid Science Department, Abiko Research Laboratory, Central Research Institute of Electric Power Industry, [2]Nuclear Power Engineering Department, Tokyo Electric Power Company, 1-3, Uchisaiwai-cho 1-chome Chiyoda-ku, Tokyo 100-8560 JAPAN, [3]Advanced Engineering Operation Center, Tokyo Electric Power Services Company, 3-3, Higashiueno 3-chome, Taito-ku, Tokyo 110-0015 JAPAN)

Since studies on tsunamis are developing with recent occurrence phenomena as turning points, it would be essential to improve further the safety and reliability of coastal power facilities by reflecting findings newly obtained from these phenomena to the technique setting design tsunami. From the above-mentioned viewpoint, the present study summarized a manual related to the setting of design tsunami for nuclear power facilities in consideration of the results of technological progress. Characteristics of the tsunami assessment method are as follows. 1) Our principle is to assess the maximum water ascent and descent levels on the basis of the tsunamis resulting from the estimated earthquakes that would occur at neighboring plate boundaries, Japan Sea eastern margin, marine active faults and according to circumstances at oversea plate boundaries. 2) Various uncertainties and errors intervene in the processes of tsunami assessment but it is difficult to decompose and indicate them one by one quantitatively. Consequently, we focus only on uncertainty of tsunami source which has major influence on tsunami assessment and contains many factors having no assured value. First, we select the greatest influence condition on calculated tsunami height at the assessment spot by varying the most dominant factor such as fault position within a reasonable range. Secondly, after fixing the extracted first factor condition we select the greatest influence condition by varying the second factor such as fault strike direction within a reasonable range. Thirdly, after fixing the extracted first and second factor conditions we select the greatest influence condition by varying the third factor such as fault dip angle. Finally, after going through such processes called parameter study we can determine conditions of all the factors. Tsunami height obtained by applying the determined conditions is expected to considerably exceed tsunami height considering the original uncertainty of tsunami source and to absorb the assessment risk generated by errors in numerical calculations and data errors of submarine and coastal configurations. Validity of this way of thinking was confirmed by the result that the tsunami heights finally obtained by the above-mentioned parameter study exceed the run-up trace heights at 185 spots on the Japanese coast. 3) Adequacy of the tsunami applied to design is verified by confirming that the tsunami height exceeds all the run-up trace heights of the historical tsunamis at a planned nuclear power plant site. In the case of no run-up trace of utility value at the site, the adequacy is verified by satisfying the following two items. a) At the site, the design tsunami height exceeds the reproduction calculation heights of the historical tsunamis. b) In the vicinity of the site, the envelop of the numerous tsunami heights obtained in the processes of the parameter study exceeds all the run-up trace heights of the historical tsunamis.

CREATION OF THE GRIDDED BATHYMETRY FOR REGIONAL TSUNAMI MODELING

Andrei G. MARCHUK, Anatoly Yu. BEZHAEV (Institute of Computational Mathematics and Mathematical Geophysics)

For the numerical modeling of tsunami waves propagation, the gridded digital bathymetry is needed. At present such a bathymetry of the required resolution is available only for a few regions. In this study, the method of creating the detailed bathymetry on rectangular grids is proposed. The information about the ocean depths can be found as soundings and bathymetric charts. A great number of depth soundings are contained in the digital databases ˝Marine Trackline Data˝ and ˝Hydrographic Survey Data˝. In the areas tightly filled in with data points, it is possible to create the digital bathymetry of a good quality. In the areas with an insufficient amount of sounding data, the information from bathymetric charts can be used for creating the digital arrays of depths. In this case, the scanned maps should

be digitized using a specially developed digitizing interface. At the final stage, the algorithm, developed by the authors, recalculates arbitrarily distributed values of depths into a detailed gridded bathymetry. For the calculation at each grid point, where depth is to be found, the algorithm uses up to 9 points from a data source. They are chosen using two criteria: the first - the points must be located in various sectors (N, NE, E, SE, S, SW, W, NW) from a grid-point being calculated. And the second - they must be the nearest ones to this point in each sector. Then the spline interpolation is used for defining the value of depth at the grid-point. Another algorithm uses the linear interpolation for obtaining depth value at the grid-point. Several new digital bathymery datasets on the rectangular grid with 30 arc seconds resolution have been created for the numerical modeling of tsunami propagation. These data include four rectangular arrays of depths, which cover a 200 km zone around the Kuril Islands and Kamchatka from 41.00° N up to 61.00° N. Tsunami propagation from real and model sources was numerically simulated. Using the proposed method it is possible to create detailed arrays of depths for different tsunami-prone regions.

THEORY OF EM MONITORING OF TSUNAMI WAVES FAR FROM A SHORE

Oleg Bencionovith NOVIK, Sergey Valentinovitch ERSHOV, Irina Borisovna MIKHAYLOVSKAYA (Inst. Terrestrial Magnetism, Ionosphere and Radio Wave Propagation Russian Acad. Sci., 117246, POB 51, Moscow, Russia, onovik@online.ru)

Tsunamis and earthquakes in near sea regions are manifestations of powerful geodynamic processes beneath the World Ocean´s floor covering about 75% of the earth surface. Electromagnetic (EM) signals associated by researches with seismic activity of ocean lithosphere have been detected, especially in Pacific regions (the most tectonically active segment of the Earth), more then once buttheir physical mechanism is not well understood. Basing on the theory of elasticity, electrodynamics, fluid dynamics and thermodynamics, we formulate a nonlinear mathematical model of seismo-hydro-EM field interaction and calculate generation and propagation of seismic disturbances of these fields (with a proper visualization) in the basin of a model marginal sea (2D schematization of the central part of the Sea of Japan), including transfer of seismic and EM energy from focal depths in lithosphere into a sea and EM emission from its surface into atmosphere, up to the low boundary of ionosphere. Mathematical investigations of algorithms and physical interpretation of numerical results were performed. Amplitude of the computed magnetic signals (500, 300, 200, 50, and 30 pT at the top of the sea bottom sedimentary layer, ocean-atmosphere interface and at the height of 10, 30 and 50 km resp., $t = 10$ s after the beginning of seismic excitation in the ocean lithosphere), their main frequency (0.25 Hz), delay of the seismic wave in regard to the magnetic signal (20 s for receivers at the shore) and other parameters of computed seismic signals are of orders observed. In particular, the computed long (150 km) seismo-hydrodynamic wave of a small amplitude (up to 20 cm by the velocity of order of a few hundreds of km/h at different points far from the shore) corresponds to observations as well. So, to discover a seismic activation in ocean lithosphereand a tsunami wave far from a shore, the magnetic recordings at the sea surface and above (buoys, balloons, proton magnetometers, and, may be, satelite instrumentation) should be combined with seismic, magnetic and temperature (0.001 K to 1 K, quartz thermo-resistors should be applied; the magnetic signalparameters see above) recordings at the sea bottom.

DEVELOPING A COMPREHENSIVE TSUNAMI SIMULATOR FOR POSSIBLE TSUNAMI DISASTER PREPAREDNESS IN A COASTAL COMMUNITY

Shunichi KOSHIMURA[1], Toshitaka KATADA[2], Noriyuki KUWASAWA[3], Akichika ISHIBASHI[3], Kimiro MEGURO[4] ([1]Disaster Reduction and Human Renovation Institution, [2]Gunma University, [3]Nippon Koei Co., Ltd, [4]University of Tokyo)

Coastal communities along the Pacific coast in Japan are under the threat of gigantic tsunamis accompanied with possible megathrust earthquakes along the Nankai Trough within 30 to 40 years. To protect the coastal residents from the tsunami, it is evident that each coastal community should have its own disaster reduction strategy and tools to evaluate if it works. The aim of the present study is to develop a comprehensive tsunami simulator to evaluate each community's tsunami disaster preparedness and mitigation strategy, that consists of constructing tsunami hazard scenario, issuing warning guidance for evacuation, communication between residents, evacuation planning, and estimation of human casualties. Tsunami hazard scenario is provided by the result of tsunami propagation and inundation modeling based on the non-linear shallow water theory, assuming possible great earthquake of Mw 8.6 along the Nankai Trough. Resident communication and evacuation analysis is based on network model theory by using one of the functions of GIS. Human casualty estimation model takes account of hydrodynamic force of tsunami inundation flow as it affects the human body to decide the possibility of evacuation. The present simulator is applied to Owase City that has a population of 24000 and is one of the most vulnerable coastal communities against the tsunami due to great earthquakes along the Nankai Trough.

TOWARDS THE OPTIMIZATION OF REGIONAL TSUNAMI WARNING SYSTEMS VIA EARLY DETECTION AND MODELING

Atilio A. ASTE[1], Modesto ORTIZ[2], Salvador F. FARRERAS[2] ([1]Oceanology Division, DHN of Peru and Cicese of Mexico, [2]Oceanology Division, CICESE Research Center of Mexico)

Early tsunami warning delivery is fundamental for inundation risk evaluation and preventive countermeasure implementation. The possibility to develop a real-time methodology to minimize flooding risk estimations uncertainly from regional tsunamis, based in the analysis of early sea level observations and modeling, is explored.Local tsunamis, like the recent Nicaragua 1992, Flores 1992, Shikotan 1994, Mexico 1995 and Peru 2001, occur more frequently than the remote trans-Pacific ones and cause severe localized damage and casualties mostly near the generation area. However, for this type of tsunamis the evaluation of expected wave heights at the arrival to nearby or remote locations is uncertain, and there is a lack of adequate criteria to decide if a widespread tsunami warning message should be issued or not. A methodology to evaluate with enough certainty and as early as possible the regional and pacific wide threat to minimize the damage and loss of lives or avoid costly and unnecessary evacuations, is needed.The propagation of tsunamis generated by synthetic earthquakes, as Impulse functions, with sources in several areas of the eastern Pacific Subduction zones, are computer simulated. This ensemble of synthetic tsunamis define a universe of Green functions. The optimum location and number of real-time seal level observing stations along the coast to minimize the uncertainty in the evaluation of source area size and location, are determined. These sea level observations determine in real-time the number and magnitude of impulse functions needed to reproduce the initial conditions.Shallow water non-linear theory for the synthetic tsunami propagation in the near shore and interaction with the coast, is considered. Non-fixed boundaries with discharges conditioned to the state of the water level at the borders, were used to model the flooding

---

and recession at the coast. The equations were solved through an explicit central finite-difference algorithm for interconnected grids of different sizes. The expected wave heights at each location are so determined in real time from their corresponding Green functions, and are already available for a more confident and less uncertain issue of tsunami warning messages to nearby and remote locations.

A TSUNAMI DETECTION SYSTEM USING RTK-GPS IN OFUNATO CITY, NORTHEASTERN JAPAN

Teruyuki KATO[1], Yukihiro TERADA[2], Shun'ichi KOSHIMURA[3], Takenori ABE[2] ([1]Earthquake Research Institute, University of Tokyo, [2]Technical Research Institute, Hitachi Zosen Corporation, [3]Disaster Reduction and Human Renovation Institution)

More than two years have passed since we deployed a new experimental tsunami detection system using RTK-GPS offshore Ofunato city, northeastern Japan. The system has been operated without any significant failure except occasional short term failures of PC or transmission system. During the experiment so far, the system was able to observe a small tsunami due to Peru earthquake of June 24, 2001, with peak-to-peak amplitude of less than 20cm. The similarity of wave form with tide gauge record at nearby tidal station of Ofunato confirmed that the present system is capable of detecting tsunami of a few centimeters, if appropriate real-time low-pass filtering is applied to the raw data. The system is broadcast to the City Hall and Fire Station of Ofunato city in real-time manner. In addition, the processed data are transferred to the web server placed at the Hitachi Zosen Corporation to disseminate the data every 30min through webpage (http://tsunami.ekankyo21.com/). Therefore, anyone can observe the sea-surface at any time at any place as far as internet is reachable. The internet system is soon be upgraded for real-time monitoring. In order to improve the system for more practical tsunami-detection and disaster mitigation system, some problems are to be solved. The hardest problem is longer-distance RTK because early warning system may be more effective if the GPS buoy is deployed farther offshore. Currently commercially available RTK software ensures only 10km at most for estimating a few centimeters in positioning accuracy. To tackle this problem, we made a short term experiment in which long-distance observation setting GPS sites farther away from the Ofunato city. The present study shows the results obtained for this experiment.

A NEW TSUNAMI DETECTION SYSTEM USING RTK-GPS FOR LONG-DISTANCE OBSERVATION

Yukihiro TERADA[1], Teruyuki KATO[2], Keiji ITOH[1], Shuichi NAGATA[1], Takashi FUJITA[1], Takenori ABE[1], Toshihide MIYAKE[1], Toshihiko NAGAI[3], Shun'ichi KOSHIMURA[4], Shin'ichi MIYAZAKI[2] ([1]Technical Research Institute, Hitachi Zosen Corporation, [2]Earthquake Research Institute, The University of Tokyo, [3]Independent Administrative Institution, Port and Airport Research Institute, [4]Disaster Reduction and Human Renovation Institution)

We propose a new tsunami detection system using RTK-GPS for observing the sea-surface at long-distance from the coast. Detection of tsunami as early as possible before its arrival to the coast is a keen inquiry for mitigating tsunami disaster along the coast. We have developed tsunami-detection systems for more than five years and a system is now in operation about 2km offshore of Ofunato city, northeastern part of Japan, for more than two years. In order to deploy a RTK-GPS tsunami buoy in farther location from the coast, however, several difficult problems need to be solved. The hardest problem is the accuracy in estimating ocean height in a few centimeters or better, because RTK-GPS allows only less than 10km to ensure its accuracy of a few centimeters. To tackle this problem, we have proposed two new algorithms in estimating ocean surface heights; PVD (Point precice Variance Detection) method and KVD (Kinematics for precice Variance Detection) method. To make the methods applicable for practical real-time operation, we have developed a new algorithm applying a Kalman fitler. The technique will be tested in our new tsunami-detection system which will be deployed 10-15 km off Muroto Promontory, Shikoku, southwestern part of Japan. The area is now highlighted in terms of special monitoring region for earthquake disaster mitigation project by the Japanese government. We plan to display a new monitoring system of ocean surface using hybrid data transmission using radio and broadband so that anyone can observe offshore GPS-buoy at any location as far as internet is available in real-time manner.

MARINE EMERGENCY RESPONSE TO A CASCADIA MEGATHRUST EARTHQUAKE AND TSUNAMI

Fred E. STEPHENSON, Josef Y. CHERNIAWSKY (Institute of Ocean Sciences)

The Cascadia Subduction Zone extends 1000 km from southern British Columbia to Northern California, and at its northern end the deformation front is less than 100 km from the coast of Vancouver Island. A megathrust earthquake in this area will have a catastrophic effect on the communities along the adjacent coast.The coastline of the west coast of Vancouver Island is very complex with many channels and inlets. Much of the island is rugged and access to many communities along the west coast is by a single road. In the event of a major earthquake slides, slumping, and bridge failures etc. will likely cut off road access to many of these communities In the days immediately following the earthquake most of the emergency response will have to come by sea. Emergency response and mitigation studies often focus on the land-based response to a tsunami, but in this instance the marine component is of equal importance. Are search and rescue (SAR) facilities and SAR vessels in these communities likely to survive a destructive tsunami, and if they do, how are local conditions going to limit their effectiveness for marine search and rescue? In response to the disaster, the Navy and Coast Guard will both dispatch vessels to the most severely effected areas. Will the tsunami and its aftermath effect the ability of vessels to navigate safely in these areas, and will it effect their ability to provide both water and land based support?A three year modelling study, funded by the Canadian Coast Guard´s SAR program, is being carried out to predict coastal sea level changes and currents in southern British Columbia harbours due to a tsunami that may result from a megathrust earthquake in the Cascadia Subduction Zone. The present modelling effort uses bathymetric grids up to two orders of magnitude finer than previous studies. The finer resolution gives more accurate results and allows us to see water level and current variations within harbours that were not possible with previous models. This will assist Coast Guard SAR in preparing emergency response plans for their facilities and for the local marine communities they serve.

ANALYSIS AND NUMERICAL MODELING OF THE NOVEMBER 18, 1929 GRAND BANKS LANDSLIDE-GENERATED TSUNAMI

Alexander B. RABINOVICH[1], Isaak V. FINE[3], Brian D. BORNHOLD[3], Richard E. THOMSON[2], Evgueni A.KULIKOV[2] ([1]P.P. Shirshov Institute of Oceanology, Moscow, Russia, [2]Institute of Ocean

Sciences, Sidney, BC, Canada, [3]Heat and Mass Transfer Institute, Minsk, Belarus, [4]International Tsunami Research, Sidney, BC, Canada, [5]University of Victoria, Victoria, BC, Canada)

The landslide-generated tsunami of November 18, 1929 that occurred at the southern edge of the Grand Banks, 250 km offshore from Newfoundland, was probably the most catastrophic tsunami in Canadian history (27 people killed). This tsunami was associated with a huge submarine slump (200 km3), triggered by a M = 7.2 earthquake. This slump transformed into a turbid flow of clay, silt, and sand that moved eastward up to 1,500 km at speeds of up to 100 km/hr, breaking many telegraph cables. The generated tsunami was observed along the Atlantic coast of Canada and the U.S, as well as on the coasts of Portugal and the Azores Islands. Tsunami waves had amplitudes of 2 to 7 m and runup up to 13 m along the coast of the Burin Peninsula (Newfoundland). To examine this tsunami we used all available historical observational data, including actual tide gauge records, and formulated a finite difference numerical model for tsunami simulation. The slide was assumed to be a thin, viscous, incompressible fluid layer; water was inviscid and incompressible. The shallow-water approximation was assumed for both the slide and water waves. The parameters of the slide were the following: slide area = 25,000 km2, thickness = 5 m, volume = 125 km3, density = 2.0 g cm-3, kinematic viscosity = 0.01, and drag coefficient = 0.0025, slide motion time = 1000 s. The preliminary results of our numerical modeling are encouraging in that the computed and observed tsunami heights and arrival times are in reasonable agreement. Further progress would be achieved if we were able to determine more precisely the slide parameters (slide thickness, volume, shape, density) and able to find additional tide gauge records of the 1929 tsunami for comparison with simulated records.

NUMERICAL SIMULATION OF TSUNAMI IN LINEAR AND NONLINEAR PROBLEMS BY IMAGINARY VARIABLE GRID SYSTEM METHOD USING NUMERICAL DISPERSION

Yoshinori SHIGIHARA, Fumihiko IMAMURA (Disaster Control Research Center, Graduate School of Engineering, Tohoku University)

Most of numerical simulations for tsunami propagation in practical problems are carried out with long wave approximation excluding a wave frequency dispersion. However, in the following cases the dispersion effect can not be ignored: (1) linear dispersion in a tsunami propagation with long distance in a deep-sea region for the Chilean tsunami of 1960 as example, and (2) nonlinear dispersion in propagation of a tsunami containing higher frequency components in a shallow region in the case such as the 1983 Japan sea earthquake tsunami. For such cases, the dispersive wave theory such as Boussinesq and KdV should be solved by implicit scheme method requiring more computing time. Imamura and Shuto (1989) proposed a unique method to use numerical error in the scheme replacing the physical dispersion. If the spatial grid size in the numerical model with the linear long wave equation can be properly selected, the numerical results show the same accuracy as the linear Boussinesq equation, saving computational time. However, this method has remained the problems in the application to complicated bathymetry with non-uniform sea bottom because it is rather difficult to change the grid size depending on the water depth. In this study, a new idea of imaginary Variable Grid System (VGS) method is proposed to improve the applicability of Imamura & Shuto (1989) method. In this method, the spatial size in the numerical scheme at each grid can be imaginarily changed to be satisfied with the condition of Imamura & Shuto (1989) in the Leap-Frog difference method for the each water depth. The variables of discharge and water level at the imaginary grid can be obtained by the interpolation from original variables by using third approximation spline function. First of all, the numerical results of the linear long wave theory using imaginary VGS method agree with theoretical solution on the flat bottom. Furthermore, the numerical results on a slope changing water depth with different spatial grids are the almost same. Secondly, we applied the method in the shallow water where non-linearity is not neglected. Since the numerical error of the dissipation induced by the up-wind scheme in the convection term reduce the higher frequency components, we need to introduce a method to reduce the damping effect. In this study, we select Iwase et al. (1998) method to introduce an artificial dissipation with the opposite sign canceling the numerical one. Numerical model of the shallow-water theory with imaginary VGS method and Iwase et al. (1998) method can simulate well wave profiles on a slope of shallow water obtained by the numerical solution of the nonlinear dispersive wave theory, showing that imaginary VGS method enables to simulate wave frequency dispersion such as a tsunami and flood tide. Moreover, we found imaginary VGS method can reduce into about 1/2 CPU time of the simulation of implicit scheme.

A HYDRAULIC EXPERIMENT AND NUMERICAL SIMULATION FOR THE WAVE BREAKING TRANSFORMATION OF SOLITON FISSION WAVES

Hiroyuki IWASE[1], Fumihiko IMAMURA[2] ([1]ECOH Co., Ltd., [2]Tohoku University)

In the 1983 Nihonkai-Chubu earthquake tsunami, soliton fission waves causing powerful wave force and damage on blocks and ships were observed in shallow water on a mild and long slope. In order to reproduce these waves including the waveform curvature effect, we have to use the Boussinesq equations as the governing equation with wave frequency dispersion and breaking. Although, the effect of dispersion is going to be included into the tsunami model, problem on the model of breaking still remains. Consequently, the numerical model with Boussinesq equations mostly overestimate wave height and the runup on land. Furthermore, it is reported that the depth integrated Boussinesq-type models underestimate the wave height in front of breaking point. So it is important to develop the numerical model with the proper dispersion as well as breaking effects in the coastal. In this study, a wave breaking model for soliton fission waves in shallow water is examined through the comparison of the hydraulic experiment and numerical simulations with various types of the models. At the first, the relation between wave height and still water depth of the wave breaking point for several solitary waves was discussed by the hydraulic experiment. At the second, we examined the model of artificial amplification of a water height, dissipation, at front of breaking point and the wave breaking model. We use the previous research work (Iwase & Goto, 2000) on the breaking models and carry out the simulation to be compared with the hydraulic experiments in order to calibrate the coefficient of the these models. The models with the calibrated one is applied in the wave crest of breaking point at front and rear wave trough. The calculation result agrees with the experiment result well on the average of wave heights before and after the breaking.

TWO- AND THREE-DIMENSIONAL NUMERICAL MODELS FOR A TSUNAMI PROPAGATION PASSING AN OBSTACLE

Sung Jin HONG, Fumihiko IMAMURA (Disaster Control Research Center, Tohoku University)

Some numerical models are tried to be developed for analyzing the resistance force interacted between wave and structures and applied with sufficient accuracy to practical problems. In the computation, however, it is normally assumed either that there are no solid structures capable of withstanding tsunami, or that the effect of a solid structure can be expressed in terms of a roughness coefficient, such as Manning´s *n*. Since the effect of obstacles are important for disaster prevention due to tsunami in shallow water and on land, it is necessary to analyze the interacted resistance force. However, so far two-dimensional numerical model with Manning´s *n* which is selected without consideration of the hydraulic characteristics could not represent the interaction between wave and structures because that model could not analyze exactly the effect of structures for tsunami. In the present study, we have proposed two kinds of numerical model. One of those models is the two-dimensional tsunami model with equivalent roughness based on shallow water theory, which can be utilized to obtain appropriate friction coefficient at the bottom using percentage of the structures. The quantitative verification about the model has been clarified through comparing with the results of upper model and experiment data that is measured by hydraulic experiment at the open-channel. In front of the obstacles, the comparison of calculated and measured data has a good agreement because reflected wave doesn't reach this region. In middle around obstacles, though physical modeling error might be predominant because tsunami is affected and reflected by structures; reflection, diffraction and refraction, which phenomena can not be included fully in the two-dimensional model, the comparion has a general agreement in specific numerical conditions. Finally, in back of obstacles, the effect of obstacle would not appear in propagation of tsunami wave after passing through obstacles, due to small physical error. In addition, we can estimate that the physical error is taked the component of linearly increasing error in the function of distance. The other is three-dimensional numerical tsunami model which can analyze the nonlinear behavior of flow around obstacles based on Navier-Stokes equations. We employed the method of MAC (Marker and Cell) method and improved it to be fitted with the experiment result.

ANALYTICAL STUDY ON SEABED DISPLACEMENT RESULTING FROM SEISMIC FAULTING

Shusaku INOUE, Tatsuo OHMACHI (. Department of Built Environment, Interdisciplinary Graduate School of Science and Engineering, Tokyo Institute of Technology)

In late years, serious damages are caused by near field tsunamis that reach the seashore within a few minutes from the occurrence of the tsunami-genic earthquake. The 1999 Hokkaido-nansei Oki, Japan tsunami still remains vividly in our memory. More than 200 persons were killed mostly by this near-field tsunami. Reportedly, the first wave of this tsunami reached the Okushiri Island within 5 minutes after the occurrence of the earthquake. In current tsunami warning systems, it usually take at least a few minutes to announce the tsunami warning, because seismic faults are estimated after colleting seismic data observed at several points. Hence, the current warning system seems to be almost helpless for near field tsunamis that will attack us within a few minutes. On this basis, we are trying to develop a new tsunami warning system whose finial target is to detect tsunamis from real-time data observed at a single point. In the first step of our development of quick and accurate tsunami warning system, we have focused our attention on the seabed displacement which will induce sea surface disturbance such as tsunamis and acoustic waves in the seawater. The sea surface disturbance associated with the acoustic waves is characterized by its large velocity and short-period components in comparison with tsunamis. Because of the large velocity, the short-period disturbance is observed before seismic tsunamis. The sea surface disturbance of the short-period components has rarely been discussed in detail. From our previous study on the dynamic displacement of seabed due to seismic faulting, it has been found that the sea surface disturbance is mainly excited by Rayleigh waves propagated along the seabed. Thus, if we can find good correlation between static uplift of the seabed and characteristics of the Rayleigh waves, we can make use of the Rayleigh waves for our tsunami-warning system. For this purpose, we have calculated the seabed displacement resulting from seismic faulting by using the boundary element method. The seabed displacement includes many items such as uplift volume, uplift width and maximum displacement in several cases with different fault parameters. As a result, it was found that the maximum displacement of the seabed is mainly governed by depth of the seismic focus and dip angle of the fault plane.

NUMERICAL SIMULATION OF LANDSLIDE TSUNAMI

Yasuyuki IWASE, Hiroshi IGARASHI, Hiroyuki FUJITA (Department of Earth and Ocean Sciences, National Defense Academy)

Submarine landslide is one of the origins of the tsunami and it maycause larger tsunami as is expected by seismic fault.We conduct numerical study of tsunami propagation generated bylandslide.In order to study the detail flow in the ocean, we develop athree-dimensional numerical simulation code for tsunami propagation.in which, the hydrostatic pressure is assumed, since the wave lengthof the tsunami is much larger than the ocean depth.Finite volume method is used and vertical length is normalized by thethickness of the fluid, i.e., distance between sea floor and seasurface, to treat vertical boundary condition easily.The landslide is modeled as the movement of a doom-like shaped mass onthe sea floor, whose height is not changed during sliding.We investigate the relationship between wave height of tsunami andvelocity of the landmass on a flat sea floor.If the speed of the landmass is slower than the tsunami wave, severalsmall waves appear and if the speed is larger, a few waves that havethe height equivalent to that of the landmass are observed.However, when the landmass speed is nearly the tsunami wavepropagation speed, a few large waves are generated, especially in frontof moving land mass.These results suggest that if the landslide with the velocity about$(gh)^{(1/2)}$ (*h* is ocean depth) occur, largetsunami can be generated independently by the magnitude of theearthquake and the size of the landslide mass. The landslide generated tsunami is simulated at Tokai area, Japan,where the earth and sand transported by large rivers is accumulatedand the potential occurrence of landslide is suggested.We assume that the earth and sand of 10 km diameter and 10 m height onthe sea bottom near Omaezaki, where the depth of sea floor is about1000 m, is slumped toward south-east direction for 28 km where theocean depth is about 2500 m.Velocity of the landslide is 120 m/s, which is equivalent to thetsunami wave velocity in the 1500 m depth ocean.A pair of large positive and negative waves (about 10 m height) haveprogressed to both south-east and north-west directions from aroundthe landslide area, while the waves in north-east and south-westdirections are very small.In this case, the tsunami propagation is also affected by thetopography of ocean bed.Diffraction of tsunami for peninsula is observed.As a result, tsunami wave higher than 1 meter hits on the south-eastarea of the Izu Peninsula and west side of the Omaezaki Cape.

THE USING OF INFORMATION ABOUT SEA LEVEL IN TSUNAMI WARNING CENTER

Tatyana N. IVELSKAYA[1], TATYANA N. IVELSKAYA[1], Peter V. DUSHENKO[1], George V. SHEVSHENKO[2], Peter D. KOVALEV[2] ([1]Sakhalin Tsunami Warning Center, [2]Marine Geology and Geophysics Institute)

For increasing of efficiency acting of Tsunami Warning System for Sakhalin area there was developed an equipment and software, which allows to solve operative and scientific problems.Though for the Sakhalin island the tsunami do not present so awesome danger, as on Pacific seaside of Kuril island, however, port of Korsakov occured flooding repeatedly, particularly powerfully under tsunami of Kamchatka, 1952 and Chilean, 1960. And 6 events of tsunami were registered on tide gauge in a port of Kholmsk (Kamchatka 1952, Chile 1960, Urup 1963, Niigata 1964, Moneron, 1971, Akita 1983).The Specialists of Tsunami Center in Yuzhno-Sakhalinsk and laboratory of tsunami of Institute of marine geology was executed installing of the equipment. This complex consists of bottom sensor and coastal center. The duty-engineer in the Tsunami Center has a possibility be connected to coastal center and get information on sea level for necessary period. The complex allows to produce counting out since period before 1 seconds. Due to this possible solve not only operative, but also different scientific problems.There were analysed records of all long wave processes, registered in port Korsakov. The tidal fluctuations dominated in records. The level of the natural long wave noise increases in highfrequency part of spectrum at passing deep cyclone that is associated with phenomena of harbor oscillation. Increasing the amplitudes of the long waves is fixed for period about 8 mines and within the range of 10-30 mines. The comparison spectrum of records with spectrum Chilean tsunami has shown the coincidence a peaks in lowfrequency of a part of spectrum. In particular, there is powerful peak in all spectrum for period around 4.8 hour, connected with resonance fluctuations between island Sakhalin and Hokkaido.The Comparative spectral analysis of the got record in Kholmsk during passing of the cyclone and in usual weather has revealled growth the energy of the fluctuations within the range of period from 2 before 25 mines that usually at tsunami, as well as presence two maximum for period beside 8 and 3 mines. There were digitized records of all tsunami, registered in port of Kholmsk. If the sources of tsunami were found in Japanese sea, caused significant increasing the energy within the range of period 5 - 25 mines, but waves, coming from the Pacific ocean, were shown in more lowfrequency part of the spectrum.The executed analysis has allowed to define the structure of frequency of the dangerous sea phenomenas, which can exist in Korsakov and Kholmsk and take into account, connected with them reinforcement of negative consequence of tsunami, which arose in this moment.

MOMENTUM AS A USEFUL QUANTITY IN TSUNAMI SCIENCE

Harold G. LOOMIS (retired)

At the time of the generation of a tsunami, horizontal forces might apply a significant impulse to the body of water producing a horizontal momentum. This would be so in the cases of pyroclastic flows into the ocean, landslides into or within the ocean, and, in some cases, horizontal motions of earthquakes. Whatever the confused water motions at the time of generation, when viscous friction has dissipated the rotational component of the motions, the resultant irrotational, long-waves will still contain all of the original momentum delivered to the water by the initial impulses, diminished only slightly by bottom friction. This momentum can be reflected and refracted by shorelines and by varying water depths as waves are. One reason why momentum might be a valuable quantity to consider is that the momentum delivered by a horizontal impulse is very directional as compared to the momentum that results from the waves spreading out from a generalized surface displacement. Therefore, tsunamis generated with a significant horizontal impulse could be more directional than tsunamis resulting only from vertical surface displacements.

TSUNAMI RUN-UP SIMULATION TAKING INTO ACOUNT DYNAMIC SEABED DISPLACEMENT DUE TO SEISMIC FAULTING

Atsushi MURAKAMI, Tatsuo OHMACHI, Shusaku INOUE (Department of Built Environment Interdisciplinary Graduate School of Science and Engineering,Tokyo Institute of Technology)

Recently authors have developed a numerical technique for tsunami simulation taking into account dynamic seabed displacement resulting from fracturing of a seismic fault, which is referred to as a tsunami dynamic simulation technique. The development of the method aims to simulate processes of tsunamis as precisely as possible by using the state of the art of numerical technology and knowledge on seismic faulting. Among the processes from generation to run-up of tsunamis, the tsunami dynamic simulation method has demonstrated to reproduce the processes of generation and propagation. Thus, the objective of the present study is to extend the ability of the method in order to make it possible to simulate the tsunami run-up process. In conventional tsunami-simulation techniques, simplifications have been employed by neglecting the dynamic seabed displacement and considering only the static contribution. The water layer is also assumed to be incompressible, regardless of its acoustic effects. In the dynamic simulation technique, however, the tsunami simulation is conducted without using these kinds of simplification and takes into account effects of both dynamic seabed displacement and acoustic waves of the seawater. In this technique, weak-coupling is assumed between the seabed and the seawater, from which the motion of the seawater is influenced by that of the seabed, but the motion of the seabed is not influenced by that of the seawater. Based on this assumption, the present technique consists of a two-step simulation. The first step is to simulate the dynamic seabed displacement resulting from a seismic faulting using the boundary element method (BEM), and the second is the generation of the seawater disturbance followed by its propagation and run-up. The seawater disturbance which includes tsunamis, is simulated by soling the Navier-Stokes equation, using the finite difference method (FDM), and imposing the velocity of the dynamic seabed displacement as an input to fluid domain at the seabed. To simulate tsunami run-up onto a coastal area, in general, we had better make the grid size as small as possible because of three-dimensional complexity in geography in and around the area. For this reason, we have introduced the so-called VOF (Volume of Fluid) based method and nesting technique into the second step simulation. The VOF method can handle the complex free surface flow like tsunami run-up, and the nesting technique enables us to conduct the simulation of a large area from the ocean to the seashore with efficiency. The present study focuses on the introduction of the VOF method and the nesting technique into the dynamic analysis simulation, and verify the validity of the introduction. In the nesting, to minimize interpolation error, the Hermite interpolation has been applied because of its higher order accuracy. To check the algorithm, several models such as dam breakage and tsunami run-up have been simulated to demonstrate its validity. Nesting gives higher resolution in the coastal area and higher resolution and VOF enables run-up simulation. The extended dynamic simulation technique will especially help us to predict the behavior of near-field tsunamis with high accuracy.

EFFECTS OF DYNAMIC FAULT PARAMETERS ON TSUNAMI CHARACTERISTICS

Masahiro TOBATA, Shusaku INOUE, Tatsuo OHMACHI (Department of Built Environment , Interdisciplinary Graduate School of Science and Engineering, Tokyo Institute of Technology)

In the conventional tsunami analysis, dynamic seabed displacement resulting from seismic

fault rupturing has been neglected and only static contribution has been considered. The initial waveform of tsunami is decided as a static displacement of the seabed and using of long wave approximation simulates tsunami propagation. Moreover, when estimating the fault model that is the cause of generating of tsunami, the fault model estimated by tsunami data often differs from seismic fault model estimated by seismic data It is thought that the cause of these problems is derived from above approximation. In order to solve these problems, actual tsunami analysis is important and effective in terms of predicting tsunami in high accuracy. In recent years, it has an interest in ´tsunami earthquake´. Tsunami earthquake generates larger tsunamis than expected from its magnitude. Seismological studies showed that the duration time is longer than that of usual earthquake, but the mechanism of tsunami earthquake is not understood yet. In Japan, the 1896 Sanriku earthquake was classified into ´tsunami earthquake´ and the damage of 22000 victims occurred. As an example of other tsunami earthquakes, there are the 1946 Aleutian earthquake, the 1992 Nicaragua earthquake, etc. The mechanism of ´tsunami earthquake´ is not understood yet and the tsunami warning system of Japan is said to be powerless to ´tsunami earthquake´. Our actual simulation considering the dynamic displacement of seabed and Navier-Stokes equation seems to be effective to find out the mechanism of tsunami generation due to ´tsunami earthquake´ In concludion, findings from the present study follow. 1. A main feature of tsunami earthquakes lies in slowness of seismic fault rupturing, for which rise time and rupture velocity of the seismic faulting are governing factors. 2. Another important feature of the earthquakes is their large magnitude such as 8 or 9 in terms of the moment magnitude. From this feature, the tsunami wave height tends to grow higher than the usual ones.   3. From the above two features, we had better try to observe Rayleigh waves of longer period up to 50 sec in order to detect the tsunamis from the earthquakes.

THE 1946 EVENT: A TRANSOCEANIC TSUNAMI GENERATED BY AN UNDERWATER LANDSLIDE

Philip WATTS[1], Gerard J. FRYER[2], Stephan T. GRILLI[3], James T. KIRBY[4], Fumihiko IMAMURA[5] ([1]Applied Fluids Engineering, Inc., [2]University of Hawaii, [3]University of Rhode Island, [4]University of Delaware, [5]Tohoku University)

The 1946 Aleutian tsunami inflicted significant far-field damage and fatalities from a narrow beam of wave energy that passed just east of Hawaii, struck the Marquesas and Pitcairn head on, and spent itself against the Antarctic Peninsula. The aftershock zone was too narrow, by a factor of five, for the main rupture to have produced such a transoceanic beam. Large near-field runup on Unimak and Sanak Islands was too large to have been generated by coseismic slip and too restricted (and too early) to have come from an earthquake´s trench axis or lower slope deformation. In the far field, the emergent and dispersive nature of the wave train on tide gauge records -- consistent with a landslide source -- contrasted markedly with the minimum-delay character of earthquake-generated tsunamis. The source region of the tsunami, determined by back-projecting travel times, cannot exist without a delay on the order of ten minutes in tsunami generation. The source region, some considerable distance from the epicenter of the main shock, is the upper slope of the Aleutian Trench, a region mantled by thick glacial deposits interleaved with thin, weak, high-stand clays. A massive slope failure is apparent in the USGS GLORIA image of the source location, with a headwall at a depth of about 100 m on the continental shelf and a scar length of at least 60 km. The failure appears to have been triggered 30 km down from the headwall at the back of a 4-km-deep mid-slope terrace. The exposed failure surface appears to have blow-outs and other signs of over-pressuring or gas hydrate eruption. An analysis of landslide motion indicates speeds approaching 200 m/s, a speed entirely consistent with other submarine landslides if the square-root-of-slide-length scaling is applied. We confirm the speed using the viscoelastic model BING, which predicts that all but the trailing tail of the landslide approached the long wave celerity. With landslide speed and tsunami speed nearly equal (but only in the direction of slide motion), slide energy is efficiently fed into the tsunami, and the far-field observations of a narrow beam and large waves are explained. We reproduce all near-field observations by coupling a 3D Boundary Element Method model of tsunami generation to the Boussinesq tsunami propagation and inundation code Geowave. For far-field simulation, we couple our tsunami source to the spherical coordinate model TUNAMI-F2 and propagate the tsunami across the Pacific Basin. We obtain a narrow beam of wave energy that matches the far-field observations. The tsunami of 1946 shows that even continental slope failures off remote shorelines can generate transoceanic tsunamis.

CHAMP GLOBAL GRAVITY FIELD RECOVERY - STATUS IN SATELLITE - ONLY AND COMBINED MEAN FIELD SOLUTION

Christoph REIGBER[1], Peter SCHWINTZER[1], Richard STUBENVOLL[1], Rolf KOENIG[1], Karl-Hans NEUMAYER[1], Franz BARTHELMES[1], Georges BALMINO[2], Richard BIANCALE[2], Jean-Michel LEMOINE[2], Sylvain LOYER[2], Felix PEROSANZ[2] ([1]GeoForschungsZentrum Potsdam, Department 1, [2]Centre National d'Etudes Spatiales, GRGS - 18, Av. Edouard Belin, 31401 Toulouse Cedex 4, France)

After being three years in orbit and delivering continuously GPS high-low satellite-to-satellite tracking and accelerometer data, the CHAMP mission has succeeded in opening a new era in global gravity field modelling. The first gravity field models, EIGEN-1S and EIGEN-2, derived from several months of CHAMP data, have already demonstrated that an accuracy improvement by almost a factor 10 could be achieved in long-wavelength gravity field recovery. In the meantime new CHAMP model versions of the mean geoid and gravity field were generated based upon a longer CHAMP data series. The CHAMP-only field was combined with other laser satellite tracking data, and normal equation systems from surface gravity and altimetry to get a higher spatial resolution. The achievements and problems of the various gravity field solution are discussed.

GRAVITY FIELD RECOVERY FROM GRACE DATA AT GFZ POTSDAM

Christoph REIGBER, Roland SCHMIDT, Frank FLECHTNER, Rolf KOENIG, Ulrich MEYER, Karl-Hans NEUMAYER, Peter SCHWINTZER, Sheng Yuan ZHU (GeoForschungsZentrum Potsdam, Department 1)

The US-German twin-satellite mission GRACE (Gravity Recovery And Climate Experiment), in orbit since March 2002, has delivered highly valuable data during the commissioning phase for assessing its gravity recovery capabilities. In addition to GPS high/low satellite-to-satellite tracking (SST), accelerometry and space-craft attitude from star sensors measured on both satellites, the GRACE mission features a micrometer precise low/low SST link between the GRACE satellites. Based on multi-months of high quality data sets estimates of the static gravity field of the Earth and its temporal variability are derived. The capability of the low/low SST data for precise gravity recovery is revealed in the determination of the static gravity field with unprecedented accuracy which is validated through comparisons to external satellite data (CHAMP) and terrestrial gravity-related quantities. Recovery of temporal variations of the Earth´s gravity field from GRACE data is in reach but still needs intensive examination. This contribution presents results and experiences from GRACE data analysis of the GFZ GRACE team.

GRAVITY FIELD TEMPORAL VARIATIONS FROM TWO YEARS OF CHAMP MISSION

Richard BIANCALE, Jean-Michel LEMOINE, Felix PEROSANZ, Sylvain LOYER (CNES / GRGS)

The new satellite missions like CHAMP and GRACE bring considerable improvements in modelling the Earth gravity field, its static part and its temporal variable part. The global approach using GPS tracking data is very CPU time consuming when computing the partials of the spherical harmonic expansion coefficients. This is why an alternative faster method in two steps has been tested and evaluated from CHAMP satellite dynamic orbit computation. The first step consists in computing reduced dynamic orbits of CHAMP using GPS SST data. These orbits are then used in a second step as pseudo-observations in order to compute gravity field model coefficients. About two years of data have been processed in both methods and results intercompared in terms of geoid, long wavelength temporal variations and calibration parameters of the accelerometer as well,

ABSOLUTE GRAVIMETRY IN THE FENNOSCANDIAN LAND UPLIFT AREA: MONITORING OF TEMPORAL GRAVITY CHANGES FOR GRACE

Juergen MUELLER, Ludger TIMMEN, Heiner DENKER (Institute of Geodesy, University of Hannover)

During the mission duration of GRACE (about five years), a temporal geoid change of about 3.0 mm can be expected in the centre of the Fennoscandian land uplift area, corresponding to a gravity change of about 10 µGal. This gravity change over five years (linear trend) can be observed with an accuracy of ± 1 µGal by absolute gravimetry. As the geoid derived from GRACE data can be determined with an accuracy of ± 0.1 mm (at spherical harmonic degrees between 2 and 50), the land uplift causes a measurable signal in the observations. Therefore absolute gravimetry can be used very well to validate GRACE results, i.e. it can provide ground truth for the satellite measurements. But it contributes also to the separation of the various time-variable parts in the GRACE data. It is planned to perform absolute gravity measurements yearly to improve the knowledge about the Fennoscandian uplift with respect to accuracy and reliability, where also the tide gauges have to be connected and monitored, and the combination with GPS data is striven for. The main result of the project will be an improved model of the land uplift (gravity and geoid changes), which can be used for the validation of the GRACE measurements. In a next step, the gravity variations and the models of temporal phenomena obtained from GRACE data analysis can further be processed and may serve as additional input for the determination of a better spatial model of the total land uplift process (synergy effect).

GRAVITY FIELD RECOVERY AND VALIDATION BY ANALYSIS OF SHORT ARCS OF A SATELLITE-TO-SATELLITE TRACKING EXPERIMENT AS CHAMP AND GRACE

Karl Heinz ILK, Martin FEUCHTINGER, Torsten MAYER-GUERR (Institute of Theoretical Geodesy, University of Bonn)

A procedure for regional gravity field determination is presented based on the analysis of short arcs of a low flying satellite as CHAMP and GRACE. The use of short arcs might have some advantages over longer ones because they are less sensitive to disturbing forces and ref-erence system parameters. Furthermore the short arcs can be adapted to the undisturbed orbit segments between thruster events of the low satellite. The mathematical setup is based on a semi-analytic method by transferring the original intersatellite observations in a time series of short arcs. The time series coefficients can be expressed by integrals of the unknown gravity field, modeled by parameters tailored to the special task. In case of a regional refinement of the gravity field space-localizing gravity field parameters defined on a discrete grid can be se-lected, as e.g. spline base functions on a triangular grid, while for global applications a spheri-cal harmonics expansion might be the proper choice. Basically, this procedure can be applied to high-low intersatellite observations as well as to low-low SST-measurements. In case of the high-low mode it is preferable to process the orbits of the low satellite directly instead of the high-low intersatellite links. The reason is that the orbits, derived from a precise kinematic orbit determination procedure based on GPS observables might be more precise then the high-low intersatellite links, provided the a-posteriori correlations of the orbit positions have been taken into account in a proper way. The method is tailored especially to regional gravity field refinements in those cases where residual gravity field effects are recognizable in the short arcs. To detect these effects, a preprocessing step based on the energy balances along the short arcs is applied. To minimize instabilities caused by the high frequent parts in the residuals a tailored regularization can be applied to stabilize the downward continuation process. Fur-thermore, residual oscillations in the solution caused by the intrinsic improperly posedness of the problem can be removed by a posteriori filtering procedure of the space localizing gravity field parameters. A critical aspect is a proper balance between the regularization parameter and the filtering method. A validation step, again based on an energy balance check along the short arcs, concludes the analysis procedure. First results are presented by using kinematic or-bits of CHAMP derived from real observations over selected regions with rough gravity field features. A mission as CHAMP is certainly not a proper candidate for a regional gravity field recovery. Therefore, to demonstrate the applicability to a tailored low-low experiment the procedure is applied to a GRACE simulation scenario.

APPLICATION OF SPACE GRAVITY SPECTROSCOPY TO CHAMP, GRACE AND GOCE

Erik W. GRAFAREND, Gerrit AUSTEN, Petar MARINKOVIC, Tilo REUBELT (Department of Geodetic Science, Stuttgart University)

This contribution introduces the latest achievements of the research done at the Department of Geodetic Science, Stuttgart University, on three major LEO satellite global gravity field recovery missions, namely CHAMP, GRACE, GOCE. Solution strategies by means of the spectral analysis of the Earth´s gravitational field are outlined. Specifically, in the case of CHAMP space gravity spectroscopy is performed by means of the analysis of kinematic satellite orbits while in the case of GRACE and GOCE spectroscopy is based on models comprised of satellite orbits and mission specific measurements, e.g. ranges, range-rates and range-accelerations (GRACE) or gravity-gradients (GOCE). For purposes of data validation and error analysis of LEO satellites directly measured values a stochastic model for the homogeneous and isotropic analysis is studied. An isotropic analysis is represented by the homogeneous distribution of measured values and statistical properties of the model are calculated. In particular, correlation structure functions are defined by n-th order tensors (Taylor-Karman tensors) for the ensemble average of a set of incremental differences in measured components. All aspects of the operationability and applicability of the Space GravitySpectroscopy approach are documented by numerical studies.

CALIBRATION/VALIDATION OF GOCE DATA BY TERRESTRIAL TORSION BALANCE OBSERVATIONS

Gyula TOTH[1], J. ÁDÁM[1], L. FÖLDVÁRY[4], I.N. TZIAVOS[2], H. DENKER[3] ([1]Department of Geodesy and Surveying, Budapest University of Technologyand Economics, P.O.B. 61, H-1521 Budapest, Hungary, [2]Department of Geodesy and Surveying, Aristotle University ofThessaloniki, Univ. Box 440, 54124 Thessaloniki, Greece, [3]Institute fuer Erdmessung, Universitaet Hannover, Schneiderberg 50,D-30167 Hannover, Germany, [4]Institute for Astronomy and Physical Geodesy, Technical University ofMunich, D-80290 Germany)

One promising method for the external validation andcalibration of the upcoming GOCE satellite missiondata is the use of ground gravity field data continuedupward to satellite altitude. There is a uniquesituation for Hungary in this respect since surfacegravity gradients are available at 20143 points overan approximately 350 by 350 km[2] area, measured bythe classical Eötvös torsion balance. The conceptof this contribution is to use these point gravitygradient observations for upward continuation to theGOCE satellite orbit in combination with differentgeopotential models and other gravity field information. The computations are based on the least squares collocationmethod and the direct numerical integration of thetorsion balance data. For the latter method, the spectralcombination technique and the classical integration kernelsare considered. Furthermore, various other data sources,such as the T_{zz} gravity gradients based on the gravity andterrain data collected within the frame of the EuropeanGeoid Project, are utilized for comparisons. Besides the comparisons between the different satellitegravity gradient computations, the results are alsoevaluated using simulated GOCE gravity gradient data overHungary. Moreover, an error analysis of the results andthe effect of using different geopotential models ispresented.

KINEMATIC PRECISE ORBIT DETERMINATION FOR GRAVITY FIELD DETERMINATION

Drazen SVEHLA, Markus ROTHACHER (FESG, TU Munich)

The main outcome of the kinematic and reduced-dynamic precise orbit determination (POD) we performed for CHAMP over a period of one year showed that kinematic orbits for the LEO satellite can be determined with an accuracy of 1-3 cm, and that, therefore, kinematic LEO positions can be used as pseudo-observations for gravity field determination. Using these kinematic orbits several gravity field models were already computed and temporal variations of the gravity field are presently studied. Among all space geodetic techniques (SLR, DORIS, VLBI, etc.) only GPS allows purely kinematic precise orbit determination where kinematic satellite positions are estimated independently of orbit altitude and force

modeling like, e.g., gravity field, air-drag, solar radiation, etc. The use of kinematic positions together with variance-covariance information as an interface to gravity field determination avoids the simultaneous adjustment of gravity field coefficient together with a huge amount of global GPS parameters, like GPS satellite clocks, GPS orbits, zero- or double-difference ambiguities, station coordinates, troposphere parameters, Earth rotation parameters, etc. External validation with SLR and comparison with reduced-dynamic orbits show that, due to the nature of the phase observable connecting epochs, kinematic positions are very smooth from epoch to epoch. This is also visiblein the variance-covariance information between epochs. As a consequence high frequency gravity signals may be extracted from these positions. In this paper we describe kinematic orbit determination as a method that can be used for High-Low SST gravity field determination. Our focus is to show the advantages and disadvantages of kinematic orbits compared to classical reduced-dynamic orbits. When kinematic positions with higher sampling are provided, numerical differentiation is more accurate and high accurate kinematic velocities and accelerations can be obtained. On the other hand, increasing the sampling of kinematic positions requires that the global IGS network has to be processed with the same sampling rate, either to compute GPS satellite clocks or to form baselines with the LEO satellite. Over the last two years we developed several approaches in kinematic and reduced-dynamic orbit determination ranging from pure zero-difference to double-difference methods with ambiguity resolution. Accuracy assessment of kinematic LEO orbits will be given using SLR data and the influence of GPS orbit and satellite clock errors will be studied. The impact of ambiguity resolution on double-difference kinematic orbits will be analyzed from the point of view of efficiency and accuracy.

EFFICIENT STOCHASTIC ORBIT MODELING TECHNIQUES USING LEAST SQUARES ESTIMATORS

Adrian JAEGGI, Gerhard BEUTLER, Urs HUGENTOBLER (Astronomical Institute, University of Berne)

Present and future satellite missions for gravity field recovery and atmosphere sounding like CHAMP, GRACE and GOCE pose very high requirements on precise orbit determination for low earth orbiters (LEO's). The approach followed so far at the Astronomical Institute of the University of Berne (AIUB) was mainly kinematic point positioning using data of the GPS receivers on board of the LEO's. On the other hand there exist a wide range of different dynamic (or reduced dynamic) orbit modeling techniques making the attempt to completely parametrize a LEO orbit. We will focus on new orbit parametrization procedures, especially on (pseudo) stochastic modeling techniques which are well suited to deal with model deficiencies. We will analyze different stochastic orbit parametrization methods (e.g., the use of instantaneous velocity changes, piecewise constant accelerations, etc.) regarding their mutual benefits using simulated measurements as well as real GPS-data stemming from spaceborne receivers. In an operational environment it is extremely important to have not only precise but also efficient orbit determination procedures available. Kalman filtering is one way of achieving this goal. We will study the efficiency of alternatives based on least squares estimators and compare them to the performance of Kalman estimators.

SATELLITE GRAVITY FOR OFFSHORE OIL AND GAS EXPLORATION

Minghua ZHANG[1], Jiaqiang ZHANG[1], Gang CAI[1], Lin WU[2] ([1]Research Center, China Geological Survey, [2]China Geological Survey)

Satellite derived gravity data can be used to delineate offshore sediment basin structures today in integration interpretation. A test area in Yellow Sea, china has proved that satellite gravity data of 10Km wave-length resolution can be used to outline not only basin boundaries, but main structures within large basins. Comparisons between satellite gravity data and ship-boarded gravity data along 20 ship survey lines, totally some 1000Km, shows that almost all the anomalies identified by ship-board gravity data can be found the similar size and features in satellite gravity data. Total absolute average difference of point-to-point comparison is less than 3mgls. Root-main-square is 7.3mgls. The satellite gravity data is thus then adopted in interpretation as a main data source, especially for the region where ship can not goes. **Detail** studies of what satellite gravity can be reveal shows, that it can delineate all the secondary structures in Yellow Sea China. Main features clearly defined by satellite gravity are the south boundary of Yangzi platform in northeast direction from Shanghai, China to Kwangju, South Korea, the northwest directional fault belts of Huangnan Basin near the coast, boundary of Huangbei Basin and its inner structures in different directions, and boundary of North Yellow Sea basin and its inner doming areas. These features are coincided with seismic reflection data interpretation. **Although** there were many ship-boarded gravity surveys in the past in Yellow Sea, resolution of a whole map of it is still not satisfied for detail interpretation to the scale of 1:1,000,000 due those surveys were of different time, different instrument and of different resolution. Satellite gravity data is now then a good replacement to this scale, and some area may be used to scale of bigger than this. And economically say, satellite gravity is much more fast and cheaper to get a general look on marine basins and structures for oil and gas exploration. It is thus adaptable as one data source in marine geological survey at least at scale of 1:1,000,000. It is of high significance in geological survey, basin structure studies, and in the first stage of off shore oil and gas exploration.

ANTICIPATED ACCURACY OF LUNAR GRAVITY FIELD MODEL FROM RSAT/VRAD MISSION

Koji MATSUMOTO[1], Kosuke HEKI[1], Hideo HANADA[1], Seiitsu TSURUTA[1], Yusuke KONO[5], Nobuyuki KAWANO[1], Takahiro IWATA[2], Noriyuki NAMIKI[3], David D. ROWLANDS[4] ([1]Earth Rotation Division, National Astronomical Observatory, [2]National Space Development Agency of Japan, [3]Kyushu University, [4]NASA Goddard Space Flight Center, [5]Radio Astronomy Division, National Astronomical Observatory)

We will report the result of feasibility study for lunar gravity field recovery mission in SELENE to be launched in 2005. Many lunar gravity filed model have been developed so far, but they are based on 2-way Doppler measurement in the near-side only. We propose two new satellite tracking methods in SELENE to improve lunar gravity filed model; (1) 4-way Doppler measurement by relaying Doppler signal to/from the main orbiter by means of a relay satellite (RSAT mission), and (2) differential VLBI measurement between artificial radio source on board the relay satellite and a VLBI satellite (VRAD mission). The former enables direct measurement of lunar gravity field in the far-side, and the latter contributes to more complete understanding of structure of lunar gravity field by adding sensitivity normal to the line-of-site direction. It is almost impossible to carry out feasibility study by analytical method because the problem is so complicated involving multi tracking methods of multi target satellites by multi tracking stations. We numerically estimated anticipated accuracy of lunar gravity filed model from SELENE by using GEODYN II and SOLVE software. Limitations on tracking data acquisition become clear as the mission goes into the detailed design phase. They include operation condition of tracking stations, duration of sunshine on satellites,

satellite visibility, antenna beam pattern, and so on. The latest analysis counting in such limitation on data acquisition shows that accuracy of lunar gravity coefficients of degrees 2-30 will be improved by one order of magnitude compared to LP100J.

NEIGE: A GEODETIC NETWORK ON MARS, TO STUDY THE INTERNAL STRUCTURE OF THE PLANET, AND THE BALANCE OF VOLATILES

Jean-Pierre BARRIOT[1], Julien VIENNE[1], Veronique DEHANT[2], Marie YSEBOODT[2], Pascal ROSENBLATT[2], Julien DURON[2], William FOLKNER[3] ([1]UMR5562/CNES, [2]Obs. Royal de Belgique, [3]Jet Propulsion Lab.)

The Netlander Geodesy and Ionosphere Experiment is part of the Netlander mission to Mars, that will land on the red planet in 2009 or 2011. Four microstations of 20kg each will materialize a reference frame on the surface of the planet. The orientation of this frame with respect to inertial space will be monitored by Doppler tracking from the microstations to a Mars orbiter, and from the Mars orbiter to the Earth. The Doppler signal will be affected by the Mars nutations, lenght of day, and polar motion. The presence of a Mars liquid core will affect sightly the nutations, and the CO_2 mass exchanges along the martian year will affect the Lenght of day and polar motion. We show that we will be able to extract these geophysical signatures after an observation time of half a martian year.

RESULTS OF THE CRITICAL DESIGN OF RSAT/VRAD MISSION INSTRUMENTS ON SELENE SUB-SATELLITES RSTAR/VSTAR FOR SELENODESY

Takahiro IWATA[1], Takeshi SASAKI[1], Tatsushi IZUMI[1], Yusuke KONO[2], Hideo HANADA[2], Nobuyuki KAWANO[2], Fuyuhiko KIKUCHI[3] ([1]National Space Development Agency of Japan, [2]Natioinal Astronomical Observatory, [3]Tohoku University)

We will report results of the critical design for the selenodetic observation system conducted by two micro sub-satellites of SELENE; Relay Satellite (Rstar) and VLBI Radio Satellite (Vstar). Global mapping of the lunar gravity field will be conducted with higher accuracies using these sub-satellites. Four-way Doppler measurements toward SELENE Main Orbiter above the lunar far side will be conducted by the Relay Satellite Transponder (RSAT)" on Rstar. Differential VLBI observations will be conducted for three pairs of S-band and a pair of X-band carriers emitted from "the Differential VLBI Radio Sources (VRAD)" on Rstar and Vstar. These sub-satellites aim to detect so small lunar gravity turbulence that they have not any orbital and attitude control equipments except a nutation dumper for spin stabilization. We have designed a simple structured and light weighted release mechanism, and confirmed the release properties by ground and on-orbit tests. Attitude and spin motions of the satellites will be settled by the release properties. Mission analysis shows that these properties affect the selenodetic observation, which has been confirmed to be analytically estimated and calibrated in data processes.

G02/07A/C25-014   1245

APPLICATION OF PZT TELESCOPE TO INSITU LUNAR ORIENTATION MEASUREMENT (ILOM)

Hideo HANADA[1], Kousuke HEKI[1], Hiroshi ARAKI[1], Seiitsu TSURUTA[2], Seiichi TAZAWA[2], Kazuyoshi ASARI[2], Tsuneya TSUBOKAWA[2], Koji MATUMOTO[1], Nobuyuki KAWANO[1], Yusuke KONO[3], Taihei YANO[4] ([1]Earth Rotation Division, National Astronomical Observatory, [2]Mizusawa Astrogeodynamics Observatory, National Astronomical Observatory, [3]Radio Astronomy Division, National Astronomical Observatory, [4]The Institute of Physical and Chemical Research)

We are proposing a selenodetic mission, In situ Lunar Orientation Measurement (ILOM) to study lunar rotational dynamics by direct observations of the lunar physical libration and the free librations from the lunar surface with an accuracy of 1 milli-arc-second as the post-SELENE project. Year-long trajectories of the stars provide information on various components of the physical librations and we will also try to detect the lunar free librations in order to investigate the lunar mantle and the liquid core. The PZT on the moon is similar to that used for the international latitude observations of the Earth except for the half mirror above the objective, a CCD with high well capacity, and the heater beneath the mercury pool. Although a star position on the focal plane does not change even if the telescope inclines in principle, the tilt of the telescope affects the star position due to aberrations of the objective in actual case. We obtained the relation between the deviation of the star position in CCD and the tilt of the telescope by ray tracing method and found that tilt of less than 100 arc seconds did not affect the star position by larger than 1 mas. Thermal test of a tube made of CFRP showed that the tube did not inclined by more than 100 arc seconds even in condition of the lunar surface. Positioning accuracy of star images on a CCD surface is approaching to 1/500 of a pixel size in laboratory experiments using a CCD.

THE IMPACT OF GPS SATELLITE CONFIGURATION ON POSITIONING

Jenn-Taur LEE (Dept. of Information Management, Ching Yun Institute of Technology, Chung Li, Taoyuan 320 Taiwan)

GPS provides the capability of global, weather-independent as well as continuous navigation and positioning, so GPS technique has been extensively applied and rapidly developed for decades. However, just like any other surveying tasks, the precision of GPS positioning is limited by the systematic and random errors that is dependent on two major factors. One is precision of observation, which is determined by various error resources such as space satellite, signal propagation, and receivers. The other is the configuration of the observed satellites. Owing to the orbit inclination of GPS satellite constellation, the satellite geometry is significantly important for the outcomes of positioning and also is closely related to the observer's site (latitude), i.e., the configuration of the observed satellites are completely different at the equator, middle, and high latitude, respectively.The visibility of GPS satellite,

which is described with azimuth and zenith angle, is introduced in this paper. With the influences of various errors based on the similar condition, a set of the observed GPS raw data is used to simulate different satellite configuration. The aim is to understand the magnitude of the positioning precision caused by GPS satellite configuration. The baseline vector processing and network adjustment was done. In addition, the preliminary analysis and conclusion is indicated in the paper.

IMPROVED DETERMINATION OF GRAVITY FIELDS FROM GRACE RANGE RATES USING A REFINED ORBITAL PERTURBATION THEORY

Cheinway HWANG, Cheng-Gi WANG (Department of Civil Engineering, National Chiao Tung University)

An improved theory of linear orbital perturbation theory is developed for range rate type of observations. This theory maps the Keplerian perturbations onto perturbations in range rate between two low earth-orbiting satellites such GRACE. The mapping functions are derived and tested using simulated range rates. Compared to existing simplified theories, the new theory yields a better fit to the range rates from numerical integrations. In the practical application, range rates based on a priori geopotential model must be first determined. Residual range rates obtained by differencing the observed and the computed range rates are used to establish observation equations for least-squares estimation of corrections of geopotential coefficients with respect to the a priori coefficients. This paper will report the improvement of gravity determination using simulated range rates of the GRACE mission.

CENTRE-OF-MASS CORRECTION OF SPHERICAL GEODETIC SATELLITES FOR MILLIMETRE LASER RANGING

Toshimichi OTSUBO[1], Graham M. APPLEBY[2] ([1]Communications Research Laboratory, [2]NERC Space Geodesy Facility)

The temporal spread of optical pulse signals due to reflection from multiple onboard reflectors is now a critical problem in satellite laser ranging. The full-rate residual profile of single-photon laser ranging can be used to model the response function of geodetic satellites, resolving the uncertainty of far-field diffraction. We constructed the response function model for three types of laser ranging targets already in Earth orbit, the LAGEOS, AJISAI, and ETALON satellites. The centre-of-mass correction depends on the ranging system and observation policy at terrestrial stations, such as a single-photon system, a C-SPAD system, and a photomultiplier system. Our numerical simulation gives the centre-of-mass correction systematically variable about 1 cm for LAGEOS and 4-5 cm for AJISAI and ETALON. This study would help the satellite laser ranging technology to make full use of its potential accuracy in the determination of geodetic parameters, especially the orbits, the terrestrial reference frame and the gravitational scale *GM*.

PHOTOMETRIC OBSERVATION OF LAGEOS-2 FOR DETERMINING ITS SPIN BEHAVIOUR

Toshimichi OTSUBO[1], Robert A. SHERWOOD[2], Philip GIBBS[2], Roger WOOD[2] ([1]Communications Research Laboratory, [2]NERC Space Geodesy Facility)

The spin rate and spin axis orientation of the LAGEOS–2 satellite were determined by analysis of photometric observation data. A photometer system developed at the Space Geodesy Facility at Herstmonceux, East Sussex, UK, was used to time solar glints from the rotating satellite at 1 ms time resolution. It was found that the spin period of LAGEOS-2 got longer from 21 sec in March 2000 to 80 sec in December 2002; and that over this period the direction of the spin axis orientation had a complicated but smooth precession with respect to the Earth´s spin axis, the inclination varying from nearly zero to 50 degrees. Moreover, the precise photometric data revealed that the direction of the spin was the reverse of that of the Earth's rotation, and that the optical alignment of a reflector surface on LAGEOS-2 can deviate from its position vector by up to 15 arcminutes. Detailed knowledge of the evolution of the spin motion will help analysts construct precise acceleration models for use in precise orbit determination of the satellite. It should be noted that the opportunities for photometric observations are time-limited because, as the spin slows over the coming years, we will gradually observe fewer and fewer glints until (as for LAGEOS-1 today) glints become very rare events.

PHYSICAL GEODESY WITH GPS

Fei LI, Wu CHEN (Wuhan university)

In the first place, the problems as following are analysed: the effect caused by GPS on the theory and methods of the physical geodesy, the change in the function of some objects investigated in physical geodesy. Secondly, the discussions on the application of Neumann boundary value problem and the determination of height system are made. Then, a new geodetic boundary value problem is researched, which includes: the definition and an corresponding integral equation, an approach solution and its application in determining the quasi-geoid and deflections of vertical and external gravity field. Finally, the advantages and problems of GPS boundary value problem in physical geodesy are discussed.

A NEW PROJECT OF GRAVITY MISSION STUDIES IN JAPAN

Yoichi FUKUDA[1], Toshimichi OTSUBO[2], Taizoh YOSHINO[2], Shuhei OKUBO[3] ([1]Department of Geophysics, Kyoto University, [2]Kashima Space Research Center, Communications Research Laboratory, [3]Earthquake Research Institute, University of Tokyo)

We have started a new project of GPS occultation and satellite gravity mission studies in Japan. This project, which is funded by MEXT (Ministry of Education, Culture, Sports, Science and Technology) for a 3 years project (FY2002-2004), primarily aims at developing a calibration free satellite observation system for monitoring the Earth´s environmental changes related to global warming. For this purpose, we try to employ two different but closely related techniques of GPS occultation and Satellite Gravity Mission, and we organized two study groups accordingly. The first group led by Toshitaka Tsuda of Kyoto University, who is also the leader of the project, devotes the GPS occultation, and the second group led by Yoichi Fukuda devotes the gravity mission studies. In this paper, we briefly introduce the project plan of the gravity mission studies in particular. It is quite a new technique to monitor the Earth´s environment, for instance, global water cycling, by measuring very small gravity fluctuation using satellites. The idea is successfully coming

---

true by the GRACE mission. However, GRACE employs a microwave link for SST (satellite to satellite tracking) and its sensitivities and spatial resolution are still unsatisfactory for the monitoring of regional scale phenomena. Thus we aim future application of a SSI (Satellite to Satellite Interferometer) mission to improve the sensitivities and spatial and temporal resolutions consequently.In this project, as feasibility studies, we carry out some basic experiments/ developments; (1) development of new precise orbit determination software, (2) studies of laser interferometer techniques by a newly developed ground simulator, (3) development of a newly designed 3-axis accelerometer and its performance test on ground. We also carry out some simulations for the further application of these techniques, and aim to propose a basic design of a future gravity mission.

MODELLING OF GPS SATELLITE CLOCKS

Veronika BROEDERBAUER, Robert WEBER (Department of Advanced Geodesy, Technical University of Vienna)

Since November 2000 the IGS (International GPS Service) provides so-called Ultra-Rapid products comprising precise GPS satellite orbits and satellite clocks. This solution, issued twice daily, contains both an observed and a predicted part. The predicted part covers a period of 24 hours. While the orbits are output to an integration of the well-known force field the clocks have to be extrapolated by means of an experienced prediction model. We present clock-prediction models for all GPS satellites currently active. In a first step all observed and predicted Ultra-Rapid clock values of the IGS Ananlysis Centres are compared to the IGS Rapid solutions. IGS Rapid solutions are usually available at 17 UTC the next day and serve in our calculations as the reference. After a linear fit the clock- rms. is calculated both for the observed (about 0.1 – 0.4 ns) and the predicted part, which in fact is just a very coarse control of the quality of the clock values. The results are displayed in diagrams at the homepage of the Department of Advanced Geodesy at the TU Vienna (http://luna.tuwien.ac.at/). In a second step the available IGS Rapid solutions and the observed part of the IGS Ultra Rapids of the past 48 hours are used as input data to a least squares adjustment to determine the coefficients of a polynomial of second order. Depending on the clock behaviour (caesium or rubidium) we add cyclic terms to predict the satellite clock values over the upcoming 24 hours. Finally our predictions can be compared with the IGS Rapid solutions and to the solutions of the individual IGS Analysis Centres. The quality of our clock predictions is usually at the sub-nanosecond level over the upcoming 6 hours and at the 3 ns level over a 24 hours period.

ORBIT DETERMINATION OF THE NOZOMI SPACECRAFT USING DIFFERENTIAL VLBI TECHNIQUE

Ryuichi ICHIKAWA[1], Mamoru SEKIDO[1], Tetsuro KONDO[1], Yasuhiro KOYAMA[1], Hiroo OHSAKI[1], NOZOMI DVLBI group[2] ([1]Kashima Space Research Center, Communications Research Laboratory, [2]ISAS, NAO, NASDA, Gifu University, Hokkaido University, and Yamaguchi University)

We performed a preliminary differential VLBI (DVLBI) observation with National Astronomical Observatory (NAO) and the Institute of Space and Astronautical Science (ISAS) to determine precise orbit of the GEOTAIL spacecraft on June 4, 2002. The purpose of this observation is to establish the positioning technology for the interplanetary spacecraft using differential VLBI in realtime. Our main concern is to determine the PLANET-B (NOZOMI) orbit just before the second swing-by on next June [Yoshikawa et al., 2001]. It is significantly important to get the timing to maneuver the spacecraft before the swing-by. However, the usual range and range rate orbit determination will not be available because it will be difficult to point the high-gain antenna mounted the spacecraft toward the earth at that time. So we need a new technique to determine the precise orbit of the NOZOMI. We performed several DVLBI observations for the NOZOMI spacecraft since September 2002 using the ˝IP-VLBI system˝ which is under development at Communications Research Laboratory (CRL) [Kondo et al., 2002]. We are developing a orbit determination software package to analyze the DVLBI observables. The VLBI delay model for finite distance radio source is already implemented in the package [Sekido et al., 2003]. The package will include the DVLBI observation scheduling to take account of the passage of the spacecraft near the quasar line of sight and the propagation delay estimating for the ionosphere and the neutral atmosphere. We will present the the orbit determination accuracy of our package and an evaluation of the propagation delay models in the meeting.

AN EVALUATION OF POSITIONING ERROR ESTIMATED BY THE MESOSCALE NON-HYDROSTATIC MODEL

Ryuichi ICHIKAWA[1], Hiromu SEKO[2], Michael BEVIS[3] ([1]Kashima Space Research Center, Communications Research Laboratory, [2]Meteorological Research Institute, Japan Meteorological Agency, [3]Pacific GPS Facility, University of Hawaii)

We evaluate atmospheric parameters (equivalent zenith wet delay and linear horizontal delay gradients) derived from slant path delays obtained by ray-tracing through the non-hydrostatic numerical weather prediction model (NHM) with 1.5 km horizontal resolution. Our ultimate purpose is to establish a new method for reducing atmospheric effects on geodetic positioning. We first seek to establish the level of positioning error due to intense mesoscale phenomena such as the passing of cold fronts, heavy rainfall events, and severe storms. The NMH provides temperature, humidity and pressure values at the surface and at 38 height levels (which vary between several tens meters and about 35 km), for each node in a 1.5 km by 1.5 km grid that covers Izu peninsula of the central Japan and surrounding ocean. We performed ray tracing experiments for the entire grid of the NHM at one epoch of the 1200 UT 3/7/1997. For each station we invert the simulated data set, consisting of 52 slant delays, using an isotropic and an anistropic delay model. The isotropic model has only one parameter - the zenith wet delay (ZWD). The anisotropic delay model of Chen and Herring (1997) has two additional lateral gradient parameters. We compare the ´true´ ZWD, computed by directly integrating the wet refractivity field of NHM, with the ZWD estimated by least squares inversion of the ´observed´ slant delays obtained by ray tracing. We did this using the isotropic and the anistropic delay models [e.g. MacMillan, 1995; Chen and Herring, 1997]. A characteristic GMS cloud pattern caused by the mountain lee waves is presented in the study area. At the east of the Izu peninsula ZWDs are lying in a north-south band about 10 km in width and about 50 km in length. This ZWD pattern is consistent with that of cloud image. Large gradient vectors are shown nearby the north-south ZWD band. In addition the biggest gradients occur at the northern part of the peninsula where topographic variations produce a much more complex distribution of water vapor. We are numerically examining positioning errors calculated from the slant delays through the NHM, assuming single point positioning and relative positioning. The behavior of the positioning errors under the atmospheric disturbance in local scale, the relation between the slant delay errors and the vertical positioning errors, and the efficiency of the reduction of the azimuthal anisotropy of the atmosphere using the anisotropic mapping function will be represented.

GROUND SIMULATOR DEVELOPMENT FOR INTER-SATELLITE LASER INTERFEROMETER

Taizoh YOSHINO[1], Hiroo KUNIMORI[2], Mizuhiko HOSOKAWA[2], Seiji KAWAMURA[3], Shigeo NAGANO[3], Isao NAITO[3], Takashi SATO[4], Masashi OHKAWA[4] ([1]Kashima Space Research Center, Communications Research Laboratory, [2]Communications Research Laboratory, [3]National Astronomical Observatory, [4]Niigata University)

Japan is one of the most active area in geophysical aspects. Hence, we have interests in the time varying gravity field observation from the space. As a feasibility study of future gravity field mapping from the space, laser interferometric technique is studied by developing the Ground Simulator to improve the sensitivity of the current inter-satellite system, GRACE, which is based on radio technique. The design of the Ground Simulator system is Mach-Zender optical interferometer type. It is composed of stabilized laser, gravity field simulator and its retrieval system. The simulator will be developed in three years. As a first step, we are going to develop a stabilized laser. Firstly, semiconductor laser (780nm) locked to Rb absorption line is developed. Expected stability is 10**-13. A prototype system and its performance including the stability data will be shown. Next year, we will improve its performance and assemble the rest of the system. Using the existing satellite laser system, GRACE satellites are observed. The observation results will be also reported. We exchange the technical information with the related technology group in Japan: a) Gravity wave detection system(TAMA300), b) NeLS (Inter-satellite optical link for communication) under R&D, c) OICETS (Optical Inter-orbit Communications Engineering Test Satellite) to be launched in 2005. Our study is supported by the fund of Ministry of Education, Culture, Sports, Science and Technology.

RELATIVISTIC VLBI DELAY MODEL FOR FINITE DISTANCE RADIO SOURCE

Mamoru SEKIDO, Toshio FUKUSHIMA (Communications Research Laboratory)

Precise VLBI delay model including general relativity is required foranalyzing VLBI data of finite distance radio source in the Solarsystem. One of the example of VLBI target is spacecraft ``NOZOMI´´,which was launched for investigation of Mars by the Institute ofSpace and Astronautical Science (ISAS). However, such VLBI delay model has not been reported so far. We derived a VLBI delay model for finite distance radio source based on linearized Parameterized Post Newtonian (PPN) metric. The derivation procedure is as follows: Making a form of relation between VLBI delay and baseline vector in the barycentric frame of the solar system, where the motion of photon is expressed simpler than geocentric frame. Introducing a transformation of time scale and spatial coordinates between barycentric frame and geocentric frame with based on PPN metric. Here we used local Minkowskian laboratory coordinates approximation by following the procedure of Hellings (1986). Deriving a form of relation between VLBI delay measured by a clock on the geoid and baseline vector measured by scale on the geoid by using the relations introduced in (1) and (2). The accuracy of the model is in a order of picoseconds. This model was implemented in a VLBI delay model computation software realized by modification of CALC, which is widely used VLBI delay model calculation software developed by NASA/GSFC. The spacecraft ``NOZOMI´´ is going to swing-by with the Earth in June 2003, then it will depart for the Mars. It is required to measure the position of ``NOZOMI´´by VLBI in the period between February and May of 2003 for accurate swing-by in June. Our VLBI delay model is used for VLBI data analysis for ``NOZOMI´´.

STUDYING ERUPTION COLUMN OF THE AUGUST 18, 2000 MIYAKEJIMA ERUPTION, JAPAN, BY CONTINUOUS GPS MEASUREMENT

Dudy DARMAWAN[1], Bambang SETYADJI[2], Fumiaki KIMATA[3], Kazuro HIRAHARA[3] ([1]Graduate School of Environtmental Studies, Nagoya University, [2]Departement of Geodetic Engineering, Institute of Technology Bandung, [3]Graduate School of Science, Nagoya University)

Miyakejima Volcano is an active basaltic andesite stratovolcano located about 200 km south of Tokyo, Japan. The recent intense activity of the volcano occurred during the period from June 26 to September 4, 2000, which was noticed by several earthquakes and summit eruptions. The largest eruption occurred on August 18, 2000, lofting up the volcanic materials more than 8 km. In this research, we attempt to study such eruption by using GPS technique. Since the eruption was not certainly associated with a large volcanic earthquake, we therefore are interested in analyzing the ejected volcanic materials distribution during the eruption. At first, we inspect the effect of the volcanic materials to GPS signal travel and eventually to the estimated GPS baseline. As will be shown, the signal travel is delayed by the volcanic materials and the baseline is extended to some centimeters. Second, we estimate the GPS excess path delay by modeling it using an integration expression derived from ray theory. The estimated excess path delay is generally about 10 cm, except for the site located in the western part of the volcano (more than 10 cm). Lastly, we estimate the distribution of the volcanic materials during the eruption by using GPS tomography technique. The result shows that the eruption was firstly detected around 17.20 JST and declined around 18.00 JST by GPS measurements. Wet delay corrections for GPS stations located near western part of the volcano are higher than other sites. The estimated tropospheric refractive index derived from the tomography technique show clearly that the high refractive value appear near western and south-western part of the island. We therefore expect that the eruption column were to be heaviest near such area. These results are consistent with information released by Japan Metrological Agency (JMA).

GROUND-BASE VERIFICATION OF FOUR-WAY DOPPLER MEASUREMENT FOR THE SELENE MISSION

Hirotomo NODA[1], Kazuyoshi ASARI[1], Yusuke KONO[1], Takahiro IWATA[2], Noriyuki NAMIKI[3], Hideo HANADA[1], Nobuyuki KAWANO[1], Zen'ichi YAMAMOTO[4] ([1]Division of Earth Rotation, National Astronomical Observatory, [2]National Space Development Agency, [3]Kyushu University, [4]The Institute of Space and Astronautical Science)

In Japan´s lunar mission called SELENE, detailed measurements of the lunar gravity field will be carried out by using two methods. The first is the differential VLBI measurement with two sub-satellites, and the second is the four-way Doppler measurement by using a sub-satellite which relays radio waves from the main lunar orbiter. Especially the lunar far-side gravity field will be directly measured for the first time by using the relay satellite, which will give us new information about the inner structure of the Moon. The instruments are now under development, and various tests of Usuda Deep Space Center (UDSC) and of instruments onboard SELENE have been conducted in order to confirm the expected function of the four-way Doppler measurement. Through these tests, it has been confirmed that our four-way measurement system has potential to determine the position and line-of-

sight velocity of the sub-satellite within the error of 1m and 0.2mm/s~0.3mm/s respectively. The test of the proto-flight-model(PFM) is also scheduled at UDSC in Feb. 2003. In our paper, the results of these ground-base tests will be reported.

QUASI REAL-TIME POSITIONING OF SPACECRAFTS USING THE INTERNET VLBI SYSTEM

Tetsuro KONDO, Yasuhiro KOYAMA, Ryuichi ICHIKAWA, Mamoru SEKIDO, Hiro OSAKI (Kashima Space Research Center, Communications Research Laboratory)

Communications Research Laboratory is developing new real-time VLBI system using Internet protocol (IP) technology to reduce network-cost and to expand connection sites of VLBI network. We call this system IP-VLBI or Internet VLBI. We are developing the system consisting of a personal computer (PC)-based sampler equipped with a PCI-bus Versatile Scientific Sampling Processor (VSSP) board and FreeBSD (and/or Linux) software to carry out an automated observation, real-time data transmission, reception and correlation. The IP-VLBI system developed at CRL is dedicated to taking over current geodetic VLBI system which usually receives 14 to 16 frequency channels at S and X bands. A VSSP board can sample 4 channel data simultaneously, hence 4 sets of boards (i.e., 4 PCs) can cover the current geodetic VLBI system and the system assembled this way is called K5. In parallel with the development of the real-time system, we are also developing a quasi-real time (QRT) VLBI system. In the QRT system data are stored in a hard disk at first, then transmitted to a correlation site with the available transmission speed of network. Off-line operation is also possible. In this case, data are transmitted after observations are made using an FTP or equivalent file transmission protocol. We started the development of technique to determine spacecraft´s position in quasi real-time using the IP-VLBI system in collaboration with the Institute of Space and Astronautical Science (ISAS). A number of VLBI observations receiving Japanese spacecraft GEOTAIL and NOZOMI have been carried out since June 2002 to establish an observation method and to evaluate the measurement accuracy, and found that it is possible to measure group delay without ambiguities for telemetry signals. Phase delay measurements are also tried to increase the measurement accuracy and results will be reported in the meeting.

THE QUALITY OF GNSS ORBITAL SOLUTIONS DETERMINED FROM SATELLITE LASER RANGING

Graham Michael APPLEBY[1], Toshimichi OTSUBO[2] ([1]NERC Space Geodesy Facility, [2]Communications Research Laboratory)

In this investigation we consider the use of precise laser range observations toperform independent checks on the accuracy of published orbits of a subset of the GPS and GLONASS navigational satellites. Laser range measurements to two GPS satellites and several of the GLONASS satellites obtained by the tracking network of the International Laser Ranging Service are compared in two ways with precise orbits computed by the International GPS and GLONASS Services; by direct comparison of SLR measurements to ranges computed from the microwave orbits, and by comparison of SLR-based orbits to the microwave orbits. Our previous work, which is also outlined here, has shown that in such comparisons it is vital to understand both the potential for systematic range ambiguity induced by the laser reflector arrays and the need for accurate on-satellite positions of the array phase centres. For the GLONASS and GPS satellites these parameters are now accurately known for the several different types of array currently in orbit, and the SLR results provide an accurate assessment of the radial quality of the IGS orbits.

PRESENT-DAY DIFORMATION IN THE ZAGROS MOUNTAINS INFERRED FROM GPS MEASUREMENTS

Faramarz NILFOROUSHAN[1], Khaled HESSAMI[2], Christopher J. TALBOT[3] ([1]Geodynamics Department, [2]International Institute of earthquake Engineering and Seismology, [3]Hans Ramberg Tectonic Laboratory, Department of Earth Sciences, Uppsala University)

Continental convergence between Arabia and Eurasia is taken up by distributeddeformation in Iran. The relative motion between these plates and hence the overall deformation across Iran is known from global plate models such as NUVEL-1(DeMets et al., 1990). The Arabia-Eurasia rotation pole at 24.6o N, 13.7 o E,Predicts a N-S convergence of about 32 mm/yr at the longitude of central Iran.For the study of recent crustal movements, geological methods need to becomplemented by geodetic methods. GPS has clear potential and advantage as compared to any other techniques (e.g. classical methods) so that it has been widely used to measure recent local/regional crustal deformation with higher accuracy. It was utilized to reflect the velocity field (i.e., orientation andrate of movements) and the strain field associated with convergence movementsbetween Arabian and Eurasian plates (Nilforoushan F. et al 2002). The main convergence is occurred in Zagros and Makran in South-West and Alborz and Kopet-Dag in the North.We present results of Global Positioning System (GPS) measurements at 36 stations across and within the Zagros Mountains, SW Iran, for 3 epochs February 1998, December 1999 and June 2001. Preliminary motion estimates show thatdeformation is distributed differently on either side of the Kazerun Fault Zone.To the east shortening is up to 10 mm/yr to SW relative to the Stable Eurasia.However, to the west stations move slower (up to 6 mm/yr) due to west. These rates are much slower than the relative convergence rates between Arabia and Eurasia of about 31 mm/yr, predicted by NUVEL-1A and 6 to 8 times than the rate calculated from summing of seismic moments. The apparent discrepancy between the rates of shortening of sedimentary cover within the Zagros and plate convergence rates suggests that the vast majority of the motion of Arabiais transferred northeastward across the Main Zagros Thrust.

A SIMULATION STUDY OF GRAVITY FIELD RECOVERY BY MULTIPLE GRAVITY SATELLITES

Keiko YAMAMOTO, Yoichi FUKUDA (Department of Geophysics, Graduate School of Science, Kyoto University)

The dedicated gravity satellite GRACE, which has been successfully launched in 2002, will provide spherical harmonic coefficients of the earth gravity field for every one month. Those extreme high precision gravity field data are expected to determine the temporal variations of the gravity fields due to time varying geophysical phenomena such as global water cycling.Although there is no doubt that even only one GRACE satellite should greatly contribute to those studies, one interesting question is how the spatial and/or temporal resolution of gravity field recovery will be improved if more than one gravity satellites will be operated simultaneously.As a matter of fact, both CHAMP and GRACE are under operating, and this means the situation of multiple satellites is real even at the present day. In future,

there may be a chance that more than one GRACE /GRACE-FO type missions could be realized simultaneously. In this study, we thus carry out simulation studies of gravity filed recovery by assuming multiple-satellite observation of GRACE and/or GRACE-FO. The simulation procedure is as follows; 1) synthesize time varying gravity fields using surface pressure data of ECMWF reanalysis data sets, 2) calculate multiple satellite positions and observe the synthesized gravity filed data, 3) calculate spherical harmonic coefficients using the observed data and compare with the true synthesized gravity fields. We tested several combinations of multiple satellites, for instance, same orbit heights with same sensitivities, different orbit heights with different sensitivities, and so on, and we finally discussed effective combination of the satellites for the gravity field recovery.

THE CONTRIBUTION OF OPERATIONAL RESEARCH TO EFFECTIVE GRAVITY MODEL IMPROVEMENT

Hussain A. SALEH (Institut de Recherches Interdisciplinaires et de Développements en Intelligence Artificielle, University Libre de Bruxelles)

With the coming of the space age, technologies have been developed that enabled a systematic observation of the entire Earth. It is being realized that in order to be able to understand the complex nature of the dynamic Earth, a multidisciplinary procedure is necessary in which the mapping of the Earth's gravity and magnetic fields with high resolution and accuracy is a prerequisite. High-resolution models of the gravity and magnetic fields of the Earth will help in modelling and understanding the structure of the Earth and the driving forces behind plate tectonics, motion associated with earthquakes, lithospheric motions, etc. In addition, a high-resolution gravity field model will help to establish a physically meaningful reference surface for oceans (within this context, the geoid). With the extensive collected (meteorological and geometrical) data sets of past, current and future geoscientific missions, ocean variations with respect of this surface can be efficiently studied on different geometrical and temporal scales. In addition, by combining these huge of collected data sets (altimetry and gravity), ocean currents can be deduced and possibly long-term effects like global sea level change can be thoroughly investigated. The developments of computationally computerised techniques that can provide a complementary procedure to combine and model gravity field information are lagging behind the general developments in the geoscience's research. Therefore, this advanced area of research using Artificial Intelligence (AI) is a promising direction to determine a global high-accuracy gravity field model with a higher resolution. In the last two decades model-based on ideas of the AI has been an important research area where new methodologies have been proposed, studied and experimented. Today AI is entering its maturity and this is witnessed by the number of applications which have been implemented and deployed, and by those which are currently under investigation. Within the Global Navigation Satellite Systems (GNSS) technology, metaheuristic techniques, which are often based upon ideas from AI have been researched, implemented, investigated and achieved good results in GNSS surveying. In this paper, these ideas are dynamically expanded to efficiently provide flexible and computerized procedures for determining a global high-accuracy gravity field model with a higher resolution. To successfully achieve this model, metaheuristic techniques, from the field of Operational Research (OR), have been proposed and implemented. These techniques are applicable to a wide range of important problems that occur in a variety of disciplines, such as statistics and engineering. OR attempts to provide a systematic and rational approach to the fundamental elements involved in the control of a problem by making decisions which, in some sense, achieves the best results in light of all the information that is available. Metaheuristic techniques play an effective role in OR applications by reducing the huge number of evaluations.

DETERMINATION OF ABSOLUTE GRAVITY VALUES USING A FG5#210 IN BANDUNG AND YOGYAKARTA, INDONESIA

Toshihiro HIGASHI[1], Yoichi FUKUDA[1], Maiko ABE[1], Shuzo TAKEMOTO[1], Sjafra DWIPA[2], Dendi Surya KUSUMA[2], Achmad ANDAN[2], Koichiro DOI[3], Yuichi IMANISHI[4], Giuseppe ARDUINO[5] ([1]Department of Geophysics, Graduate School of Science, Kyoto University, [2]Geothermal Division, Directorate of Mineral Resources Inventory, Indonesia, [3]National Institute of Polar Research, [4]Ocean Research Institute, University of Tokyo, [5]UNESCO Office, Jakarta)

In November 2002 we carried out absolute gravity measurements for the first time in Bandung and Yogyakarta, Indonesia. Hitherto there was no absolute gravity station in Indonesia, therefore the absolute gravity measurements had been strongly desired. At first, we installed the absolute gravimeter FG5#210 at the Geological Museum in Bandung. Absolute gravity measurement was performed from November 15 to 20 in 2002. Measurements are repeated at intervals of 15 seconds and one set consists of 160 drops in 40 minutes. Number of total drops was about 20,000. The data are corrected for the solid earth tides (tidal gravity factor 1.164), the ocean tides, the pole tide (using IERS Bulletin A), the atmospheric pressure (admittance of 0.3µgal/hPa), and the instrumental height. For the vertical transfer correction, we measured by two LaCoste and Romberg gravimeters and obtained the gravity gradient of —2.743µgal /cm. We determined the absolute gravity value at metal mark on the floor of the Geological Museum using a gravity vertical gradient. Obtained preliminary absolute value is 977976.7019 mgal. The primary base station of gravity for Indonesia (DG-0) is established in the same Museum. We carried out the relative gravity measurements at absolute gravity point (metal mark) and DG-0 using the LaCoste and Romberg gravimeters. The obtained result is consistent with about 20µgal. On November 22-26, we also carried out the absolute gravity measurements in Yogyakarta near Merapi volcano. Number of total drops was about 15,000 and the gravity gradient is — 2.873µgal /cm. The tentative gravity value obtained after the same corrections is 978203.0919 mgal. Determined absolute gravity values will contribute not only for the establishment of a precise gravity network in Indonesia but also for the detecting of gravity changes caused by seismic and volcanic activities.

THE NEW GRID OF GRAVIMETRIC TERRAIN CORRECTIONS OVER TURKEY COMPUTED FROM HIGH-RESOLUTION DIGITAL TERRAIN MODEL

Ali KILICOGLU, Mehmet Emin AYHAN, Coskun DEMIR, Orhan FIRAT, Ersin AKIZ (Department of Geodesy, General Command of Mapping)

Terrain correction, which represents the gravitational attraction of topography deviating from the Bouguer plate, generates a gravity signal that must be removed from any modelling process. The digital terrain model (DTM) including the bathimetry for Turkey on a 450 x 450 meter grid has enabled the computation of gravimetric terrain corrections. DTM was the result of the combination of a number of regional and global sources of topography, and was checked against systematic errors and isolated error points. The rectangular prism of constant density (2.67g/cm3) is used for numerical integration of the terrain effect. The effect of the far topography up to 50 km from the computation point was taken into account. A pre-tested technique with standardized inputs -such as appropriate algorithm, DTM resolution and quality, innermost area computation, effect of near/far topography- was used in this study. GRAVSOFT gravity field software package, in which the terrain correction computation with many features is fully implemented, was used in order to compute terrain corrections on a regular grid of 450 x 450 meter. Then, the total topographic effect including the effect of the Bouguer plate and plus terrain correction at the same grid was computed for further use in Bouguer anomaly computation. These products can be used in practice by interpolating at any desired station. The maximum, mean and standard deviation of the computed terrain corrections on land points were found to be 99.9 mGal, 1.79 mGal and 4.23 mGal respectively. The relation between terrain corrections and the topography was investigated using spectral techniques.

CALIBRATION OF THE SUPERCONDUCTING GRAVIMETER WITH AN ABSOLUTE GRAVIMETER FG-5 IN BANDUNG, INDONESIA

Maiko ABE[1], Toshihiro HIGASHI[1], Yoichi FUKUDA[1], Shuzo TAKEMOTO[1], Sjafra DWIPA[2], Dendi Surya KUSUMA[2], Achmad ANDAN[2], Yuichi IMANISHI[3], Koichiro DOI[4] ([1]Department of Geophysics, Graduate school of Science, Kyoto University, [2]Geothermal Division, Directorate of Mineral Resources Inventory, Indonesia, [3]Ocean Research Institute, University of Tokyo, [4]National Institute of Polar Research)

Since December 1997, gravity observations using a superconducting gravimeter (SG TT-70 #008) have been carried out in Bandung in cooperation between the Graduate School of Science, Kyoto University and the Volcanological Survey of Indonesia (VSI). In order to obtain reliable gravity data by means of SG observation, it is necessary to calibrate the SG system by comparing results with absolute gravimeter (AG). We carried out AG measurements by employing the FG-5 (#210) during the period November 10~19th 2002 at the Geological Museum near the Bandung SG station. We carried out 227 sets each of which has 160 drops of measurements at 15 seconds intervals. The total number of drops was 36,320, and we used 29,000 drops for the SG calibration. The calibration factor preliminary obtained is -52.281±0.10µGal/V. This value is in good agreement with the currently adopted values of -52.23µGal/V. The precision of the newly obtained factor is about 0.2 %. Although the precision may be slightly worse than those required for the studies of Earth tides and dynamics in the Earth´s deep interior, there are still some blunders in the AG data sets and the precision could be improved by removing those data.

NEW GRAVITY ANOMALY MAPS FOR ARGENTINA: MAGARG 2003

Eduardo Andres LAURIA[1], Maria Cristina PACINO[2], John Derek FAIRHEAD[3], Denizar BLITZKOW[4] ([1]Instituto Geográfico Militar, [2]Universidad Nacional de Rosario, [3]GETECH, [4]Universidade de Sao paulo)

Gravity surveys have been carried out in Argentina over the last century by Instituto Geográfico Militar, academic institutions and oil and mining companies. Part of these data was already used to produce several gravity maps on the national territory. However, the large number of new height and gravity data acquired during the past few years demands the reprocessing of the updated gravity data to enhance and maximise its use.Furthermore, recent developments in geodetic and geophysics applications require precise geoid models, which demand good quality gravity grids.In this sense, new gravity maps (bouguer and free air anomaly) were produced.This contribution describes the reprocessing of existing gravity data as well as the improvements reached from this process.All the activities are developed under the umbrella of the National Commitee of the International Union of Geodesy and Geophysics (Subcommitee of Geodesy).

A PRACTICAL COMPARISON OF HELMERT'S FIRST AND SECOND METHOD OF CONDENSATION IN THE PRECISE GEOID DETERMINATION

Szabolcs ROZSA, Bernhard HECK (Geodetic Institute, University of Karlsruhe)

According to the widely applied Helmert´s second method of condensation, the topographic masses are condensed to a surface layer, which is situated on the geoid. In this case the downward continued free-air anomalies are equal to the Faye-anomalies supposing the vertical gravity gradient to be equal to the normal vertical gravity gradient. Heck proposed to use a generalized method of condensation involving a deeper conpensation level, because of the roughness of the residual anomaly field in the previous case. This procedure extends Helmert´s first method of condensation, where the topographic masses are shifted to a layer situated 21 km below the geoid. In this paper the gravimetric geoid solutions are computed for Hungary in order to compare the two methods. For the calculations altogether 58800 gridded terrestrial mean free-air anomalies are used, with the spatial resolution of 1.5´ and 1´ in the E-W and N-S directions respectively. Moreover a DEM with the resolution of 500m is used for calculating the effect of the topographic masses. However in order to investigate the effect of the depth of the condensation layer, the calculations have been made using different condensation depths. In order to compare the results to GPS/levelling data, altogether 308 GPS/levelling points are also included in the investigations, which are distributed equally over the study area. Out of these stations altogether 95 have a levelled elevation which stems from measurements after the GPS campaigns.

PREDICTION OF VERTICAL GRAVITY GRADIENTS USING GRAVITY AND ELEVATION DATA

Gyula TÓTH[1], Szabolcs ROZSA[2] ([1]Budapest University of Technology and Economics, Department of Geodesy and Surveying, H-1521, Budapest, Muegyetem rkp. 1-3., [2]University of Karlsruhe,

Geodetic Institute, D-76128, Karlsruhe, Englerstr. 7.)

The vertical gravity gradients play an important role in the reduction of absolute gravity measurements and in the geoid determination, too. In order to enhance the precision of the gravity reductions and the geoid computations the difference between the vertical gravity gradient of the real and normal gravity fields should be taken into account. In this paper the vertical gravity gradients are computed by prism integration using constant and variable densities for the crustal masses and a high resolution (10m) digital elevation model to represent the topography in the Sóskút test area. On the other hand gravity gradients are predicted from 1610 point gravity data using the least-squares collocation method, too. The calculated gradient values are compared to each other, and they are validated using terrestrial measurements in 6 points in the Sóskút test area. The measurements of the vertical gravity gradients were carried out by the Lorád Eötvös Geophysical Institute and have the accuracy better than 80E, and are within the interval of 3189-3805E. The vertical gradient values calculated from the DEM are in the interval of 3123-4171E , and the values fitted to the measured values with the root-mean-square of 290E, and the maximal residual of 400E. Moreover the application of the predicted gravity gradients in the precise gravimetric geoid determination is investigated, and the effect of variable gravity gradients is also computed for the study area.

GRAVITY-BASED FAULT MAPPING: THE ISHIKARI LOWLAND OF HOKKAIDO, JAPAN

Akihiko YAMAMOTO (Institute of Seismology and Volcanology, Hokkaido University)

The Ishikari Plain is characterized by the largest alluviallowland (the Ishikari Lowland) in Hokkaido, Japan. In theeastern margin of this plain lies the Ishikari Teichi TouenFault Zone (ITTFZ) which borders on the Miocene hill belts(Iwamizawa, Kurisawa and Umaoi hills). In the central part nearSapporo City of this plain, the Nopporo Hill is bordered bylargely WNW-ESE striking faults, the Nopporo Hill Fault Zone(NHFZ). Past gravity studies in the Ishikari Lowland showedthat low anomalies corresponding to Quaternary sediments aredominant over the plain, whereas detailed gravity structuresparticularly across the ITTFZ and the NHFZ have not beenreported so far. This research examines gravity structures ofthe Ishikari Lowland by focusing relief-shaded Bouguer gravity,specifically to relocate the faults (the ITTFZ and the NHFZ),and to present a gravity-based active fault mapping in the plainfor correct determination of fault segmentation. Gravityanalyses are based on dense gravity data measured by variousinstitutes. Bouguer anomaly relief is produced by illuminatingthe light from eight directions to effectively display thedetailed gravity features varying laterally along the azimuthdirection. The active fault distribution in the region ismapped through the relief-shaded Bouguer anomaly. A striking linearity of the relief-shaded Bouguer gravity alongthe ITTFZ is found on most of the relief maps, particularly onthe maps for the azimuth of the due east and west. Thislineament shows a good agreement with distributions of both theold and new active faults in the northern and southern parts ofthe ITTFZ. In the central part of the ITTFZ, however, thelineament in the relief-shaded Bouguer map does not bear a goodcorrelation with the active fault distributions. It is alsoshown that the ITTFZ largely consists of N-S oriented twoparallel fault zones and their gravity anomalies associated withtwo high anomaly belts reflect the complicated subsurfacestructure. In addition, the gravity relief for the azimuth ofthe due north (or south) exhibits a remarkable lineament,extending southward from near Bibai, whose southwardcontinuation can be traced to the south-east until south ofAtsuma along the westernmost boundaries of pre-Neogenevolcanics. This implies that the geometry of the southern endof the known fault system (the ITTFZ) provides continuity alongthe relief-shaded Bouguer lineament roughly to the south-east.While gravity anomalies around the Nopporo Hill are small inamplitude and are associated with no abrupt gravity changescompared to its topography and surrounding fault distributions.Any of relief-shaded Bouguer gravity maps does not show a sharplineament around the NHFZ. This implies that no sharp densitycontrast is appreciable around the NHFZ at depths.

OPTIMISATION OF DENSITY PARAMETER IN GRAVITY PREDICTION FROM BATHYMETRY

David Michael SPROULE[1], A.H.W. KEARSLEY[1], R. FORSBERG[2] ([1]School of Surveying and Spatial Information Systems, University of New South Wales, [2]KMS, National Survey and Cadastre, Denmark)

This paper describes experiments conducted to examine the combination of gravity values predicted from bathymetric data with observed gravity data to increase the resolution of offshore gravity data. The density parameter in the prediction is optimised empirically. The gravity effect resulting from bathymetric features can provide short wavelength features of the gravity field, but at longer wavelengths subsurface features begin to influence the gravity signal. By using a combination of observed gravity and gravity predicted from bathymetry, the long wavelength features present in the direct observations can be preserved while using the bathymetric data to fill-in the short wavelength features. The computation scheme is described, and some numerical results are presented. The effect of increasing the distance between the observed gravity data is examined. For the calculation of the gravity signal arising from the bathymetry, a single density value is chosen for the entire area. Due to density variations this density may not be optimal. Different density values are tested to examine the effect this choice has on the resulting predicted gravity.

A VERSATILE GRAVIMETRY/GRADIOMETRY SIMULATION SOFTWARE

Olivier JAMET[1], Yassine AZZOUT[2] ([1]Laboratoire LAREG, Ecole Nationale des Sciences Geographiques, [2]Ecole Superieure d'Ingenierie Leonard de Vinci)

Context: With the forthcoming GOCE mission, that will provide gradiometric measurements from space, it will be possible to study geophysical phenomena at horizontal resolutions from 50km to 100km. Besides, the improvement of the accuracy of the ground measurements let us forsee the possibility to compute regional geoids at one centimeter accuracy. For both reasons, we need to better understand the relation between the crustal structure and the gravity field computation, and are developing a new software for simulating the potential field and its derivatives from a given geology at the local to regional scale. **Theory:** On areas wider than 50km, the approximation of a flat Earth does not hold, and the formulas for the prism, as published by Nagy et al. (2000) are not sufficient. We use the aproach of Petrovíc (1996), which allows to express the potential of any homogeneous polyedral body, as well as its derivatives. These expressions are suitable to compute the gravity potential, acceleration and gradiometry from a 3D model of the crustal structure though a simple scan of its edges. Though, their accuracy dropps down when the point of interest is located far away from the egdes of the 3D model. This is in particular the case when simulating satellite measurements. To cope with this issue, we propose an approximate expression, whose accuracy is assessed, and which allows to compute the potential (and its first and second derivatives) at a given accuracy at any point of the 3D space. **Software specifications:** The

---

software computes the potential and its derivatives at given locations (from ground to satellite orbit altitudes) of the gravity generated by polyhedral structures supplied in cartographic coordinates and formatted to VRML 2.0. The output can be formatted to scattered measurement points, acquisition lines, or regular grids. **Application:** We present the results of such a computation for the granitic basement on a 100km wide area of the west of France. This example allows to evaluate the effect of the uncertainty of the rock density on the geoid computation. **Further work:** Further developments will include the contribution of the long wavelenghts of the potential through a mixing of the results with existing spherical harmonic models of the geopotential. Acknowledgement: We thank the French Bureau de Recherches Geologiques et Miniere for supplying us with the geological data presented in this study. **References:** (Petrovíc 1996) S. A GRAVITY DATABASE OF SOUTHWEST JAPAN: APPLICATION TO BOUGUER GRAVITY IMAGING IN KYUSHU DISTRICT, SOUTHWEST JAPAN

Ryuichi SHICHI[1], Akihiko YAMAMOTO[2], Takeshi KUDO[3], GRG SWJ[4] ([1]Chubu Univ., [2]Hokkaido Univ., [3]Tono Geoscience Center, [4]Gravity Research Group in Southwest Japan)

Two large gravity databases in Japan have been issued for public use in 2000 and 2001. One is the ˝Gravity CD-ROM of Japan˝ published by the Geological Survey of Japan (GSJ) (GSJ, 2000). The other is the ˝Gravity Database of Southwest Japan˝ published by the Gravity Research Group in Southwest Japan (GRGSWJ) (2001). Both databases were formed mutually complementary in their distributions of gravity data. Consequently, by combining these two databases, gravity data of southwestern area of the Japanese Islands lose their non-closely-spaced character and spread evenly over the area. Although both databases have been compiled with a higher precision of about 1 mgal, they still contain gravity data with a precision no better than a few milligals or more which are not accurate enough for a detailed mapping. We are now executing further revisions to remove those poorly-calibrated data by careful scrutiny. We have accomplished this revision in the area of Kyushu District, southwest Japan, and it becomes possible to draw very precise gravity anomaly atlas which fully guarantees a precision of 1 mgal in the whole area. Characteristic features of a new precise gravity anomaly in Kyushu District are tersely summarized as follows; (1) The Aso Caldera, central Kyushu, is characterized by a prominent low gravity anomaly accompanying several closed minima inside the caldera. This gravity depression is nearly circular shaped, with a steep rim and a flat bottom. Gravity changes along the rim have the amplitude of more than 10 mgal/km. This implies that the Aso Caldera has a piston-shaped cylinder (not funnel-shaped) structure. (2) The Oita-Kumamoto Tectonic Line (OKTL), running nearly along the Tertiary-PreTertiary geologic boundary in central Kyushu, is considered to be a westward extension of the Median Tectonic Line from Shikoku District. By forming a belt-like structure of 5-10 km width, a dominant steep gravity gradient zone which is running through the Aso Caldera is observed along the ENE-WSW trending OKTL. Southwestward continuation of this gradient zone is passing through the northern coast of the Uto Peninsula and can be traced to Hondo (central Amakusa, southern part of the Inner Zone of Kyushu). Adjacent to the north of this steep gradient zone lies a huge and strong low anomaly belt. (3) A strong negative Bouguer anomaly is observed over the Hyuganada Basin, southeastern Kyushu, and characterized by a sharp inlandward increase of Bouguer gravity. This gravity low constitutes arcuate-shaped depression whose northwesternmost boundary is sharply cut by Pre-Tertiary volcanics. This implies that subsurface structure beneath the basin may be correlated to the tectonic drug caused by subduction of the Philippine-Sea Plate. (4) Trend-reduced Bouguer gravity shows a large positive anomaly over the Pre-Tertiary formations in the northern part of Kyushu. In contrast, negative anomalies are dominant over the Pre-Tertiary formations in the southern part of Kyushu, particularly around the Kyushu Mountains. While the Amakusa Islands are characterized by a strong gravity high in detrended Bouguer map, which is well corresponded with Paleogene formations.

REPEATED MEASUREMENTS OF GRAVITY WITH THE ABSOLUTE GRAVIMETER FG5 #210 AT MATSUSHIRO, JAPAN AND COMPARISON WITH THE SUPERCONDUCTING GRAVIMETER T011

Yuichi IMANISHI[1], Toshihiro HIGASHI[2], Yoichi FUKUDA[2], Mitsuyuki HOSHIBA[3], Kazuya KOKUBO[3] ([1]Ocean Research Institute, The University of Tokyo, [2]Department of Geophysics, Graduate School of Science, Kyoto University, [3]Matsushiro Seismological Observatory, Japan Meteorological Agency)

We have been conducting absolute gravity measurements at Matsushiro Seismological Observatory, Japan Meteorological Agency. The measurement site is a gravity station called the Fundamental Gravity Station (FGS) built by Geographical Survey Institute. This station is located in the gravimeter room inside the major tunnel of the observatory, about 2 m apart from the superconducting gravimeter (SG) T011. The main purpose of the measurements is to monitor the long term gravity changes by combining absolute gravity data with continuous gravity data from the SG. This should help also in calibrating the instrumental drift of the SG. In addition, comparison of the two gravimeters provides an opportunity for calibration of the instrumental sensitivity of the SG. Since this station is in a very good condition in terms of ground noise level and environment, it is expected that long term changes in gravity (if any) could be observed with high accuracy. The absolute gravity measurements took place in April 2000, December 2000, December 2001 and August 2002. The same instrument (FG5 #210) and procedure were used throughout these four experiments. The experiments spanned from one to four weeks. In each experiment, the measured gravity values followed a normal distribution, and the determination of the local gravity acceleration appeared to be successful. The gravity estimates (referred to the top of the FG5 metal plate) from these experiments are, in the MKS unit, 9.797729815 ± 0.000000072 (April 2000), 9.797729769 ± 0.000000090 (December 2000), 9.797729948 ± 0.000000099 (December 2001) and 9.797729845 ± 0.000000070 (August 2002). Among these, the December 2001 result may be regarded as an outlier, which could be attributed to instability of the rubidium clock used for our FG5. Evidence show that, in the December 2001 experiment, the frequency may have been lower than the prescribed value by some parts in 10^9. This should have resulted in an estimate of gravity acceleration larger than the true value by $(5\text{-}10)*10^{-8}$ ms^{-2}. This fact points to the necessity of precise calibration of the rubidium clock against other frequency standards, such as a well-calibrated rubidium clock or a cesium clock, which we have already included in our routine. On the other hand, the SG at Matsushiro has been very stable and had no large steps in these years. The instrumental drift of the SG T011 is almost linear in time, and the residual gravity indicates small changes probably associated with hydrological effects. Aside from the December 2001 result, the absolute gravity data are in agreement with the SG data within $(2\text{-}4)*10^{-8}$ ms^{-2}. No clear evidences for secular changes in gravity have been observed.

ABSOLUTE GRAVITY MEASUREMENTS IN IRANRESULTS OF BASE GRAVITY NETWORK & ALBORZ PROJECT

Morteza SEDIGHI[1], Jacques HINDERER[2], Kourosh GHAZAVI[1], Roger BAYER[2], Faramarz NILFOROUSHAN[1], Brenard LUCK[2], Farokh TAVAKOLI[1], Martine AMALVICET[2], Hamid Reza NANKALI[1] ([1]National Cartographic Center, [2]CNRS of France)

National Cartographic Center (NCC) of Iran, IPGS_CNRS/ University of Strasbourg and LGTS-CNRS/ University of Monpellier II from France in a common project, measured the absolute gravity of Gravity Base Network of Iran. The measurements at seven stations of Network were done during 2000 and 2002. The absolut gravimeter was FG5(#206) from Strasbourg university. The computations was done by new version of Absolute Gravity Data Acquisition and Processing Software. During the computation we tested all possibility for tidal and ocean loading corrections. The results show the precision from 1.40 - 4.04 µGal. The Berger tidal model + FES ocean loading corrections give better results in computations. We hope to finish the network in 2003.

G03/07P/D-013	Poster	1400-035

ESTABLISHMENT OF NEW GRAVITY CALIBRATION LINE FOR IRAN

Kourosh GHAZAVI, Farokh TAVAKOLI (Gravity and geoid, National cartographic center)

In recent years, 2000-2002, most important gravimetery activities in Iran were involved with absolute gravity measurements on stations of Gravity Base Network of Iran (GBNI). In collaboration with French scientist from university of Strasbourg 9 absolute stations of this network were measured by FG5 absolute gravimeter with accuracy about 3 mGal.For establishment of new Iranian National Gravity calibration line (INGCL)we used 5 stations of GBNI that are located along north west to south east direction of Iran. All old stations were inspected and those were located nearthe roads or damaged were reconstructed. In north - west part old line were changed in order to connect new line to absolute station at Tabriz and thenextend it to Bazargan at near the boundary of Turkey. New line divided into 2 main parts. North part which begins from Bazargan, continues to absolute station of Tabriz next to Rasht (one of the relative station of GBNI) andfinally reaches to absolute station at Tehran, capital of Iran. This part contains 38 stations along about 800 km where mostly located in rough area.South part begins from Tehran to absolute station of Qom then from there connected to absolute station at Esfehan and finally continues to absolute pointin Shiraz. This part contains 25 stations along about 1000 km.All stations were measured simultaneously with 3 relative gravimeter(ScintrexCG-3M) that 2 of them manufactured last year and the other one 6 years ago. Each part of this line occupied 2 times, i.e. from Tehran to Bazargan (in north)or Shiraz (in south) and vice versa. In addition observations carried out usingA-B-C-B-A method and in each station we measured at least 5 measurements to reach 5 mGal accuracy for repeatability of readings. Then all readings werechecked and bad observations removed from survey files, after that readings corrected for drift and tide by OASIS MONTAJ software. Between each two absolutestations, relative differences of 2 new gravimeters were controlled withabsolute difference values and errors were adjusted. We computed the absolute value of each station with accuracy better than 10 mGal by combination of corrected results that obtained from observations of 2 new gravimeters.Comparing difference of these values with which were measured by old gravimeter,using Least Square Adjustment method, old gravimeter was calibrated withaccuracy about 100 ppm which is in order of best accuracy for calibrating of relative gravimeters on calibration lines.

IDENTIFICATION OF LONG-WAVELENGTH ERRORS IN AUSTRALIAN GRAVITY ANOMALIES AND GEOID HEIGHTS USING CHAMP DATA

Will FEATHERSTONE (Western Australian Centre for Geodesy, Curtin University of Technology)

This study quantifies long-wavelength differences (from ~850 km to ~5,000 km) between terrestrial free-air gravity anomalies in the Australian region and gravity anomalies implied by the EIGEN2 global geopotential model, which is derived purely from the CHAMP dedicated satellite gravimetry mission. An 850 km low-pass cosine filter is used to remove the high-frequency components from the terrestrial gravity anomalies. Given the homogeneous and accurate long-wavelength CHAMP data, the differences are attributed to long-wavelength errors in the Australian gravity anomalies, due to a combination of observation and reduction errors. These long-wavelength differences are then used to quantify the effect on the regional gravimetric geoid model, using the unmodified Stokes kernel and no limit on the cap radius (i.e., all terrestrial gravity anomalies in the region). The unmodified Stokes kernel is used with no cap radius because, unlike some modified kernels with limited cap radii, it does not high-pass filter terrestrial gravity data errors during the transformation to the geoid. As such, this represents a somewhat worst-case scenario of how the long-wavelength terrestrial gravity anomaly errors could affect the Australian gravimetric geoid model.

COMPILATION AND EVALUATION OF A CONSISTENT MARINE GRAVITY DATA SET SURROUNDING EUROPE

Heiner DENKER, Markus ROLAND (Institut fuer Erdmessung, Universitaet Hannover)

Various institutions have collected shipborne gravimetric measurements during the last decades. Due to different standards used for the processing of the observations and the necessary corrections, significant inconsistencies exist between different cruises. This contribution aims at producing a consistent marine gravity data set surrounding Europe, which can then be used for high precision geoid modelling, dynamic sea surface topography estimation, and other applications. Besides our own marine gravity data holdings, data were collected from the Bureau Gravimetrique International (BGI), the National Imagery and Mapping Agency (NIMA, formerly DMA), and the National Geophysical Data Center (NGDC). The area of investigation is spanning the latitudes from 20°N to 80°N and the longitudes from 40°W to 40°E. The quality of the data varies between the individual cruises, as they originate from many different projects over a long period of time. Hence, systematic errors are likely to exist. Such errors can be significantly reduced by a crossover adjustment of the individual ship tracks. As the track information is not available for all cruises, this information was regenerated by different procedures. Furthermore, duplicate sources were removed before the crossover adjustment. The crossover adjustment is based on a bias per track error model. The adjustment of about 2 million observations in more than 20000 tracks lead to a consistent high quality marine gravity data set. The RMS of the about 60000 crossover differences reduced by a factor of 2 to 3 through the adjustment process. The final RMS crossover difference is about 3 mgal. The second part of this contribution deals with the evaluation of the marine gravity data set using altimeter derived gravity anomalies from different sources. These comparisons also prove the effectiveness of the crossover adjustment.

GRAVITY CHANGES IN CHINA CONTINENT

Hui LI, Guangyu FU, Shaoan SUN, Dongzhi LIU, Xiaoquan WANG, Aiming XIANG, Canfei XING (Institute of seismology, CSB)

Since 1988, three times gravimetry in China Continent had been carried out in 1998, 2000 and 2002 by employing absolute and relative gravimeters. The gravity network comprised of about 400 gravity stations.This paper firstly analyses the repeation of the measurements, and then the gravity changes are calculated, at last the precision of gravity changes and their relationship to the strong earthquake is discussed. According to the results, we get following points: 1) the repeated measurement stations is about 340, 2) precision of gravity changes about 30microGal is reliable, 3) the gravity changes are among the +150 to -120 microgal, 4) the gravity changes is strongly related to the strong earthquake, the common feature is about the gravity decrease before the quake, and increase after quake, especially for the Kunlun quake (Ms8.1) occurred in November 11, 2001. Before the quake, the gravity change around the epicenter is decrease, which spread out over than 1000KMx1000KM, the maximum changes reach to 120microGal. Compared gravity before and after quake, we found the gravity changes is recovering individually, and typical four-quadrant distribution is displayed covering whole western half China Continent. This will benefit to our geodynamics study.

THE ESTIMATION OF WATER MASS REDISTRIBUTION ON GRAVITY EFFECT

Xuhua ZHOU, Houze HSU, Bin WU (Institute of Geodesy and Geophysics, Chinese Academy of Sciences)

Using monthly mean precipitation and temperature data over 7000 land meteorological station, TOPEX/Poseidon Satellite Altimeter data, WOA98 temperature and salinity model in multi-layers seawater, the gravity variation for some superconducting stations are estimated by the change of continental water and oceanic mass redistribution. Synthesizing the predicted gravity variation caused by change of continental water and oceanic mass redistribution, the result indicate that the effect on gravity observation caused by water mass redistribution has exceeded the accuracy of gravity observation, and it can achieve 5 microgals in some stations. In addition, we also discuss the effect of using different load Love numbers and continental water storage models on the estimation result.Key Wards: Gravity, Water mass redistribution

TERRAIN CORRECTION ON THE MOVING EQUAL AREA CYLINDRICAL MAP PROJECTION OF THE SURFACE OF A REFERENCE ELLIPSOID

Alireza A. ARDALAN[1], Abdolreza SAFARI[1], Erik W. GRAFAREND[2] ([1]Department of Surveying and Geomatics Engineering, University of Tehran, [2]Department of Geodesy and GeoInformatics, Stuttgart University)

An operational algorithm for computing the ellipsoidal terrain correction based on the application of closed form solution of the Newton integral in terms of Cartesian coordinates in the cylindrical equal area map projected surface of the reference ellipsoid has been developed. As the first step, the mapping of the points on the surface of a reference ellipsoid onto a cylinder passing through the parallel of a point on the surface of reference ellipsoid, i.e. the cylindrical equal area map projection, has been closely studied and the corresponding map projection formulas are derived. Ellipsoidal mass elements with various sizes on the surface of the reference ellipsoid are selected and the gravitational potential and the vector of gravitational intensity of those mass elements have been computed via the solution of Newton integral in terms of ellipsoidal coordinates. The four edge points of base area of the selected ellipsoidal mass elements on the surface of reference ellipsoid are transferred into cylindrical equal area map projection and using the transformed area elements, Cartesian mass elements with the same height as that of the ellipsoidal mass elements are constructed. Using the close form solution of the Newton integral in terms of Cartesian coordinates the potential of the Cartesian mass elements are computed and compared with the same results based on the application of the ellipsoidal Newton integral for the ellipsoidal mass elements. The results of the numerical computations show that difference between computed gravitational potential of the ellipsoidal mass elements and Cartesian mass elements in the cylindrical equal area map projection is less than $1.6*10^{(-8)}$ m^2/s^2 for a mass element with the cross section area of 10m*10m and the height of 10000m. For a mass element with cross section area of 1km*1km with the height 10000m the difference between computed gravitational potential based on the two aforementioned methods is less than $1.5*10^{(-4)}$ m^2/s^2. The results of the numerical computations indicate that a new method for computing the terrain correction based on the closed form solution of the Newton integral in terms of Cartesian coordinates and with accuracy of ellipsoidal terrain correction has been achieved! In this way one can enjoy the simplicity of the solution of the Newton integral in terms of Cartesian coordinates and at the same time the accuracy of the ellipsoidal terrain correction, which is needed for the modern theory of geoid computations!

UNIFIED EUROPEAN GRAVITY REFERENCE NETWORK 2002 (UEGN2002)

Gerd BOEDECKER[1], Olivier FRANCIS[2], Ambrus KENYERES[3] ([1]Bavarian Academy of Sciences / BEK, Munich, Germany, [2]European Centre for Geodynamics and Seismology / Institut Supérieur de Technologie, Luxembourg, [3]FOMI Satellite Geodetic Observatory, Penc, Hungary)

The latest realisation of the Unified European Gravity Reference Network has been prepared in 1994 (UEGN94), covering 11 West European countries. Since that time significant work has been done (e.g. in the frame of the UNIGRACE project) that focused on the establishment of absolute gravity stations in Central and East European countries. The European Subcommission of the IGGC (International Gravity and Geoid Commission of the IAG) promoted to complete the unification of the gravity networks on the continental level. During the IAG2001 Scientific Assembly held in Budapest in September 2001, the decision was taken that a new continental gravimetric reference network (so-called UEGN2002) has to be realised. The UEGN2002 network covers 25 countries, the expected number of stations exceeds 1000. The data processing is done using raw absolute and relative gravity observations. The tidal corrections are computed on a uniform manner and based on the most advanced standards. The common adjustment of all observations provides a homogeneous reference stations set throughout Europe and hence contribute to the common European infrastructure. The presentation will provide a status report including the countries and stations involved, the models used and preliminary results.

COMPARATIVE ANALYSIS OF DIFFERENT ADJUSTMENT METHODS FOR THE HUNGARIAN PART OF THE UNIFIED EUROPEAN GRAVITY NETWORK (UEGN)

Geza CSAPO[1], Marta KIS[1], Lajos VOLGYESI[2] ([1]EOTVOS LORAND GEOPHYSICAL INSTITUTE, [2]BUDAPEST UNIVERSITY OF TECHNOLOGY AND ECONOMICS)

The first version of the Unified European Gravity Net (UEGN) was set up in 1993, based on the participation of 11 countries. The aim was basically the generation of the unified European geodetic basement for global geologic and geodynamic purposes. The unified scale of the network is ensured by numerous absolute gravimetric stations. Since 1995 further countries (inter alia Hungary) have been joined to the unified network. In this paper the adjustment of the Hungarian net part consist of 39 points is presented by the authors. The observed data were also adjusted by the help of robust procedures besides the least squares method, as both a free and a constrained network. A comparative analysis of the results achieved by the different methods is also presented in this paper.

VALIDITY CONTROL OF THE SEA GRAVITY DATA; CASE STUDIES

Abdolreza SAFARI, Alireza A. ARDALAN (Department of Surveying and Geomatics Engineering, University of Tehran)

The sea gravity data, which are collected via shipborne techniques, due to the measuring environment at sea, are usually with low accuracy and contaminated with various systematic errors. One of the current problems of the international gravity centers like BGI is how to control the validity of the sea gravity data. In this paper we are offering a new method for validity control of sea gravity data based on satellite altimetry and the modern high-resolution geopotential models. The main steps of this method are as follows: First, the accuracy of the selected geopotential model at the test area is determined. Having assured of the accuracy of the geopotential model at the test area the instantaneous sea level height from satellite altimetry is used to compute the gravity data at the sea surface. The computed gravity data is then used to test the validity an existing sea gravity data set. The details of the theory and the results of the case studies will be presented.

APPLICATION OF ALTIMETRY DATA FOR GRAVITY RESEARCH IN THE BLACK SEA

Ivan Vladimirovich LYGUINE[1], Vjacheslav Romanovich MELIKHOV[1], Andrey Alexsandrovich BULYCHEV[1], Vladimir Alexseevich LYGIN[2] ([1]Geophysical Department, Geological faculty, Moscow Lomonosov M.V. State University, [2]Marine Gravity and Magnitometry Department, NIPIoceangeophysics, Krymskaya 18, Gelendjik, Krasnodar region, RUSSIA)

From ideology of altimetry measurements follow that optimal regions for altimetry are open zones of the World Ocean, where depths' measurements have minimal deviations. But there is a necessity for clearing up a question about possibility of application altimeter data not only for open regular abyssal parts of seas, but for investigations of dynamic active sea areas with sharply cross-bottom (e.g. mid-ocean ridges), offshore and enclosed seas, continental shelf and transit zones with strong effect of shore relief. It is very important for Russia because of insufficient studying its north coasts. We studied amplitude and phase characteristics of altimeter data (Predict-relief, Topex-relief, Sandwell-gravity-2, Topex-gravity) in comparison with results of high-accuracy square marine gravity surveys and detailed bathymetry for some areas of the Black Sea. We found out, that contemporary processing system of satellite altimeter tracks is the same both for open marine areas and for transit zones. In the future such defects can be eliminating, but "dead" zone along-shore will be exist. Taking into account bias marine gravity data and Topex-Gravity calculated anomalous gravity field of the Black Sea is not worse than data of average-scaled gravity surveys of 197x years. Determined that altimeter data may be used only for areas far from continental shelf (~100 km) for 1: 500 000 scale and only under the control of marine surveys.

COMPUTATION OF A GEOPOTENTIAL MODEL FROM GOCE DATA USING FAST SPHERICAL COLLOCATION - A SIMULATION STUDY

C.C. TSCHERNING[1], Dimitrios N. ARABELOS[2] ([1]Department of Geophysics , University of Copenhagen, Julane Maries Vej 30, 2100 Copenhagen, Denmark, [2]Department of Geodesy and Surveying, Aristotle University of Thessaloniki, 54124 Thessaloniki, Greece)

Realistic orbit for GOCE from IAG SC7 was used to create a 0.5 T_{zz} grid of simulated data at mean satellite altitude. To this purpose, the SC7 positions along the orbits were converted from the inertial frame to geodetic coordinates in an earth-fixed frame. From these values the contribution of EGM96 to degree 24 was subtracted and the resulted data set was used to predict the 0.50 T_{zz} grid, covering the area of the Earth from -83° to +83° latitude using local Least-Squares Collocation. Noise was added to the simulated data using an optimistic and a pessimistic model of the noise. The simulated data sets were used to generate geopotential coefficients using Fast Spherical Collocation (FSC), with a global covariance function. Different experiments were carried out: (a) using a grid obtained from noise-free data and (b) using grids obtained from the data with noise. In all cases, the results of the computations are assessed by comparing the simulated input data with corresponding data from the predicted geopotential coefficients.

CALIBRATION AND VALIDATION OF GOCE GRAVITY GRADIENTS

Johannes BOUMAN[1], Radboud KOOP[1], Roger HAAGMANS[2], Juergen MUELLER[3], Nico SNEEUW[4], Christian TSCHERNING[5], Pieter VISSER[6] ([1]SRON National Institute for Space Research, The Netherlands, [2]European Space Agency, ESTEC, [3]Institut fuer Erdmessung, University of Hannover, [4]Department of Geomatics Engineering, University of Calgary, [5]Department of Geophysics, University of Copenhagen, [6]Delft Institute for Space Research, Delft University of Technology)

GOCE will be the first satellite ever to measure the second derivatives of the Earth´s gravitational potential in space. With these measurements it is possible to derive a high accuracy and resolution gravitational field if systematic errors have been removed to the extent possible from the dataand the accuracy of the gravity gradients has been assessed. It is therefore necessary to understand the instrument characteristics to setup a valid calibration model. The calibration parameters of this model could be determined by using GOCE data themselves or by using independent gravity field information. Also the accuracy or error assessment relies on either GOCE data or independent data. We will demonstrate how state-of-the-art global gravity field models, terrestrial gravity data and observations at satellite track

crossovers can be used for calibration/validation. In addition we will show how GOCE data or high quality terrestrial data could play a prominent role in error assessment.

THE EGYPTIAN GEOID EGGG2003

Hussein A. ABD-ELMOTAAL (Civil Engineering Department, Minia University)

An optimum combination of all currently available free-air gravity anomalies in Egypt and neighbouring countries (both point values and gridded points on land and sea) is considered in this investigation. The best data combination is used to compute the gravimetric geoid for Egypt in the framework of the well-known remove-restore technique using a set of 30˝ x 30˝ and 3´ x 3´ Digital Height Models for computing the effect of the topography and its compensation on the gravity anomalies and on the geoid undulations (the indirect effect). The so-called window technique has been used to avoid the double consideration of some of the topographic-isostatic masses in the neighbourhood of the computational point. The commonly used Airy-Heiskanen isostatic hypothesis is applied (with and without window technique). The EGM96 global geopotential model and its adapted version according to the window technique are used till different upper degrees N_{max} (to get a better fitting to the Egyptian gravity field) for computing the effect of the reference field. The gravimetric geoids are computed for Egypt using Stokes´ integral in the frequency domain by 1-D FFT technique. The computed geoids are scaled/fitted to the GPS/levelling derived geoid. A wide comparison between the geoids computed in this investigation is carried out.

THE NEW GRAVIMETRIC GEOID MODEL FOR TURKEY (TG03)

Ali KILICOGLU, Mehmet Emin AYHAN, Coskun DEMIR, Orhan FIRAT, Ersin AKIZ (Department of Geodesy, General Command of Mapping)

The geoid model referring to a global geocentric datum is essential in the determination of orthometric heights by GPS/leveling. The new Turkish Geoid-2003 (TG03) was computed as new and more data were available. Heterogeneous data (gravity, topography and geoid heights) were used by Least Squares Collocation (LSC) in a remove-restore procedure. EGM96 was used as the reference model of the earth's geopotential. The data used consist of surface gravity anomalies, gravity anomalies derived from ERS1, ERS2 and TOPEX/POSEIDON altimetry data, GPS/levelling geoid heights, and topographic heights. Surface gravity values are in Modified Potsdam Datum, and the free air anomalies were computed in GRS80. No surface gravity data were used outside the Turkish border while topographic heights were obtained from GTOPO30 global topography. The RTM effect of the topography was computed using a high-resolution Digital Terrain Model (450x450 m). The DTM used consist of high-resolution topographic heights within the borders, and dense bathymetry near the shoreline. Evenly distributed GPS/leveling geoid heights were introduced so as to compute the final geoid in agreement with GPS ellipsoidal heights. Ellipsoidal heights of the GPS/levelling points refer to well-established Turkish National GPS Network (aligned to ITRF96), while orthometric heights refer to Turkish National Vertical Datum (fixed to mean sea level). The geoid and geoid prediction at the observation points gave an internal precision below 3 mGal and 10 cm respectively. The geoid heights at 3'x3' grid points within Turkey (25E-46E, 35N-43N) were computed to be further interpolated in practical use. The final geoid was tested at GPS/levelling stations, which were not used in the computations, and the external accuracy was found to be within a decimeter as varying with respect to the data distribution and density.

ACCURACY ASSESSMENT OF THE AVAILABLE GEOID MODELS IN ALGERIA

Sid Ahmed BEN AHMED DAHO[1], J.D. FAIRHEAD[2], S. KAHLOUCHE[1], A. ZEGGAI[1] ([1]Geodetic Laboratory, National Centre of Spatial Techniques, [2]GETECH-University of Leeds - Department of Earth Sciences - Leeds LS2 9JT - United Kingdom)

The determination of orthometric heights by traditional techniques, such as spirit levelling, is known to be a difficult and expensive task, especially in big countries like Algeria where the establishment of a levelling network covering all parts of the country would be impractical and furthermore may not be possible principally in the mountainous areas and in the south of the country. On the other hand, the combined use of GPS heights and geoid heights provides an efficient alternative to derive orthometric heights and therefore, to avoid the arduous task of precise spirit levelling. In this paper we want to determine, the best combination possible among the available geoid models in Algeria with GPS/Levelling that gives sufficiently accurate results in order to check the possibility to substitute the classical spirit levelling. For this study, we have used two national gravimetric geoid models, all have been computed by Geodetic Laboratory of the National Centre of Spatial Techniques from two sets of gravity data supplied respectively by BGI in 1997 and by the Geophysical Exploration Technology Ltd (GETECH) in 2002, and three global geopotential models namely OSU91A, EGM96 and GPM98b. The GPS data are collected from the international TYRGEONET project and the local GPS/Levelling surveys with baseline length ranging from about 3 to 800 km. However, and in order to minimise all possible datum inconsistencies and others systematic effects between geoid and GPS/Levelling undulations, we have tested various kinds of functions. The number of stations GPS used in this investigation was 246; the most of these points are located in the north of Algeria, which 16 are benchmarks of the first order levelling network. Only ten well distributed GPS levelling points are used as benchmark points. The remaining points were used to check the quality of the fitting different gravimetric geoid solutions to a set of GPS levelling points. The data used in framework of this work and their distribution, the adopted methodology, the computation procedure, and the obtained results will be presented and widely discussed.Key words: GPS/Levelling, Geoid undulations, Geopotential model.

ON THE DETERMINATION OF MARINE GEOID MODELS BY LEAST-SQUARES COLLOCATION AND SPECTRAL METHODS USING HETEROGENEOUS DATA

Georgios S. VERGOS, Ilias N. TZIAVOS, Vassilios D. ANDRITSANOS (Department of Geodesy and Surveying, Aristotle University of Thessaloniki)

In the frame of the EU-sponsored GAVDOS project the need of a new high-resolution and high-accuracy geoid model for the calibration of the satellite altimeters (e.g., JASON-1, ENVISAT and EURO-GLOSS) and for sea level monitoring purposes has become apparent. This is mainly due to the fact that the already available solutions have been determined using outdated datasets and fail to meet the wanted, cm-level, accuracy requirements. To determine the new geoid models multi-satellite (ERS1, GEOSAT, TOPEX/POSEIDON (T/P)) altimetry and land and marine gravity data have been used. Furthermore, two global geopotential models, namely EGM96 and GPM98b, have been employed to describe the long wavelengths of the gravity field spectrum, while the effect of the bathymetry has been

taken into account using recently developed local Digital Depth Models (DDMs). Several solutions have been estimated, based on the different data and methods used, presenting a resolution of 5 and 3 arcmin. The estimation of the purely altimetric, gravimetric and combined geoid models has been performed using the Fast Fourier Transform (FFT) based Input Output System Theory (IOST) and Least Squares Collocation (LSC). The accuracy of the new models has been determined through comparisons with T/P data and other geoid solutions for the area under study. Finally, the consistency between the solutions has been assessed by comparing the geoid height value they provide for the Gavdos Tide Gauge (TG) station on the isle of Gavdos. From the results it is shown that the precision of the new geoid models is close to 1 cm, their accuracy ranges between 5 and 10 cm level and their differences at the TG station between 0.2 - 10 cm.

OPTIMAL MARINE GEOID DETERMINATION IN THE ATLANTIC COASTAL REGION OF ARGENTINA

Clauda TOCHO[1], Georgios S. VERGOS[2], Michael G. SIDERIS[3] ([1]Facultad de Ciencias Astronomicas y Geofisicas, Observatorio Astronomico, [2]Department of Geodesy and Surveying, Aristotle University of Thessaloniki, [3]Department of Geomatics Engineering, University of Calgary)

The determination of an optimal high-accuracy and high-resolution marine geoid model for the Atlantic coastal region of Argentina is investigated using satellite altimetry and shipborne gravity data. Altimetric data from the latest releases of the mapping phases of the ERS1 and GEOSAT satellite missions are used together with marine gravity data to estimate altimetric, gravimetric and combined marine geoid models for the area. The effect of the Quasi-Stationary Sea Surface Topography (QSST) is taken into account in correcting the altimetric Sea Surface Heights (SSHs) to derive geoid undulations. Special emphasis is placed on reducing the effects of the Sea Surface Variability (SSV) on the densely spaced altimetric SSHs with low - pass filtering and through a regional crossover adjustment scheme. The satellite and shipborne data are combined in the spectral domain, in an effort to improve the overall accuracy of the purely gravimetric and altimetric solutions close to the coastline. The accuracy of the final models is assessed through comparisons with stacked year-three TOPEX/POSEIDON (T/P) SSHs, known for their high precision. The results show that a purely altimetric geoid accurate at the 5 to 7 cm level, in terms of the standard deviation of the differences with T/P SSHs, is feasible while the pure gravimetric solution gives poorer results by about 10 - 15 cm. By combining the satellite and shipborne data with the proposed algorithms the accuracy of the gravimetric geoid model is improved by about 30 - 40%.

IMPROVED FITTING BETWEEN GRAVIMETRIC AND GPS/LEVELLING GEOIDS USING AN EXTENDED SIMILARITY TRANSFORMATION MODEL: A CASE STUDY IN JOHOR, MALAYSIA

Christopher KOTSAKIS[1], Muhammad N.J.P. VELLA[2] ([1]Department of Geomatics Engineering, University of Calgary, Calgary, Alberta, Canada, [2]Center of Geodetic and Geodynamic Studies (CGGS), Faculty of Engineering and Geoinformation Science, University of Technology Malaysia, Johor, Malaysia)

The comparison between gravimetrically-derived and GPS-derived geoid undulations, over a network of spirit levelled benchmarks (BMs), is a standard procedure in geodetic practice. The differences obtained from such comparisons provide useful information for studies involving: (i) the optimal fitting of gravimetric geoids to local vertical datums through ties to GPS/levelling BMs, (ii) the unification of different vertical datums by satellite positioning methods, and (iii) the external accuracy evaluation of gravimetrically computed geoids with GPS and levelling data. To facilitate these types of applications which depend, one way or another, on the combination of ellipsoidal, orthometric and geoid heights, various ˝low-order˝ parametric models are implemented to describe the general trend of the discrepancies between gravimetric geoid surfaces and local vertical datums. Additional modelling procedures, based on the use of least-squares collocation and other interpolatory-type schemes, are often applied to the remaining residuals to capture the finer details of these differences and to further improve the transition between geometric and orthometric heights. In this paper we study the performance of a general 8-parameter transformation model for low-order fitting of gravimetric geoid surfaces to GPS/levelling data. The model is based on a differential similarity transformation concept and it provides a straightforward generalization of the classic 4-parameter trend corrector surface that is usually applied in GPS-geoid tayloring applications. A case study for a control test network located in the state of Johor in Malaysia is presented, using both global and regional gravimetric geoid solutions along with national GPS and levelling databases. The results show an improvement in the fitting performance of almost 50% when the extended 8-parameter model is applied for trend removal, as opposed to the use of the simpler 4-parameter version. Additional numerical comparisons with other low-order parametric models of polynomial type (up to fourth degree) have also been performed, which further demonstrate the effectiveness of the extended similarity-based transformation to describe the long-wavelength differences between gravimetric geoids and local vertical datums.

GRAVIMETRIC GEOID COMPUTATION IN THE ANDES

Claudia Noemi TOCHO[1], Michael G. SIDERIS[2], Graciela FONT[1] ([1]Facultad de Ciencias Astronomicas y Geofisicas. Universidad Nacional de La Plata, [2]Department of Geomatics Engineering, University of Calgary)

As a preliminary analysis for the development and evaluation of a precise gravimetric geoid for Argentina, different gravimetric geoid solutions were computed using different gravity reduction techniques in the roughest area of the country. The rugged area bounded by latitude 20° S to 42° S and longitude 72° W to 68° W was chosen to compute the geoids using the following terrain reductions methods: Helmert's second condensation method, Rudzki's inversion method, the Airy-Heiskanen topographic-isostatic reduction, and the residual terrain model (RTM) method. The remove-restore method was employed using the most homogenised gravity database (with data blunders were removed) referenced to a unified datum, the EGM96 global geopotential model and different digital elevation models, to take into account the short-wavelength component of the gravity signal. Different values of the maximum degree of the geopotential model were used to compute residual gravity anomalies. For these reduced gravity anomalies, geoid undulations were estimated using Stokes's integral with different cap sizes in order to investigate the effect of truncating the geopotential model in favour of local gravity. Stokes's formula was evaluated using the rigorous spherical kernel by the one-dimensional fast Fourier transform algorithm. The external accuracy of the gravimetric geoid models was evaluated by comparing them with undulations derived from GPS/leveling data. A four-parameter transformation and a seven-parameter transformation model were used to remove the systematic datum differences between the gravimetric geoid and the GPS/leveling undulations, and the possible long wavelength errors of the geoid.

TOWARDS A PRECISE GEOID MODEL FOR ARGENTINA

Maria Cristina PACINO[1], Eduardo Andres LAURIA[2], Denizar BLITZKOW[3] ([1]Department of Geotopocartografia, Universidad Nacional de Rosario, [2]Instituto Geografico Militar, [3]Universidade de Sao Paulo)

Several improvements as regards gravity and height data have been done since the calculation of previous geoid models for Argentina.Thus, thousands of new gravity stations had been measured, new DTMs had been calculated and hundreds of GPS/levelling points had been acquired.The reprocessing of preexisting and new data in the framework of the remove-restore technique yielded to GeoArg2003, a new geoid model for Argentina.This paper describes the procedure for geoid computation, statistical evaluations of the model and some improvements from previous geoid charts.All the activities are developed under the umbrella of the National Commitee of the International Union of Geodesy and Geophysics (Subcommitee of Geodesy).

ADVANCES IN THE CENTIMETER GEOIDAL DETERMINATION OF MEXICO

Antonio HERNANDEZ-NAVARRO[1], Mario Alberto REYES-IBARRA[2] ([1]Coordinador de Geodesia, Direccion General de Geografia, Instituto Nacional de Estadistica, Geografia e Informatica, [2]Director General, Direccion General de Geografia, Instituto Nacional de Estadistica, Geografia e Informatica)

This contribution shows the works made in Mexico by the *National Institute of Statistics, Geography and Informatics (INEGI)* to obtain a centimeter geoidal solution for the interest region. The solution adopted use the Stokes-Helmert scheme, developed at University of New Brunswick under leadership of Prof Petr Vanicek.

WAVELET EVALUATION OF SOME SINGULAR GEODETIC INTEGRALS

Michael G. SIDERIS[1], Quanwei LIU[2] ([1]Department of Geomatics Engineering, University of Calgary, [2]Applanix Corporation, Richmood Hill, ON, Canada)

The wavelet transform is a powerful tool in evaluating singular geodetic integrals. Due to its localization properties in both of the time (space) and frequency (scale) domains, and because the kernels of some geodetic integrals have singular points and decay smoothly and quickly away from the singularities, a large number of wavelet transform coefficients of the kernels become zero or negligible, and only a small number of wavelet transform coefficients are significant. It is thus possible to significantly compress the kernels of these integrals in a wavelet basis by neglecting the zero coefficients and the small coefficients below a certain threshold. Therefore, wavelets provide a convenient way for evaluating these integrals efficiently, in terms of fast computational speed and savings of computer memory. In this contribution, a modified algorithm for the wavelet evaluation of Stokes?s integral is presented. The same modified algorithm is also applied to the evaluation of the Vening Meinesz and terrain correction integrals, whose kernels have stronger singularities than that of Stokes?s kernel. Numerical examples illustrate the efficiency and accuracy of the wavelet methods.

KMS2002 GLOBAL MARINE GRAVITY FIELD, BATHYMETRY AND MEAN SEA SURFACE

Ole B. ANDERSEN[1], Per KNUDSEN[1], Steve KENYON[2], Ron TRIMMER[2] ([1]National survey and Cadastre - KMS, [2]National Imagery and Mapping Agency, St Louis, USA)

During the last three years the KMS global marine gravity field has been improved in corporation with National Imaginary and Mapping Agency (NIMA). These improvements have resulted in a release of KMS99 and KMS2001 gravity fields. Especially, the KMS99 gravity field presented a significant improvement in comparisons with marine observations, as well as global coverage within the 82 degree parallels by adding the ERS-ERM data. The subsequent, KMS2001 only resulted in minor improved gravity field modelling. A new revised global high resolution marine gravity field KMS2002 is presented in this Combining this fine-tuning with careful edition of data are expected to improve the KMS2002 gravity field, in particularly coastal regions. Improved resolution and data coverage in particularly ice-covered regions are other improvements which is currently under investigation. The KMS gravity field modelling approach uses the observed sea surface height anomalies relative to EGM96 and converts these into gravity using FFT techniques. For the KMS2002 focus has been on improved mapping of the intermediate wavelength (100-250 km) of the gravity field using the exact repeat mission data from the TOPEX/POSEIDON and ERS-2 satellite missions. The KMS2002 gravity field is accompanied with a high-resolution bathymetry model and a high resolution mean sea surface.

G03/07P/D-036 Poster 1400-058

ARCTIC ALTIMETRIC GEOID AND GRAVITY FIELD

Ole B. ANDERSEN, Per KNUDSEN (National survey and Cadastre - KMS)

The new global high resolution marine gravity field KMS2002 has been improved in several ways. One of this is improved modelling of the intermediate to long wavelength (100-1000 km) of the gravity field using the exact repeat mission data from the ERS-1 and 2 altimetry in the Arctic Ocean, and modelling of intermediate wavelength (100-250 km) in other regions of the world. Satellite altimetry from the TOPEX/POSEIDON and ERS-2 Exact repeat missions was used for the study. Altimetry indicate large offsets between the altimetric mean sea surface and the EGM96 geoid errors in the Arctic Ocean, the Caspian Sea, the Pacific Trench regions and several other regions, i.e. the Canary Islands in the Atlantic Ocean. GEOSAT altimetry shows a consistent mean sea surface slope of more than 10 meters relatively to EGM96 crossing the Caspian Sea. Assuming that the mean dynamic topography (MDT) is small/neglectable in the Arctic Ocean and the Caspian Sea the observed "mean sea surface" can be turned directly into residual geoid signal and associated gravity field anomalies. In other regions of the world where MDT is known to be present, the MDT can be removed using spherical harmonic function before computing residual geoid signal. Preliminary long wavelength gravity field model from the GRACE satellite mission, will hopefully be available to validate the findings from satellite altimetry.

A MODEL OF GRAVITY FIELD OF THE EARTH COMPILED ON THE BASIS OF ABSOLUTE VALUES OF GRAVIT

Simeon G. KOSTIANEV, Stoyan AVDEV (Dept. of Mathematical Geophysics, University of Mining & Geology)

An optimal point model of the global gravity field has been compiled on the basis of data for absolute values of gravity. It has been composed of point masses. Optimum parameters of the masses have been determined by the least squares method. This model is univalent and stable for the set of data used and provides the best description of the field with the least number of parameters of its sources. It pproximates the used absolute values of the gravity with a mean squared error about 40 mGal, and only for data in the USA territory - 30 mGal. The field of the optimum point model is similar to the field of the rotary elipsoid (the normal gravity field), and the other anomalies - to the free air anomalies. An advantage of the point model of the global field of the Earth in comparision to the elipsoidal one is its flexibility and higher precision for information processing and its application in geophysics and geodesy.

EVALUATION OF NEWTON'S INTEGRAL IN SPACE AND FREQUENCY DOMAIN

Michael KUHN[1], Kurt SEITZ[2] ([1]The Western Australian Centre for Geodesy, Curtin University of Technology, [2]Geodetic Institute, University of Karlsruhe, Germany)

Newton´s integral can be evaluated either in space domain by a direct integration approach or in frequency domain by a spherical harmonic approach. In the first approach Newton´s integral is evaluated by a discretised numerical integration using the gravitational potential (or its derivatives) caused by regularly shaped bodies such as prisms or tesseroids (i.e. spherical volume elements). In the second approach Newton´s integral is expressed by spherical harmonic expansions of height or density functions, which can be interpreted as the gravitational effect of different mass layers. This paper studies the theoretical and practical differences between these two approaches. Therefore the gravitational effect of the global topographic masses described by a digital elevation model (DEM) is evaluated using both approaches and subsequently compare the results. Hereby the direct integration approach is realized by using the gravitational effect induced by tesseroids. Numerical examples are given for evaluation points located directly on the Earth´s surface and at different heights (e.g. flight levels) above it.

CONCEPTS OF A REGIONAL GEOID DETERMINATION OUT OF MASS MODELS

Urs MARTI (Swiss Federal Office of Topography)

The Swiss geoid CHGEO98 is in use now for several years. It is a combined solution of astro-geodetic, gravimetric and GPS/leveling measurements. Its accuracy of about 3 cm could be verified in most regions by many new measurements (mainly GPS/leveling) after the calculation of CHGEO98. But despite of this high accuracy there remain some systematic differences between gravimetry and the deflections of the vertical on one side and GPS/leveling on the other side that reach maximal amounts of about 7 cm. These differences generally show a north-south trend but also some local effects. They are supposed to be a consequence of weaknesses in the geoid solution rather than of systematic errors in leveling or GPS. Therefore new efforts aim to improve the national geoid model. One part is the introduction of new measurements (gravimetric, astro-geodetic and GPS-leveling) in poorly covered regions or in areas where local discrepancies appear. Another part is the improvement and introduction of new mass models into the geoid determination. In the solution CHGEO98 the principal models, besides of a few local density models, were a 25 meter DEM and a model of the crust-mantle boundary (Moho). Both models only were available for a limited area of about 50 to 100 km around the country. This limitation most probably leads to long wavelength errors of the geoid. Our new models practically cover the whole earth. This should reduce the global trends in the error of our solution and together with improved local 3D density models should bring us a step forward in the determination of a ´Newtonian´ geoid out of mass models only. The poster shows the concept of the new geoid (CHGEO2003) and the first results which are mainly the effects of the newly introduced mass models such as global DEM, density models and Moho, but also the atmospheric effect and the influence of local density anomalies.

ON THE NUMERICAL SOLUTION OF PARAMETERS OF THE LEAST SQUARES MODIFICATION OF STOKES' FORMULA

Artu ELLMANN (Geodesy Group, Department of Infrastructure, Royal Institute of Technology)

In regional gravimetric geoid determination, it has become customary to utilize the modified Stokes' formula, which combines regional terrestrial data with a global geopotential model (GGM). The modification of Stokes' formula, originating with M.S. Molodensky, aims to reduce the truncation error that occurs when the area of Stokesian integration is limited to a spherical cap. Over recent decades several modifications of Stokes' formula have been presented, but many of them aim at reducing the truncation error only. With access to a recent high-degree GGM, the truncation error loses some of its significance, and the errors of the geopotential coefficients become more important. One should also consider the erroneous terrestrial data within the integration area. A modification method, proposed by L.E. Sjöberg in 1984 (with later developments), allows least squares minimization the influence of any known or estimated, random or systematic errors in geoid modelling. In this approach, depending on the local gravity data quality, the chosen radius of integration, and the characteristics of the used GGM, the modification parameters s_n vary. This study concerns the numerical computation of the parameters s_n. New satellite gravity missions (i.e. CHAMP, GRACE and GOCE) are expected to improve significantly the accuracy of geopotential models. Of particular interest is the evaluation of the impact of future (i.e. post-GOCE) geopotential coefficients. For this purpose simulated error degree variances are utilized. A set of least squares modification parameters is determined from the system of linear equations, aiming at minimizing of the global mean square error of geoid estimator. Some difficulties may be encountered when practically computing the least squares modification parameters. In particular, for certain parameters the design matrix suffers from numerical ill-conditioning. Therefore, a special regularization procedure must be undertaken to stabilize the numerical solution. In particular, the Philips-Tikhonov regularization method seems to be satisfactory in providing a solution for the modification parameters. Numerical results are presented to illustrate the applicability of the obtained least squares modification parameters in geoid modelling by comparing with GPS-levelling data.

A NUMERICAL COMPARISON OF DIFFERENT ELLIPSOIDAL CORRECTIONS TO STOKES' FORMULA

Artu ELLMANN (Geodesy Group, Department of Infrastructure, Royal Institute of Technology)

Stokes' formula for the gravimetric geoid modelling holds only on a spherical boundary. However, gravity anomalies are observed on the Earth's surface, which can be approximated by an ellipsoid. This suggests that the observed anomaly must be upward or downward continued to a sphere, before Stokes' integral can be applied. This procedure, however, is often neglected in practical computations. The systematic error caused from neglecting the flattening of the ellipsoid may reach several decimetres. Hence, for an accurate geoid model it is important to estimate the effect of the Earth's flattening. Different authors have studied the ellipsoidal correction for the original Stokes' formula. A new solution for computing the ellipsoidal correction for Stokes' formula was recently derived by L.E. Sjöberg. Here the two cases – the original and the modified Stokes' formulas are considered. The new ellipsoidal corrections can also be expressed by means of the spherical harmonics of a GGM, and the new method allows the estimation of the ellipsoidal corrections directly on the geoidal height, which is a computational advantage. In order to assess the applicability of the new approach, this paper describes various methods for computing the ellipsoidal corrections, and compares them numerically. It is notable that the approaches disagree either in their appearance or numerical results. Furthermore, the solutions are given in different coordinate systems (geocentric, geodetic and ellipsoidal) and they are related to various boundaries. Consequently, different approaches are not directly comparable, and some scaling factors need to be introduced. Compared to other approaches the new formulas are much simpler and easier to implement in practical computations. In contrary to the original Stokes formula, the ellipsoidal corrections for the modified Stokes' formula, which combines regional terrestrial gravity data with a global geopotential model (GGM), have received less attention in the geodetic literature. This is caused by the misleading assumption that this correction is negligible. However, the results of numerical investigations demonstrate that the ellipsoidal correction for the modified Stokes' formula may be significant in areas with large gravity anomalies and in higher latitudes.

FAST LEAST SQUARES COLLOCATION WITH FILTERED HETEROGENEOUS DATA IN GEOID DETERMINATION

Kosasih PRIJATNA[1], Roger HAAGMANS[2] ([1]DEOS, Physical, Geometrical, & Space Geodesy, Delft University of Technology, [2]European Space Agency, ESTEC)

The method of least squares collocation has been utilized succesfully ingravity field modelling, especially in geoid determination. A disadvantage in using the method can occur when dealing with large number of data due to the correlation between them. In such situation we have to invert a nearly full matrix of large dimension. It needs much space in terms of computer memory and is very time consuming. The matrix is largely shaped by thesignal covariance describing the signal correlation among data, and assuminga limited or no correlation among the errors. The covariance functions usually used in physical geodesy decay approximately exponentially with distance. By choosing spectral weights (bandpass filters), applying these to the covariance function, and subsequently truncating the function at a certain maximum spatial distance, a sparse covariance matrix can be constructed. Having such a sparse structure, the matrix inversion can be handled more easily. In this paper, the application of the above mentioned algorithm on localgeoid determination for Indonesian region will be described and investigated. The geoid determination is based upon combination of heterogeneous data types for a kind of multi-resolution solution. The data are global geopotential model, GOCE´s vertical gravity gradients, and terrestrial or airborne gravity data.

THE DETERMINATION OF A PRECISE GEOID FOR PARANA STATE, BRAZIL

Marcia C.L. QUINTAS, Vivian FERNANDES (Department of Geomatics, Federal University of Parana)

Geoid determination is one of the most fundamental problems in geodesy. The precise model of the geoid not only enable us to transform satellite-derived heights to physically meaningful heights based on The Earth's gravity field, but also plays an important role in geophysics and oceanography. The intention of this paper is to construct a regional geoid on the basis of gravity anomalies in Parana State, Brazil. In order to achieve this goal, a database was designed to integrate gravity and topographic data, as well as their attributes. Those data have been collected in Parana State and surroundings by different organizations, such as Federal University of Parana (UFPR), Sao Paulo University (USP) and Energy Company of Parana State (COPEL) since 1985. This study comprises: the preparation of terrestrial gravity and terrain data; the use of appropriate geodetic datum during gravity data reduction; the selection of the best fitting global geopotential model; the application of the gravimetric terrain corrections; the gridding of the gravity anomalies prior to geoid computation; and comparisons of a preliminary Parana State gravimetric geoid solution with geometrical control, provided by Global Positioning System (GPS) measurements in conjunction with leveling data. This study also uses a geographic information system (GIS) to overlay different kind of maps. The GIS database constructed for this work includes graphic and nongraphic data. They are stored in conventional alphanumeric formats and linked with GIS technology.

DETERMINATION AND EVALUATION OF SHENZHEN GEOID, P.R.CHINA

Zhicai LUO[1], Jinsheng NING[1], Zhanji YANG[2], Yongqi CHEN[3] ([1]School of Geodesy and Geomatics, Wuhan university, [2]Land Planning Department of Shenzhen, Shenzhen 518028, P.R.China, [3]Department of Land Surveying and Geo-Informatics, The Hong Kong Polytechnic University)

The geoid of Shenzhen with one-kilometer resolution, has been constructed with remove-restore technique using the following data: (1) 65 GPS/leveling data with the accuracy better than 2 cm and about 10 kilometers average station interval, (2) 3608 gravity data on land with the accuracy better than o.1mGal and one-kilometer resolution, (3) 1262 gravity data on sea with the accuracy of 1.6mGal and one-kilometer resolution, (4) 343 gravity data in Hong Kong with 2-4 kilometers resolutions, (5) digital terrain model with 100m resolutions covering the whole territory of Shenzhen, and (6) earth's gravity field model WDM94 as reference model. Then the modeled geoid heights were compared with the observed ones derived from 29 GPS/leveling data with the accuracy better than 2cm that not applied to the construction of Shenzhen geoid. The test results show that the standard deviation of the differences is ±1.4 cm, and that the overall relative accuracy is better than 10-6.

USE OF STOCHASTICALLY MODIFIED KERNELS IN AUSTRALIAN GRAVIMETRIC GEOID COMPUTATION

Will FEATHERSTONE[1], Lars SJOBERG[2] ([1]Western Australian Centre for Geodesy, Curtin University of Technology, [2]Department of Infrastructure, Royal Institute of Technology)

Gravimetric geoid models of Australia have been computed using a combination of the EIGEN2 and EGM96 global geopotential models, the 2001 release of the Australian land gravity database, the version 2 GEODATA 9 arc-second digital elevation model, and GMGA02 satellite altimeter-derived marine gravity anomalies. Residual geoid undulations were computed using the 1D-FFT technique with the spherical Stokes kernel and two stochastically modified kernels: Wenzel's spectral combination and Sjöber's biased least squares modification. Attempts were also made to optimise the integration radius using a nation-wide set of 1013 GPS-levelling data. This paper will present a summary of the theory used, and the results of comparisons of the various gravimetric geoid models, for different kernel modifications and cap radii, with GPS-levelling data on the Australian Height Datum.

THE CHAMP DATA FOR GEOID STUDY IN INDONESIAN REGION

Adolfientje KASENDA[1], Bill KEARSLEY[1], Av OLESEN[2] ([1]SCHOOL OF SURVEYING, UNSW, [2]National Survey and Cadastre - Denmark)

To date, every Indonesian gravimetric geoid has suffered from the inaccuracy and poor coverage of the gravity information within the region. The 1981 geoid model which was based on the global Marsh and Chang geoid model was reported to have ±5 m accuracy. The INDGED96 computed from the available terrestrial data in combination with the potential model OSU91A improved the accuracy to ±1.5 m or better, at least in the western parts of the country.With the advent of new global geopotential models based upon satellites launched specifically for gravity field studies, our understanding of the regional gravity field in this region should improve significantly, especially in the long to medium wavelengths. In order to test these expected improvements, we analyse the results from the newly released global coefficient potential - Eigen2, derived from the orbit analysis of the gravimetric satellite CHAMP. These parameters (gravity anomalies, geoid heights) are evaluated and compared to those derived from the existing terrestrial data, and from EGM96. We find that Eigen2 model still has severe deficiencies in this area, in some regions showing a bias of more than 200 mGal over an area of 5 degrees. The associated geoid heights are also compared to EGM96 geoid model and to GPS/Leveling results at control points, and show similar large discrepancies.

G03/07P/D-047   Poster   1400-069

DEVELOPMENT OF A HIGH RESOLUTION HEIGHT REFERENCE SURFACE FOR GERMANY USING GRAVITY AND GPS/LEVELLING DATA

Heiner DENKER[1], Johannes IHDE[2], Juergen MUELLER[1], Uwe SCHIRMER[2] ([1]Institut fuer Erdmessung, Universitaet Hannover, [2]Bundesamt fuer Kartographie und Geodaesie)

Two methods are investigated for the computation of a high resolution height reference surface (quasigeoid) for Germany using gravity and GPS/levelling data. Both methods are based on the remove-restore technique and use the global geopotential model EGM96, point gravity data with a spacing of a few km, a digital terrain model and GPS/levelling control points. The first method uses a two-step procedure. First, the gravity and terrain data are combined with the global geopotential model using the least squares spectral combination technique with integral formulas. Then a smooth corrector surface is developed from the GPS/levelling data by least squares collocation, including a signal and a trend component. The corrector surface is added to the gravimetric quasigeoid, giving the final height reference surface that is consistent with the GPS and levelling data in Germany. The second method is based on a common adjustment of the EGM96 reduced gravity and height anomaly observations using point masses and appropriate weight relations. The point masses are arranged at depths of 5 km, 30 km and 200 km. Both computation techniques are studied from the methodological and numerical point of view. The results are intercompared and discussed. The agreement of both techniques is at the cm level. The final result from this project shall serve as a standard for the transformation of GPS heights into levelling heights in Germany.

STRATEGIES FOR A NEW EUROPEAN GEOID COMPUTATION

Heiner DENKER[1], Riccardo BARZAGHI[2], Rene FORSBERG[3], Ambrus KENYERES[4] ([1]Institut fuer Erdmessung, Universitaet Hannover, [2]Politecnico di Milano, Istituto di Topografia, [3]National Survey and Cadastre, Geodetic Division, Copenhagen, [4]Inst. of Geod., Cart. and Remote Sensing, Satellite Geodetic Observatory, Budapest)

Continental-scale (quasi)geoid models are nowadays required with an accuracy at the 1 cm level in order to meet the demands of geodesy (especially GPS heighting), geophysics, oceanography and engineering. Since 1990, the development of a high resolution (quasi)geoid model for Europe is supported through the International Association of Geodesy (IAG), Gravity and Geoid Commission, Subcommission Europe, with the Institut für Erdmessung (IfE) serving as a computing center in this project. Within the new structure of the IAG, it is planned to setup a working group within the framework of the International Gravity Field Service (IGFS) in order to continue this work and to support the derivation of an improved (quasi)geoid model for Europe. The most recent European geoid and quasigeoid model EGG97 was published in 1997. The model has an accuracy at the cm level over distances up to a few 100 km in areas with a good data coverage and accuracy, while long wavelength errors of about 0.1 to 1 ppm exist in many regions. These long wavelength errors are coming from the inaccuracies of the underlying global gravity field model and systematic errors in the terrestrial data. Furthermore, high resolution gravity field data is lacking in the EGG97 model for many countries in East Europe and in some marine areas. Hence, the accuracy of the EGG97 model is not homogeneous. Several improvements of the European geoid and quasigeoid model EGG97 appear to be possible now or in the near future. Such improvements comprise the use of better global gravity field models from the new satellite gravity field missions, new terrain data sources (e.g., GTOPO30, SRTM), updated or new terrestrial and airborne gravity data sets (e.g., Arctic Gravity Project, regional geoid projects in the Nordic and Mediterranean areas), the optimal merging of ship and altimetric gravity anomalies, the inclusion of GPS/levelling data, and improved gravity field modelling techniques. In order to make an update of the existing European (quasi)geoid model possible, international cooperation with persons and institutions all over Europe is essential. The poster outlines the status and possible improvements of the European (quasi)geoid, and shall serve as a basis for discussions with interested people.

IMPROVING LOCAL GEOID MODEL OF TAIWAN USING TWVD2001 GPS/LEVELING DATA

Kwo-Hwa CHEN, Ming YANG, Kun-Shu CHANG (Department of Surveying Engineering National Cheng Kung University)

From 2000 to 2003, a new national vertical datum, Taiwan Vertical Datum 2001 (TWVD2001) has been established. The datum was built by combining the observations of geodetic leveling; Global Positioning System (GPS) and surface gravity collected at 2065 newly established benchmarks within a network of 4500-km first-order leveling lines. The existing local geoid model of Taiwan was calculated using observations of sea surface gradients derived from satellite altimetry, land gravity anomalies, ship gravity anomalies, and the EGM96 model. The accuracy of this model was approximately ± 20~30 cm. In this study, the GPS/leveling data within the TWVD2001 network was used to improve the accuracy of the local geoid model of Taiwan using the least-squares collocation (LSC) technique. The results were then compared with independent, near-fault GPS/leveling data obtained from 223 GPS monitoring points and leveling benchmarks in 232-km leveling lines. Comparison results show that the accuracy of the improved model has reached ± 10 cm.

COMBINING TERRESTRIAL AND MARINE GRAVITY FOR GEOID MODELLING IN VENEZUELA

Gustavo A. ACUNA[1], Wolfgang BOSCH[2] ([1]Laboratorio de Geodesia Fisica y Satelital, La Universidad del Zulia, [2]Deutsches Geodätisches Forschungsinstitut (DGFI))

For the region 285°E-305°E and 0°N-20°N, covering the territory of Venezuela, a new geoid model with a resolution of 1´x1´ has been derived through the combination of terrestrial and marine gravity anomalies. The EGM96 geopotential model was used as reference for the large-scale structure of the regional gravity field. High resolution digital elevation models were taken to compute the topographic corrections. The marine gravity anomalies were obtained from multi-mission satellite altimetry, combining data of Seasat, Geosat, ERS-1, ERS-2, TOPEX/Poseidon and GFO. The mean water level of the POCM model was used to correct the marine geoid for ocean dynamic heights. Overall, more than 6 million data points were used. Least Squares Collocation was used for the gridding of residual gravity anomalies. In order to solve the Stokes integral Fast Fourier Transform in spherical approximation was applied. Comparison to previous geoid models suggest that the new model provides an essential improvement. Independent evaluation with precise GPS positioning and leveling indicate that the precision of the new geoid model is better than three decimeter.

COMPARISON OF NEW GEOID MODELS AND EIGEN-2S IN THE NORTH ATLANTIC REGION

Ove Christian Dahl OMANG[1], Rene FORSBERG[2], Gabriel STRYKOWSKI[2] ([1]Department of Mapping Sciences, Agricultural University of Norway, N-1432 AAs, Norway, [2]Geodynamic Dept., National Survey and Cadastre (KMS), Rentemestervej 8, DK-2400 Copenhagen NV, Denmark)

As a result of the dedicated gravity satellite missions CHAMP, GRACE and GOCE new geopotential models will arive. These models are expected to give a better representation of the long wavelength part of the Earths gravity field than previous geopotential models. A two step test procedure was executed to verify the quality of the EIGEN-2S geopotential model compared to the EGM96 model. Our test area covered the North Atlantic Sea region, including the Greenland Sea and the Norwegian Sea. The verification of the geopotential models and the creations of the new geoid models were split into a two step procedure.In the first step, a set of geoids, based on the geopotential models only, were created by varying the spherical harmonic degree, n_{max}.In the second step, a gravimetric geoid was produced by combining the *best* geopotential model and available gravity data. A set of these geoids were created by varying the truncation degree in the Stokes function. The resulting geoids were compared to GPS networks in the Nordic countries and to mean sea surface height (MSSH) data from ERS-2, TOPEX/POSEIDON and GFO missions over the ocean. Results from the first step show that the EIGEN-2S geopotential model give better fit to GPS and MSSH than EGM96 up to degree 50.Results from the second step show similar features as in step 1 but not that evident. Gravimetric geoids using EIGEN-2S as a reference model give better fit to the GPS and GFO MSSH data up to degree 20 and for ERS-2 up to degree 60.

RGQG-2003: THE NEW GEOID AND GRAVITY FIELD MODEL FOR TERRITORY OF RUSSIA AND SEA AREAS AROUND RUSSIA

Petr P. MEDVEDEV[1], V. NEPOKLONOV[2] ([1]Geophysical Center of Russian Academy of Sciences, [2]29 Research Institute of the Defence Ministry RF, Moscow, Russia)

The remove-restore procedure with the newly created geopotential model as reference field complete up to degree and order 360 was used for computationof the detailed quasigeoid for land territory and sea areas around Russia. The numeric model of the Russian Gravimetric Quasigeoid – 2003 (RGQG-2003)obtained in 2003 is the grid of quasigeoid height values over common reference ellipsoid calculated with latitude (B) and longitude (L) spacing of 5´ for 40°<B≤90°, 26°≤L≤192°. The computations were based on a data set consisting of 5'x 5' mean gravity anomalies and topography information of updated geodesy, satellite altimetryand gravity data base. The topography data were represented by detailed digital terrain model. The structure of the data base and processing system presented. The gravimetric geoid heights was compared with heights obtained by GPS-leveling and European geoid EGG97 for western region of Russia. The comparison with geoid heights derived from recent geopotential models and satellite altimetry data was made as well. The Russian Gravimetric Quasigeoid – 2003 (RGQG-2003) will be accessible via Geophysical center RAS web-server. The present state and future opportunitiesare considered. The research is supported by RFBR (Project 01-07-90106).

ON THE PRECISE CONVERSION BETWEEN GEOID AND QUASI-GEOID

Shaofeng BIAN[1], Jianhua XU[2] ([1]Department of Engineering, Navy University of Engineering, [2]Bei Sanhuanzhonglu 69, Beijing 100088)

Geoid and Quasi-geoid are two important reference surfaces in physical geodesy,The conventional conversion was discussed in the book of Physical Geodesy writtenby Haiskanen and Moritz. This conversion is not adequately accurate. We follow theidea presented by Sjoeberg and presented a more accurate conversion.

REFINED COMPUTATION OF THE (QUASI)GEOID MODEL FOR COLOMBIA USING THE NEW GRAVITY SATELLITE MISSIONS

Laura SANCHEZ (Instituto Geografico Agustin Codazzi, Bogota, Colombia. Presently at the Dresden University of Tecgnology, Germany)

In Colombia, the comparison of GPS-derived geoid undulations with gravimetric geoid models presents still discrepancies in the decimetre-level. To find the origin of these discrepancies a new gravimetric (quasi)geoid model is computed. The available local (terrestrial, aerial) gravity observations were re-processed in order to avoid possible inconsistencies in the short wave components. The result is a homogeneous set with approximately 80 000 gravity points. The long wavelength component is calculated using a global gravity model derived from the new satellite missions. Since the topographic and geological features in Colombia are very complicated, the formulation of mass distribution hypothesis to geoid and orthometric height computation is too difficult. In the same way a quasigeoid model is estimated. The gravimetric geoid undulations (and height anomalies) are compared with those obtained from combining ellipsoidal heights from GPS and orthometric (or normal) heights from spirit levelling.

NKG-2003 GEOID MODEL OF THE NORDIC AND BALTIC AREA

Rene FORSBERG[1], Gabriel STRYKOWSKI[1], Dag SOLHEIM[2], Harli JURGENSON[3] ([1]Kort & Matrikelstyrelsen, Rentemestervej 8, DK-2400 Copenhagen NW, Denmark, [2]Geodetic Division, Statens kartverk, Kartversveien 21, N-3511 Honefoss, Norway, [3]Estonian Agricultural University, 51014 Tartu, Kreutzwaldi 64, Estonia)

A new geoid model of the Nordic/Baltic area have been made, using spherical FFT methods and terrain reductions, similar to the earlier geoid model NKG96. A number of new data sources have been incorporated, especially in Norway, Sweden, around the Baltic Sea, and in the interior Danish waters and northern Germany. The model incorporates the NKG airborne gravity survey of the Baltic Sea 1999, and large geoid changes are evident due to this survey, especially in the marine regions. The geoid is compared to GPS-levelling data, and a local geoid is fitted to GPS in Denmark as an illustration of an operational regional cm-level GPS geoid.

NEW GEOID COMPUTATIONS IN TAIWAN

Gwo-Chyang TSUEI (Department of Civil Engineering, National I-LAN Institute of Technology, Taiwan)

With the rapid expansion applications of GPS positioning and the improvement of positioning accuracy. There is a demanding need for an unified gravimetric geoid of high accuracy. It can be used together with the GPS-derived heights to provide orthometric heights. A new, high-resolution and high-precision geoid has been computed for the Taiwan area, ranging from 21.55 ° N to 25.50 ° N in latitude and 119.50 &deg E to 122.45 &degE in longitude. Using EGM96 geopotential model, 3 ' * 3 ' mean gravity anomaly grid and digital terrain model carried out the computations. The remove-restore technique was adopted for the computation of terrain effect by Helmert's condensation reduction. The contribution of the local gravity data to the geoid was computed strictly by the ID-FFT technique, which allows for the evaluation of the discrete spherical Stokes' integral without any approximations. In this study, we compared the difference of the geoid undulations computed by 2D spherical FFT and ID spherical FFT method. We also tested the adapt ability of using EGM96 to calculate the gravitational quantities in the region of Taiwan. The terrain effects on the geoid computation were also studied. The comparison of the gravimetric geoid with GPS/leveling-derived undulations shows the RMS is less than 10cm.

SATELLITE-TO-SATELLITE TRACKING IN HIGH-LOW MODE:RELATIONSHIPS AND FEATURES

Rafael A. KASCHEEV (Department of Astronomy, University of Kazan)

Future prospects for developing comprehensive planetary gravity models will depend on the new satellite techniques. Several satellite gravity field mapping missions, such as CHAMP, GRACE, GOCE, SELENE are on the way in order to improve the terrestrial and lunar gravity fields with high resolution. The satellite-to-satellite tracking (SST) which measure the effect of the potential difference on a satellite pair is expected to be able to determine the gravity to a greater accuracy than is feasible by the classical approach of satellite geodesy. At this takes place, not only the static part of the gravity field can be determined with unattained accuracy also some temporal effects can be detected. The concept of SST is possible either in the low-low (GRACE) or in thehigh-low (CHAMP, SELENE) modes. In the later case only one satellite is placed into a low orbit while the other satellite describe orbits with high altitudes. Intersatellite range-rate data measure the difference between the velocity perturbations along the direction of the intersatellite range in the process. This study is concerned with gravity field recovery from high-low satellite-to-satellite relative line-of-sight (LOS) velocity measurements transformed into LOS accelerations through numerical differentiation procedure. This allows to construct an observation equation of HL SST LOS velocities in terms of observation equation of LOS acceleration. A brief description of the solution used here is the following. Based on reported observation equation of LOS acceleration a transformation into the local reference frame is performed. This frame whose principal plane contains both satellites is rotating with respect to the planetary center of mass. Appropriate harmonic coefficients related to each local orbital configuration at each point in time are lumped coefficients. These lumped coefficients would constitute linear combinations of the harmonic coefficients of the gravity potential model compatible with inertial reference frame. To search for an orbital configuration provides most accurate gravity parameters a number of plausible orbits are considered. Using the proposed model least squares error analysis is performed by computer simulation. The results of this analysis indicate that a significant improvement in the errors of gravity parameters are obtained when the satellite orbital planes are considerably separated. Namely, it is desirable to pick the difference in inclination of two orbital planes between 30°-50°. It also shown that the positions of both satellites must be known with sufficient accuracy, for that purpose appropriate measurements (using GPS, for example) remain to be made. Furthermore, it was found that the uncertainty in a reference gravity model is the main error source using SST method. The work was supported by Ministry of Education of Russian Federation, Grant E00-7.0-4.

GOCE GRAVITY FIELD RECOVERY

Hans SUENKEL[1], Roland PAIL[2], Peter PESEC[1] ([1]Space Research Institute, Austrian Academy of Sciences, [2]Graz University of Technology, Dept. Theoretical Geodesy)

The European Space Agency is preparing for its first dedicated gravity fieldmission GOCE (Gravity Field and Steady-state Ocean Circulation Explorer) witha proposed launch in 2006. The mission´s goal is the mapping of the Earth´s static gravity field with a very high resolution and utmost accuracy on a global scale. GOCE is a drag-free mission, flown in a circulate and sun-synchronous orbit at an altitude between 240 and 250 km. Each of the two operational phases will last for 6 months. GOCE is based on a sensor fusion concept combining high-low satellite-to-satellite tracking (SST) and satellitegradiometry (SGG).The transformation of the GOCE sensor data into a scientific product of utmost quality and reliability requires a well-coordinated effort of experts insatellite geodesy, applied mathematics and computer science.The central issue of GOCE data processing is the determination of the globalgravity field model using three independent mathematical-numerical techniqueswhich had been designed and pre-developed in the course of several scientificpreparatory studies of ESA:1. The direct solution which is a least squares adjustment technique based on   a pre-conditioned conjugated gradient method (PCGM). The method is   capable of efficiently transforming the calibrated and validated SST and SGG observations directly or via lumped coefficients into harmonic coefficients of the gravitational potential.2. The time-wise approach considers both SST and SGG data as a time series. For an idealized repeat mission such a time series can be very efficiently transformed into lumped coefficients using fast Fourier techniques. For   a realistic mission scenario this transformation has to be extended by an iteration process.3. The space-wise approach which, after having transformed the original   observations onto a spatial geographical grid, transforms the pseudo- observations into harmonic coefficients using a fast collocation technique.A successful mission presupposed, GOCE will finally deliver the Earth´s gravity field with a resolution of about 70 km half-wavelength and a globalgeoid with an accuracy of about 1 cm.

EVALUATION OF GRAVITY DATA BY EIGEN-1S MODEL IN CHINA

Yang LU, Hongling SHI (Key Laboratory of Dynamic Geodesy, Institute of Geodesy and Geophysics, Chinese Academy of Sciences)

Plan along with the satellite gravity field missions of puts into practice and provided the powerful research tool for the research of the Earth gravity field, the high accuracy global gravity field models derived from the satellite gravity missions CHAMP, GRACE and GOCE are expected to significantly improve the gravity field in terms of a homogeneous and high accuracy and resolution. To date the CHAMP mission has led to a new global long wavelength gravity field model called EIGEN-1S, which firstly adopted the satellite to satellite tracking techniques. The model has the ability to study long wavelength errors of the terrestrial gravity data. First the long wavelength gravity field components will be studied based on the EGM96 model and the EIGEN-1S model. Second we utilize the 2D Gaussian low-pass filter to distill the long wavelength components of the terrestrial gravity data, including mainland gravity anomalies, marine gravity anomalies and gravity anomalies derived from satellite altimetry, for China and its vicinity. The gravity data will be devoted to study the long wavelength agreement between the terrestrial data and the global models. The results shown that the global gravity field models EIGEN-1S and EGM96 are consistent up to about degree 36, while above this degree the EIGEN-1S may have inferior estimates. The evaluation of the terrestrial gravity data for China by comparison with the EIGEN-1S model has confirmed the existence of larger errors and systemic discrepancy. The majority of larger errors appear in the Northwestern and the Tibet plateau of China, the maximal long wavelength error achieves 28mGal. It was found apparent inconsistencies between the EIGEN-1S model and altimeter data on the Northwestern Pacific, which a mean discrepancy on long wavelength component is about 2.5mGal and increase about 4.0mGal in offshore. The reasons for the revealed errors may be traced back to lacking or poor quality gravity data, especially in the Western mainland of China, while in offshore we suspect datum inconsistencies or errors in the ship surveying data and satellite altimeter data.

CHAMP GRAVITY FIELD MODEL UCPH2003_01

Carl Christian TSCHERNING, Eva HOWE, Lars STENSENG (IAG)

The German CHAlleging Minisatellite Payload (CHAMP) was launched in July2000. It carries a GPS reciever and a three-axes accelerometer.From GPS meassurements a precise orbit of the satellite in August 2001 hasbeen determined by DEOS at TU Delft.With these orbits and pre-processed accelerometer data it has been possible todetermine a global gravity field model to degree and order 90. The gravity fieldmodel has been determined using least squares collocation and by consideringenergy conservation.The satellite loses kinetic energy due to external forces. The tidalpotential from the sun and the moon, energy dissipation and the explicit timevariation of the gravitational potential in inertial space are taken intoaccount.

THE IMPACT OF THE NEW MISSIONS DATA IN THE DEVELOPMENT OF FUTURE GRAVITY MODELS

Errico C. PAVLIS (JCET/UMBC - NASA/GSFC)

JCET is contributing to NIMA's current effort to enhance the geopotential model underlying the World Geodetic System 84 (WGS 84), and in particular, with the incorporation of data from new missions such as CHAMP and GRACE at present, and GOCE in the future. One of the many enhancements that the new development incorporates is the modeling of temporal variations for the long wavelength components of the field, in order to avoid aliasing of these signals and a consequent degradation in the quality of the new model. The Terrestrial Reference Frame (TRF) plays an important role in the multi-technique monitoring of temporal variations in the gravitational field and its very low degree and order components, as well as changes in the inertia tensor as a result of angular momentum exchanges in the Earth system. Currently, and until we accumulate several years of GRACE data, the best data source for determining these variations are satellite laser ranged geodetic targets (such as the LAGEOS, ETALON, AJISAI, STARLETTE, STELLA, etc.). We are now routinely analyzing Satellite Laser Ranging (SLR) data from ETALON 1 and 2, along with our nominal data set from LAGEOS and LAGEOS 2 for this effort. While the data from these satellites provide the definition of the underlying TRF, its crust-fixed orientation, and the temporal variations in the long wavelength, the detailed components of the gravitational model will be primarily determined from the data of dedicated missions such as CHAMP, GRACE, and GOCE in the future. We present here preliminary results of a new analysis of our expanded data set for the definition of the long wavelength harmonics of the geopotential. The data

were reduced using NASA Goddard's GEODYN/SOLVE II software. We will discuss our solution and compare with other solutions based on data from new missions alone, or in combination with other satellite and surface gravimetric data.

COMPARISON OF DIFFERENT DOWNWARD CONTINUATION METHODS OF AIRBORNE GRAVIMETRY DATA

Felix MUELLER (Institut of Theoretical Geodesy, University of Bonn)

The determination of the precise gravity field and the geoid represents a central task in geodesy. Despite the fact that spaceborne gravity field missions such as CHAMP, GRACE and GOCE will improve our knowledge of the Earth's gravity field in the short, medium and long wavelength parts in the near future, it is necessary to supplement this gravity field information with available terrestrial data and additional measurements in those areas where no gravity field information is available or where its precision is not sufficient. In this matter airborne gravimetry provides a fast and reliable method especially for those regions which are difficult to access. With respect to the spectral representation of the gravity field airborne gravimetry is capable to fill the gap in the range of wavelength between 1 and 50km. With current airborne gravity systems an accuracy of 2 to 3 mGal (rms) with a resolution of 6 to 15km can be achieved and has been proven by experiments. Data processing becomes more significant to meet the demands for a geoid with centimeter-accuracy. Besides the task of preprocessing which results in band-limited gravity disturbances at flight level, the choice of a proper downward continuation method gains in importance. In general the downward continuation is an improperly posed problem and requires regularization, which in principle results in filtering the noise. Regularization is indispensable in satellite geodesy and some effective techniques have been proposed. Nevertheless, various questions are still open and no satisfying procedure exists how to scale the regularization parameter which rules the balance between noise and signal. In case of airborne gravimetry especially in those cases where the airplane cruises at relatively high altitudes even more questions are still open. In this investigation different downward continuation methods are compared and the impact of regularization of airborne gravimetry data is shown. It is investigated whether it is useful to apply a filtering technique in a subsequent post processing step. The investigations are based on simulated data sets to control the results and applied to a real test area.

EFFICIENT CALCULATION OF TOPOGRAPHIC REDUCTIONS BY THE USE OF TESSEROIDS

Kurt SEITZ, Bernhard HECK (Geodetic Institute, University of Karlsruhe)

The calculation of topographic reductions is one of the most time-consuming operations in geoid and quasi-geoid calculation as well as ingeophysical interpretation of the gravity field. A new procedure, based on so-called tesseroids (volumetric mass elements bounded bygeographical grid lines and surfaces of constant heights), has been further developed. The formulae describing the potential and theattraction of spherical tesseroids is shortly reviewed; the respective volume integrals are solved by Taylor expansions of 3rd order. Testcomputations show the high numerical efficiency of this method in comparison with the generally used prism formulae. Exploiting theproperties of this approach provides further refinements, e.g. in considering ellipsoidal tesseroids.

DISCUSSION OF BOUGUER ANOMALY

Petr VANICEK[1], Robert TENZER[1], Lars E. SJOBERG[2], Zdenek MARTINEC[3] ([1]Department of Geodesy and Geomatics Engineering, University of New Brunswick, [2]Division of Geodesy, Department of Geodesy and Photogrammetry, Royal Institute of Technology, [3]Department of Geophysics, Faculty of Mathematics and Physics, Charles University in Prague)

In this paper we attempt to answer some of the questions that people started to ask recently. These were: Is the spherical version of the complete Bouguer anomaly the same as the standard planar version? How can the complete Bouguer anomaly be continued downward to the geoid from the surface of the earth? Is the complete Bouguer anomaly harmonic above the geoid? In order to answer these, and other questions, we have had to go back to the very basic principles and definitions of the theory of gravity field. We had to introduce the distinction between solid" (defined in the 3-D sense) and "surface"(defined in the 2-D sense) gravity anomalies, and show how these two are related. Then we showed that the spherical complete Bouguer anomaly is quite different from the standard variety. While the spherical kind is indeed harmonic above the geoid, the standard kind is not. While the spherical kind can be continued from the surface of the earth down to the geoid using the Poisson approach, the standard kind cannot.

RIGOROUS ORTHOMETRIC HEIGHT

Petr VANICEK, Robert TENZER, Marcelo SANTOS (University of New Brunswick, Department of Geodesy and Geomatics Engineering)

In this paper, a rigorous definition of the mean value of gravity along the plumbline is formulated. The mean gravity along the plumbline is evaluated as a sum of the mean value of gravity generated by earth's masses within the geoid and the mean value of the gravitational attraction generated by topographical masses. By removing the gravitational attraction of topographical masses from the gravity generated by the whole earth, the gravitational field above the geoid becomes harmonic.Approximating the geoid by the geocentric reference ellipsoid, the geoid-generated gravity,i.e.,the No Topography gravity"(Vaníček et al., 2003), is split into the normal gravity and the "No Topography gravity disturbance"(Tenzer and Vaníček, 2003). The mean "No Topography (NT) gravity" is then evaluated as a sum of the mean values of the normal gravity and the NT-gravity disturbance along the plumbline. The mean value of the NT-gravity disturbance along the plumbline is evaluated through upward continuation of the NT-gravity disturbances referred to the geoid in the "No Topography space" Applying the Poisson theory, we solve Dirichlet's boundary value problem for each point between the earth surface and the geoid along the plumbline to obtain individual point values. Then we perform the integral averaging of all these values to get the desired average. Alternatively, when the NT-gravity disturbances are known on the earth surface, Dirichlet's inverse problem is solved to obtain the mean NT-gravity disturbance. To the average of geoid-generated gravity we add the average of gravitational attraction generated by topography. The gravitational attraction of topographical masses is computed for each point along the plumbline by means of Newton's integral over the topographical masses around the world and averaged in the integral sense between the earth surface and the geoid. Based on the rigorous definition of mean gravity, the rigorous relation between the orthometric and normal heights is also formulated. Not surprisingly, this relation turns out to be just a function of the mean values of the gravitational attraction of topographical masses and the NT-gravity disturbance along the plumbline.

GRACE LEVEL-1 DATA PROCESSING

Gerhard L. KRUIZINGA, William I. BERTIGER, Kelley E. CASE, Christopher J. FINCH, Larry J.ROMANS, Michael M. WATKINS, Sien C. WU (California Institute of Technology, Jet Propulsion Laboratory)

The beginning of the science processing for the GRACE mission, called Level-1 processing, consists of data reformatting, data compression, editing,and precise time tag alignment based on GPS precise orbit determination for the formation of the dual one way range. This task is performed at the Jet Propulsion Laboratory, California Institute of Technology (JPL) GRACE Science Data System team working in cooperation with the Physical Oceanography Data Active Archive Center (PO-DAAC). In this poster an overview will be given of the data flow from raw telemetry (Level-0) to Level-1 data which is used to estimate gravity fields by the Level-2 processing centers at the Center for Space Research, University of Texas at Austin, Geo Forschungs Zentrum,Potsdam and JPL. Furthermore, the quality control assessment for all dataproducts will be discussed as well as experience gained by processing the GRACE data set. Finally an overview will be given of all science data products to be distributed to the science community and the method of distribution.

THE QUASI-GEOID OF SOUTH AMERICA AFTER ONE DECADE OF IMPROVEMENT ON THE DATA

Denizar BLITZKOW[1], Ana Cristina Cancorro MATOS[1], Maria Cristina LOBIANCO[2], Carlos Alberto Correia CASTRO JR.[2] ([1]Department of Engineering Transportation, University of Sao Paulo, [2]Instituto Brasileiro de Geografia e Estatistica - DEGED)

A very strong and international effort has been made in the last ten years to improve the distribution and quality of the gravity and topography data in order to determine the quasi-geoid of South America. The study has improved the gravity data, digital terrain model (DTM) and GPS observations on the leveling network. Most countries in South America have participated to this challenging study which resulted in an important contribution for the establishment of an altimetric reference for South america that is linked to the quasi-geoid model. In this paper, the activities that have been coordinated by EPUSP and IBGE are described. The work has involved many organizations in Argentina, Brazil, Chile, Colombia, Ecuador, Paraguay, Uruguay and Venezuela. The list of organizations involved in each country are too many to reference, but, include the Military Institutes in most of the countries, Universities and government agencies. Contribution of GETECH - University of Leeds and NIMA are also acknowledged. The study has paid particular attention to the different computation softwares used used to generate the quasi-geoid in order to guarantee a reliably and accurate solution. As a consequence, this presentation compares the different computations. The results of the new computations using the improved coverage data, DTM and softwares are presented and discussed.

GEOIDAL MODEL OBTAINED BY MULTILAYER PERCEPTION NEURAL NETWORK

Paulo Cesar Lima SEGANTINE[1], Tule Cesar Barcelos MAIA[2] ([1]Department of Transportation, University of São Paulo-EESC/USP, [2]Department of Civil Engineering at University Catholic of Goias)

This paper has the goal to show the artificial neural networks as a tool in the geoidal undulation model. In the first part of the project, was developed a neural network applying Multilayer Perception (MLP) technique to estimate the geoidal undulation gave by geopotential model EGM96. It was chosen an area between the -17° and -27° parallels and -43° and -53° meridians. It was determined different geopotential undulation with grade and order equal 50, 70, and 360 of EGM96 to verify the approximation of surface gave by the neural network in relation to the gave by EGM96. For neural network training it was organized a 5'x5ÅEgrid of undulations related with EGM96 and another one 1'x1 Egrid for each surface created to verify the network learning. For each file, containing the input signal and neural network output, it was done four different types of data normalization. It was changed the activation functions types, the numbers of layers and neuron of the artificial network with the intent to get the best result. All the preliminaries results for the geoidal undulations represented by the MLP neural network type has be shown the average differences of 5mm for geopotential models with short grade and order (50 and 70) and extremes errors around 9mm and -7mm in the grid edge. The amplitude of geoidal undulations was from the 6.270m to -12.653m. For he grade and order equal to 360 the mean differences were around 20mm with extreme errors of 17cm and -6cm in the grid edge too. The MLP network used in the surface representation has 747 coefficients. The result

obtained in this research has shown that the artificial neural networks are efficient tools to determine surfaces that do not have a defined mathematical form.

ANALYTIC FORMULAS FOR THE GRAVITATIONAL GRADIENTS GENERATED BY TRIANGULAR VERTICAL PRISMS WITH SLOPED TOPS

Christopher JEKELI, Puttipol DUMRONGCHAI (Geodetic Science, Ohio State University)

Analytic formulas for the gravitational gradients generated by rectangular blocks are well known and routinely used to generate the gradient field from finite element models of the near-field terrestrial masses. We have developed closed analytic formulas for triangular vertical prisms with sloped tops. These can be used to generate the gradients of finite element models produced by a triangulation of a surface. Such finite element models have a continuous bounding surface and thus are smoother than the rectangular block models. It is shown that higher-order smoothness in the model surface yields elliptic integrals for the gradients that, therefore, are not amenable to further reduction to closed analytic expressions. Numerical examples derived from a digital elevation model with constant density are used to compare the generation of gradients due to the triangular-prism and rectangular-block finite element models.

VECTOR AIRBORNE GRAVIMETRY FOR IMPROVED GEOID DETERMINATION

Juan Gilberto SERPAS, Christopher JEKELI (Geodetic Science, Ohio State University)

Airborne gravimetry is now a proven technique to obtain high-resolution geoid undulations with accuracies approaching a few cm, in relative precision. The usual approach relies on the standard solution to a boundary-value problem where the boundary values are the vertical gravity disturbances measured with an airborne gravimeter or accelerometer. We have shown that measuring the horizontal disturbances with an airborne three-dimensional GPS/INS configuration yields the relative geoid using simple line integrals with comparable precision. Combining the vertical and horizontal gravity disturbances naturally improves the solution, especially near the edges of a survey area, where the solution to the standard boundary-value problem is subject to the largest model errors. Both least-squares collocation and Hotine's integral combined with line integrations can be used to obtain the geoid from all disturbance vector components. We apply both methods to derived data as well as observed disturbances collected in the Canadian Rockies (supplied by the University of Calgary).

DETERMINATION OF INDONESIAN GRAVITY FIELD FROM COMBINATION OF SATELLITE ALTIMETER, SURFACE GRAVITY AND DIGITAL TERRAIN MODEL DATA

Leni S. HELIANI, Yoichi FUKUDA, Shuzo TAKEMOTO (Graduate School of Science, Kyoto University)

The Indonesian gravity field have been computed from combination of satellite altimeter, surface gravity, digital terrain model and EGM96 geopotential model data by means of Least Square Collocation (LSC). This is adopted to solve the variability of utilized data. Two spectral methods were also used in sub-area for investigation purposes, and demonstrate that three methods have almost similar results. Comparison with GPS-levelling shows substantial improvement over INDGED96 , the previous geoid model, and depicts the application of local coordinate in leveling data. However, large differences show in comparison with tide gauge data, which mainly due to differences in reference system among the compared data. From connection between the comparison with GPS-levelling and with tide gauge data, suggests the possibility of the present Indonesian height system is higher than the actual by about 1.2 m.

CHALLENGING THE LIMIT IN THE DEVELOPMENT OF A SUPER HIGH RESOLUTION EARTH GRAVITY FIELD MODEL

Kefei ZHANG[1], Yang LU[2], Rod DEAKIN[1], Norm EDWARDS[1] ([1]Department of Geospatial Science, RMIT University, [2]Wuhan Institute of Geodesy and Geophysics, Chinese Academy of Science)

A new Australian regional geopotential model (AGM_RMIT5400) with spherical harmonic coefficients to degree and order 5400 has been developed using the "tailoring" method. The new model incorporates state of the art development in extra-terrestrial gravity field recovery techniques (EIGEN-1S model from the dedicated satellite gravity missions, CHAMP), state of the art satellite information (satellite altimetry, GPS) and other heterogeneous data (land and marine gravity, air-borne gravimetry, local gravimetric geoid and digital terrain model etc.).High-powered computing facilities are necessary in order to perform the intensive computations with the huge amount and variety of data involved and the numerical stability problem. The Victorian Partnership for Advanced Computing (VPAC) high performance computing facility (a 128 processor Compaq Alphaserver SC, with 64 Gbyte of memory and 1.4 Tbyte of disk) is used. The numerical stability of the Legendre function has been investigated using both double and quad precision arithmetic over different areas of the earth. It is demonstrated that the highest degree and order model that can be developed is limited to about 2200 when double-precision arithmetic is used. It is also found that the numerical stability problem occurs around latitude of ±40°. It is demonstrated that a much higher degree and order gravity field model can be developed when quad-precision arithmetic is used. This paper presents the new development of the model (AGM_RMIT5400) including its methodology, new data sources, numerical stability, special computation requirements, limitations and detailed evaluation against "the ground truth data". It is shown that the RMS differences between AGM_RMIT5400 and the mean land gravities and the latest Australian gravimetric geoid (AUSgeoid98) are ±2.62mGal and ±0.14m respectively. It is concluded that the new model offers significant improvements when it is compared with any existing high degree and order models. Further comments regarding a number of challenging issues in the development of a super-high geopotential model are presented.

THE AUSTRIAN GEOIDRECENT STEPS TO A NEW SOLUTION

Norbert KUEHTREIBER[1], Bernhard HOFMANN-WELLENHOF[1], Erhard ERKER[2], Norbert HÖGGERL[2], Erich IMREK[2] ([1]Institute of Geodesy, Graz University of Technology, [2]Federal Office of Metrology and Surveying (BEV), Vienna)

A recomputation of the new Austrian geoid denoted as GEOID2000" has beenfinished and the results will be released soon. GEOID 2000 is a common project of the BEV in Vienna

and the Graz University of Technology, Institute of Geodesy under the umbrella of the Austrian Geodetic Commission. In a first step, all data sets had to be improved. The BEV established a high precision height model with a resolution of 45 x 49 m. Furthermore, the data sets including gravity anomalies, deflections of the vertical, density and satellite data have been updated and checked.The territory of Austria serves as ideal test area for applying different computational methods. At the Institute of Geodesy in Graz, existing methods for the geoid determination were tested with respect to their usability and achievable precision. As a result of the investigations, the remove-restore technique and least squares collocation was used for the computation. Finally, the optimal combination of the geoid solution with geoid heights resulting from GPS-levelling has been investigated. An overview of the computation process and the main results are discussed in the paper.

TOPEX ALTIMETRIC MEAN SEA LEVEL AND GRAVIMETRIC GEOID ON THE NORTH OF ALGERIA

Salem KAHLOUCHE, Ali RAMI, Sid Ahmed BENAHMED DAHO (Laboratory of Geodesy - National Center of Space Techniques)

The mean sea level is processed from Topex altimetric measurements collected on the Algerian coasts (on the South West of the Mediterranean Sea) during a three months period (April 20 to July 28, 2000).The model used, based on the Barrick-85 model, permits the determination of the instantaneous sea surface heights for 80 cycles distributed on 8 orbital arcs.The pre-processing of the raw data (electromagnetic bias, low reflected power,...) permit the selection about 75 % of the measurements. The processing of the fitted data, by polynomial adjustment, is done after the correction of the main disturbed effects (instrumental correction, ionospheric and tropospheric propagation,...) and the reduction of the radial component of the orbital error. The analysis of the mean arcs in the crossing points by the least squares adjustment allows a centimetric accuracy of the mean sea level.The surface obtained was extrapolated to the North of Algeria (surroundings the coasts) and compared to a gravimetric geoid calculated with a set of BGI free air gravity anomalies and GETECH data using the FFT techniques implemented in the Geofour program [Tscherning, 1994].The metric difference obtained is due to the insufficient altimetric and gravimetric data distribution, and to the extrapolation method used. The availability of an exhaustive gravity measurement, particularly the gravity cruise data (sea data), and a long period altimetric measurement, will allow a strong comparison between the surfaces.

ON TOTAL LEAST-SQUARES ADJUSTMENT WITH CONSTRAINTS

Burkhard SCHAFFRIN[1], Yaron FELUS[2] ([1]Department of Civil and Environmental Engineering and Geodetic Science, The Ohio State University, Columbus, Ohio 43210-1275, U.S.A., [2]Department of Surveying Engineering, Ferris State University, Big Rapids, Michigan 49307 - 2291, U.S.A.)

For calibration purposes, oftentimes various datasets are compared in such a way that observations enter the coefficient matrix of a Linear Model ("errors-in-variables"). In such a case, the Total Least-Squares approach would be appropriate that was pioneered by G. Golub and Ch. Van Loan in the early eighties. In essence, rather than solving the usual normal equations system for the estimated parameters, the smallest singular values of a slightly extended system is set to be zero, and its eigenvector is re-scaled to provide the estimated parameter vector. The authors have recently presented their studies that show the potential of this technique to provide improved variograms for geostatistical Kriging applications. Sometimes, however, stability or slow convergence problems may occur with the algorithm as designed so far. In order to increase the stability, additional parameters have been introduced to represent the functional model under investigation, but with a number of constraints that keep the original redundancy unchanged. In the end, the same Total Least-Squares Fit is supposed to result after fewer iterations from the newly developed scheme that, for the first time, allows the integration of constraints between the parameters. A few simple, but typical examples will show the performance of this powerful approach to solving a case that was long considered "untreatable" by the original TLS algorithm.

NONLINEAR FILTERING OF CONTINUOUS SYSTEMS: FOUNDATIONAL PROBLEMS AND NEW RESULTS

Peiliang XU (Disaster Prevention Research Institute, Kyoto University, Gokasho, Uji, Kyoto 611-0011, Japan)

This paper is to extend the work of Xu (1999) on discrete nonlinear filtering to the continuous systems. The new results are summarized as follows: (i) we work out a second order unbiased prediction of the true state governed by a vector stochastic differential equation; (ii) we derive a set of coupled differential equations for a new truncated second order nonlinear filter and its variance-covariance matrix from the frequentist point of view. The new filter is proved to be unbiased to the second order approximation; and most importantly, (iii) comparing our new filtering and accuracy results with the literature on nonlinear filtering has indicated that more than forty years of nonlinear filtering of continuous systems may have had fundamental defect in the foundation.

GNSS BEST INTEGER EQUIVARIANT ESTIMATION

Peter J.G. TEUNISSEN (Department of Mathematical Geodesy and Positioning, Delft University of Technology)

Carrier phase ambiguity resolution is the key to high precision Global Navigation Satellite System (GNSS) positioning and navigation. It applies to a great variety of current and future models of GPS, modernized GPS and Galileo. The so-called 'fixed' baseline estimator is known to be superior to its 'float' counterpart in the sense that its probability of being close to

the unknown but true baseline is larger than that of the 'float' baseline, provided that the ambiguity success rate is sufficiently close to its maximum value of one. Although this is a strong result, the necessary condition on the success rate does not make it hold for all measurement scenarios. In this contribution we will answer the question whether or not it is possible to take advantage of the integer nature of the ambiguities so as to come up with a baseline estimator that is always superior to both its 'float' and 'fixed' counterparts. We will show that this is indeed possible, be it that the result comes at the price of having to use a weaker performance criterion.

SENSITIVITY ANALYSIS FOR GNSS INTEGER CARRIER PHASE AMBIGUITY VALIDATION TEST

Jinling WANG, Hung-Kyu LEE, Steve HEWITSON, Chris RIZOS, Joel BARNES (School of Surveying and Spatial Information Systems, University of New South Wales, Sydney, NSW 2052, Australia)

Global navigation satellite systems have been widely used for many precise positioning and navigation applications. In satellite-based precise positioning, the determination of correct integer carrier phase ambiguities is the key. Therefore much effort has been invested in developing a robust quality control procedure which can validate the ambiguity resolution results. Such a quality control procedure has been traditionally based on the so-called F-ratio Test. A major shortcoming of the F-ratio measure is that its probability distribution is still unknown, which precludes the possibility of defining the confidence level for the ambiguity validation test. To overcome such a shortcoming, a new ambiguity validation test based on the so-called W-ratio Test has been proposed (Wang J. et al., 1998: A discrimination test procedure for ambiguity resolution on-the-fly, Journal of Geodesy, 72:644-653). This paper presents a sensitivity analysis for the new ambiguity validation test based on the W-ratio. The analysis is concerned with the sensitivities of the W-ratio measure to undetected gross errors, unmodelled (remaining) systematic errors, and various specifications in the stochastic models, as well as geometric strength due to a variety of satellite constellations (such as GPS, GPS/pseudolite and GPS/Galileo combinations).

G04/07P/C25-005   1620
GPS ON-THE-FLY AMBIGUITY SEARCH BY FUZZY-LOGIC MULTI-CRITERIA DECISION MAKING TECHNIQUE

Stefan LEINEN (Institute of Physical Geodesy, Darmstadt University of Technology)

On-the-fly (OTF) ambiguity search is the most challenging task in kinematic GPS positioning with high accuracy (few centimetres level). Starting with an approximate position all combinations of integer values lying in a specified search volume have to be considered as potentially correct ambiguity values. From these the solely correct integer set has to be selected based on certain criteria. In terms of decision theory this task is a multi-criteria decision making (MCDM) problem. The candidate integer sets form the alternatives whose plausibilities are assessed by means of various attributes, i.e. the selection criteria in this application. Based on this assessment the decision is made if the correct ambiguity values can be identified or not. Usually the criteria or attributes in OTF ambiguity search are formulated as tests of values derived from the data evalution using the candidate integers against thresholds which might be based on statistics, experience, or other assumptions. Results of such tests are crisp in the sense that only two statements are possible: test is passed or not. High-precision OTF GPS positioning is affected by a number of uncertainties: cycle-slips and signal reaquisition, multipath, vegetation, tropospheric and ionospheric refraction etc. lead to varying noise and systematic effects of unknown size in the data. Its impossible to account for all such effects in the data evaluation. This means that one has to deal with a more or less un-quantifyable amount of uncertainty. Doing MCDM in the crisp way as described above means to ignore these uncertainties. Depending on the measurement conditions the risk of false solutions might be high and the reliability respectively low. Clearly the use of such a method is limited to optimal conditions only. In this presentation a fuzzy-logic MCDM technique is introduced for application to the OTF ambiguity search problem. This approach is motivated by the fact that the theory of fuzzy sets and systems might facilitate the proper handling of the above described uncertainties in data and mathematical model. The mathematical formulation of the fuzzy-logic MCDM is presented and its key features and characteristics are investigated in comparison with the traditional crisp MCDM procedure. In addition the performance of both kinds of MCDM methods when applied to exemplary data sets is compared in terms of success rate, reliability and working range (distance of rover to base station under different conditions).

G04/07P/C25-006   1640
PARAMETRIC VERSUS NON-PARAMETRIC METHODS FOR OPTIMAL WEIGHTED AVERAGING OF NOISY DATA SETS

Christopher KOTSAKIS[1], Ilias N. TZIAVOS[2] ([1]Department of Geomatics Engineering, University of Calgary, Calgary, Alberta, Canada, [2]Department of Geodesy and Surveying, Aristotle University of Thessaloniki, Thessaloniki, Greece)

The problem of optimal weighted averaging of multiple data sets that correspond to noisy recordings of a given signal is studied. Identified as one of the most primitive applications of least squares methods, data averaging can be employed either at the pre-processing stage of geodetic data analysis (e.g., for noise reduction in repeat-track altimetric data profiles), or as a stand-alone tool in cases where an unknown signal needs to be estimated by a linear combination of its ensembles. In view of the continuously increasing load of gravity field and altimetry data coming from current and future satellite missions, data fusion procedures which utilize signal averaging techniques provide an efficient tool for many areas of geodetic research. Generalizing the classic averaging problem in statistics where the mean of a single random variable is approximated by the sample mean of a set of its values, signal averaging offers interesting hidden challenges from a theoretical as well as an applied viewpoint. For instance, the noise correlation in the individual data sets is not taken into account if a single scalar weighting factor is assigned to each signal ensemble. In order to overcome this limitation, more general averaging schemes must be introduced that allow for: (i) the auto-correlation of data noise within each signal ensemble, and (ii) the noise cross-correlation among the different ensembles, to be properly considered. In any case, the determination of the optimal ensemble weights according to a mean-square-error (MSE) criterion requires the knowledge of the noise covariance (CV) function for each data set, which is often not available in practice. An alternative weighted averaging method will be presented herein which is free of any a-priori assumptions about the statistical characteristics of the noise and/or the underlying signal. Our approach is based on the minimization of an empirical signal-to-noise ratio and it results in optimal ensemble weights than can be directly computed from the available data values. Hence, it essentially provides a non-parametric technique for weight determination since any hypothesis regarding the second-order statistics of the data noise is avoided. Various numerical tests are presented using simulated gravity anomaly profiles with both white and coloured Gaussian random noise. The experiments include comparisons between simple (uniform) and weighted averaging

schemes for noise reduction in the observed gravity anomaly signal, and reveal the significance of proper weighting, especially for cases with very high noise level in the input data sets. Our empirical non-parametric approach for weight determination also shows satisfactory results which justify its use in practice, when a-priori statistical information for the data noise is not available.

THE STATISTICAL INFERENCE OF EIGENSPACE COMPONENTS OF A SYMMETRIC RANDOM DEFORMATION TENSOR

Jianqing CAI, Erik W. GRAFAREND (Department of Geodesy and GeoInformatics, University of Stuttgart)

The *eigenspace components* (principal components, principal directions) of random deformation tensors, for instance strain and stress, are of focal interest in geodesy, geophysics and geology. They play an important role in interpreting the geodetic phenomena like earthquakes (seismic deformation), plate motions and plate deformations among others. Let us assume that the strain or stress tensor has been directly observed or indirectly determined by other measurements. According to the *Measurement Axiom* such a symmetric tensor is *random*. For its *statistical inference*, we assume that the random tensor is *tensor-valued Gauss-Laplace normal distributed*. The *eigenspace synthesis* relates the eigenspace elements to the observations by means of a nonlinear vector-valued function establishing a *special nonlinear multivariate Gauss-Markov model*. For its linearized form we have succeeded to construct *BLUUE* of the eigenspace elements and *BIQUUE* of its variance-covariance matrix. The related *linear hypothesis test* has documented large confidence regions for the eigenspace components, namely *eigenvalues and eigendirections*, based upon real measurement configurations. They lead to the statement *to be cautious* with data of type extension and contraction as well as the orientation of principal stretches. In lieu of a case study, *statistical inference* is applied to the observations of geodetic surface strain rate tensor in two-dimensions and the seismic strain rate in three-dimensions.

SAMPLING-BASED STATISTICAL INFERENCE FOR HIGH-RESOLUTION GRAVITY MODELS

Juergen KUSCHE[1], Karl-Rudolf KOCH[2], Brigitte GUNDLICH[3] ([1]PHYSICAL GEOMETRICAL AND SPACE GEODESY, TU DELFT, [2]THEORETICAL GEODESY, BONN UNIVERSITY, [3]MATHEMATICAL GEODESY AND POSITIONING, TU DELFT)

For a spherical harmonic (SH) model of the Earth´s gravity field, it is desirable to have a stochastic quality description. The idea is topropagate this stochastic model into a quality description for various derived quantities such as geoid heights or height differences, gravityanomalies, or satellite orbits. The common approach is to compute thevariance-covariancematrix of the SH model by inverting the normal equations in the firstplace.There are some problems related to this approach: (1) For high-resolution models, a large matrix of normal equations has to beassembledand explicitly inverted. (2) Error propagation to gridded linearfunctionslike geoid heights requires intensive computations. (3) For quantitiesthat donot exhibit a simple linear relation to the harmonic coefficients, error propagation is only possible if a linearization is appropriate.In contrast, statistical inference for gravity models and derivedquantitiescan be based on Monte Carlo integration. A sampling method will thenproviderandom realizations of the SH model. By exploiting the Gibbs sampler, wecan avoid an explicit inversion of the matrix of normal equations. We have generated error samples for the EGM96 model and for a projection of a GOCE-derived model. Using improved Monte Carlo estimation, only very few samples are necessary for linear and nonlinear errorpropagations.

SYNTHETICALLY ADAPTIVE ROBUST FILTERING FOR SATELLITE ORBIT DETERMINATION

Yuanxi YANG[1], Yuanlan WEN[2] ([1]Xian Research Institute of Surveying and Mapping, [2]College of Aerospace and Material Engineering, National University of Defense Technology, Changsha)

The quality of the satellite orbit determination is rested on the knowledge of perturbing forces acting on the satellite and stochastic properties of the observations, and ability of controlling various kind of errors. After a brief discussion on the dynamic and geometric orbit determinations, a Sage adaptive filtering and robust filtering are reviewed. A new synthetically adaptive robust filtering based on a combination of robust filtering and Sage filtering is developed; It is shown, by derivations and calculations, that the synthetically adaptive robust filtering for orbit determination is not only robust but also simple in calculation. It controls the effects of the outliers of tracking observations and the satellite dynamical disturbance on the parameter estimates of the satellite orbit.

EQUIVALENT-SOURCE MODELING TO IMPROVE PRECISE GEOID DETERMINATION

Gabriel STRYKOWSKI (National Survey and Cadastre, Rentemestervej 8, DK-2400 Copenhagen NV, Denmark, E-mail:gs@kms.dk)

 Present day methods of precise geoid determination involve gravity reductions [e.g. residual terrain model (RTM), Helmert's second method of condensation or different topographic-isostatic reduction methods]. These methods use the gravity and terrain information as is. Only very large inconsistencies between the two data types can be detected. Clearly, the quality of the final geoid is limited by the quality of input data. This limitation cannot be bridged by any conventional method unless it includes a detailed cross-validation between the above data types. Such cross-validation is justifiable on physical grounds; any gravitational signal must be generated by a physical source (Newton's law). Furthermore, geophysical bounds on the possible intensity of mass density contrasts combined with the high quality of present day digital elevation models (DEM) constrain the local sources and the local gravitational field. A special problem with respect to the original definition of the geoid by Gauss and Listing is that in standard methods a simplified mass density contrast for the topography is traditionally used, e.g. 2670 kg/m³. It means, that even if a gravitational signal is generated by an intra-topographic source, it is implicitly associated with a source below the geoid. Consequently, in standard geodetic methods (and except for the topography) the local source of the residual gravitational signal should be perceived as a gravi-equivalent source below the geoid. In my presentation I will discuss and demonstrate how to model reasonable local sources and quantify in what way they will constrain the

geoid. The main idea is to model sub-centimeter geoidal height differences for small horizontal separation distances (1 km -10 km) by imposing the existence of a local geophysical source. One can safely claim that a change of geoid over small horizontal distances, if real, must be related to such local source. Distant or large sources cannot produce such effect. In fact, the more elevated the terrain the better the modeled geoidal height differences. The content of this contribution coincides with the work of IAG's Special Study Group 4.188.

A MINIMUM ENERGY CONDITION FOR THE INVERSE GRAVIMETRIC PROBLEM

Olivier JAMET[1], Michel DIAMENT[2] ([1]Laboratoire LAREG, Ecole Nationale des Sciences Geographiques, [2]Laboratoire de Gravimetrie et de Geodynamique, Dept. Geophysique Spatiale et Planetaire (UMR 7096), Institut de Physique du Globe de Paris)

The problem of finding the density distribution of the Earth from gravity data is called the inverse gravimetric problem. It is well known that this problem has no unique solution. A possible approach to force the uniqueness of the solution is to impose the solution to realize a minimum of energy, that is to be the equilibrium distribution. Several authors have considered this possibility by setting the energy to the sole energy of the potential field, called the potential energy. It is then necessary to impose constraints on the density distribution, so as to avoid that the material collapse towards the center of the Earth. H. Moritz (1990), for instance, considers that a given density intervall occupies a fixed volume, and computes, under this condition, the figure of the equilibrium ellipsoid. We consider the more general case of the real Earth, and assume we know the potential outside of it. The density distribution is modeled as a function of the 3D space member of a Hilbert space. We suppose its second derivatives exist inside the earth (but of course not at its boundary). We show that searching the minimum potential energy density distribution under constraints such as Moritz´s is equivalent to maximizing a norm within a convex set. As a consequence, the solution is necessarily located at the boundary of this convex set. It is thus highly dependent from the imposed constraints. In order to formulate an equilibrium condition leading to a better solution, we propose to introduce a compression energy in the formulation of the energy to be minimized. We choose the state equation of Murnaghan to express this compression energy, and show that, under widely admitted hypothesis (in particular on the choice of the value of the first derivative $K´_0$ of the bulk modulus), the minimum of the total energy exists. We discuss then, with $K´_0=4$ (which is a reasonable value for the upper mantle), several properties of the minimum energy density distribution. All the density distributions ρ of minimum energy have the same potential energy and obey to a differential equation of the form : $\rho(k_1 + k_2 \nabla.(\rho^2 \nabla\rho)) = 0$ (where k_1 and k_2 are constant, $\nabla.$ and ∇ are respectively the divergence and gradient operators). We are still far from a general demonstration of the uniqueness of the solution, but our work is a first step towards such a result. In future works, we plan first to tackle the uniqueness problem for the equilibrium figure of the ellipsoid. References: H. Moritz (1990) *The figure of the Earth : Theoretical geodesy and the Earth´s interior*, Ed. Wichmann

SUCCESSIVE APPROXIMATIONS IN THE SOLUTION OF A WEAKLY FORMULATED GEODETIC BOUNDARY-VALUE PROBLEM

Petr HOLOTA (Research Institute of Geodesy, Topography and Cartography)

Though for many purposes a sphere or an ellipsoid approximate the figure of the Earth fairly well, the real shape of the Earth´s topography causes effects that continuously stimulate a considerable research effort. In contrast to the concept of the so-called shrinking parameter in a classical setting, successive approximations are applied in the treatment of the effect within a variational or a weak formulation of the problem. In this connection the role of the analytical continuation and of its interpretation in approximating the solution by means of linear combinations of basis functions is discussed. Related functional estimates are investigated in the process of iteration steps. Some problems associated with a particular choice of basis functions and their construction through spherical and ellipsoidal harmonics are also treated. Various singularity functions and also reproducing kernels are in the focus. Finally, as a part of the process of successive approximations, problems are approached that are associated with an oblique derivative of the solution (i.e. the disturbing potential) in the boundary condition.

ELLIPSOIDAL SPECTRAL PROPERTIES OF THE EARTH'S GRAVITATIONAL POTENTIAL AND ITS FIRST AND SECOND DERIVATIVES

Karla BÖLLING, Erik W. GRAFAREND (Department of Geodetic Science, Stuttgart University)

The spectral analysis of the Earth's gravitational potential, its first and second derivatives is performed in spherical / ellipsoidal harmonics relative to the *International Reference Sphere / International Reference Ellipsoid*. The highlights of the diagrammatic approach are: (i) Up- and downward continuation of *gravity gradients*, (ii) Downward continuation of *gravity gradients* (four tensor-valued harmonic functions) to the *gravitational potential* on the *International Reference Figure*, (iii) *Direct Conversion* of *external gravity gradients to geoidal undulation* by means of the spherical / ellipsoidal *Bruns Formula*. The *International Reference Ellipsoid* has been chosen as an equipotential surface in the SOMIGLIANA-PIZZETTI reference potential field.

G04/08A/C25-005   1000

ELLIPSOIDAL CORRECTIONS TO GRAVITY ANOMALIES OBTAINED FROM SATELLITE ALTIMETRY DATA

Bernhard HECK, Kurt SEITZ (Geodetic Institute, University of Karlsruhe)

Gravity anomalies over oceanic regions can be derived from satellite altimetry data, assuming that the (corrected) altimeter heights can beidentified with geoidal heights. Generally the practical solutions of this problem are based on a simplified relationship between gravityanomalies Δg and geoidal heights $N=T/\gamma$, involving spherical and constant radius approximation. In the space domain these simplificationsresult in a spherical integral, the inverse Stokes integral. A more accurate solution of the respective inverse Stokes problem is achieved by retaining the first order ˝ellipsoidal effects˝ in theboundary condition relating Δg and T, neglecting terms of order f^2 (f= flattening of the reference ellipsoid). These ellipsoidal effects arecomposed of three constituents, depending on the geometrical flattening f, the dynamical flattening J_2, and the angular velocity ω ofthe Earth´s rotation. In the paper, two first-order solutions of the extended, ellipsoidal problems are considered, both keeping the general structure of theinverse Stokes integral. In the first procedure, a correction term is added to the gravity anomalies calculated from the spherical integral,while in the second one the geoidal heights - entering the spherical integral - are corrected. A numerical evaluation of the ellipsoidalcorrections for both approaches is provided on the basis of the EGM96 geopotential model, showing a dominant low-frequency behaviour of

thecorrection terms.

G04/08A/C25-006   1050

GRAVITY RESPONSE OVER A FRACTAL SUBSURFACE REPRESENTED BY VORONOI TESSELLATION

Vijay P. DIMRI, Ravi Prakash. SRIVASTAVA (National Geophysical Research Institute, Hyderabad, India)

Inversion of geophysical data is carried out in two steps: in first step geophysical response is computed for a pre-assigned geometry and in second step this response is compared and corrected till there is satisfactory match between computed and observed values. In gravity method the first step is performed by assuming the geometry of interfaces, which could be planar and near parallel or nearly planar so that they can be represented with splines. Alternatively the space is assumed to be filled up by polygons or polyhedra, which in turn are represented by their vertices. If the vertices are perturbed, in second step i.e. inversion, there would be no guarantee that the space is still filled up or that the polyhedra do not overlap or the regions do not become reentrant. In this work interfaces or tessellating domains are represented by a set of geometric points and a small number of additional parameters. These geometrical points and parameters can be perturbed by any amount without getting into representational problems faced by the conventional techniques. To accomplish such representation Voronoi tessellation is used, which in two-dimensional space consists of enclosing every center by a Voronoi polygon such that a common edge of adjacent polygons is a perpendicular bisector of the line joining the centers on the two sides of that edge. Here, the notion of the Voronoi tessellation is generalized by using L^p distances, instead of the Euclidian distances so that Voronoi domains are not necessarily polygonal or polyhedral, where p can hold any value. This approach is used here to generate the fractal subsurface representation, which is quite close to the realistic geometry than the conventional planer or polygonal representation. The technique is illustrated here to obtain synthetic gravity response over a fractal subsurface generated by Voronoi tessellation using L^p norm distance.

G04/08A/C25-007   1120

ASYMPTOTIC DISLOCATION THEORY OF A SPHERICAL EARTH FOR CALCULATING CO-SEISMIC DISPLACEMENTS

Wenke SUN, Shuhei OKUBO (Earthquake Research Institute, University of Tokyo)

To study response of the Earth to seismic dislocation, the Earth is often simplified into simple geometric models, such as a half-space, a homogeneous sphere and a stratified sphere, and corresponding dislocation theories are presented. The theory for a half-space is usually expressed in analytical form (Okada, 1985; Okubo, 1991) and is easily applied to study or inverse seismic faults due to its mathematical simplicity. However, validity of these theories is limited to a near field because the Earth's curvature and radial heterogeneity are not included. Sun and Okubo's (2002) recent study indicates that both curvature and vertical layering have significant effect on co-seismic deformation field. On the other hand, since modern geodesy is able to detect far-field deformation, even a global co-seismic deformation, dislocation theory for a more realistic earth model is demanded to interpret the deformation. Sun and Okubo (1993, 1998) and Sun et al. (1996) presented theories to calculate global displacement and gravity change caused by arbitrary dislocations in spherically symmetric earth models. These theories, however, are hard to be applied due to their mathematical complicity. To overcome the disadvantages exist in the above dislocation theories, therefore, this study presents a new theory for calculating asymptotic displacements excited by a point dislocation in a spherically symmetric earth model as an approximation of the dislocation theory for a spherical earth model (Sun et al., 1996). This theory is derived in an analytical form by employing the reciprocity theorem (Okubo, 1993) and the asymptotic solutions of an elastic earth to tidal, press and shear forces (Okubo, 1988). This theory is mathematically simple and physically reasonable since it includes earth sphericity and radial structure. Both theoretical and numerical investigations indicate that the theory is valid for all types of seismic sources and for an epicentral distance of at least 20° with a relative error less than 1% compared to results calculated by the dislocation theory for a spherical earth model (Sun et al., 1996). For a vertical strike-slip source, the asymptotic theory is valid for the enter earth surface. The numerical results given in this research are calculated for a homogeneous earth model. Comparison of the asymptotic results with both the exact results and the corresponding flat-earth results shows that for any distances the exact results are approximated better by the asymptotic results than by the flat-earth earth results. Especially, the asymptotic theory is obviously superior to the flat-earth theory due to a big sphericity effect for the tensile opening on a vertical fault. Owing to its mathematical simplicity, this theory can be applied easily to calculate co-seismic displacement, just as the theory for a half space earth model like Okada (1985).

G04/08A/C25-008   1140

TOPOLOGICAL VECTOR SPACE OF HARMONIC FUNCTIONS AND THE TRACE OPERATOR

Fernando SANSO, Giovanna VENUTI (DIIAR - Politecnico di Milano)

In physical geodesy there is an approach to model the problem of determining the earth gravity field, which heavily relies on the theory of boundary value problems (BVP); since the ˝solution˝ in the end is the harmonic anomalous potential, T, which is harmonic outside the earth surface, these problems are naturally formalized as BVPs in spaces of harmonic functions. So, given a harmonic T belonging to some Hilbert or, more generally, to some topological vector space of harmonic functions, one has an operator B transforming T into some function which for simplicity is here considered as defined on the bounding sphere, S. Solving the BVP is then inverting B. To study this problem one has first to understand the characteristics of the boundary operator B in its direct action. When T belongs to classical Sobolev spaces, there are well known trace theorems defining the regularity of $(BT)_s$. This has been generalized, several decades ago, by Cimmino when $(BT)_s$ is assumed to belong to L^2_s. The paper considers the full scale of Hilbert spaces which include Sobolev spaces of any order and their duals, giving a theorem on the generality of the -1/2 rule. The most general case of functions harmonic in the open domain outside the sphere is considered too.

THE USE OF ENERGY BALANCE RELATIONS FOR VALIDATION OF GRAVITY FIELD AND ORBIT DETERMINATION RESULTS

Karl Heinz ILK, Anno LOECHER (Institute of Theoretical Geodesy, University of Bonn)

The measurement of the gravity field of the Earth is based on the field and balance equations of all physical systems, which are involved in the measurement process. The balance equa-tions describe the exchange of dynamical quantities, as for example energy, momentum or moment of momentum. Future satellite borne measurement techniques, as

SST and SGG are based on local measurement principles while the classical techniques exploit accumulated dis-turbing effects of the inhomogeneous gravity field onto the satellite's motion. Energy ex-change relations of the satellites' motion with the gravity field of the Earth seem to be useful for the validation and the consistency check of gravity field models and orbit determination results when applied in the sense of a forward computation process. Integrations techniques as well as downward continuation procedures, frequently applied for this validation task, are avoided in this procedure. It is well-known that both procedures are susceptible for numerical errors and regularisation effects, respectively. In this paper the balance equations for the en-ergy exchange as well as motion and energy integrals are derived for satellite orbits as well as for the satellite-to-satellite motion within the gravity field of the Earth. The formulation is based in principle on the Hamiltonian formulation of classical mechanics. It is well-known that the classical energy balance which describes the exchange of kinetic and potential energy is valid only in case of conservative forces. Therefore, in case of a constantly rotating Earth the Jacobi-Integral has to be applied instead of the simple energy balance relation along the orbits. The Jacobi integral has to be extended if the rotation of the Earth is considered not uni-form any more and time variable disturbing forces as tidal forces exerted by the Moon and the Sun, Earth tides etc. and surface forces as e.g. air drag and solar radiation pressure have to be included into the balance relation. The same holds if the sum of all surface forces are meas-ured in-situ by accelerometers. With these extensions energy balance relations represent an independent tool for validation of gravity field solutions and dynamic or reduced dynamic orbit determinations based on these fields. Applied to a pure kinematic orbit determination re-sult, the energy balances are able to detect deficiencies of gravity field recovery results over certain regions. The procedure is applied to various simulation scenarios and to orbits derived from a pure kinematic orbit determination of CHAMP as well as to GPS satellites. The appli-cation of the procedure to relative orbits as in case of satellite-to-satellite tracking is demon-strated as well.

BIHARMONIC SPLINE WAVELETS VERSUS GENERALIZED MULTI-QUADRICS FOR CONTINUOUS SURFACE REPRESENTATIONS

Rainer E. MAUTZ[1], Burkhard SCHAFFRIN[2], Julia KASCHENZ[3] ([1] Department of Civil and Environmental Engineering and Geodetic Science, The Ohio State University, Columbus, Ohio 43210-1275, U.S.A. 2. Department of Astronomical, Physical and Mathematical Geodesy, Technical University of Berlin, Germany, [2]Department of Civil and Environmental Engineering and Geodetic Science, The Ohio State University, Columbus, Ohio 43210-1275, U.S.A., [3]GeoForschungsZentrum Potsdam, Department 1: Geodesy and remote sensing, Telegrafenberg C3, D-14473 Potsdam, Germany)

In some respect, the continuous representation of surfaces such as the geoid, the topography, or other spatial phenomena, is superior to discrete forms like the TIN (Triangular Irregular Network) or a raster DEM (Digital Elevation Model) as long as these surfaces exhibit a certain degree of local smoothness. One of the well-established methods is based on Universal Kriging which, under certain conditions, can be shown to give equivalent results to interpolations with splines or Hardy's multi-quadrics, respectively. In this contribution, we shall concentrate on the special study of biharmonic spline wavelets and of generalized multi-quadrics (which may or may not form a wavelet basis by themselves), with the emphasis on increased efficiency - which is oftentimes a problem with Kriging (also known as "least-squares collocation") - while maintaining the local approximation quality up to the desired resolution. As a third interpolation technique a newly developed global search algorithm will be adapted to this environment. It is based on heuristic methods that would allow the user to handle gridded as well as arbitrarily scattered data. The number of coefficients for data representation using the global optimization will be extremely small and the magnitude of deviations still acceptable. On the other hand, long computation times have to be taken into account. Concerning the functional model one may face fewer restrictions for its structure when using global methods because no derivatives have to be computed and no approximate values need to be provided. Some geodetic examples will show the potential of the new techniques, particularly in view of the more classical Fourier analysis.

G04/08P/C25-002   1430
APPLICATION OF WAVELET TRANSFORMATION FOR INTELLIGENT STRUCTURAL HEALTH MONITORING USING MEMS-BASED INERTIAL SENSORS

Naser M. EL-SHEIMY[1], Aboelmagd NOURELDIN[2], Mahmoud R. TAHA[3] ([1]Department of Geomatics Engineering, [2]Department of Electrical and Computer Engineering, Royal Military College, Kingston, Ontario, Canada, [3]Stantec Consulting Ltd. , Calgary, Alberta, Canada)

The premise in using principles of vibration-based damage identification in structural health monitoring (SHM) is that when damage occurs, the mechanical properties of the structure stiffness" will be altered and thus the vibration response of the structure to externally applied loads and environmental conditions will be changed. Although, the concept looks simple, system development for SHM of civil infrastructure is challengeable. This is because of the low frequency of the excited structures and the limited effect of local damage on vibration characteristics of these structures which are attributed to their relatively large mass. A new intelligent SHM system that measures (senses) multiple responses of the structure under unknown set of loads is currently being developed and examined. The small size and low cost of force-balanced Microelectromechanical systems (MEMS) based inertial sensors make them a preferable alternative in the new system. This article describes the use of MEMS based inertial sensors in SHM systems of civil infrastructures. The paper examines some of the challenges in utilizing low-cost MEMS sensors including the need to enhance its stability, repeatability, to control its drift and to limit/filter its noise.The paper also introduces the Wavelet multi-resolution analysis as a promising technique for damage identification. Analytical analysis of simulated as well as genuine sensor signals significantly corrupted by other noise signals showed that the wavelet multi-resolution analysis was able to separate the different frequency components and to identify the original simulated structural response. The input signal to the wavelet algorithm will be basically decomposed into two parts: first called "the approximation" of the input signal includes the normal structural frequencies and some highly attenuated disturbances. Second, called "the details" of the input signal contains the noise component of the sensor signal and other disturbances. Automization of the systems necessitates the utilization of intelligent algorithms. Thus, the Wavelet analysis output is supplied to artificial intelligence algorithms (here neural-fuzzy inference system) to convert the problem of damage identification into a systematic pattern recognition problem

REMOVE-RESTORE DATA COMPRESSION FOR SATELLITE GRAVITY GRADIOMETRY

Wolfgang KELLER (Geodetic Institute,University Stuttgart)

The dominating method for gravity field recovery from satellite gradiometrydata is the so-called time-wise approach. This approach leads to huge normalequations with an almost

block-diagonal form.On the other hand, in the so called space wise approach only 2*N*N observation,placed on a special regular grid, would be sufficient to recover the gravityfield up to the resolution limit N.The paper aims at an approch to condense the huge amount of observation datainto representative normal data, prescibed to the nodes of the integrationgrid. For this purpose a remove-restore technique is applied .The gravity fieldsolution of the CHAMP mission is subtracted from the observations which leads tosynthetic gravity gradient observations of the residual gravity field. Theresidual gravity field is much smoother than the original one. From the data ofthe smoothed residual field the residual data in the nodes of the integrationgrid can be easily interpolated. After interpolation the effect of the CHAMPgravity field has to be restored again, leading to the so called normal data.It can be shown that the error of this remove-restore compression technique isbelow 0.001 E.U.From the normal data in the nodes of the integration grid the sphericalharmonics coefficients can be recovered by a combination of FFT along theparallels and Gaussian quadrature along the meridians.

ON THE USE OF ID-FFT TO INVERT GEODETIC INTEGRALS

Ramon V. GARCIA, Castulo A. ALEJO, Anibal I. ARANA, Carlos R. MORAILA (UNIVERSITY AUTONOMOUS OF SINALOA)

The use of the 1D-FFT technique to evaluate geodetic integrals has the capability of being more efficient than direct numerical integration and more precise than 2D-FFT methods. A similar situation exists for the inversion case. Nevertheless, the errors associated for instance to the deconvolution involved may make the 1D-FFT method less precise than the direct numerical integration method. An inversion method based on 1D-FFT deconvolution is presented. In order to handle larger data set, the method is implemented using the iterative projected Landweber method, which is used for solving constrained least square problems and allows to reduce deconvolution associated errors. The method is almost as precise as the direct matrix inversion approach but still computationally more efficient.Two cases are studied using synthetic data. One is the downward continuation of gravity anomalies from the Earth's surface to the geoid employing Poisson's integral and the other is the inversion of Hotine's integral to obtain gravity disturbances from geoid undulations. For the case of downward continuation the stabilization is made using the Tikhonov regularization technique. Convergence is also analyzed and comparisons with respect to the direct matrix inversion method using simple Jacobi's iteration are presented.

APPLICATION OF CLEBSCH-GORDAN COEFFICIENTS AND ISOMORPHIC FRAME TRANSFORMATIONS TO INVERT EARTH'S CHANGING GEOMETRICAL SHAPE FOR CONTINENTAL HYDROLOGICAL LOADING AND SEA LEVEL'S PASSIVE RESPONSE

Geoffrey BLEWITT[1], Peter J. CLARKE[2], David LAVALLEE[1], Konstantin NURUTDINOV[2] ([1]Nevada Bureau of Mines and Geology, and Seismological Laboratory, University of Nevada, Reno, [2]School of Civil Engineering and Geosciences, University of Newcastle upon Tyne)

The hydrological cycle induces mass exchange between the oceans and continents, and redistribution of water within the continents. In turn, relative sea level passively responds to the change in shape of both the geoid and the ocean bottom. The time variation in these two surfaces must self-consistently relate to the total mass redistribution. Here we show formally how, if given a time series of station coordinates from a global network of geodetic stations, we can invert for the separate contributions to the total mass redistribution due to water on the continents and water in the oceans. If we characterize the deformation of the solid Earth in terms of a truncated vector spherical harmonic expansion, the solution to this problem can be formulated in terms of Clebsch-Gordan coefficients, which are familiar for the calculation of branching ratios in elementary particle physics. As part of a rigorous solution to this problem, we formally address the definition of reference frame by applying the concept of an ″isomorphic frame transformation,″ which conserves the formal theoretical relationship between surface deformation and load distribution by a simultaneous translation of origin and change of degree-one load Love numbers. We show explicitly how the solution to the inversion problem is derived and implemented, and we present examples of this procedure in practice using real GPS data from the IGS network.

PHYSICAL CORRELATION? IT MAY BE DANGEROUS!

Mikhail D. GERASIMENKO[1], Nikolay V. SHESTAKOV[2], Minoru KASAHARA[2] ([1]Laboratory of Geodesy and Geodynamics, Institute of Applied Mathematics FEBRAS, [2]Institute Seismology and Volcanology, Hokkaido University)

Unknown and inestimable systematic errors that influence on different observations give a reason for introducing the physical correlations and not just algebraic ones. Especially it is important in case of GPS measurements. For example different researchers have obtained values of correlation coefficients regarding these reasons of up to 0.85 for identical satellite configuration. They attempt to introduce these correlations or some correlation functions into post-processing of GPS measurements. As illustrated in our report, it may be very problematic in practice and could lead to extraordinarily wrong results. One of these unexpected effects may be artificial increasing of the weight P of the final results. In limit we could obtain $P \to \infty$ as a result if weight even of one observation $p \to 0$. This is a clearly absurd result and it has no physical sense. That is why the formal estimates of accuracy do not reflect the real situation in case of physically correlated observations. Such artificial accuracy improving has no physical sense. We have met this phenomenon when we developed the software for optimal GPS geodetic network design for fault- mechanics studies. Considering this undesirable phenomenon we do not exclude the necessity for revision of some methods used for improving of GPS results, especially methods are using a different non-diagonal covariance matrices of observations.

EXPERIMENTS OF ADAPTIVE FILTERS FOR KINEMATIC GPS POSITIONING APPLIED IN ROAD INFORMATION UPDATING IN GIS

Yuanxi YANG, Yingze TANG, Qingtian LI, Yijiang ZOU (Xian Research Institute of Surveying and Mapping)

The experiments for the road information updating in the geographical information system by using GPS receiver mounted on a vehicle have been performed in Xian area of China. The navigation software accompanied with the GPS receiver, Sage filtering method and a new developed adaptively robust Kalman filtering method are employed and compared in the experiments. It is shown by experiments that the new adaptively robust filtering is not only simple in calculation but also robust in controlling the influences of the outliers of the GPS pseudoranges and kinematic state disturbing of the vehicle.

THE ANALYTICAL COLLOCATION OF THE ERROR DISTRIBUTION

Shi-Jian ZHOU, Yunlan GUAN, Tieding LU, Deyan ZANG (Dept. of Surveying Engineering,East China Institute of Technology)

It is well known that the error for the observational data be exist always, the error be eliminated is one of the main task for the survey data processing. To obtain the best estimated results, the error processing should be obey the optimal principle, such as the Least Square(LS) principle, but the optimal principle be determined should based on the property and the distribution type of the observational error, so that the distribution type of the observational error must first be established before the observational error processing. In the traditionally, the distribution type of the error has been determined using the distribution collocation test method or figure method by magnitude of errors, but it is difficult to obtain the specific distribution of the error, and there exist cockamamie for implement and complex for computation, therefore, the suitable method to determined the error distribution must be found. To obtain the reasonable method that more than the traditional method, the authors have proposed that the error distribution be collocated using the exponential distribution. The exponential distribution is a general distribution that can describe the arbitrary sequential distribution while the distribution parameter p is different, the property and the characteristic for the exponential distribution have been discussed in this paper. The analytical collocation method that determine the specific distribution of error has been proposed first by the authors, the main idea for the analytical collocation is that the known parameter A,C of the exponential distribution and the distribution parameter p are determined using the error interval value and the frequency for the special error interval, the computational formulae have been derived in detail , so that the explicit expression for the error distribution can be described by the parameter A,C of the exponential distribution and the distribution parameter p. Finally, the two numerical examples have been calculated and analyzed, the experiment results show that the analytical collocation method of the error distribution is very convenient and feasible, the computational results are identical with conventional methods obtained by the references.

ESTIMATION OF VARIANCE COMPONENTS THROUGH A COMBINED ADJUSTMENT OF GPS, GEOID AND LEVELLING DATA

Georgia FOTOPOULOS, Christopher KOTSAKIS, Michael G. SIDERIS (Department of Geomatics Engineering, University of Calgary)

The method of GPS-levelling for obtaining orthometric heights is not a new concept. In fact, as a result of case studies that have been conducted in different regions all over the Earth, the question of whether GPS-levelling can provide a viable alternative to traditional techniques is no longer an issue. The important question that should be asked and has yet to be satisfactorily solved is, ´What accuracy level can be achieved using this approach?´ Over the past decade, numerous advances have been made which have placed us in a position where we can begin to address the issue with more confidence, namely (i) improved mathematical models/techniques for dealing with GPS and geoid data, (ii) increased data availability for gravimetric geoid models, and (iii) improved data processing capabilities. In this paper a statistical approach for estimating the variance components of heterogeneous groups of observations is used in the combined adjustment of GPS, geoid and levelling data. Specifically, the minimum norm quadratic unbiased estimation (MINQUE) algorithm is employed to determine the individual variance components for each of the three height types. The challenges encountered when implementing this well-known algorithm in practice with real data sets from Canada and Switzerland are discussed. The analysis provides some indication into the practicality and usefulness of estimating variance components in mixed vertical networks. Notably, the estimation of realistic variance components provides us with important insight with regards to the GPS-levelling problem in addition to other uses of combined GPS, geoid and levelling data, such as assessing the accuracy of a gravimetric geoid model.

STOCHASTIC MODELLING ISSUES FOR NETWORK-BASED GPS POSITIONING

Tajul MUSA, Jinling WANG, Chris RIZOS (School of Surveying and Spatial Information Systems, The University of New South Wales, Sydney NSW 2052, Australia)

The development of network-based GPS techniques has enabled the performance of conventional single reference station, carrier phase-based techniques to be also extended over longer baselines. Using a network-based approach, real-time kinematic (RTK) positioning is carried out using concepts such as the Virtual Reference Station (VRS). However, the key to precise positioning using VRS-RTK techniques is the resolution of the carrier phase ambiguities between the reference receivers in the network. Advances in functional models and stochastic modelling of observations have been made during the last half decade or so. This paper focusses on the challenge of stochastic modelling, because most GPS data processing algorithms still assume that raw measurements are independent and have the same accuracy. Such an assumption is clearly not realistic. An investigation of the stochastic properties of VRS observations is being conducted with a view to constructing appropriate VCV matrices that optimise the ambiguity resolution process within VRS network. A better understanding of the stochastic properties of VRS networks will lead to an increase in the ambiguity success rate, hence permitting fast ambiguity resolution to support VRS-RTK positioning. This paper describes the challenges of stochastic modelling, and presents results of investigations by the authors.

PERFORMANCE COMPARISON OF THE BIEU ESTIMATOR WITH THE FLOAT AND FIXED GNSS AMBIGUITY ESTIMATORS

Sandra VERHAGEN, Peter J.G. TEUNISSEN (Departement of Mathematical Geodesy and Positioning, Delft University of Technology)

The goal of ambiguity resolution is to make optimal use of the available information, and it is the key tho high precision GNSS positioning and navigation. However, it should only be applied in case the probability of correct integer ambiguity resolution, i.e. the success rate, is very close to one. In that case, the probability that the fixed baseline will be closer to the true but unknown baseline is larger than that of the float baseline. Clearly, this condition will not be fulfilled for each measurement scenario, and that means that for low success rates a user will prefer the float solution. However, there exists a baseline estimator that will always be superior to its float and fixed counterparts, albeit that this superiority is measured using a weaker condition. This baseline estimator is the Best Integer Equivariant Unbiased (BIEU) estimator. In this contribution, the three different estimators are compared. For that purpose, we will focus on the geometry-free GNSS models, either single frequency or dual frequency. The performance of the estimators is compared based on their probability density functions, the mean squared errors of the different estimators, and the probabilities that the baseline estimators are within a certain convex region symmetric with respect to the true baseline. This will provide information on whether or not the BIEU estimator could be useful in positioning applications.

GPS BASELINE PROCESSING ASSISTED WITH DAUBECHIES AND SPLINE FUNCTIONS

Jenn-Taur LEE (Dept. of Information Management, Ching Yun Institute of Technology, Chung Li, Taoyuan 320 Taiwan)

To reach the highly accurate GPS positioning and navigation, the cycle slip detection and fixing of GPS phase observations in the pre-processing stage is necessary and important, because few cycle slips can break down the precision of GPS positioning and navigation to meter level or worse. The conventional approaches to handle the cycle slips are generated from the linear combination of GPS phase observations, which can normally resolve the cycle slip problem, but not perfect. The wavelet technique is a new tool for digital signal processing and GPS observations are also the digital signal, so the wavelet technique applied to control the cycle slips of GPS phase observations is the major subject in this study.Since the Daubechies function has the multi-resolution and de-noising capability to overcome the drawbacks of the conventional approaches, a new algorithm was developed to do the wavelet transformation and the simulated experiments were used to investigate the feasibility and reliability of the wavelet technique after reviewing the conventional approaches. It finds that the proposed approach can detect the tiny slips and then the cycle slips can be repaired by spline function for the real GPS observations. Finally, the baseline vector solution is more precise than that obtained from the conventional processing.

USING SECOND-GENERATION WAVELETS ON A SPHERE TO GENERATE A MULTIRESOLUTION OF GRAVITY ANOMALIES

Christopher JEKELI, Xiaopeng LI (Geodetic Science, Ohio State University)

We define wavelets on the sphere according to the theory of Sweldens and Schröder using an icosahedral triangulation as the coarsest subdivision level. Finer subdivisions are obtained by successively dividing each triangle into four equal triangles. The seventh-level subdivision is approximately similar to a 0.5 deg x 0.5 deg spherical coordinate grid. With basis functions defined according to the butterfly" scheme, we use a wavelet transform to decompose the gravity anomaly on the sphere as implied by the EGM96 model. This signal is re-constructed using lossy inverse wavelet transforms at various levels and compared to the original in order to assess the utility of using such representations, with different data compression ratios, for further processing in the geodetic boundary-value problem.

PATCHING LOCAL EMPIRICAL COVARIANCE FUNCTION - A PROBLEM IN ALTIMETER DATA PROCESSING

Per KNUDSEN (National Survey and Cadastre, Geodesy)

In least squares collocation a covariance function model that agrees with the empirical covariance function should be used in order to obtain optimal estimates. When estimations are carried out in a local area is is advised to use a covariance function that reflects the local statistical characteristics. When gravity field modelling is carried out in larger regions a subdivision of the region into smaller areas is carried out in order to handle the data. Such a procedure may create problems in the estimation since the use of the optimal local covariance function may give different results at borders since the statistical characteristics change from one area to the next area. In the processing of altimetry for the KMS marine gravity fields such problems exist. In this study the variability of statistical parameters in the North Atlantic Ocean is analysed. Furthermore, some ways of describing and modeling spatially varying (non-homogeneous) covariance functions are presented.

COMPUTATION OF GEOPOTENTIAL COEFFICIENTS FROM GRAVITY ANOMALIES ON THE ELLIPSOID

Sten CLAESSENS, Will FEATHERSTONE (Western Australian Centre for Geodesy, Curtin University of Technology)

The computation of spherical harmonic geopotential coefficients from gravity anomalies is a fundamental stage in all modern geoid computation. For the evaluation of low-degree coefficients, a numerical least-squares adjustment is usually applied, but because of the large computational burden of this numerical method, analytical formulas are normally used for higher degrees. The standard approach is to compute the coefficients on a bounding sphere from upward-continued surface data, and this approach was used for the construction of early geopotential models such as OSU86. This approach also forms the basis for an iterative solution that has been developed by Petrovskaya (J.Geod., 2001). The OSU91 and EGM96 models were based on an alternative procedure developed by Jekeli (Manu.Geod., 1988) (the ´etalon´ solution), based on an expansion of the geopotential in the form of an ellipsoidal harmonic series, which is then transformed into a spherical harmonic series. Recently, Sjöberg (J.Geod., in press) has formulated an approach in which the coefficients can be determined from the disturbing potential on the ellipsoid using Green´s

second identity. However, his formulation makes use of series that are limited to terms of the order of the first numerical eccentricity-squared, which is not sufficient for the computation of geopotential coefficients of medium and high degrees due to slow convergence. It is shown in this paper that the influence of the individual terms in the series even increases over the first few terms, but then decreases always leading to convergence. Therefore, more terms need to be taken into account in the case of high degrees, and for this reason Sjöberg´s theory is expanded to include an arbitrary number of higher order terms. For this purpose, a general expression for the complete series has been derived in this paper, which depends on a newly derived relation between associated Legendre functions. This new relation makes it possible to transform a Legendre function multiplied by the sine of latitude to an arbitrary power into a sum of Legendre functions of equal order. Finally, ellipsoidal corrections to coefficients of odd or even degree terms respectively are given as a summation over weighted odd or even coefficients of the same order. The weighting functions depend only on the shape of the ellipsoid (semi-major axis and first numerical eccentricity) and the degree and order of the coefficient to be evaluated, and they can easily be computed. This new method will be compared numerically to Jekeli´s ´etalon´ solution and Petrovskaya´s iterative solution. In these comparisons the accuracy and efficiency of the approach will be determined and this will reveal whether it is a viable alternative for earlier solutions.

ADVANCED HARMONIC DEVELOPMENT OF THE EARTH TIDE GENERATING POTENTIAL

Sergey M. KUDRYAVTSEV (Department of Celestial Mechanics, Sternberg Astronomical Institute, Moscow State University)

First we present a new technique for spectral analysis of a function tabulated over a long period of time. Expansion of the function directly to Poisson series can be made where both the amplitudes and arguments of the series´ terms are high-degree polynomials of an independent variable (e.g. of time) as opposed to the classical Fourier analysis where the terms´ amplitudes are constants, and the arguments are linear functions of time. This leads to an improvement in accuracy of the spectral analysis of the function over long-term intervals and allows one to better separate terms of close frequencies. The technique is applied to make a new harmonic development of the Earth tide generating potential (TGP) over two thousand years centered at epoch J2000.0. The adopted model of the TGP accounts for the Moon, Sun, Venus, Mars, Jupiter, Saturn, and Mercury gravity attraction as well as for the Earth flattening effects. The latest NASA/JPL long-term ephemeris DE/LE-406 has been used as the source of the Moon and planets coordinates. The final development of the TGP made with use of the new technique includes some 27,000 terms of amplitudes down to the level of $1*10^{-8}$ m²/sec² and is valid over 1000AD–3000AD. Calculation of gravity tides at a mid-latitude station (BFO Schiltach, Germany) by using the new TGP development is made in order to check the quality of the latter. The obtained accuracy in calculation of gravity tides at the station is better than 0.025/0.4 ngal (the r.m.s./maximal error, respectively) when comparing with a benchmark gravity tide series numerically computed with use of the most accurate ephemeris DE/LE-405 at every hour within 1600-2200 (the complete period of time covered by the ephemeris). It exceeds the accuracy of the best previously made harmonic development of the TGP (Hartmann and Wenzel, 1995; Roosbeek, 1996) by a factor of at least 3 and is stable over a much longer interval of time. The work is supported in part by grant 02-02-16887 from the Russian Foundation for Basic Research.

GENERALIZED BOUGUER ANOMALY (1): BOUGUER ANOMALY FREE FROM THE BOUGUER REDUCTION DENSITY AND THE FUNDAMENTAL EQUATION OF PHYSICAL GEODESY

Kyozo NOZAKI (5428)

In this study, we present a new concept of the generalized Bouguer anomaly, which is defined upon the datum level of gravity reduction of an arbitrary equi-potential surface with a non-zero elevation. Discussions are particularly focused on how to realize the ρ_B-free Bouguer anomaly, namely, the generalized Bouguer anomaly that is free from the assumption of the Bouguer reduction density, and what is meant by the ρ_B-free Bouguer anomaly in relation to the fundamental equation of physical geodesy. First, we define and formulate the generalized Bouguer anomaly by taking into account the four distinct quantities: the elevation (orthometric height) of the datum level of gravity reduction, geoid height, vertical gradient of gravity anomaly, and the truncation angle in a spherical scheme of gravity corrections. Secondly, we introduce a concept of the specific datum levels such that the generalized Bouguer anomaly is not affected by the topographic gravitational effects. Upon the specific datum levels, the equations of the generalized Bouguer anomaly become free from the Bouguer reduction density and/or the terrain correction. Thirdly, by utilizing these equations, an approximate equation for estimating the Bouguer reduction density is derived from the gradient of free-air anomaly with respect to the specific datum levels. Finally, in a simple case of neglecting the vertical gradient of gravity anomaly, a formula to compute a Bouguer anomaly on the geoid is shown by level transformation of the generalized Bouguer anomaly from the specific datum level to the level of geoid. These procedures give a new approach to obtain a Bouguer anomaly distribution, which is free from the assumption of the Bouguer reduction density. Also, it is pointed out that the generalized Bouguer anomaly upon the specific datum level is the gravity disturbance that defines the fundamental equation of physical geodesy. The author expresses sincere thanks to Dr. Shozaburo Nagumo, Professor Emeritus of the University of Tokyo, the chief technical adviser of OYO Corporation, for his enthusiastic encouragement and frequent discussions throughout the research. Also the author wishes to express his grateful thanks to Professor Shuhei Okubo of the University of Tokyo for his hearty guidance and critical comments, and to Professor Yoshio Fukao of the University of Tokyo for his stimulating discussions and continuous encouragement during the research. The author's thanks are also extended to Drs. Masaru Kaidzu and Yuki Kuroishi of the Geographical Survey Institute for their helpful discussions on the basic concepts of the modern physical geodesy.

G04/08P/D-013 Poster **1400-120**

GENERALIZED BOUGUER ANOMALY (2): ON THE SIMULTANEOUS ESTIMATION OF THE BOUGUER REDUCTION DENSITY, GEOID HEIGHT AND BOUGUER ANOMALY UPON THE NORMAL ELLIPSOID SURFACE

Kyozo NOZAKI, Koji IWAMOTO, Kenichi OSHITA

In the present study, we present a new method on the simultaneous estimation of the Bouguer reduction density, geoid height and Bouguer anomaly upon the normal ellipsoid surface. This new method is based on the free-air anomaly *FA*, which is equivalent to the *gravity anomaly* in the modern physical geodesy, and the specific datum levels of gravity reduction, which is introduced in the theory of the generalized Bouguer anomaly proposed by Nozaki (2003, another presentation of IUGG 2003). The specific datum levels h_{d0}, h_{d1} and h_{d2}

---

are so defined as that the generalized Bouguer anomaly ($\Delta g_{;b,bd}$), which is defined upon the datum level of an arbitrary equi-potential surface at h_d, is not affected by the topographic gravitational effects. On the other hand, the free-air anomaly *FA* is represented as a function of each specific datum level h_{d0}, h_{d1} and h_{d2}, respectively. Then, we plot the free-air anomaly (*FA*) as a longitudinal axis against the identical axis of abscissa as $h_d = h_{d0}$, h_{d1} or h_{d2} for every gravity station. In this paper, we call the diagram of these plots *FA* vs. h_d *diagram*. The characteristics found in the *FA* vs. h_d *diagram* are summarized as follows: 1) One can observe the gradients dFA/dh_{d0}, dFA/dh_{d1} and dFA/dh_{d2} of regression lines h_{d0}-line for *FA* vs. h_{d0} plot, h_{d1}-line for *FA* vs. h_{d1} plot, and h_{d2}-line for *FA* vs. h_{d2} plot, respectively. 2) There exists, in general, an intersection C(Δh_d, $\Delta\gamma_0$) of regression lines h_{d1}-line and h_{d2}-line. The intersection C does not generally coincide with the origin (0,0). Note that the intersection C is definite because the h_{d1}-line and h_{d2}-line are computable from the known quantities. and 3) One can draw a specified regression line for *FA* vs. h_{d0} plot (h_{d0}-line) such that it passes through the intersection C. Note that h_{d0}-line originally has a degree of freedom for parallel translation along the abscissa because the defining equation of h_{d0} contains an unknown quantity of the elevation of the normal ellipsoid h_e. For 1), it is shown that one can estimate the Bouguer reduction density from the gradients dFA/dh_{d0} of h_{d0}-line and dFA/dh_{d1} of h_{d1}-line. For 2) and 3), it is shown that the value of the abscissa Δh_d must be h_e when we adjust the specific datum level h_{d0} to Δh_d. Namely, the geoid height (N) is given as $N = -\Delta h_d$. Also, it is demonstrated that the intersection C(Δh_d, $\Delta\gamma_0$) must satisfy the equation $\Delta g_{b}\,\Delta hd=\Delta\gamma_0+\beta\Delta h_d$ (β is the vertical gradient of the normal gravity field), which is equivalent to the fundamental equation of physical geodesy. This equation implies the generalized Bouguer anomaly at Δh_d ($\Delta g_{b}\,\Delta hd$), which is equivalent to the gravity disturbance upon the normal ellipsoid whose elevation is $h_e = \Delta h_d$, can be computed from the known quantities Δh_d and $\Delta\gamma_0$ at the intersection point C.

GLOBAL ISOTROPIC ISOSTATIC RESPONSE FUNCTION IN TERMS OF ZONAL SPHERICAL HARMONICS

Hussein A. ABD-ELMOTAAL (Civil Engineering Department, Minia University)

Geophysical evidences prove that the density anomaly is proportional to the earth´s radius vector (the depths). Hence, one may assume that the density anomaly is linearly related to the topography by a convolution of the topography and an isotropic kernel function. Accordingly, one can derive that the vertical derivative of the isostatic potential (the attraction of the compensating masses) is also a convolution of the topography and an isotropic isostatic response function. Such an isostatic response function can be determined by deconvolution. The paper gives the necessary derivation of such a deconvolution by means of spherical harmonics. A practical determination of the isotropic isostatic response function needs the harmonic analysis of both the topography and the attraction of the compensating masses. Creating compensating masses by means of an isostatic hypothesis already implies an assumption of the earth´s isostatic response. Instead, one may wish to compute the isostatic response of the earth without postulating an isostatic hypothesis. This may be achieved by the principle of inverse isostasy, by which we aim to have zero isostatic anomalies. Thus, the attraction of the compensating masses equals the Bouguer anomalies with a negative sign. The harmonic analysis of the Bouguer anomalies is thus a combination of the harmonic analysis of the topographic potential and the already existed global (free-air) reference models. Two global reference models have been used. They are: EGM96 model (complete to degree and order 360) and GPM98CR (complete to degree and order 540). The needed harmonic analysis of the topography has been carried out using TUG87 and TBASE digital height models after smoothing to 20´ and 30´ resolutions. The results show that the isotropic isostatic response functions derived by inverse isostasy behave in the same sense as those postulated by flexure models (Vening Meinesz isostatic model).

PARANA BASIN: AN ISOSTATIC MODELING USING A GEOGRAPHIC INFORMATION SYSTEM TO DELINEATE THE MAIN BASEAMENT STRUCTURES

Marcia C.L. QUINTAS (Department of Geomatics, Federal University of Parana)

This paper presents a contribution to the localization of the main basement structures of the Parana Basin. This Ordovician-Cretaceous sedimentary basin is intracratonic and located in the S-SE portion of Brazilian territory. In order to achieve this goal, a quantitative method of determining the state of isostasy at a geological feature was used in this study. This method assumes that free air gravity anomalies are caused by topography and its compensation, and attempts to determine a function which, when convolved with topography, reproduces the gravity anomaly. The advantage of this method is that this function may be derived from observational data, independent of a particular isostatic model. Approximately 7,100 gravity stations took part in this study and those data were collected by different organizations, such as Federal University of Parana (UFPR), Sao Paulo University (USP), National Observatory (ON) and Mining Company (CPRM). With the modeling was possible to identify variations in the basement gravimetric signature, revealing different compositions. The main result of this study using isostatic modeling was to compute the gravimetric anomaly caused by sediments and igneous rocks that fulfill the basin, and the "root" created by the isostatic adjustment. This study uses Kriging methods with a geographic information system (GIS), to overlay and delineate the main basement structures of the Parana Basin. The results are not discussed with a geological insight.

STOCHASTIC BOUNDARY VALUE SOLUTIONS TO SATELLITE GRAVITY GRADIOMETRY

Zhicai LUO[1], Xueguang CHENG[2], Jinsheng NING[1] ([1]School of Geodesy and Geomatics, Wuhan university, [2]School of Mathematics and Statistics, Wuhan University)

Satellite gravity gradiometry (SGG) is known as one of the most promising techniques for the future progress in the determination of global gravity field. The gradiometry data is given at satellite altitude, but the solution of gravitational potential is needed at the surface of the Earth. Hence, the solution of satellite gravity gradiometry problems somehow includes the harmonic downward continuation. This process is known to be unstable. Therefore, additional ground gravity data has to be included to improve the solution. Considering the stochastic properties of gradiometry data, the stochastic satellite gradiometry boundary value problem is formulated as the functional model and the stochastic model in the paper. Then the practical solution model is derived using pseudodifferential operator theory (PDOT) and general function in Sobolev spaces, and stochastic harmonic field theory in Hilbert spaces.

COLLOCATION VERSUS NUMERICAL INTEGRATION IN GOCE DATA ANALYSIS

Federica MIGLIACCIO[1], Mirko REGUZZONI[1], Fernando SANSO[1], CarlChristian TSCHERNING[2]

([1]DIIAR - Politecnico di Milano, [2]Department of Geophysics - University of Copenhagen)

The spacewise approach to the analysis of satellite borne data, e.g. from a gradiometric mission like GOCE, amounts to analyse such data in a way similar to the solution of a boundary value problem. This can be done indeed in several ways, for instance by applying numerical integration formulas, when the boundary functionals have a relatively simple forms like T_{rr} or $T\lambda\lambda$, by some least-squares approach or by collocation. In particular this technique can be applied to extensive grids of data, e.g. $1^\circ \times 1^\circ$ grids, thanks to the recent implementation of a procedure called Fast Spherical Collocation. It is believed that the collocation approach, through the damping of high degrees corresponding to some prior information on the degree variances, can control better than the other techniques the aliasing between degrees which are not modeled and those that enter into the final solution. This problem is analysed by applying two techniques, namely the numerical integration and the collocation, to the same simulated data sets, with or without measurement noise. This provides as well a comparison of the noise propagation through different gridding procedures. The effect of spherical gaps on the two solutions is investigated too.

SERIES EXPRESSION FOR NORMAL GRAVITY ABOVE THE REFERENCE ELLIPSOID

Ziqing WEI (Xian Research Institute of Surveying and Mapping)

A Taylor series expression for normal gravity above the reference ellipsoid, if it could produce results with desired accuracy, would be preferable to the exact expression in closed form in terms of numerical manipulation. A series expression yielding normal gravity with sub-microgal precision for high geodetic heights has been developed on the basis of the exact formulas expressed in terms of ellipsoidal coordinates μ,β,λ. The series expression for total normal gravity at geodetic height h at geodetic latitude ϕ assumes the form $\gamma = \gamma_0 + (\zeta_0 + \zeta_2 \cos^2\phi + \zeta_4 \cos^4\phi)h + (\eta_0 + \eta_2\cos^2\phi + \eta_4\cos^4\phi + \eta_6\cos^6\phi + \eta_8\cos^8\phi)h^2 + (\rho_0 + \rho_2\cos^2\phi + \rho_4\cos^4\phi + \rho_6\cos^6\phi)h^3 + (\sigma_0 + \sigma_2\cos^2\phi)h^4$ where γ_0 is the normal gravity at the ellipsoidal surface; $\xi_0, \xi_2, ..., \sigma_0, \sigma_2$ are constant coefficients. Also, series expansions have been developed for components γ_n and $\gamma\phi$ of the total normal gravity vector as well, γ_n being collinear with the geodetic normal line and $\gamma\phi$ orthogonal to it and in the meridian plane. As examples, numerical constants for the series expansions for the 1980 ellipsoid and WGS84 ellipsoid are given in the presentation. Results show that the accuracy of computed total normal gravity as well as its component in geodetic height is better than 0.1μGal for height up to 20km and than 0.3μGal and 1μGal for up to 50km and 70km respectively, proofing its superiority to existing formulas.

MEAN ORBITAL MOTION OF A CONSTELLATION OF GEODETIC SATELLITES: NEW RESULTS FOR GEODYNAMICS

Florent DELEFLIE, Pierre EXERTIER, Gilles MÉTRIS, Philippe BERIO, Olivier LAURAIN (Department CERGA of OCA / GRGS Grasse)

New developments have been achieved since a few years to improve the theory of mean orbital motion of artificial satellites : in particular, singularities with eccentricity have been removed from the averaged equations of dynamics, which are integrated in a numerical way. It is now therefore possible to compute mean orbits of geodetic satellites over large time scales (typically : from 10 to 20 years). By linking geodynamical phenomena to corresponding effects on the orbits, this long period approach enables to study the changes of the gravity field of the Earth over large spatial scales. For these studies, we use « observed » mean elements which have been carefully computed from Satellite Laser Ranging (SLR) measurements, and which have been first reduced by classical orbit fits on short arcs. The results are one single long arc per considered satellite : over 22 years for LAGEOS-1, 10 years for LAGEOS-2, 18 years for STARLETTE, 15 years for AJISAI, 9 years for STELLA. In this context, the adjustment of geodynamical parameters is now based on the combination of observation equations deduced from these long arcs. In this paper, we investigate the long term evolution of the first zonal terms of the Earth gravity field (typically : from J2 to J6). In particular, we adjust the static and the secular parts, and we give time series of these coefficients which enlightens small but cumulative effects. We observe also how redistribution of oceanic mass around the equator can affect the value of the dynamical flattening of the Earth (J2dot). As a consequence, we show that specific geodynamical parameters are all the more well decorrelated one from another as the orbits have a long period of time, this taking advantage of our method.

MULTISCALE STABILISATION PROCEDURE FOR THE INVERSE DIRICHLET PROBLEM

Juraj JANAK[1], Karol MIKULA[2], Vladimir MINARECH[3] ([1]Department of Theoretical Geodesy, Slovak University of Technology, [2]Department of Mathematics and Descriptive Geometry, Slovak University of Technology, [3]student, Slovak University of Technology)

In geodesy the inverse Dirichlet problem can be encountered in geoiddetermination process

and it is known as downward continuation of the gravity data. The aim is to obtain the gravity data on the boundary surface, i.e. on the geoid. If the gravity data is a harmonic function above the geoid, the problem can be solved and the solution is theoretically unique. From numerical point of view the solution is inherently unstable, meaning that even a small fluctuation in the input function can result in a large respond after the downward continuation. Short wavelength fluctuations are enlarged more then the long wavelength disturbances. Therefore a standard stabilising procedure is to create mean values of the input function with the sufficiently large discretization step. Such a procedure has some disadvantages, e.g. it is not possible to continue downward a function in a detailed resolution because the original discretization step is enlarged. In this contribution we suggest to use a multiscale stabilisation procedure based on a successive decreasing of the input data smoothing. In this procedure the original discretization step is preserved. Both stabilisation procedures are compared and tested.

ON DISCRETE SCHEMES IN DOWNWARD CONTINUATION OF GRAVITY

Wenke SUN (Earthquake Research Institute, University of Tokyo)

According to geodetic boundary value theory, gravity is required to be known on geoid, i.e., observed gravity on a terrain surface must be transformed onto geoid. This transformation is called downward continuation of gravity. For this purpose, discretization of the Poisson integral is necessary (Bjerhammar, 1962; Heiskanen and Moritz, 1967), so that the gravity field on geoid can be obtained by solving the discretized linear system. Bjerhammar (1962) studied this problem for the first time using a point scheme; i.e., he discretizes the Poisson integral by simply taking a point value of Poisson kernel at an observed point. This point scheme was also adopted by other scientists up to the present. Vanicek et al. (1996) and Sun and Vanicek (1998) studied downward continuation of a 5´x5´ mean Helmert gravity anomaly. They discretized the Poisson integral using a double mean scheme. They proved that a discretized system of Poisson integral equations can always be solved (Bjerhammar, 1962; 1987) for 5´x5´ discretization. However, numerical investigation indicated that the double mean scheme engendered tedious numerical work, greatly constraining its application potential. On the other hand, although the above two systems of linear equations are mathematically tractable, they produce different gravity on geoid for the same input (Martinec, 1996; Sun and Vanicek, 1998). The main reason for the discrepancy is considered to arise from discretization of the Poisson kernel; while this problem has not received much attention up to the present. Actually, mathematical solvability does not mean that its solution is correct. The key point is whether the system is well structured, or, whether discretization is reasonable. Therefore, this research investigates some discretizztions of the Poisson integral. A single mean scheme is proposed to overcome the disadvantage of the double mean scheme. Basically the single mean scheme is the same as the double one, but it is numerically simple since it greatly reduces numerical work. Comparison between the point and mean schemes shows that, for a limit topographical grid size, the point discrete scheme presents a serious theoretical problem, i.e., it greatly devalues gravity on geoid, and even gives suspicious result for an extreme case. It is found that difficulty of dealing with the Poisson integral is due to behaviors of the Poisson kernel. Numerical analysis indicates that the diagonal values for the point scheme on a 5´ by 5´ division are much larger than those of the mean scheme. Therefore, a careful consideration of constructing matrix coefficient of the discrete system of the Poisson integral is much more important. A basic principle of a valid discretization for any integration is that the discrete kernel function value should well-approximate the true value on each grid; otherwise discretization will bring a serious error to result.

GLOBAL OPTIMUM SEARCH REGARDING THE PERIODOGRAM BASED ON INTERVAL NEWTON METHOD

Rainer E. MAUTZ[1], Svetozar PETROVIC[3] ([1]Department of Civil and Environmental Engineering and Geodetic Science, The Ohio State University, Columbus, Ohio 43210-1275, U.S.A., [2]Department of Astronomical, Physical and Mathematical Geodesy, Technical University of Berlin, Germany, [3]GeoForschungsZentrum Potsdam, Department 1: Geodesy and remote sensing, Telegrafenberg A 17, D-14473 Potsdam, Germany)

When fitting a physical model to a given set of observations, the estimation of the model parameters becomes a minimization problem. Is the model nonlinear, this optimization problem may have many local minima. In case that the approximate values for the parameters cannot be provided with sufficient precision, a global search is required. Recently, heuristic point methods like Simulated Annealing or related random-based strategies have been applied to geodetic parameter estimation problems. Although they seem to work in general, the user has to accept the large computational burden and the lack of reliability. In this contribution an Interval Newton Method is proposed as a bounding method. It consists of a gradient method for attaining local solutions and a global strategy by a so-called feasible point finder, which identifies all roots (zeros) of a function. The feasible point finder becomes a global optimization technique when applied to the objective function minus the value of the previous lowest local minimum. A unique root will indicate that the global solution is found. The feasible point finder guarantees the identification of the root (if unique) or roots by systematically excluding all areas without feasible root. An application of the feasible point finder requires the continuity of functions and the existence of the first derivative. Geodetic L2-Norm based target functions fulfill this condition. Finding the best fitting sine function for an observational dataset is a global optimization problem for the frequency variable. Plotting the estimate of the power spectral density (PSD) of a signal using the ˝periodogram˝ function, the large number of local minima becomes obvious. Fourier techniques oftentimes fail - in particular when the data are not equidistant. Point methods do not make use of the function´s derivative and cannot guarantee a global solution since there is no information between sampled points. Applying the proposed interval method to the ˝frequency˝ problem, it now becomes possible to guarantee the global solution within finite time. An upgrading toward time-dependent frequencies and multi-dimensional problems looks promising.

ON COSMOLOGICAL ORIGIN OF CERTAIN GEODETIC FEATURES OF THE EARTH (I)

Akindele Oluwole ADEKUGBE-JOSEPH (-)

The slight westward deflection in the north and eastward deflection in the south of continental plates; the observed ratio of polar diameter to equatorial diameter of the earth of about 0.997 and the inclination to ecliptic of the earth's rotational axis at angle 66.5°, have been explained as local consequences of a new cosmological model. An instantaneous rate of increase of earth's radius of 0.108cm/yr, as well as instantaneous relative drift rate of 0.108 $\Delta\phi$ cm/yr of two points with longitudinal separation $\Delta\phi$ along the equator, have also been calculated within the new model, as consequences of the expansion of the earth with the universe. These numbers as well as the westward deflection in the north and eastward deflection in the south of continental plates are slowly increasing. This first part of this article

is devoted to the summaries of a new two-theory approach to relativistic gravitation and the new cosmological model based on it.

G04/08P/D-026 — Poster — 1400-133

ON COSMOLOGICAL ORIGIN OF CERTAIN GEODETIC FEATURES OF THE EARTH (II)

Akindele Oluwole ADEKUGBE-JOSEPH (-)

This second part of this article is devoted to the local consequences on the earth of the new cosmological model summarized in the first part. The rotational slanting of the earth of 66.5° is linked to the calculated rate of expansion, dR/dt = 0.92c, of the edge of the universe at present, where c is the speed of light. The rotational slanting of the earth is therefore epoch dependent and slowly increasing. The oblateness of the earth of 0.997 is recalculated as 'length contraction′ of the earth of the new epoch dependent cosmological metric, as an alternative approach to the existing Newton's approach to the calculation. Continental drift, polar wandering and slight westward deflection in the north and eastward deflection in the south of continental plates are explained as consequences of the expansion of the earth with the universe. An excellent agreement of the rotational slanting of 66.5° and oblateness of 0.997 of the earth, as well as calculated continental drift rate of 0.108Δφ cm/yr of two positions with longitudinal separation Δφ along the equator and polar wandering rate of 0.108 cm/yr, with derived cosmological data of the rate of expansion of the edge of the universe of 0.92c, Schwarzschild radius D_0 of the universe of 10^{10} light years and half-period of the cycle of expansion and contraction of the universe of 13 billion years has been found.

DATUM TRANSFORMATION SOFTWARE TKY2JGD FROM TOKYO DATUM TO A GEOCENTRIC REFERENCE SYSTEM

Mikio TOBITA (Geographical Survey Institute)

Coordinate transformation software ″TKY2JGD″, which supports the revision of Japanese national geodetic Datum from Tokyo Datum (with Bessel ellipsoid) to Japanese Geodetic Datum 2000 (JGD2000=ITRF94, with GRS80 ellipsoid), was developed. The software includes a GUI program ″TKY2JGD for Windows®″ and a transformation parameter file. The program reads the parameter file and conduct bilinear-interpolation with four parameters at four corners to transform a coordinate inside the four corners. The parameter file contains about 380,000 sets of regional transformation parameters at each grid, which spacing is 30 and 45 sec second in latitude and longitude, which are about 1km, respectively. The transformation parameters are expressed as dB, latitude difference in arc second, and dL, longitude difference in arc second. The differences are due to differences in coordinate system and ellipsoid, and distortion of the national geodetic network (i.e., Tokyo Datum). By estimating only the difference due to the network distortion, the precision of the transformation has improved, because the difference in coordinate system and ellipsoid is known and systematic. The transformation parameters depend on the ellipsoidal height of the position, because surfaces of the two ellipsoids are slightly inclined (~17 arc sec). For example, 3,800m ellipsoidal height (e.g., Mt. Fuji) introduces 32 cm of horizontal positional error. To reduce this error, ellipsoidal height at each grid is required. Very fortunately, ″Japanese Geoid 96″ and 50m-spacing Digital Elevation Model (DEM) were just released in 1997 and 2000, which means we could calculate ellipsoidal height at each grid by adding the geoidal height and the orthometric height harmonizing their reference systems and reference ellipsoids. A user does not need to input any height. The position on the ground surface will be automatically transformed by TKY2JGD. ″Kriging″ method was adopted for filling grids using dB and dL of about 38,000 precise geodetic network stations, i.e., first-order, second-order, and third order triangulation points. Though the Kriging method is computationally intensive, recent high-powered CPU could make the grid interval small. The above new algorithms and the small grid interval provided transformation precision of 1.4 cm. The parameters also cover 58 island areas, which are in independent geodetic reference systems. To indicate regions that may have large transformation errors mainly due to crustal deformation, an error index (square root of summation of squared gradient of dB or dL) was developed and the distribution of the index was mapped in color. The high precision and the wide coverage of TKY2JGD software will reduce the total cost of transition to the new national datum, reducing the need of re-survey or re-adjustment.

THE ROLE OF ALGEBRA IN MODERN DAY GEODESY

Joseph AWANGE[1], Erik GRAFAREND[2] ([1]Department of Geophysics, Kyoto University, [2]. Department of Geodesy and GeoInformatics, University of Stuttgart)

Algebra, in particular the ″Abelian Group″ and the ″Semi Group″ (also known as ″Monoid′) axioms which form a ″ring with identity′ are employed to define the ″polynomial ring′. The polynomial ring theory enables the solution of geodetic observations that can be converted into (algebraic) polynomial rings via the ″Multipolynomial resultant″ or ″Groebner basis″ approach. It is shown that the adoption of algebraic approach alleviates the need for *iteration* and *approximation* procedures common in numerical methods. Several geodetic examples are presented to validate the proposed role of Algebra in Geodesy. These examples include; the *GPS atmospheric sounding*, the *transformation of Geocentric Cartesian coordinates into Ellipsoidal (Baltic Sea Level Project)*, the *P4P positioning problem* and the *Conformal C_7 7 parameter transformation problem* among others. The overriding advantage of the algebraic approach is the *removal* of the requirement of *approximate starting values*, they are *non iterative* and enable the *detection of outliers*.

IGGOS SCIENCE RATIONALE

Reiner RUMMEL[1], Gerhard BEUTLER[2] ([1]Institute for Astronomical and Physical Geodesy, Technical University Munich, [2]Astronomical Institute, University Bern)

The Integrated Global Geodetic Observing System (IGGOS) will provide the scientific and infrastructure basis for all geodetic global change research. The objective of IGGOS is to integrate in a well-defined global terrestrial reference frame (1) the orientation and rotation of our planet, (2) the geometric shape of the earth's surface (solid earth, ice and ocean) and its temporal variations and (3) the stationary and time variable gravity field. In order to meet its objectives these three components have to be combined with a relative precision of 1 p.b.b. or better and with a spatial and temporal consistency and stability over decades. This will allow - as a unique and novel contribution to earth system research to monitor and investigate global deformation processes, global mass balance/imbalance and mass exchange among system components. IGGOS will, therefore, become the central geodetic research focus related to earth sciences. It shall represent the official contribution of IAG to United Nation's Integrated Global Observing Strategy and to all relevant international research pro-grams related to global change.

G07/10A/A03-002 — 0920

TERRESTRIAL REFERENCE FRAME REQUIREMENTS WITHIN THE IGGOS PERSPECTIVE

Claude BOUCHER, Zuheir ALTAMIMI (IGN France)

One of the main objectives of the promising and challengingIAG project IGGOS (Integrated Global Geodetic Observing System)is the availability of the Global Terrestrial Reference Framefor Earth Science applications, particularly Earth Rotation,Gravity Field and geophysics. With the experience gained withinthe ITRF activities (IERS, IGS), the combination method proved its efficiencyto establish a global frame benefiting from the strength of thevarious techniques and, in the same time, underline their bias andweaknesses. In this paper we focus on the limitation factorsinherent to each technique and to the combination, such as thecurrent status of the observing networks, distribution of thecollocation sites and their quality and accuracy of the combinedframe parameters. Results of some TRF and EOP simultaneouscombinations will be used to illustrate the current achievementand to help drawing up future goals and improvements in the IGGOSframework. Beyond these technical aspects, the overall visibility and acceptance of ITRS/ITRF as international standard for science and applications is discussed.

G07/10A/A03-003 — 0940

THE IGGOS VIEWED FROM THE SPACE GEODETIC SERVICES

John M. DOW[1], Werner GURTNER[2], Wolfgang SCHLUETER[3] ([1]ESA/ESOC, [2]University of Bern, Switzerland, [3]BKG-Fundamentalstation, Wettzell, Germany)

The Space Geodetic (Technique) Services of the International Association of Geodesy, viz. the International VLBI Service for Geodesy and Astrometry (IVS), the International Laser Ranging Service (ILRS) and the International GPS Service (IGS) will make major contributions to the proposed Integrated Global Geodetic Observing System (IGGOS) through the provision of time series of parameters which describe the fundamental components of global reference frames, in particular the International Celestial Reference Frame (ICRF) and the International Terrestrial Reference Frame (ITRF), and parameters of the transformation between them (EOPs, nutation, origin, scale). The three techniques VLBI, SLR and GPS are represented by services which in the last years have taken over the coordination of the supporting components including observation sites, data routing and management, and analysis facilities, and finally the responsibility for consolidated product delivery by timely provision of high quality time series, with temporal latency in some cases approaching near real time. The results of the different services reflect the distinct characteristics of the technique observables, which are partly similar and partly complementary. Due to the independence and different sensitivity of the techniques, systematic errors between the three techniques can be detected by appropriate combination of the results and to some extent at the level of the observables. Such a procedure will increase the reliability and the consistency of the products in satisfying the requirements of IGGOS. This paper reviews the different techniques with regard to their advantages and indicates sources of systematic errors. It will focus on requirements which have to be fulfilled for the combination of the service-dependant time series and might provide a basis for discussion on future plans in order to evolve the services themselves towards fulfilling the objectives of IGGOS.

THE IERS - A SERVICE FOR A GLOBAL EARTH OBSERVING SYSTEM

Bernd RICHTER[1], Markus ROTHACHER[2], Jan VONDRAK[3] ([1]BKG, Frankfurt am Main, Germany, richter@iers.org, [2]FESG, TU Munich, Germany, rothacher@bv.tum.de, [3]Astronomical Institute, Prague, Czech Republic, vondrak@ig.cas.cz)

The International Earth Rotation Service (IERS) was established in 1987 by the International Astronomical Union (IAU) and the International Union of Geodesy and Geophysics (IUGG). Over the last years the availability of and the easy access to highly accurate and consistent products of the IERS has become of vital importance for geodetic, geodynamic and geophysical projects. Future research and in particularthe new satellite missions will require an accurate global reference frame as a crucial basis to accomplish their scientific goals, be it for precise orbit determination, monitoring of sea level change or other geodynamic and geophysical purposes. The IERS is responsible for the appropriate combination of the IGS, IVS, ILRS technique centre (TC) products into official IERS products as well as for the long-term and internal consistency of these official products. The responsibilities of the IERS to establish and maintain the celestial and terrestrial reference frames and supply the earth orientation parameter series are taken over by the corresponding IERS product centres ICRS Centre, ITRS Centre and EOP Centre. The Rapid Service/Prediction Centre with its publication of twice weekly bulletins of preliminary and predicted earth orientation parameters completes the wide range of products. The Global Geophysical Fluids Centre with its 8 special bureaus provides relevant geophysical data sets and related computational results to the scientific community which are the base for, e.g., appropriate correction models for atmospheric, oceanic and hydrological influences on IERS products.Under the guidance of the IERS Conventions Editorial Board the Conven-tion Centre continues the IERS conventional models, constants and standards. The Analysis Coordinator monitors the TC and PC activities to ensure the quality and timeliness of the products,whereas the methods of integrating the different observation techniques into a consistent global observing system of the Earth will be developed by the Combination Research Centres.

THE GRAVITY FIELD AND IGGOS

Rene FORSBERG[1], M.G. SIDERIS[2], C.K. SHUM[3] ([1]Department of Geodynamics, [2]Department of Geomatics Engineering, University of Calgary, Canada, [3]Dept. of Civil and Environmental Engineering and Geodetic Science, Ohio State University, USA)

The gravity field of the earth is a natural element of IGGOS. Gravity field quantities are special in the way that measurements at the ppb-accuracies, matching the earth geometrical

parameter determination, is either a function of wavelength (e.g., the long-wavelength mm-geoid from satellite gravity field missions), or based on point sampling (absolute gravimetry), from which anomalous quantities of much lower accuracy are derived by normal gravity field models. From an IGGOS global perspective, one of the main challenges is to ensure the consistency of the global and regional geopotential and geoid models, and the temporal changes of the gravity field at large scales. The International Gravity Field Service, an umbrella "level-2" IAG service under preparation (incorporating the International Gravity Bureau, International Geoid Service, International Center for Earth Tides, and new services on satellite measurements and digital terrain models), would be a natural key element contributing to IGGOS. Major parts of the work of the services would, however, remain separate from the IGGOS contributions, which should focus on the long-wavelength issues and the procedures for local data handling and reductions etc., ensuring validity of long-wavelength gravity field spatial and temporal variations.

ALTIMETRY AS A NEW SERVICE IN IGGOS

Wolfgang BOSCH[1], C.K. SHUM[2] ([1]Deutsches Geodätisches Forschungsinstitut (DGFI), [2]Ohio State University (OSU))

Today, research and applications in geodesy and other geosciences arebased on space techniques with internationally coordinated services,that take care of data collection, analysis, generation and distribution ofproducts, recommendations of scientific standards, and research forinnovative use of the particular geodetic technology.IERS, IGS, IVS and ILRS are examples of such services for Earth rotation,GPS applications, Very Long Baseline Interferometry, and Laser tracking respectively.These services - most of them operating under the umbrella of the Federationof Astronomical and Geophysical Data Analysis Services, FAGS, - will become elements of the new Integrated Global GeodeticObserving System, IGGOS. Satellite altimetry is another space technique, proven to be extremely importantfor geosciences, in particular geodesy, oceanography and geophysics:Over the oceans the figure of the Earth is today far better known thanover most parts of the continents. Altimetry contributed essentially to animproved knowledge of the Earth gravity field and will continue its impact onhigh resolution gravity field determination - even in the context with the newdedicated gravity missions CHAMP, GRACE and GOCE. Altimetry is also criticalfor research in climate change signals such as sea level rise, ice sheet massbalance, El Nino/La Nina, decadal oscillations (PDO, NAO),general ocean circulation including quantifying total heat transportsacross ocean basins. Satellite altimetry, with currently six missions (ERS-2,T/P, GFO, JASON, ENVISAT, ICESAT) operating simultaneously, is poisedto be an operational instrument in future plans such as U.S. NPOESS. In spite of its impact, there is up to now no internationally coordinatedservice for altimetry. Up to a certain level product generation and distributionis mostly performed by the agencies that operate altimeter missions.However, altimeter data bases are definitely non-uniform and partially not up-to-date.Therefore, a few centres or small groups outside these agencies harmonized thedata and generate ″value-added″ products. Many scientific users with exceptionallyresults did rely on such ″value-added″ products.The paper considers conditions and requirements for the establishment of analtimeter service as a core element of IGGOS. Technical, scientific,operational as well as political aspects are discussed.

GEOPHYSICAL NUTATION AND POLAR MOTION MODELS AS CONTRIBUTION TO IGGOS

Véronique DEHANT (Royal Observatory of Belgium)

Nutation and polar motion are motions of a conceptual axis in space and in aframe tied to the Earth. Most of the geophysical contributions to these motions can becomputed from modeling the Earth interior and the forcing acting on it. This is thecase for the gravitational forcing of the Moon, the Sun and the planets on Earth. Thispaper present the computed aspects of these contributions to nutation and polarmotion and show how well integrated geodetic observing system such as Very LongBaseline Interferometry, may help to understand the physics of the Earth interior.Additionally, the Earth gravity field coefficients need to be known to compute othercontributions than the classical long-term contributions, showing the importance ofthe gravity field for Earth rotation studies as well. Additional contributions from the external geophysicalfluids such as the atmosphere and ocean forcing at the same frequencies as nutations, can be computed.Their contributions to polar motion at long timescale are computed from generalcirculation models. We shall examine the short term contribution to polar motion aswell, and show how important it is to have global observation in these field too.Considering the necessary interdisciplinary approach of nutation and polar motion modeling, and the increasing needs for precision of the future models, this paper shows the advantages that could be obtained from converging researches and emphasises the importance of an Integrated Global Geodetic Observating System.

A UNIFIED GLOBAL HEIGHT REFERENCE SYSTEM AS A BASIS FOR IGGOS

Johannes IHDE[1], Hermann DREWES[2], Laura SANCHEZ[3] ([1]Federal Agency for Cartography and Geodesy, [2]Deutsche Geodätische Kommission, [3]Instituto Geografico Agustin Codazzi)

A global height reference system is based on gravity field parameters, sea surface and a three-dimensional geometric reference frame. Gravity measurements, tide gauge records, ITRF coordinates, and spirit levelling are combined for the realization of a reference frame in collocation points. Satellite gravity missions, airborne gravimetry, satellite altimetry over oceans and land, and radar interferometry contribute to an integrated surface model. Observations and parameters have to be consistent with respect to the used standards, conventions and models. They have to provide unified reference surfaces (geoid and sea surface). The continental reference systems of Europe (EUREF, ECGN) and South America (SIRGAS) are considering these requirements in their strategies. Slightly different definitions and realizations will be discussed.

THE INTEGRATED GLOBAL GEODETIC OBSERVING SYSTEM (IGGOS) VIEWEDFROM THE PERSPECTIVE OF HISTORY

Gerhard BEUTLER[1], Hermann DREWES[2], Andreas VERDUN[1] ([1]Astronomical Institute, University of Bern, [2]Deutsches Geodätisches Forschungsinstitut)

Towards the end of the 19th century astrometric observations couldbe made with an accuracy of a few tenths of an arcsecond. Theaccuracy stayed roughly on this level, till the space age openedthe door for milliarcsecond (mas) astrometry. Astrometricobservations allowed it at the end of the 19th century to provethe existence of polar motion. The insight that polar motion isalmost unpredictable led to the establishment of the InternationalLatitude Service in 1899. Similar observation techniques allowedit to create geodetic networks of continental size.The insight that big networks can only be set up throughinternational collaboration led to the establishment of aninternational collaboration called ``Central European ArcMeasurement´´, the predecessor of the International Association ofGeodesy (IAG). The scope of IAG activities was extended already inthe 19th century to include gravity. The IAG and the ILS were thetools (a) to establish and maintain the terrestrial and thecelestial reference systems, including the transformationparameters between the two systems, and (b) to determine theEarth´s gravity field.Satellite techniques and astrometric radio-interferometrytechniques revolutionized geodesy. Satellite Laser Ranging (SLR)and methods based on the interferometric exploitation of microwavesignals (stemming from Quasars and/or from satellites) allow it torealize the celestial reference frame with (sub-)mas accuracy, theglobal terrestrial reference frame with (sub-)cm accuracy, and tomonitor the transformation between the systems with a high timeresolution and (sub-)mas accuracy. This development led to thereplacement of the ILS through the IERS, the International EarthRotation Service in 1989.In the pre-space era the Earth´s gravity field ``could´´ only beestablished by terrestrial methods. The determination of theEarth´s gravitational field was truly revolutionized twice in thespace era, namely first by observing geodetic satellites usingoptical, Laser, and Doppler techniques, secondly by implementing acontinuous tracking using spaceborne GPS receivers in connectionwith satellite gradiometry. The sequence of the satellite gravitymissions CHAMP, GRACE, and GOCE allow it to name the first decadeof the 21st century the ″decade of gravity field determination″.The techniques to establish and monitor the geometric andgravimetric reference frames are about to reach a mature state andwill most likely be the prevailing tools of the following decades.It is our duty to work in the spirit of our forefathers bycreating similarly stable organizations within IAG with thedeclared goal to produce the geometric and gravimetric referenceframes (including their time evolution) with the best availabletechniques and to make accurate and consistent products availableto wider Earth sciences community as a basis for meaningfulresearch in global change. IGGOS, the Integrated Global GeodeticObserving System is IAG´s attempt to achieve these goals. It isbased on the well-functioning and well-established network of IAGservices.

THE IGGOS AS A PARTNER IN THE IGOS AND OTHER GLOBAL PROJECTS

Philip Leslie WOODWORTH[1], Thorkild AARUP[2] ([1]Proudman Oceanographic Laboratory, [2]Intergovernmental Oceanographic Commission)

Research into global change has long been recognised as requiring global networks based on space and in-situ systems, together with programmesof scientific investigation to exploit the data sets. IGGOS has the potential for providing many of the necessary geodetictools needed for global change research.This presentation will discuss the relationship of the proposed IGGOS activityto the existing G3OS (Global Ocean/Terrestrial/Climate Observing Systems) and to its place within the Integrated Global Observing Strategy (IGOS).

G07/10P/A03-003　　　　　　　　　　1440
MESI - A POSSIBLE GFZ CONTRIBUTION TO IGGOS

Christoph REIGBER (GeoForschungsZentrum Potsdam, Department 1 Geodesy & Remote Sensing)

In the context of the restructuring process of the Hellmholtz association research centers, GFZ and some others geoscience oriented HGF centers are presently developing a program entitled ″Geosystem: The Changing Earth″. This program aims to understand and quantify global processes in the solid Earth, and its interaction with the atmosphere and hydrosphere as a prerequisite to provide society with appropriate strategies to safeguard future life on our dynamic planet. The tasks will be to continuously measure and model key geoprocesses, to monitor the status and trends of the system Earth, to understand and assess the impact and risk of these processes for the human habitat, and to develop geotechnologies for the use of the Earth's subsurface. For this purpose, a large-scale Modular Earth Science Infrastructure (MESI) will be established and operated in national and international collaboration. This modular infrastructure integrates near-Earth satellites, air —borne sensing systems, a global network of permanent geophysical and geodetic stations, observatories, mobile instrument arrays, as well as drilling devices and integrated analytical and experimental facilities. Components of MESI could be designed and developed as integral part of the International Global Geodetic Observing System (IGGOS). The presentation will explain the MESI architecture, its functions and schedules and will develop ideas for integration steps into international over-arching structures, such as the planned IGGOS.

INTEGRATION OF SPACE GEODESY: A US NATIONAL GEODETIC OBSERVATORY

Thomas P. YUNCK, Ruth E. NEILAN (Jet Propulsion Laboratory)

In the interest of improving both the performance and efficiency of space geodesy a diverse group in the US, in collaboration with IGGOS, has begun to establish a unified National Geodetic Observatory (NGO). To help launch this effort an international team will conduct a 3-year program of joint research into the technical issues of integrating SLR, VLBI, and GPS geodesy to produce a unified set of global geodetic products. The goal is to improve measurement accuracy by up to an order of magnitude while lowering the cost to current sponsors. Principal benefits will be to open new vistas of research within both the Geody-namics and Surface Change themes while freeing funds for scientific studies. The NGO campaign will be conducted in full partnership with, and under the auspices of, the Interna-tional Associa-tion of Geodesy (IAG) as a central element of the IGGOS (Inte-grated Global Geodetic Observation System) project. The international collaboration will be conducted within, and will make full use of, the IAG?s existing international services (IGS, IVS, ILRS, and IERS). A principal secondary goal is to expand and diversify international sponsorship of space geodesy. Under NGO the space geodetic techniques in the US will operate within an independent, self-governing federation to create a unified system architecture and establish joint goals, priorities, and proposals, guided by a shared strategic vision. The aim is to bring stability and continuity to providers and users alike while pushing the limits of geodetic accuracy, improving efficiency, nurturing emerging techniques, responding quickly to changing needs, and reducing the financial burden to current sponsors. Specific objectives are to: -- Review the current state of space geodesy: -- Develop the analytical underpinnings of integrated space geodesy: -- Unify the planning and operations for space geodesy within NASA and internationally: -- Broaden sponsorship by enlisting the many institutions and agencies that use and benefit from space geodetic products Initial seed funding for NGO, to support organizational activi-ties and assist the technical analysis, will come from the Solid Earth and Natural Hazards Program within NASA?s Earth Science Enterprise. The NASA contribution will be amplified many-fold by the efforts and contributions of our US and international partners through the broader IGGOS. Other

essential proposals are under review, including one for an integrated geodetic data system known as INDIGO (Interservice Data Integration for Geodetic Operations), also submitted to NASA. INDIGO will offer improved efficiency in geodetic science by providing uniform access to heterogeneous space geodetic data systems and will extend the GPS Seamless Archive (GSAC) philosophy to all geodetic data types. This presentation will review the status and prospects for NGO and INDIGO, and describe their roles as elements of the greater IGGOS campaign.

DORIS AS A POTENTIAL PART OF A GLOBAL GEODETIC OBSERVING SYSTEM

Pascal WILLIS[1], Yoaz E. BAR-SEVER[2], Gilles TAVERNIER[3] ([1]Institut Geographique National, [2]Jet Propulsion Laboratory, [3]Centre National d'Etudes Spatiales)

In 1990, the first DORIS receiver has been launched around the Earth on the SPOT-2 satellite. Since the end of 1992, there has been always more than 2 DORIS satellites continuously and 6 in 2002 after the sucessful launches of JASON, SPOT-5 and ENVISAT. Since 1990, the DORIS tracking network has been very stable and possesses a lot of collocation with other fundamental geodetic techniques. With newly improved DORIS on-board receivers and the increase in the number of DORIS measurements, it is now possible to obtain more precise ground stations coordinates using only a week of observations. The goal of this paper is to present the current accuracy currently achived at JPL using the Gipsy/Oasis software in a free network approach for different types of geodetic results : ground stations time series of coordinates for weekly and monthly solutions, ground stations positions and velocities, geocenter variations, global scale factor monitoring, earth orientation parameters. In particular, emphasis will be put on new results obtained in 2002 with the new type of DORIS receivers and the availability of 6 satellites simultaneously. Finally, we will discuss the opportunity of bringing DORIS as a new participant of a Global Geodetic Observing System, as the DORIS analysis community is now almost ready to begin operation as an IAG geodetic scientific service.

THE IGGOS AS THE BACKBONE FOR GLOBAL OBSERVING AND LOCAL MONITORING:A USER-DRIVEN PERSPECTIVE

Hans-Peter PLAG (Geodetic Institute, Norwegian Mapping Authority, Kartverksveien 21. N-3511Honefoss, Norway, e)

The Integrate Global Observing Strategy (IGOS) emphasises the necessary transition from scientific to operational observing systemsserving both scientific and non-scientific users. Another focus of IGOSis the accessibility of data, products and information for user.A key geodetic contribution for both the three Global Observing Systems (G3OS) and initiatives like the European Global Monitoring for Environment and Security (GMES) is an accurate, long-term stable, and easily accessible reference frame as the backbone. Many emerging scientific as well as non-scientific high-accuracy applications require access to an unique, technique-independent reference frame decontaminated for short-term fluctations due to global Earth system processes. Such a reference frame can only be maintained and made available through an integrated global geodetic observing system providing sufficient information on changes in the Earth figure and gravity field. A likely candidate for this future unique global reference frame, in fact, is the ITRF. In designing the IGGOS, it may be worthwhile to take, at least for a moment, a user-driven top-down approach. Based on a number of examples from monitoring of infrastructure, point positioning, maintenance of national references frames to global changes studies, likely future accuracy requirements for a global terrestrial reference frame can be set up as function of time scales. Briefly, expected accuracy requirements for a large range of high-accuracy applications are less than 5 mm for diurnal and sub-diurnal time scales, 2-3 mm on monthly to seasonal time scales, better than 1 mm/yr on decadal to 50 years time scales. Using these requirements, specifications of a geodetic observing systemmeeting the requirements will be ventilated. Focus will be on selected topics of the complete chain from observations to high-accuracy end-users, including the observation network, quality assurance and user access. For the latter,specifications leading to *easy* access will be proposed. With respect toquality assurance based on system monitoring and performance assessment,principal considerations for the observational network will be discussed.

IMPROVEMENTS TO THE NEW MONGOLIAN REFERENCE FRAME MONREF 97 AND PLANS FOR IMPROVEMENTS TO THE MONGOLIAN GEOID

Mijiddorj SAANDARI (Director Monmap LLC)

The Mongolian GPS network consists of 38 stations and one GPS station serving approximately 49000-sq. km. The GPS network survey was executed on the existing second order triangulation points to approximately estimate seven parameter datum conversion coefficient between WGS-84 and local system Krassovsky end to establish a primary high accuracy GPS network with ITRF connection in Mongolia. MONREF 97 is now realized at 38 points at 34 different locations (at these locations there are 2 or three points - Ulaanbaatar, Sukhbaatar and Hovd). To perform geodetic surveying in an efficient way the GPS network need to be further densified. It is also important to determine the permanent reference station at SACaC, ULB01, in MONREF 97. As mentioned above the orthometric height system will not be replaced. To meet the requirement of today and the future this leveling network need to be renovated and improved by GPS leveling. Furthermore a geoid model is needed for the link between the three dimensional system MONREF 97 and the orthometric height system based on the Baltic Sea Level. A geoid modeling will make height determination with GPS leveling and results of SRTM possible for very large areas. For establishing a geoid model, more densified ground gravity measurements and airborne gravity survey have to be considered. To maintain the high accuracy the MONREF 97 reference system has to be monitored, by repeated campaigns , permanent GPS reference stations and also tracking stations, to keep track on the tectonic movements within the country.

G07/10P/D-004 — Poster — **1400-088**

COMBINATION OF VLBI, GPS, AND SLR OBSERVATIONS AT THE OBSERVATION LEVEL

Per Helge ANDERSEN (Div. E, Forsvarets forskningsinstitutt)

Forsvarets forskningsinstitutt (FFI, the Norwegian Defence Research Establishment) has during the last 18 years developed a software system called GEOSAT (Andersen, 1995) for the analysis of any type of high precision space geodetic observations. A unique feature of GEOSAT is the possibility of combining any combination of different space geodetic data at the observation level with one consistent model and one consistent strategy. This is a much better strategy than the strategy in use today where different types of observations are processed separately using analysis software developed specifically for each technique. The results from each technique are finally combined a posteriori. In practice the models implemented in the software packages differ at the 1-cm level which is almost one order of magnitude larger than the internal precision of the most precise techniques. Another advantage of the presented method is that for example VLBI and GPS can use the same tropospheric model with common parameterization. The same is the case for the Earth orientation parameters, the geocenter coordinates and other geodetic or geophysical parameters.The analysis with GEOSAT is automated for the combination of VLBI, SLR and GPS observations. The data are analyzed in batches of one day where the result from each daily arc is a SRIF array (Square Root Information Filter). A large number of SRIF arrays can be combined into a multi-year solution using the CSRIFS program (Combination Square Root Information Filter and Smoother, Andersen 2000). Four parameter levels are available and any parameter can, at each level, either be represented as a constant or a stochastic parameter (white noise, colored noise, or random walk). The batch length (i.e. the time interval between the addition of noise to the SRIF array) can be made time- and parameter dependent. GEOSAT and CSRIFS have been applied in the analysis of VLBI and SLR data (LAGEOS I & II) from the period January 1993 to Dec 2002. A few hundred arcs also include GPS data. Earth orientation parameters, geocenter motion, station coordinates and velocities, and GPS transmitter antenna phase center offset and nadir variation were estimated simultaneously with the coordinates of the radio sources and satellite orbital parameters. Recent software improvements and results of analyses will be presented at the meeting.

G07/10P/D-005 — Poster — **1400-089**

DEVELOPMENT OF THE GPS ISRAELI ACTIVE NETWORK

Yosef MELZER, Moshe ROSENBLUM (Survey of Israel)

The Survey of Israel is planning to develop and progress the GPS Israeli Active Network (GIAN) during 2003. In 1996, the first 3 stations were established during the national GPS geodetic campaign. Today, 11 permanent GPS stations are in continous operation. In 2002 we realized that great progress should be made in order to serve present and future needs. It motivated us to plan the various aspects of the GPS active network development, and to make arrangments to carry it out. Our plan is to develop the following components of GIAN: Technology: Servers, Software, Communication, Internet. Professional: Geodetic regulation, Geoid model, Geodetic software, Datum upgrade. Products: Files, Archive, Software, Knowledge. Technical Support: Basically to the geodetic community. Research and Science: Geodynamics, Reference frame. The poster describes our plans and strategy in this matter.

G07/10P/D-006 — Poster — **1400-090**

AN ONLINE SATELLITE ALTIMETRY DATA PROCESSING SYSTEM: ADS CENTRAL

Tilo SCHOENE[1], Achim HELM[1], Alexander BRAUN[2], Hanjiang WEN[1], Christoph REIGBER[1] ([1]GeoForschungsZentrum Potsdam (GFZ), Germany, [2]now at Byrd Polar Research Center, Ohio, USA)

Answering the emerging questions about human-driven climate changes and, more specifically, the sea level change, an interdisciplinary interpretation of various data sets is needed. Several groups on the national and international level are recently active in building up services to facilitate the access to geoscientific data to a broader community, especially the access to higher level products. GFZ Potsdam is currently developing the Modular Earth Science Infrastructure (MESI) into which the German Earth Science and Information System (GESIS) is integrated. In the frame of GESIS the Altimeter Database System (ADS) has been already developed and implemented. The ADS module provides high quality altimeter data for a variety of different altimeter missions and, moreover, processing capabilities for radar altimetry data to a wide range of users. ADS is an attempt to offer easy access to the daily growing satellite altimetry database and numerous geophysical correction models and orbits. Due to the effectiveness of the underlying data structure and software system, new missions and models can be added to the system at any time. The system has undergone several tests by external and internal users successfully and has been proven to be very useful. Especially to those users not having convenient access to a satellite altimetry data processing system and database, ADS offers new possibilities for research activities. ADS can be accessed worldwide via the internet based user-interface ˝ADS Central˝ with a standard browser at http://gesis.gfz-potsdam.de/ads. After a registration process the system offers higher level standard products, calculated routinely from the harmonized and inter-calibrated satellite database. Additionally, ADS allows to generate individual user specific products. The user is able to perform several processing and analyzing steps, e.g. to generate mean sea surface height grids, to extract altimetry data time series around a given location, to analyze parameter variability, or to perform a crossover analysis. Furthermore, the user can specify general parameters like the time interval or regional subsets and may select different correction models (e.g. tidal models). It is further possible to enter several quality parameters to optimize the data for individual applications. These individual user defined products are automatically processed by ADS at GFZ Potsdam and are subsequently distributed to the user.

G07/10P/D-007 — Poster — **1400-091**

THE ORIGIN OF THE TRF FROM SATELLITE LASER RANGING

Erricos C. PAVLIS (JCET/UMBC - NASA/GSFC)

The origin of the Terrestrial Reference System (TRS) is realized through the adopted coordinates of its defining set of positions and velocities at epoch, constituting the conventional Terrestrial Reference Frame (TRF). Since over two decades now, these coordinates are determined through space geodetic techniques, in terms of absolute or relative positions of the sites and their linear motions. The continuous redistribution of mass within the Earth system causes concomitant changes in the StokesÅEcoefficients describing the terrestrial gravity field. Seasonal changes in these coefficients have been closely correlated with mass transfer in the atmosphere, hydrosphere and the oceans. The new gravity-mapping missions, CHAMP and GRACE, and to a lesser extent the future mission

GOCE, address these temporal changes from the gravimetric point of view. For the very low degree and order terms, there is also a geometric effect that manifests itself in ways that affect the origin and orientation relationship between the instantaneous and the mean reference frame. Satellite laser ranging (SLR) data to LAGEOS 1 and 2 contributed in this effort the most accurate results yet, demonstrating millimeter level accuracy for weekly averages. Other techniques, like GPS and DORIS, have also contributed and continue to improve their results with better modeling and more uniformly distributed (spatially and temporally) tracking data. We will present the results from our latest analysis of several years of LAGEOS 1 and 2 SLR data, assess their accuracy and compare them to results from the various other techniques. Finally, we will look into potential improvements in the future, which will likely lead us to even finer resolution and higher accuracy through the constructive combination of the individual time series.

G07/10P/D-008 — Poster — 1400-092

GLOBAL COMPARISON OF SLR, DORIS, AND GPS POSITION TIME SERIES FOR COLLOCATED SITES

Joelle NICOLAS[1], Laurent SOUDARIN[2], Jean-Mathieu NOCQUET[3], Zuheir ALTAMIMI[4], David COULOT[5] ([1]Observatoire de la Côte d'Azur / CERGA, [2]Collecte Localisation Satellites, [3]Department of Earth Sciences / Oxford University, [4]IGN/ENSG/LAREG, [5]IGN/ENSG/LAREG OCA/CERGA)

In space geodesy, and in all its scientific applications, the accuracy of the terrestrial reference frame plays a crucial role in the expression of the results. The current accuracy reached by space geodetic techniques allow the estimation of quasi-periodic station displacements at a few or even a sub-centimeter level mainly due to the loading effects induced by mass redistribution in the oceans, the atmosphere and continental water. The magnitude of such signals requires an optimal definition of the underlying terrestrial reference frame and its time evolution. In this study, we focus on the comparison of position time series obtained for the 1997-2002 period provided by three independent geodetic techniques: Satellite Laser Ranging (SLR), Doppler Orbitography and Radiopositioning Integrated by Satellite (DORIS), and Global Positioning System (GPS) for geodetic sites where these techniques are collocated. Since these sites are used to tie the different solutions from different techniques for the International Terrestrial Reference Frame (ITRF) computation, it is crucial to study their time behavior and the level of agreement between techniques at these locations. Our SLR time series is based on monthly LAGEOS -1 and -2 combined solutions. The DORIS time series is based on monthly solutions with a combination of the data of the SPOT-2, -3, -4, and TOPEX/POSEIDON satellites. The GPS time series is derived from weekly combined global solutions. Time-dependent displacements of stations usually have magnitude close to the accuracy of each individual geodetic technique, and it still remains difficult to extract the geophysical signal from possible artifacts inherent to each space geodetic technique. We use the comparison of our three independent solutions to re-assess uncertainties and determine possible bias associated with each individual technique or processing strategy. The possible origin of the discrepancy noticed between the 3 techniques is also discussed. Special attention is paid to the vertical component for which the geophysical signal is stronger and for which the microwave techniques DORIS and GPS have a less accurate determination than the SLR technique. The comparison allows us to distinguish the common signal observed by the three techniques and to extract the geophysical signal from the noise inherent to each individual geodetic technique. We finally propose a discussion on the possible geophysical meaning of the extracted signal.

THE IERS INFORMATION AND DATABASE SYSTEM

Bernd RICHTER, Wolfgang SCHWEGMANN, Wolfgang R. DICK (Department of Geodesy, Bundesamt fuer Kartographie und Geodaesie)

The IERS information system includes information about the structure, the organisation and the publications of the IERS as well as products from the various Product Centres. General information related to the fields of Earth rotation and reference frames will complement the system. All products within the IERS are generated by an enormous investigation of human and financial resources. Typically they are applied by professional users operating standard procedures of information technologies to receive the data from the various IERS product centres. To make the products also available to a broader scientific and non-scientific community a strategy is going to be developed how the diversity of information within the IERS can be presented in a customer friendly way. Presently facts about all IERS products (e.g. ITRF, ICRF, EOPs, etc.) including links to the product centres and the related data are listed in the IERS Information System. In the future, the IERS Central Bureau will operate a Data Centre to store and archive all data which are necessary for the IERS products and also those which are necessary to re-compute the products. As IERS database input, meta information will be extracted from the archived IERS products and data. The individual database tables will reflect the structure of the represented data and the dependencies between them. Special requests can then be generated to browse all available data with respect to a specific concern. The Central Bureau will utilize the latest technology in Internet-based information exchange with open access to data files and employing security features as required today. Thus, the information system will be run on an Apache Web Server, while the open source relational database management system PostgreSQL is used to model and store the meta information of the products. The Web interface to access and browse this information is realized in PHP, a widely-used general-purpose scripting language that is especially suited for Web development and can be embedded into HTML. Examples will be given how the information about the main IERS products is obtained and stored in the database and how it can be browsed to perform specific requests on the data.

THE CONTRIBUTION OF THE IERS TO THE IGGOS CONCEPT

Bernd RICHTER[1], Markus ROTHACHER[2], Jan VONDRAK[3] ([1]Department of Geodesy, Bundesamt fuer Kartographie und Geodaesie, [2]Technical University Munich, Munich, Germany, [3]Astronomical Institute, Prague, Czech Republic)

The International Earth Rotation Service (IERS) established in 1987 as an inter-union service by the International Astronomical Union (IAU) and the International Union of Geodesy and Geophysics (IUGG), accepted as member of FAGS, understands itself as a substantial part of the future IGGOS. Over the last years the availability of and the easy access to highly accurate and consistent products of the IERS has become of vital importance for geodetic, geodynamic and geophysical projects. Future research and in particular new satellite missions will require the most accurate, reliable and consistent global reference frame as a crucial basis to accomplish their scientific goals, e.g., precise orbit detemination, monitoring of sea level change or other geodynamic and geophysical challenges. The IERS is making use of the advantages and strengths of the individual space techniques by appropriately combining the IGS, IVS, ILRS technique centre (TC) products and supplementary information into official IERS products, striving for the long-term and internal consistency of these official products. The concept of IGGOS is based on the

integration of the three pillars of geodesy, namely the geometry and kinematics, Earth orientation and rotation, and gravity field and dynamics. The IERS already provides important combined products to the first two pillars, i.e., the celestial and terrestrial reference frames and Earth orientation, with its ICRS, ITRS and EOP Centres complemented by the Rapid Service/Prediction Centre. With the guidance of the Analysis Coordinator the Combination Research Centres started the development of methods and software to integrate the different observation techniques into a consistent set of products as a contribution to a future global integrated observing system. The PC and Combination Centre activities will ensure the realisation, reliability and timeliness of these new products. The Convention Centre continues to develop and promote the IERS conventional models, constants and standards to generate consistent and rigorous combined products. Concerning the third pillar it should be mentioned that the IERS functions already include significant non-geometric components, e.g., monitoring of the geocentre and other contributions from the Global Geophysical Fluids Centre. These are the basis of appropriate correction models for atmospheric, oceanic and hydrological influences on all three IGGOS pillars and for the study of geodynamic processes of the Earth system. The IERS sees its participation in the IGGOS project as an organisational and scientific challenge.

QUINS - GRADIOMETRIC MISSION WITH FIVE MICROSATELLITES

Erik W. GRAFAREND[1], Gerrit AUSTEN[1], Oliver BAUR[1], Petar MARINKOVIC[1], Mohammad A. SHARIFI[1], Hans P. ROESER[2], Maria V. SCHOENERMARK[2] ([1]Department of Geodetic Science, Stuttgart University, [2]Institute of Space Systems, Stuttgart University)

˝QUINS˝ is a proposed satellite mission beyond the new satellite missions CHAMP, GRACE and GOCE. A cluster of four nearby microsatellitestrack each other relative to a fifth *master micro satellite* by *Nano Distance Measurements*. All microsatellites are equipped with smallbut efficient electrical propulsion systems enabling formation flights with different satellite constellations, e.g. line, cross, triangles, tetrahedron.The *master micro satellite* is packed with the required and essential technology, serves a main computer system and will provide the downlinkto the ground stations. The additional four smaller microsatellites are identical and carry a mnimum technology package to fulfil the performance.The GRACE observation principle is applied. The four nearby satellites form a high resolution gradiometer of low costs. The satellite system ˝QUINS˝ is simulated and first gradiometric results of the *Eötvös tensor* are presented with respect to thebarycentre of the satellite cluster. They document a very high resolution of the Earth´s gravity field, one order better than possible today. According to the optimal life time of ˝QUINS˝ the long term time variations of the terrestrial gravity field can be detected.

THE INTERNATIONAL LASER RANGING SERVICEAND ITS SUPPORT FOR IGGOS

Michael R. PEARLMAN[1], Carey E. NOLL[2], Van S. HUSSON[3] ([1]Harvard-Smithsonian Center for Astrophysics, [2]NASA Goddard Space Flight Center, [3]Honeywell Technical Solutions Inc)

The International Laser Ranging Service (ILRS) was established in September 1998 as a service within the IAG to support programs in geodetic, geophysical, and lunar research activities and to provide data products to the International Earth Rotation Service (IERS) in support of its prime objectives. Now in operation for more than four years, within the ILRS develops (1) the standards and specifications necessary for product consistency and (2) the priorities and tracking strategies required to maximize network efficiency. The Service collects, merges, analyzes, archives and distributes satellite and lunar laser ranging data to satisfy a variety of scientific, engineering, and operational needs and encourages the application of new technologies to enhance the quality, quantity, and cost effectiveness of its data products. The ILRS works with (1) the global network to improve station performance, (2) new satellite missions in the design and building of retroreflector targets to maximize data quality and quantity and (3) science programs to optimize scientific data yield. The ILRS Central Bureau maintains a comprehensive web site as the primary vehicle for the distribution of information within the ILRS community. The site, which can be accessed at: http://ilrs.gsfc.nasa.gov is also available at mirrored sites at the Communications Research Laboratory (CRL) in Tokyo and the European Data Center (EDC) in Munich. The ILRS currently includes more than 40 SLR stations, routinely tracking more than 20 retroreflector-equipped satellites and the Moon in support of user needs. Through international partnerships, the global distribution of SLR stations continues to improve, especially in the Southern Hemisphere, where coverage has been historically weak. The recently established stations in Tahiti (MOBLAS-8) and Hartebeesthoek, South Africa (MOBLAS-6) are already very important contributors to the network. The Totally Integrated Geodetic Observatory (TIGO), the multi-technique facility developed by the BKG, is now also fully established the site at Concepcion, Chile. New missions added to the ILRS tracking roster over the past two years include CHAMP, GRACE-A and -B, Jason (in tandem with TOPEX), ENVISAT (in tandem with ERS-2), REFLECTOR, Meteor-3M, and ADEOS-II. An intensive tracking activity has also been undertaken on the Etalon satellites to support EOP and gravity field studies. During the last two years, the ILRS has addressed very important challenges: (1) Data from the field stations are now submitted hourly and made available immediately through the data centers for access by the user community, (2) Tracking on low satellites has been significantly improved through the subdaily issue of predictions, drag functions, and the real-time exchange of time biases, (3) Analysis products are now submitted in SINEX format for compatibility with the other space geodesy techniques, (4) The Analysis Working Group is heavily engaged in Pilot Projects as it works toward an ILRS ˝standard˝ global solution, and (5) SLR has significantly increased its participation in the International Terrestrial Reference Frame (ITRF) activity.

DEVELOPMENT OF TWO COLOR INTERFEROMETER FOR DISTANCE MEASUREMENT WITH AN AUTOMATIC CORRECTION OF AIR REFRACTIVE INDEX

Souichi TELADA, Ichiro FUJIMA, Hirokazu MATSUMOTO (Length Standard Section, National Metrology Institute of JAPAN AIST)

A two color heterodyne interferometer has been developed as a reference standard for a laser interferometer and an electronic distance meter.An accuracy of a distance measurement with a light wave in air is mainly caused by a refractive index of air. In order to obtain the refractive index of air along the light path, it is necessary to measure the environment of the air, such as temperature, pressure, humidity and carbon dioxide. But it is hard to measure the parameters over a long optical path.So, we have made a two color interferometer which can correct the refractive index of the air without measuring the environmental parameters. The refractive indices for two wavelengths are different in the same air. The refractive index of the air can be corrected based on the difference.The two color interferometer consists of two independent heterodyne interferometers. One uses the fundamental wavelength of a Nd:YAG laser (1064nm). The other uses the second harmonic wavelength of the laser (532nm). Both beams travel along the same path and interfere with each other. After the interference, these are separated and each beam goes to each photo

detector. For the two color interferometer, the accuracy becomes about 65 times worse than that of each interferometer. The ´65´ depends on both wavelengths. In order to obtain the difference between two optical lengths measured by each interferometer in the air with high accuracy, common noises for the interferometers are reduced by changing reference arm lengths with a feed back servo technology. In this way, it is successful to measure the distance with an accuracy of 10^{-8} relatively with 100 m linear stage in the NMIJ optical tunnel. The accuracy depends on an accuracy of the constant of ´65´ which is calculated from an equation for refractive index of air called Ciddor´s Equation.

THE INTERNATIONAL VLBI SERVICE FOR GEODESY AND ASTROMETRY (IVS) AND ITS PROSPECTIVE

Wolfgang SCHLUETER[1], Nancy VANDENBERG[2] ([1]Bundesamt fuer Kartographie und Geodaesie, Fundamentalstation Wettzell, [2]NVI, Inc. / Goddard Space Flight Center)

The VLBI technique has been employed in geodesy for nearly 40 years. Covering intercontinental baselines with highest accuracy, monitoring Earth rotation at the state of the art and providing the quasar positions as the best approach to an inertial reference frame, VLBI significantly contributed to the tremendous progress made in geodesy over the last decades. VLBI was a primary tool for understanding the global phenomena changing the "Solid Earth". Today VLBI continuously monitors Earth rotation and its variations and also crustal movements in order to maintain global reference frames, coordinated within the International VLBI Service for Geodesy and Astrometry (IVS) – a service of the IAG and IAU. Science and applications set the requirements for the realization and maintenance of global reference frames at VLBI's technical limitations. VLBI as the unique technique for providing a celestial reference frame and for deriving the full set of Earth rotation parameters, plays the fundamental role of generating the basis for many applications and research in the geosciences. IVS coordinates the international collaboration of organizations which operate or support VLBI components in order to provide the support for geodetic, geophysical and astrometric research and operational activities, to promote research and development activities and to interact with the community of users of VLBI products. As service of the IAG and IAU the IVS has taken over responsibility for the provision of the VLBI products, their quality and timeliness. Since 2002 the IVS observing program has been set up promoting the quality and availability of products towards the requirement of the coming up IGGOS. This paper describes the operations of IVS, summarizes and qualifies its products generated continuously. Prospective developments and wishes for the products and the related observing programs are given.

FROM NETWORKS OF STATIONS TO SPATIALLY CONTINUOUS LAND SURFACE DISPLACEMENTS:INTEGRATION OF TECHNIQUES AT REGIONAL SCALE

Susanna ZERBINI[1], Johannes IHDE[2], Alessandro FERRETTI[3], Luciano LAGO[1], Bernd RICHTER[2], Fabio ROCCA[4], Claudia ROMAGNOLI[5], Dietrich SIMON[2] ([1]Department of Physics, University of Bologna, [2]Bundesamt fuer Kartographie und Geodaesie, Frankfurt am Main, Germany, [3]Telerilevamento Europa, Milano, Italy, [4]Dipartimento di Elettronica ed Informazione, Politecnico di Milano, Italy, [5]Dipartimento di Scienze della Terra e Geologico Ambientali, Universita' di Bologna, Italy)

Space geodetic techniques provide the means to monitor in a global reference systemhorizontal as well as vertical velocities of stations on the Earth´s surface. Space observationsalso allow tying together ensembles of terrestrial measurements performed at different spatialscales and temporal resolution. However, fine-tuning in the knowledge of these motions hasnot yet been reached and it constitutes an important step for the next decade or so. Landsurface variations or changes are taking place continuously at very different spatial andtemporal scales ranging from very local to global, and from seconds to millions of years.Among the space techniques, SLR, VLBI and CGPS (continuous GPS) provide information,which is continuous in time, however in space the information is limited to the station location.On the other hand, techniques such as InSAR and Lidar have proven capability to providespatially continuous information, which, however, is limited in temporal coverage. There aremany challenges that we are faced with in the attempt to understand the processes responsiblefor land surface changes/variations and to acquire a predictive capability in order to mitigatethe relevant risks and to define the implementation of practical societal applications. Amongthem, there is a primary need for defining and establishing an appropriate observationalmethodology characterized by the capability to measure, with high accuracy, spatially and timecontinuous deformations of the land surface. Space, airborne and terrestrial techniques can beadopted and used together by taking advantage of the complementary strengths of thedifferent techniques. A contribution towards the realization of such an observational capacityis provided. We describe the ensemble of space and terrestrial techniques, which wereco-located in southeastern Po Plain and along the Adriatic coast, in Italy, to study, inparticular, land subsidence. One example is the Medicina station, near Bologna, were CGPS,VLBI, a superconducting gravimeter and a multitude of terrestrial in formation is available. Forthe Adriatic coast a first comparison between CGPS and InSAR is presented.

DEVELOPMENT OF AN EUROPEAN COMBINED GEODETIC NETWORK (ECGN)

Johannes IHDE[1], Trevor BAKER[2], Carine BRUYNINX[3], Oliver FRANCIS[4], Jacques HINDERER[5], Ambrus KENYERES[6], Jaakko MAKINEN[7], Hans ROHDE[8], Jaroslav SIMEK[9], Herbert WILMES[1] ([1]Federal Agency for Cartography and Geodesy, [2]Proudman Oceanographic Laboratory, [3]Royal Observatory of Belgium, [4]European Center for Geodynamics and Seismology, [5]Ecole et Observatoire des Science de la Terre, Institut de Physique du Globe de Strasbourg, [6]FÖMI Satellite Geodetic Observatory, [7]Finnish Geodetic Institute, [8]International Hydrographic Bureau, [9]Research Institute of Geodesy, Topography and Cartography)

In order to ensure the long-time stability of the terrestrial reference system with an accuracy of 10^{-9} in the global scale and for Europe the interaction between different time dependent influences of the system Earth to the terrestrial reference system and the related observation has to be considered in the evaluation models. The proposal is to establish a kinematic EUROPEAN COMBINED GEODETIC NETWORK (ECGN) to combine the spatial and height reference system with earth gravity field parameter estimation. It is in agreement with the planned IAG project of an Integrated Global Geodetic Observation System (IGGOS). ECGN is an European network for the integration of time series of spatial/geometric observations (GNSS - GPS/GLONASS and in the future GALILEO), gravity field related observations and parameters (gravity, tides, ocean tides), and supplementary information (meteorological parameters, surrounding information of the stations e.g. eccentricities and ground water level). The call for participation is from the point of view of time structured in two stages. The first call is directed to the implementation of the ECGN stations following the concept of the project. The ECGN stations have the standard observation techniques GNSS (GPS/GLONASS, GALILEO), gravity (super conducting gravimeter and/or absolute gravimeter), levelling connections to nodal points of UELN/EVRS and meteorological

parameters. Standard for the ECGN stations is a local network for the derivation of eccentricities in a 1 mm accuracy level in all three spatial components. All ECGN stations are part of the EPN. For the observation techniques guidelines has to be fulfilled. In parallel to the first call the ECGN working group has to prepare the second step for the call of analysis and investigations. The main action of the ECGN working group in the first step is a pilot study of combination of different observations with available stations to get experiences in combination of spatial information with gravity field related data. For super conducting gravimeter data the GGP data centre could be used for data collection. Leveling data of ECGN will be collected at the UELN/EVRS data center. Local data centers for absolute gravity data and super conducting gravimeter data should be installed in the first stage by the ECGN working group.

THE INTERNATIONAL GEOID SERVICE:ACTIVITIES AND FUTURE PLANS

Riccardo BARZAGHI, Fernando SANSO, Ludovico BIAGI, Alessandra BORGHI (DIIAR-Politecnico di Milano)

The International Geoid Service (IGeS) promoted in the last four years several activities centred on geoid computation. One of the main task of IGeS was to promote and organise schools on geoid determination, focussed on theoretical and practical aspects.Four international schools have been organised by IGeS in the last years. The general purpose of these schools was to prepare new graduate students, young scientists and employees of national agencies and services or industry staff to use and compute gravimetric geoids for the main scientific and technical applications.Furthermore, IGeS has actively participated in a relevant project for geoid determination in South America, which was carried out in strict co-operation with NIMA and the Escola Politecnica Universitade de Sao Paulo. Future plans will involve IGeS in geoid estimation activities in Antarctica and in South Africa and in the estimate of the new European geoid.IGeS web has also been updated during these last four years and contains at present regional geoid estimates, global geopotential models and software for geoid computation.Another important activity, which has been continued an improved, was the publication of the IGeS Bulletin that became a reviewed scientific journal. Finally, IGeS proposed, together with BGI, NIMA, ICET and GFZ, the creation of a new IAG service, the International Gravity Field Service (IGFS). This new structure aims at collecting, validating and distributing data and software with the purpose of determining the gravity potential of the Earth, or any of its functional, and the surface of the Earth.

THE INTERNATIONAL GPS SERVICE TRACKING NETWORK: ENABLING DIVERSE STUDIES AND PROJECTS THROUGH INTERNATIONAL COOPERATION

Angelyn W. MOORE, Ruth E. NEILAN (Jet Propulsion Laboratory, California Institute of Technology)

The International GPS Service (IGS), formulated beginning in 1989 and formalized in 1994, was founded on the collaborative operation of approximately 30 permanent GPS stations to benefit global geodynamics. The same cooperative principles, today applied to a network of over 300 stations, still serve to maximize global benefit without unnecessary duplication of investment in global infrastructure. The scope of applications of the dataset has grown to include atmospheric, oceanographic, subdaily, and low-earth orbiter activities through working groups and pilot projects fostered within the IGS in the now traditional IGS spirit of collaboration. These activities and the IGS infrastructure are viewed as critical elements to the Integrated Global Geodetic Observing System. This presentation will review the present nature of the IGS tracking network and its ability to support new applications.

FROM CLEARINGHOUSE SYSTEMS FOR SATELLITE PRODUCTS TO INTEGRATED DATAWAREHOUSE SERVICES FOR SCIENTISTS, DECISSION MAKER AND THE INTERESTED PUBLIC

Bernd RITSCHEL, Knut BEHRENDS, Stephan BRAUNE, Sebastian FREIBERG, Ronny KOPISCHKE, Hartmut PALM, Andrea SCHMIDT (GFZ Potsdam, Data Center)

The scientific products based on the GFZ satellite mission CHAMP and the JPL, CSR and GFZ collocated GRACE mission are managed by the related CHAMP-ISDC respectively GRACE-ISDC. Every Information System and Data Center (ISDC) consists of six main components. The operational system is responsible for the product input and output. The clearinghouse, the heart of the ISDC has been designed as a powerfull catalog system based on mandatory product metadata. All products are stored and archived in the product archive system consisting of an online RAID harddisc part and a quasi online tape part, designend for backup reasons. The product ordering system controls the access to the products depending on the different user requests. Spatial retrieval and presentation as well as product visualization are features of the datawarehouse component. The access to requested information and products are realized by a customer-friendly WWW based graphical user interface. Whereas the ISDCs are developed and operated as solitary project dependend systems, the scheduled GESIS (German Earth Science Information System) will network and integrate unique information and products. One main component of GESIS will be a powerfull datawarehouse. Clearly, this system will base on a harmonized portfolio of most different products of different projects or missions managed by the different ISDCs. In the foregound of GESIS stands the processing and solution of sophisticated geo-scientific problems wich are require a variety of information and products. Diverse scientific services from spatial product retrieval to complete scientific processing workflows will be provided by GESIS. Furthermore, services for decission maker, e. g. in the area of disaster and risk management or specific services for the interested public will be integrated.

A CONTRIBUTION OF THE GEODETIC OBSERVATORY PECNY, CZECH REPUBLIC, TO INTERNATIONAL GEOSCIENTIFIC SERVICES AND PROJECTS

Jaroslav SIMEK, Jan DOUSA, Jakub KOSTELECKY, Vojtech PALINKAS (Geodetic Observatory Pecny, RIGTC)

The Geodetic Observatory Pecny has been operating since 1957. Since the beginning its activities have been oriented to astrometric and satellite positioning, to continuous gravimetric observations and to analysis and interpretation. In 1995 the GOP became an IGS operational station. Nowadays it regularly provides a variety of observation files of GPS and GLONASS satellites ranging from 1 second/15 minute to 30 second/1 day files. The EUREF Local Analysis Center GOP has been operating at the Observatory since the beginning of 1997 and at present it is processing 35 stations of the European Permanent Network. The EUREF LAC GOP is also involved in the EUREF special project ˝Troposphere˝ and in the action COST716 (applications of ground-based GPS for meteorology) by continuous evaluation of ZTDs from observations of 39 permanent GPS stations for the

G

numerical weather predictions. In support of near-real time applications a special data center was established in 2000/2001. The activities of the analysis center GOP were extended by a regular production of hourly orbits of the GPS satellites. The gravimetric earth tides have been regularly observed at the GOP since 1970 and the results have been provided to the International Center on Earth Tides (ICET). Thanks to significant instrumental upgrades achieved at the end of nineties the records of classical gravimeters (Gs15 No.228 and LCR 137) have been processed at the ICET along with the results of superconducting gravimeters. Parallel to gravimetric tidal observations the environmental effects (meteorological parameters , ground water level) have been recorded. After 14 absolute gravity measurements carried out in the period 1978 - 2001 systematic absolute measurements have been carried out by the absolute meter FG5 No.215 since August 2001. The time series includes up to the end of Jan 2003 35 absolute gravity campaigns. A complex approach aimed to a combination of space geodetic observations with terrestrial relative and absolute gravity measurements and environmental information results in joining the newly launched project of the European Combined Geodetic Network (ECGN). The activities of the GOP are described in detail and illustrated by examples of results coming from individual activities.

Presiding Chairs: A.G. Jones, Y. Ogawa

GAI.08/08A/A14-001   **0830**

THE ELECTRICAL STRUCTURE OF THE CRUST AND UPPER MANTLE ALONG PROFILE CROSS CONJUNCTION AREA BETWEEN TIBET PLATE AND NORTH CHINA PLATE

Guoze ZHAO, Yan ZHAN, Ji TANG, Xiaobin CHEN, Qianhui DENG, Jijun WANG, Junmeng ZHAO (Institute of Geology, China Seismological Bureau)

MT data has been recently obtained along 5 profiles in conjunction area of Tibet Plate (TB) and North China plate (NC). The longest profile of about 950km started from Dari in north-eastern margin of TB at southwest end of the profile, then crossed North-South Seismotectonic Belt (NSSB) and ended at Jingbian in Ordos plate of NC in NE direction. The RRI 2-D inversion method was used in the profile and 2-D electrical structure was obtained.The electrical structure of the profile shows that four sub-blocks appeared. They are, from southwest to northeast, Bayankela block (Bb), Qinling-Qilian block (QQb), Haiyuan block (Hb) and Ordos block (Ob). The boundaries between each two adjacent blocks from southwest to northeast correspond to Maqin fault belt (F1), Lanzhou fault belt (F2) and Majiatan-Dashuikeng fault belt (F3) respectively.Different characteristic images of resistivity existed in four blocks. Low resistivity zones in the crust appeared in three blocks Bb, QQb and Ob at depth of about 25km, 15km and 27km respectively. But in the Hb block no large area with low resistivity occurred. Resistivity distribution of Hb is just representative of margin area of 4 plates (about 200km width): TB including Bb and QQb is to southwest side of F2. NC is to northeast side of F3. Alashan plate is in NW side and South China plate is in SE side. This area (Hb) is also called as Conjunction Area (CA). The CA is a part of the NSSB where quite a lot big earthquakes occurred according to the history record especially in the surrounding boundary area of the CA. Lanzhou earthquake (M=7, 1125), Tianshui earthquake (M=8, 1654) and Haiyuan earthquake (M=8.5,1920) located respectively near west, south and east boundary of CA.F1 is eastern section of a big fault belt (Kunlun fault). Kunlun earthquake (M=8.1,2001) occurred in the western section of this fault. The electrical structure shows that F1 is a bigger electrical boundary. Some other faults were also detected along profile. Except for Haiyuan fault being the bigger the others are the smaller. Seismic reflection/refraction data along same profile indicates that the Moho discontinuity becomes shallower from southwest to northeast, (from around 60 km to around 40 km). The low velocity zones in middle crust appeared in Bb, QQb and Hb, but not in the Ob. The agreement and disagreement between low resistivity zones and low velocity zones in the mid-lower crust was discussed. It is postulated that low resistivity zones in Bb, QQb and Ob blocks are caused by the fluids in the crust. Due to the deformation of the crust was week in these blocks, porous water in layers of mid-lower crust was preserved well and shown bigger zones of low resistivity. Due to deformation of the crust in CA area (Hb block) was serious, the layer with porous water may be suffered from strong deformation. Therefore no bigger zone with low resistivity appeared.

LONG PERIOD MAGNETOTELLURIC MEASUREMENTS IN NW- HIMALAYA: IMPLICATIONS FOR MANTLE CONDUCTIVITY

Baldev Raj ARORA, Gautam RAWAT, Vipul NAGAR (Indian Institute of Geomagnetism)

Long period magnetolluric (10-10,000s) measurements are undertaken along a profile extending across Indus Tsangpo Suture(ITS) in Northwest Himalaya.The data supplements the information on the electrical state of the deeper parts of the upper mantle than that was probed earlier by the broadband MT data(300Hz-1000s).The dimensionality analysis shows period dependence strike. In period range below ~700s,the strike is dominantly directed along N 40°W and shows good correspondence with the regional tectonic fabric.However for periods greater than ~700 s, the strike direction is N-S or 10°W, when the phases of single column are same but show significant phase split for two principle polarizations.The uniformity of the strike and near constant phase split around 4000 s at all stations could be a pointer of anisotropic layer at the base of the lithosphere. The nature of vertical fields along the profile is used to constrain the anisotropy or lateral variations in the conductive layer at depth. The varying strike directions in the upper mantle and crust are are discussed in terms of the past trajectory of the indian plate motion and post-collision rotation.

ELECTROMAGNETIC IMAGING OF THE INDIA-ASIA COLLISION ZONE

Alan G. JONES[1], Jessica E. SPRATT[2], K. Doug NELSON[2], Martyn J. UNSWORTH[3], The INDEPTHMT Team ([1]Geological Survey of Canada, Ottawa, Canada, [2]Syracuse University, Syracuse, U.S.A., [3]University of Alberta, Edmonton, Canada)

Project INDEPTH was initiated in 1992 to develop a better understanding of the deep structure and mechanics of the Himalaya-Tibet region, and magnetotelluric surveying was added during INDEPTH Phase II in 1995. Broadband and long period data were acquired in 1995 along a N-S transect crossing the India-Asia collision zone, the Yarlung-Zangbo suture, at 90E longitude. However, these data failed to penetrate to the deep crustal and mantle depths due to low solar activity, and the thick and conducting crust. Deep crustal and mantle information is key for this region to provide a test of the model of subcretion to southern Tibet by the stiff Indian mantle lid. In order to obtain such information, and to provide a second image of the Yarlung-Zangbo suture zone to test along-strike variability, a magnetotelluric experiment was performed in 2001 along longitude 92E, containing an ultra-long period component. MT data were acquired at 28 locations along the new profile, with long period data at 15 of these. Modelling of these data allows a comparison of possible along-strike variation of the Indus-Zangbo suture by comparing the results from this survey with those obtained in 1995. Initial comparisons indicate a similar along-strike electrical conductivity structure even in fine details, suggesting that the dynamic processes are similar.

GAI.08/08A/A14-004   **0930**

DEEP GEOELECTRIC MODEL OF THE TIEN SHAN LITHOSPHERE AND SOME GEOGYNAMIC IMPLICATIONS

Anatoly K. RYBIN, Vlad BATALEV, Gennady TCHELOCHKOV, Elena BATALEVA, Ilia

SAFRONOV (Scientific Station of Institute for High Temperatures-Association, RAS, Bishkek-49, 720049, Kyrgyz Republic)

The Tien Shan orogen area in Central Asia is an ideal, but not simple natural laboratory for investigating processes of lithospheric-mantle formation and evolution. Six dense submeridional profiles of magnetotelluric and magnetovariation soundings in active Central Tien Shan region and the relatively stable neighboring Kazakh Shield and Tarim Plate are integrated to provide a view of large scale structure, tectonic activity, fluid state, thermal regime and strength of the crust and upper mantle. Regional 2-D electrical structure with latitudinal EM-strike was revealed. Basic element of this model is the conductive layer in the middle-lower crust which resistivity varies from north to south from 50-100 Ohm.m to 7-15 Ohm.m. Top surface of layer is rised beneath Tien Shan orogen. Total longitudinal conductivity of this layer is equal about 300-400Sm beneath northern parts of profiles, and the maximal value of 2000Sm is reached beneath Middle Tien Shan. Major active fault zones of Tien Shan are imaged as different geoelectric structures, in first order, with low resistivity blocks (faults: Nikolaev Line, Central-Terskey, Atbashi-Inilchek) and high resistivity blocks (Talas-Fergana Fault). Comparison magnetotelluric and seismic tomographic results gives the basis to consider that simultaneous decrease of both electrical conductivity and seismic wave velocity could be explained by the small fluid content. The coincidence of water content estimated for independent geoelectric and seismic data serve as the strongest argument for the fluid nature of the conductive zone. Porosity and permeability of the upper and lower crust were estimated using the combined analysis of MT and seismic data. Three different-scale factors which are principal candidates for creating of mechanically weakened condition of rocks with high conductivity are considered. The found spatial correlation between surface deformation field, distribution of weak seismicity and geometry of the conductive layer in the Earth's crust beneath Central Tien Shan indicates that the deformation field constructed on GPS data and seismic distribution is uniform tectonic process response which is connected to deep structure of the Earth´s crust obtained with the help of MT-study. Weak seismicity of researched territory occurs above a conductive layer horizon, apparently, because it's viscous nature cannot serve for accumulation of elastic stress. As continuation of geoelectric results interpretation, the regional Tien Shan geodynamical schematic model based on combined geophysical data was constructed. Crustal conductive layer, according MT, geology, seismotomography data, takes place in basement of Tarim's underthrusts at the depth 35-45 km and uplifts to the surface beneath Tien Shan. To the east from Talas-Fergana Fault this conductive layer takes place at the depths from 20 km in the southern margin to 30-35 km in the northern part, it has some inclination and loss of electrical activity beneath Kazakh platform. Conductive layer bounds earthquake hypocenters distribution. Assumption that zone of Tien Shan lower crust's conductive layer is plastic-viscous zone, which was formed, mainly, as result of pressure indentation of Tarim plate to middle-lower Tien Shan crust was done. More complicated interplay of Northern Tien Shan crust's blocks and southern edge of Kazakh plate could be noted.

MANTLE UPWELLING IN THE WEST OF KYUSHU ISLAND AND ANOMALIES OF TEMPORAL GEOMAGNETIC VARIATIONS

Hiroaki TOH[1], Sawako HOMMA[2] ([1]Dept Earth Sciences, Toyama University, [2]Graduate School of Science and Technology, Toyama University)

A nation-wide dataset of induction vectors has been obtained so far (Fujiwara and Toh, 1994). The dataset consists of more than 100 land sites and around 20 seafloor sites. If the coast effect, arising from the complicated land-sea distribution and the deep seas in the vicinity of Japan, is subtracted out using non-uniform thin sheet approximation (McKirdy et al., 1985), it is clear that there exist three major induction anomalies in terms of large residual vectors. They are those around the Hokkaido Island, Central Japan and in the west of the Kyushu Island. The former two are those strongly influenced by conduction effects of Tsugaru Strait and Ishikari Sedimentary Basin (Nishida, 1976), and the well-known Central Japan Anomaly (Rikitake, 1970). The anomaly in the west of Kyushu Island has already been pointed out by previous workers (Handa et al., 1992; Shimoizumi et al., 1997) to show residual vectors with intense westward components.In this study, the possible existence of a mantle upwelling western off Kyushu Island was examined by a newly developed Genetic Algorithm (GA) inversion using the non-uniform thin-sheet approximation as a forward engine. GA inversion yielded a model that has a large conductance anomaly in East China Sea, western off Kyushu, and it successfully reproduced the westward components. The conductance anomaly ranged from southwestern edge of the Korean Peninsula to Goto Islands, Nagasaki, Japan and was found to require additional conductances of the order to 10 [4] S.

MAPPING PLATE BOUNDARIES USING MT ETHOD ALONG THE LONGITUDINAL VALLEY, EASTERN TAIWAN

Chow-Son CHEN, Chien-Chih CHEN (Institute of Geophysics)

Taiwan is located on the convergent boundary between the Eurasian plate on the west and the Philippine Sea plate on the east. The Longitudinal Valley (LV) of eastern Taiwan is believed to be the suture zone between these two plates. In order to detect the subsurface structure and locate the LV fault, magnetotelluric (MT) surveys were carried out. Two units of five component wide-band MT system (Phoenix MTU5) and 2 units of two component telluric system (Phoenix MTU2E) were used to map geoelectric structures beneath the LV. All of these equipments were synchronized using GPS. More than 40 soundings were uniformly covering this valley during 2002. The 2-D apparent resistivity and phase response has been obtained from the observed data. The inversion process by using smoothness constraint obtained the resistivity structure. Both qualitative and quantitative interpretations indicate that the resistivities variations observed to be closely correlated to the change of the surface geology of the LV down, at best, to a depth of the upper 20 km. The resistivity pattern in the western part of the LV is apparently higher, in contrast with an average lower resistivity in eastern LV. This feature correlates well with the surface geology of continental crust on the west to oceanic crust on the east. Moreover, the organized 3-D plots also suggested one predominant electrical discontinuity in the LV, which agrees well with the known suture trace on the surface between the Philippine Sea and the Eurasian plates. The present 3-D configuration of the resistivity patterns also supports the geologic viewpoint that the LV is undergoing severe compression-closure action; the northern part of the valley seems to have been already closed; while the southern part remains opened.

RESISTIVITY STRUCTURE OF THE WESTERN PART OF THE NORTH ANATOLIAN FAULT ZONE BY MAGNETOTELLURICS METHOD

S.Bulent TANK[1], Yoshimori HONKURA[1], Yasuo OGAWA[1], Naoto OSHIMAN[2], Mustafa Kemal TUNCER[3], Masaki MATSUSHIMA[1], Cengiz CELIK[3], Elif TOLAK[1] ([1]Tokyo Institute of Technology, [2]Kyoto University, [3]Bogazici University)

The deep crustal resistivity structure of the western part of the North Anatolian Fault (NAF) Zone has been investigated by using Magnetotelluric (MT) method, since the area is considered as one of the most seismically active zones in the Earth. Several MT profiles were set up in a region where the strike-slip fault separates into two branches. In this study, we introduce two-dimensional models of these profiles. The inversion code used in the creation of the models was developed by Ogawa and Uchida (1996). Both transverse magnetic (TM) and transverse electric (TE) modes were used for the apparent resistivity and phase data that were inverted. A remarkable similarity has been detected between the models and the surface geology. Particularly, the sediments of Izmit Bay basin and an anticline that is cut by the southern branch of the NAF, were clearly seen. Another striking result of the models was that the resistivity is low in general between the two branches of the NAF. The aftershocks of the 17th August 1999 Izmit earthquake clusters on the edge of resistive regions neighbouring the conductor regions supporting the idea of fluid involvement in the earthquake generation process.

TRANS-EUROPEAN SUTURE ZONE (TESZ) AND ITS GEODYNAMIC INTERRELATION WITH THE VRANCEA SEISMOGENIC SLAB, ROMANIA

Dumitru I. STANICA, Maria STANICA (Institute of Geodynamics of the Romanian Academy, 19-21, J.L.Calderon Str, R-70201,Bucharest, Romania)

Despite the vast number of previous TESZ studies, manyquestion about its extent and distribution in the crustand upper mantle persist. While the seismic techniquesare well suited to identifying structural boundaries,they have a more difficult time quantifying physicalproperties, thus other complementary methods are needed.Here we present results obtained from another technique,the magnetotelluric (MT) method, which is sensitive tothe bulk electrical resistivity in lithosphere, toexplain both the TESZ's interrelation with seismogenicvolume and the effect of the geodynamic torsion processof the relic slab, as a possible mechanism for triggeringthe seismic events in the Vrancea zone. In this respect,the results based on the deep MT soundings carried outalong five profiles, placed on seismic active area andits surroundings, electromagnetic tomographic imagesaccomplished at different levels in depth (20km, 40km,60km, 100km, 150km and 200km), including a map drawn upat the brittle/ductile transition zone in the lowercrust, as well as the MT specific parameters obtained byusing the tensor impedance decomposition technique,permitted us to get the following information: (1) theTESZ on the Romanian territory is well marked by a deeplithospheric scar, delineated by a very high electricconductivity anomaly, along the Eastern Carpathians andplays a main role in the confining clearly enough boththe seismogenic relic slab and the European Platform,thus emphasizing the continental origin of the firs one,too; (2) the progressive counterclockwise changes of theslab strike direction within the intermediate-depthinterval (70-150 km), suggesting the continuous torsionprocess of the relic slab. We consider that thisgeodynamic process, mainly generated by asthenosphericcurrents, may be associated with the appearance of cracksinside of the slab, and, together with the dehydration-induced faulting, may represents a realistic mechanismfor triggering the intermediate-depth earthquakesoccurred in the Vrancea region.

CONDUCTING LOWER CRUST BELOW EASTERN GHAT MOBILE BELT EASTERN INDIA

Kalyan Kumar ROY[1], S. DEY[2], S. SRIVASTAVA[3], T. DUTTA[4] ([1]Deaprtment of Geological Sciences, Jadavpur University, [2]Department of Geology and Geophysics,Indian Institute of Technology, [3]AFPRO, [4]Schlumberger Bombay Oil Field)

Magnetotelluric survey from Khorda to Jiral across rivers Mahanadi and Brahmani in Proterozoic Eastern Ghat Mobile Belt (EGMB) within the MT signal time period range of 0.25 seconds to 4096 seconds was carried out using Metronix MMS 02E. From Khorda to Athgarh the data were first inverted using 2D RRI in TE and TM mode. RRI models were chosen as the initial guesses for REBOCC(Reduced Base Occam) inversion. TE (Tipper mode) and TE+TM+TP (Joint inversion) mode inversions were done with improved convergence level. Joint inversion mode reveal that high grade granulite facies rocks like khondalites, charnockites and granulites do not exit in their present high resistive form below 7 /8 km depth. Beyond that depth the crust is highly conducting. Information from deep seismic sounding reveal that the crust is transpatent up to 7/8 km. Beyond that depth, the crust is highly reflective and ductile. High conductivity and high ductility are complementary information. Earth's crust is horizontal below EGMB for a stretch of about 100 km. Several major faults exit along the profile. Therefore collision of the EGMB with the Archaean Singhbhum craton is a possibility. Graben type of structures below Mahanadi river and presence of major faults near Brahmani river are responsible for percolation of meteoric water. That might have generated an upper crustal conductor of about 10 km thick. Khondalites, granulites and charnokites contain plenty of biotites, graphites, banded iron formations (BIFs) and magnetite quartzites. These highly conducting metallic and nonmetallic minerals getting mixed with meteoric water in this rifted terrain generated highly conducting lower crust. TE, TM and TP mode MT models show the signatures of Moho and Lithospere-Astheno=sphere boundary at depths 38km and about 100km respectively. Signature of Moho came out in this terrain because of high conductivity of the lower crust. Electrical conductivity of olivine at moho temparature may be considerably less than those of granufacies rocks in the lower crust. Theoretical one dimensional modeling revealed that detectibility of Moho enhances when the crust mantle structures are mor or less horizontal. Estimation of the depth of the lithosphere-asthenosphere boundary by TE, TM and TP mode are more or less the same. Since vertical component of the magnetic Field Hz originares in the presence of lateral heterogeneities in plane wave Electromag-Netics, Hz component should be included in interpretation. Induction of tipper mode is Just one of the ways to include Hz.

LITHOSPHERIC ELECTRICAL CONDUCTIVITY STRUCTURE FROM MAGNETOTELLURIC STUDIES IN SOUTH INDIAN SHIELD REGION

Naganjaneyulu K., Harinarayana T. (National Geophysical Research Institute, India)

Deep geoelectric structure of Eastern Dharwar Craton and Southern Granulite Terrain were accomplished with 106 magnetotelluric (MT) stations. MT stations were acquired along 6 different profiles with a total length of over 600 km. An east-west trending 200 km long profile across the Proterozoic Cuddapah basin was occupied with 21 MT stations. Towards the south, north-south trending profiles crosses the major shear zones viz., Palghat Cauvery shear zone and Moyar Bhavani shear zone. The terrain boundary of the Dharwar craton towards north and Southern Granulite Terrain towards south has shown marked variation in electrical resistivity. The data were subjected to both 1-D and 2-D modeling. The Cuddapah basin boundaries towards the east and western parts of the profile were clearly demarcated in the present study with a sharp change in electrical resistivity. The basement resistivity structure also showed significant variation below the basin as compared to adjacent region.

The upper crust is high resistive (> 10000 ohm-m) on either side of the basin, while it is less resistive (1000 ohm-m) within the basin. The mid-lower crust is less resistive (500 - 2000 ohm-m) all along the profile. In Southern Granulite Terrain, Moyar Bhavani shear zone has exhibited anomalous high conductivity. The derived models are correlated with other geophysical methods viz. gravity and deep seismic sounding. For example, conductive layer at mid-lower crust showed good correlation with low velocity layer at many locations. The correlation of the anomalous geophysical properties of conductivity, density and velocity revealed the juxtaposition of crustal blocks controlled by major faults/shear zones. Lithospheric electrical conductivity structure in the south Indian shield region is compared with the other shields viz. Canadian shield, Baltic shield and discussed.

PRECAMBRIAN INDIAN SHIELD REGION – THERMALLY UNDERESTIMATED DUE TO FLUIDS –

Vijay K. RAO, S.N. PRASAD (National Geophysical Research Institute, CSIR)

A detailed study of seismic and electromagnetic models and features detected thereof at various depths, in the Indian shield region around Hyderabad has been carried out in conjunction with thermal characteristics, delamination process, underplating and Poisson's ratio. Studies reveal that the nature of Hyderabad crust at the crustal / sub-crustal level is either of constant composition or anisotropic medium connected with amphibolites and the velocities are close to Paleozoic crust The nature of the crust of the Indian shield is yet to be fully explored in the backdrop of Paleozoic tectonothermal processes. Pan -African orogeny and associated tectonothermal processes have been experienced by whole of the Indian sub- continent. In order to get some tentative estimate, an attempt has been made following an empirical relationship, to deduce the age of the crust based on the modeled thickness of the crust. Poisson's ratio suggests that hornblende is the possible mineral in amphibolite rocks or amphibolite facies for the existence of mid-crustal conductor. An excess of this mineral has been found to be an indicator of lower Paleozoic crust; and is connected by differentiation process around Moho. It has also been inferred that possibly Hyderabad region was reactivated during early Paleozoic that initiated the formation of Gondwana rifts. Existing heat-flow values seem to have been underestimated because of fluid pockets in the crust due to amphibolite's dewatering in the mid-crust, restricting the migration of heat to the surface. We suggest delaminated differentiation in the lithosphere in the region has possibly resulted in crustal thinning and formation of Hale's discontinuity. This discontinuity existing in the range of 90 —110 km matches global pattern and brings the association of fluids in sheared zones of upper mantle.

ELECTRICAL CONDUCTIVITY STRUCTURE BENEATH EUROPE ESTIMATED BY GDS METHODS

Takao KOYAMA[1], Hisayoshi SHIMIZU[2], Hisashi UTADA[2] ([1]IFREE, Japan Marine Science and Technology Center, [2]Earthquake Research Institute, University of Tokyo)

We had estimated a 1-D reference model of the electrical conductivity beneath the Pacific by inverting MT and GDS responses calculated from long submarine cable voltage data as well as geomagnetic data from several observatories/stations, taking into account the effect of conductivity contrast of the ocean and land in the inversion (Utada et al., 2003). This structure indicates jumps at 400 km and 650 km depths by two and a half orders of magnitude, respectively. The profile is very similar to the result of the laboratory measurement of electrical conductivity of mantle materials (Xu et al., 1998). Next question is whether this radially symmetric model can be used as a global reference. In this study we tried to examine whether the present model obtained from Pacific data is consistent with data from Europe. Hourly mean values for 1960 - 1999 at 7 geomagnetic observatories in Europe were used. The GDS responses were estimated in the periods from 5 to 100 days, in which the external source of geomagnetic field variations can be well approximated by P_1^0 distribution in the geomagnetic coordinate. As the result of D+ and Occam´s inversions, these responses indicate that the electrical conductivity at the lower mantle is higher by two orders of magnitude than one at the upper mantle. Sharp boundaries of the electrical conductivity in the transition zone were not detected because we used GDS responses at only long periods and they are not sensitive to jumps of the electrical conductivity around this zone. These responses are consistent with the model response from the 1-D reference model beneath the Pacific. On the other hand, the joint D+ analysis by using all the magnetic field data showed that the observed responses are inconsistent with a 1-D model. This means significant 3-D heterogeneity may exist beneath Europe.

CONDUCTIVITY AT CRUSTAL AND UPPER MANTLE DEPTHS: GLOBAL, CONTINENTS, EUROPE

Oldrich PRAUS, Vaclav CERV, Svetlana KOVACIKOVA, Josef PEK, Jana PECOVA (Geoelectricity,Geophysical Institute, Acad.Aci.)

To obtain resistivity estimates at global and continental scales, specifically for the European region, we have started new analysis of geomagnetic long period variation data obtained from NGDC in Boulder. Analysis that is being performed recently, involves three large blocks of data: (i) Hourly means of XYZ components in individual months of minimum solar activity year 1965 with no gaps in data were at our disposal for 24 observatories distributed mainly in Europe and North America. On interpolating data with only isolated missing hourly means, we increased the number of observatories to the total of 43. Removing five D-days for each month, we calculated monthly mean Sq and estimated subsequently 6 Fourier harmonic components. (ii) As the monthly completeness of the data re-duces the number of stations and global coverage, we used special individual Q-days selected and recommended by Schmucker (GJI, 1999). Estimates of 6 time harmonic components were obtained at a number of observatories increased to about 80 - 85. This analysis has been completed for blocks of Q-days in October and May 1965.(iii) The time series of three-year 1096 daily means of the XYZ geomagnetic components for interval of 1958,59,60(maximum activity)

and 1963,64,65 (minimum activity) at 41-43 world observatories were processed by FFT and power spectral analysis. Among spectral peaks for certain bands of periods between 8 and about 50 days, the dominating were those corresponding to 27-day variation and its harmonics at 13 and 9 days.Using the results of analyses in form of the real or complex vectors as input for the spherical harmonic analysis, we obtained complex coefficients Xjm and Zjm, separated the internal/external fields and transformed them to the substitute perfect conductor with its corresponding depth. The estimates are summed up in a graph.Magnetotelluric sounding data recorded at the observatory of Budkov (49.08o N; 14.02o E) provided us with esti-mates of the apparent resistivity distribution in the crust and uppermost mantle of the Bohemian Massif (BM) rep-resenting a resistive consolidated block of the Variscean branch of the European Hercynides. Independent estimates of electrical resistivity at mid-mantle depths were provided by Schultz & Larsen´s (1987) complex inductive scale lengths (ISL) for previous observatory Pruhonice (49.99o N; 14.55o E) (closed in 1972 for industrial noise condi-tions). we present estimate of both observatories in a joint curve representing the resistivity distribution at the mid-mantle depths of the BM. The results for long periods suggest resistivities approaching the lower limit of the deep geomagnetic sounding estimates and they also fit with reasonable scatter to resistivity ranges at several other Euro-pean observatories.Acknowledgement: The results were obtained within the project No. 205/03/1001 supported by the Grant Agency of the Czech Republic.

EMTESZ - ELECTROMAGNETIC PROBING OF THE TRANS EUROPEAN SUTURE ZONE

Vaclav CERV[1], Josef PEK[1], Maxim SMIRNOV[2], Tomasz ERNST[3], Vladimir SEMENOV[3] ([1]Geophysical Institute AS CR, [2]Uppsala University, [3]Institute of Geophysics PAS)

The Trans European Suture Zone (TESZ) marks the division of the European continent in a Phanerozoicpart to the west and a Proterozoic part to the East. The project EMTESZ is directed towards a magnetotelluric study of this zone along several profiles preferentially coinciding with recent refraction seismic lines in Poland. The studies aim at inferring the main features of the resistivity structure of the lithosphere-asthenosphere system by using modern broad band magnetotelluric array measurements. We present the results of pilot measurements in 2001 and 2002 from the northwestern part of the TESZ in Pomerania. We will focus on the quality of earth response functions with respect to man/made noise known to create considerable problems for MT soundings in Poland. Several long period magnetotelluric measurements together with magnetovariational responses from near observatory Belsk give us possibility to estimate the regional geoelectrical structure of the upper part of the mantle. A preliminary model of the geoelectric structure of the crust across the TESZ will be presented.

INVERSION MODELS OF THE CONDUCTANCE IN THE THIN SHEET ON THE EASTERN MARGIN OF THE EUROPEAN HERCYNIDES

Svetlana KOVACIKOVA, Vaclav CERV, Oldrich PRAUS (Geophysical Institute, Academy of Science, Czech Rep.)

The results of inversion modeling of conductance distribution on the contact of the Bohemian Massif with the West Carpathians are presented. The regionof interest represents a contact zone of the Paleozoic Hercynian and Tertiary Carpathian orogenic systems. Their marginal zones are characterized by significant contrasts of the electrical conductivity in the middle and lower crust indicated by the induction vectors distribution. With respect to the periodrange of the recorded data (1000 - 6000) approximation with the unimodal thin sheet at a specified depth both in free space and in the medium with defined conductivity is used. Our inversion algorithm is based on minimization of a parametric functional, that sums the squared norm of the data residuals and stabilizing functional, and employs conjugate gradient optimization. The minimum gradient support focusing is used for generation of focused conductance images with respect to specific character of the geomagnetic induction anomalies, which are connected with sharp tectonicboundaries. Model transfer functions are calculated in original profile points.

MAGNETOTELLURIC SOUNDING IN THE NAIPER COMPLEX, EAST ANTARCTICA

Akira YAMAZAKI[1], Peter DOLINSKY[2], Minoru FUNAKI[3], Naoto ISHIKAWA[4], Yasuo OGAWA[5] ([1]Seismology and Volcanology Research Department, Meteorological Research Institute, [2]Hurbanovo Magnetic Observatory, Geophysical Institute of Slovak Academy of Sciences, [3]National Institute of Polar Research, [4]Graduate School of Human and Environmental Studies, Kyoto University, [5]Volcanic Fluid Research Center, Tokyo Institute of Technology)

The Napier Complex in Enderby Land, East Antarctica, is one of the oldest complexes in the world, as reported 3930 Ma. The 42nd Japanese Antarctic Research Expedition(JARE42, 2000-2001) carried out a magnetotelluric(MT) survey in the Mt.Riiser-Larsen Area, located on the eastern coastline of Amundsen Bay, East Antarctica, in order to investigate the resistivity structure of the Napier Complex. It was a first trial as JARE to perform a full-scale MT survey in Antarctica. The wide-band MT system (Phoenix Ltd. MTU-5), which frequency range is 0.00055 Hz to 320 Hz, was used for the survey. The MT measurement was carried out at six stations around Richardson Lake. Among these, one station was on the middle of frozen Richardson Lake, and others were on moraine deposits. The ranges of the survey area were about 5km east and west, and 3km north and south. The acquired MT data were influenced by non-uniform source field contributions from the auroral electrojet. However, since impedance tensor and transfer function were obtained stably within the period of 100 s, we thought the influence is small and applied a usual MT analyses within that period. The survey area is surrounded by complicated coastline. There is Adams Fjord to the south and Amundsen Bay to the west. In order to estimate the coastline effect, we performed 3-D MT forward calculation by modeling the depth of surrounding sea. From this estimation, it is found that the observed induction arrows can be explained by coast effect roughly except 0.1 Hz to 1 Hz arrows which points to west especially and the impedance tensors are not influenced so seriously within the period of 100 s. These MT sounding curves obtained at each station are roughly the same. The general features of the obtained one dimensional resistivity structure are high resistivity layer from surface to 8km depth, relatively low resistivity layer 8-28km depth and high resistivity layer below 28km depth. This feature of the resistivity structure may be similar to that of the other continental shields.

GAI.08/08P/D-006   Poster   1400-141

THE CONDUCTIVITY STRUCTURE IN THE BACK-ARC REGION BENEATH JILIN AND LIAONING PROVINCE, NE CHINA

Ji TANG[1], Makoto UYESHIMA[1], Hisashi UTADA[1], Guoze ZHAO[2], Masahiro ICHIKI[3], Minzhi MA[4], Yuanchao LIU[5], Xiuqing JIANG[5] ([1]Earthquake Research Institute, University of Tokyo, Japan, [2]Institute of Geology, China Seismological Bureau, China, [3]IFREE, JAMSTEC, Japan, [4]Seismological

Bureau of Jilin Province, China, [5]Seismological Bureau of Liaoning Province, China)

Long-baseline magnetotelluric (MT) and geomagnetic depth sounding (GDS) experiments have been conducted for studying the upper mantle electrical conductivity structure and understanding the geodynamic process of the Pacific back-arc beneath Jilin and Liaoning province, NE China since 1998. 9 sites MT responses were determined up to a period of 10^5 s by using telephone lines with baseline lengths of 10-40 km at 6 stations. GDS responses were obtained for the longer period ranges (up to 10^6~10^7 s) at Changchun, Jilin province. RRRMT data processing method was employed for estimating both MT and GDS responses. Static shifts of MT responses were estimated and corrected with the aid of the rho+ inversion scheme which combines MT and GDS responses by assuming $P_{\bot}^0$ source for the GDS responses. The responses were then inverted by using the OCCAM inversion to determine a smooth 1-D conductivity structure. The conductivity models display several stable boundaries at the depth of about 20 - 30km, 100km, 400 km and 600 km which correspond to lower crustal high conductivity layer, the bottom of lithosphere and the transition zone between upper and lower mantle respectively. The electrical conductivity structures between southern and northern Changchun are different, especially, at the transition zone of the mantle. In the northern of Changchun, the transition zone is several times more conductive than that of the southern area. However the conductivity of the mantle transition zone beneath the investigation region is several times to one order more conductive than those of other tectonic settings obtained by Neal et al., 2000. One possibility is that the subsurface conductivity structure reflect existence or non-existence of the stagnant slab in NE China. Beneath north Changchun area, high conductivity of transition zone may correspond to the presence of a stagnant slab with fluid. *: Ji Tang has backed to Institute of Geology, China Seismological Bureau, China, since may 30,2003 e-mail:jitang@163bj.com

MAGNETOTELLURIC OBSERVATIONS IN THE WESTERN PART OF THE NORTH ANATOLIAN FAULT ZONE

S. Bulent TANK[1], Yoshimori HONKURA[1], Yasuo OGAWA[1], Naoto OSHIMAN[2], M. Kemal TUNCER[3], Masaki MATSUSHIMA[1], Cengiz CELIK[3], Elif TOLAK[3] ([1]Tokyo Institute of Technology, [2]Kyoto University, [3]Bogazici University)

Magnetotelluric (MT) surveys were carried out to investigate the deep resistivity structure in the western part of the North Anatolian Fault Zone (NAFZ), which was subject to a major rapture during the 17th August 1999, Izmit Earthquake. The geology of the study area is complex since it is positioned between the two branches of the North Anatolian Fault. MT is preferred as a method for investigating the crustal structure of the fault zone, because it is an efficient method for detecting the presence of fluid in a media by monitoring the resistivity. Recent observations state that there is high correlation between the earthquakes and fluids. Two-dimensional inversions were performed in four profiles by using the code developed by Ogawa and Uchida (1996). The frequency range for the inversions is between 320 Hz and 0.001 Hz, which is enough to resolve upper-crust structures. The results show that the area is getting more conductive approaching west. The aftershocks tend to occur on the highly resistive areas around the mainshock hypocenter. On the western profiles, on the other hand, aftershocks are occurring in relatively conductive areas. This property of the fault may be related to the heterogeneity of the fault. Here, in this poster presentation we are showing two-dimensional inversion models of two profiles.

GAI.08/08P/D-008   Poster   1400-143

MANTLE CONDUCTIVITY STRUCTURE BELOW THE MARIANA ISLAND ARC

Tada-nori GOTO[1], Nobukazu SEAMA[2], Masahiro ICHIKI[1], Kiyoshi BABA[1], Katrin SCHWALENBERG[3], Noriko TADA[4], Hisanori IWAMOTO[4], Hisashi UTADA[5], Kiyoshi SUYEHIRO[1], Hiroaki TOH[6] ([1]Japan Marine Science and Technology Center, [2]Research Ctr Inland Seas, Kobe Univ., [3]Univ. of Toronto, [4]Earth and Planetary Sci., Kobe Univ., [5]Earthquake Research Inst., Univ. of Tokyo, [6]Dept. of Earth Sciences, Toyama Univ.)

The Mariana Islands are located in the eastern part of the Philippine Sea. Typical island arc tectonics and backarc spreading characterize the region. Mantle upwelling zones exist below the Mariana Islands which form the recent magmatic arc, below the Mariana Trough in the backarc, and below the serpentine seamounts in the forearc. These upwelling zones are probably related to various tectonic features in the Mariana region. However, the deeper structure in this region is not clear, yet. Here, we make a preliminary report of a seafloor electromagnetic experiment in the Mariana region with special attention to the mantle conductivity below the Mariana island arc. The electrical conductivity of the upper mantle is known to be sensitive to temperature variation, the degree of partial melting, and/or the presence of water. Ten Ocean Bottom Electromagnetic instruments (OBEMs) were deployed in the Mariana region in October 2001 to image mantle upwelling zones and dehydration processes in context with the subducting plate. In 2002, five instruments were retrieved. Here, we present the results obtained from two OBEM sites in the vicinity of the Mariana Islands; one located near the arc axis and the other at the eastern edge of the Mariana Trough. At both sites, high quality EM data were recorded for about six months. We used the magnetotelluric (MT) sounding method and a 2-D inversion technique developed by Goto et al. (2003) to derive the conductivity structure below the Mariana island arc. The best fitting model shows on one hand a highly conductive mantle below the Mariana Trough (about 70km in depth). On the other hand, the mantle conductivity below the Mariana Islands is two orders of magnitude less than below the Mariana Trough. This abrupt change of conductivity implies that the conductive mantle wedge is not related to temperature, but to the presence of water in the mantle. We think that this possibly affects the backarc opening procedure in the Mariana Trough. The remaining OBEM sites are located in the Mariana Trough and will be useful to discuss the mantle conductivity structure there in more detail. Also, an international seismological survey has been started in 2001, and an international seafloor electromagnetic experiment will be conducted in 2005-2006. All these additional information will help us to infer the properties of the mantle wedge more clearly.

ABOUT THE PHASE DIFFERENCE OF VERTICAL COMPONENT OF SQ FIELD IN THE CENTRAL JAPAN

Masahiro ICHIKI[1], Hisashi UTADA[2] ([1]IFREE, JAMSTEC, [2]ERI, University of Tokyo)

Rikitake et al. (1956) analyzed magnetic variation in Japan during a geomagnetically quiet period between 1952 and 1955, and pointed out that there is a phase progress in the vertical component of Sq field at Kakioka geomagnetic observatory (KAK) relative to those at other observatories. From this observation, they proposed a qualitative model in which the phase shift can be attributed to anomalous distribution of the mantle electrical conductivity. However, three-dimensional (3-D) numerical modeling has been realized and Kuvshinov et al. (1999) showed that this phase shift of Sq field variations at KAK can be explained by the induction in the oceans, where Schmucker(1985)'s 1-D conducitvity model was used as the background. On the other hand, we analyzed the Sq field variations by the different data

processing. Using hourly values of 3 components of magnetic field in 1964 and 65, the transfer functions of each component of magnetic field at each observation site were calculated to a reference site. First, we reexamined the phase responses of transfer function for KAK and other observation sites in Japan. Irkutsk observatory in Russia was chosen as a reference site. At period of 24 hours, the phase response of vertical component at KAK tends to progress indeed and that of Memambetsu observatory also indicates the same tendency. These results consist with the study of Kuvshinov et al.(1999). However that of Kanoya observatory in Japan seems not to be anomalous behaviour, although it locates close to a coast. With regard to the influence from the tides, we calculated power spectrum density. The superimposed amplitude of P1, S1 and K1 is dominant relative to the amplitude of M1 and O1 for the vertical component at KAK.

NEW FAST METHOD OF THREE-DIMENSIONAL INVERSION OF MAGNETOTELLURIC DATA

Michael S. ZHDANOV, Nikolay G. GOLUBEV (Department of Geology and Geophysics, University of Utah)

Interpretation of magnetotelluric data over inhomogeneous geological structures is still a challenging problem in geophysical exploration. We have developed a rapid 3-D MT inversion method and a computer code based on full nonlinear conjugate gradient inversion and quasi-analytical (QA) approximation for forward modeling solution (Zhdanov and Hursan, 2000; Zhdanov, 2002). Application of the QA approximation in forward modeling and Frechet derivative computations speeds up the calculation dramatically. However, in order to control the accuracy of the inversion, our method allows application of the rigorous forward modeling in the intermediate steps of the inversion procedure and for the final inverse model. The main distinguishing feature of this algorithm is application of the special stabilizing functionals that allow construction of both smooth images of the underground geoelectrical structures and models with sharp geoelectrical boundaries. The 3-D magnetotelluric inversion code has been carefully tested on synthetic models and applied to the practical MT data collected in an area with complex geology. The rapid inversion of the array magnetotelluric data (observed with the hundreds of multi-frequencies observation stations) can be done within a few minutes on a PC to generate the full 3-D image of subsurface formations on a large grid with the tens of thousands cells. The new fast 3-D MT inversion technique has been applied to three-dimensional MT data collected in the areas with complex geology. We demonstrate that for such complex geoelectrical models the 3-D inversion can provide a much more adequate interpretation of the array MT data than conventional 2-D inversion.

MAGNETOTELLURIC 2-D AND 3-D INVERSIONS USING MARKOV CHAIN MONTE CARLO (MCMC) :PRELIMINARY RESULTS

Hendra GRANDIS[1], Toru MOGI[2], Elena Y. FOMENKO[3] ([1]Dept. Geophysics and Meteorology - ITB, [2]Institute of Seismology and Volcanology, Hokkaido University, [3]Computer Science Center of Moscow State University)

A fully non-linear inversion scheme based on bayesian Markov Chain Monte Carlo (MCMC) algorithm has been developped for magnetotelluric (MT) 1-D and thin-sheet models. Application for both synthetic and field data from various scale showed satisfying results with reference to synthetic models and local geology. The paper will describe an attemp to apply the MT inversion algorithm to 2-D and 3-D cases. We incorporate existing 2-D and 3-D MT forward modelling algorithms to our inversion method. The 2-D and 3-D forward modelling are solved using finite-element and staggered grid finite-difference methods respectively. Tests using simple conductivity models showed that there are problems remain to be studied further : (i) equivalence or ambiguity, (ii) sensitivity or resolution in terms of ˝a priori˝ conductivity values. Additionally, efficient and faster forward modelling algorithm is needed since MCMC based inversion is a slow and computer intensive method. Partially resolving the forward modelling due to conductivity change of only one grid or cell might improve the algorithm. Nevertheless, the fact that the algorithm showed decreasing error or misfit is encouraging.

PARAMETERIZATION AND FUNDAMENTAL MODELS FOR EM INVERSION

Igor Ivanovich ROKITYANSKY (Institute of magnetism)

Inversion of any observational data into new knowledge about object under study implies three main stages: parameterization, approximation and optimization. Complex real object, the Earth, possesses infinite number of details, so its precise description is possible only by infinite quantity of numerical parameters. Observation data at any epoch are limited, contain uncertainty and therefore can define only limited number of parameters with limited accuracy. The rest remains undefined and can be selected arbitrarily. Parameterization aims to select the model of real object, adequate to the data in hand and all a-priori information. Parameterization is not formalized, it results from the guess-work of the investigator guided by knowledge of physical regularities, as well as by experience and intuition. The following stages of interpretation (approximation and optimization) are formalized and yield the result (model parameters) in computational regime, but they act only within framework of the parameterization chosen. If parameterization turns out to be unsuccessful, the computed model strongly differs from the real object. Therefore, the parameterization is of primary importance. Catalog of fundamental models (FM) is a useful tool to improve parameterization and therefore the interpretation of real data. FM is a simplified and generalized model of a set of real geoelectric structures, characterized by specific behavior of observed response functions (impedance, magnetic parameters, etc.) to be distinguishable from any other FM. The beginning of the catalog can be as follows: 1) 1D models; 2) 2-D models: 2a) Compact anomalies that are characterized by identical anomalous magnetic fields at long periods under the same longitudinal conductance, 2b) Edge of very wide conductor (e.g. sea, contacts), 2c) Transverse transparent anomalies, which are not seen in B-polarization but clearly seen in E-polarization, 2d) Transverse shunting anomalies.when B-polarization apparent resistivity runs at long periods well below E-polarization; 3) Quasi-2D models: 3a)

Elongated anomalies of varying conductance that can be recognized by comparative analysis of MVP and MTS data even on a profile; 4) Local 3D on 1D background (local scatterers, not resolved spatially by data, are not included in model and considered as geological noise), 5) Local 3D on 2D background. As an example, the modeling results for S-form local structure with 2D continuation are presented, which can be used for 3D inversion. The knowledge of fundamental models helps to make right natural decomposition of inverse problem for a complex geoelectrical structure into a set of more simple problems. The outlined ideology is applied to real data.

INVERSION OF AMT DATA FOR KIMBERLITE EXPLORATION

Alexander K. SARAEV[1], Mikhail I. PERTEL[1], Mikhail N. GARAT[2], Alexander V. MANAKOV[2], Yuri G.PODMOGOV[2] ([1]St. Petersburg State University, [2]ALROSA Co Ltd.)

Kimberlite fields are connected with linear tectonic zones, which appear as series of close on direction deep kimberlite controlling faults. These faults are filled usually by dolerite dikes and can be easily mapped using magnetic methods. Kimberlite pipes inside the kimberlite fields are located along faults of another type - kimberlite hosting, but mapping of them is more difficult, because they are not filled by dikes and do not create significant magnetic anomalies. These faults are appeared weakly at the Earth surface and only in depths more then of 400-600 m they are breccial zones. Kimberlite pipes have usually a low resistivity contrast in comparison with the hosting rocks. Overlaying horizons have significant heterogeneity and include local conductive objects. These features of the kimberlite hosting faults and kimberlite pipes require the increased depth of investigations, high accuracy of measurements and reliability of data interpretation of used electrical prospecting methods. The audiomagnetotelluric soundings (AMTS) method has a good perspective for kimberlite exploration. A primary field in the AMTS has simple structure (plane wave) and using this model we can ensure the authentic data interpretation. Tensor measurements provide the obtaining of reliable results in heterogeneous media. The depth of investigation of the AMTS in the kimberlite fields makes usually from 50 to 1000 m. The surveys using the AMTS method with ACF-4 instrument were carried out for diamond prospecting in Yakutia and Archangelsk regions (10 pipes were investigated). Different character of appearance of the faults depending on the component of impedance tensor was shown. Both 1-D and 2-D inversions were used at the data interpretation. It was found that the upper parts of the faults in interval of frozen rocks from 0 to 300-400 m have a complicated structure. The dipper parts of them in interval from 500 to 1000 m correspond to breccial zones filled by mineralized water. They have the low resistivity of 2-6 Ohmm and can be confidently mapped on the AMTS data. When the search of the kimberlite pipes the low resistive parts of the pipes (2-10 Ohmm) were observed in the depths from 300 to 600 m. These intervals of pipes have the most noticeable resistivity contrast in comparison with hosting rocks. The frozen rocks at the pipes have the significant variability of thickness. This feature can be used for the search of sites, perspective for localization of kimberlite pipes or groups of the pipes. The surveys show the big informative value of studying of kimberlite hosting rocks in interval from 300 to 1000 m and the possibility to solve the problem of kimberlite exploration using the AMTS method.

GLOBAL OPTIMIZATION OF MAGNETOTELLURIC FIELD DATA COLLECTED ACROSS THE ARCHAEAN_PROTEROZOIC CONTACT IN THE EASTERN INDIA USING FINITE ELEMENT FORWARD MODEL WITH ADVANCED LEVEL ELEMENTS

Kalyan Kumar ROY[1], N.S.R. MURTHY[2] ([1]Deaprtment of Geological Sciences, Jadavpur University, [2]Infosys Ltd,)

Two dimensional magnetotelluric forward modeling was done applying finite element method using eight nodded isoparametric elements and Galerkin's weights. The source code written in C was used as a forward model to invert the magnetotelluric field data collected across the Archaean-Proterozoic contact near the northern margin of the Eastern Ghat Mobile Belt and the southern boundary of the Singhbhum Archean craton. Genetic Algorithm(GA) and Very Fast Simulated Annealing(VFSA) was used for inversion of field data.25 pairs of initial models and 15 bit string for a single element are observed to be sufficient to handle two dimensional geoelectromagnetic problems with desired level of convergence. More than 250 generations of populations in GA and more than ten thousand iterations in VFSA were necessary to get complete convergence. Highly conducting crushed contact of the granulite facies rocks in the south and green schist facies rocks in the north could be mapped near Kamakshyanagar, Dt.Dhenkanol, Orissa, India Plots of telluric vectors and induction arrows supported this observation.

GAI.10/09A/A11-006   **1015**

INVERSION OF MAGNETOTELLURIC DATA ALONG REGIONAL PROFILE IN THE NORTH-EAST OF RUSSIA

Pavel Yu PUSHKAREV[1], Mark N. BERDICHEVSKY[1], Alexander V. LIPILIN[2], Leonid L. FELDMAN[3], Robert G. BERZIN[4], Arsen K. SULEIMANOV[4], Andrei G. YAKOVLEV[5], Denis V. YAKOVLEV[5], Elena V. ANDREEVA[5], Igor M. SBORSHIKOV[5] ([1]Geophysical Department, Moscow University, [2]Ministry of Natural Resources, Moscow, Russia, [3]Department of Ministry of Natural Resources, Magadan, Russia, [4]Spetsgeofizika State Enterprise, Moscow Region, Russia, [5]North-West Limited, Moscow, Russia)

In order to study the deep geological structure of vast oil-producing and ore-bearing areas of Russia, complex geophysical surveys (including seismic, electromagnetic, gravimetric, magnetometric and geochemical investigations) are now conducted along a number of regional profiles. In particular, such geophysical surveys have been fulfilled along the profile, which crosses Magadan and Chukotka regions in the North-East of Russia. During 2001 and 2002 the southern part of the profile (830 km long) was studied.Three modifications of magnetotelluric (MT) method were applied here. Audio-frequency MT soundings were performed with a relatively small spacing between sites (1 km) to provide detailed information about near-surface structure. Standard (middle-range) and deep (low-range) MT soundings allowed to study the Earth's crust and upper mantle. They were fulfilled using larger spacings (3 and 12 km, respectively). Magnetovariational (MV) soundings played a key role in studying deep conductive zones.Phoenix Geophysics MTU-5 and Russian-made CES-M equipment were used. The remote reference data processing was carried out.The analysis of impedance tensor and tipper matrix revealed rather strong horizontal inhomogeneity of the medium and helped to choose the strike directions. In order to reduce near-surface distortions, the static shift correction of the apparent resistivity curves was performed. To obtain the geoelectric cross-section along the profile, a smoothed-structure 2D inversion of MT data using Geosystem WinGeoLink software was used. To verify the anomalies revealed, a number of inversions were performed using different data subsets and inversion parameters. 3D modeling was also accomplished to study the distortion effects caused by resistivity variations along the regional strike. The constructed geoelectric cross-section was considered together with seismic results, obtained at the same profile.Inside the Okhotsko-Chukotsky volcanic belt (near the coast of the Okhotskoye Sea) several deep

conductive zones have been discovered. It is remarkable that the seismic Moho boundary is not clearly seen in these zones. Therefore the possible explanation of the nature of these zones is that they are permeable and contain rising flows of mantle fluids. This information is important for the mineral deposits prognosis.Further to the North-East the profile crosses the Yano-Kolymskaya folded system. Here some shallower conductive zones have been outlined. They are associated with the increase of sediments thickness and tectonic activation.

IMPROVEMENT IN TARGET RESOLUTION BY JOINT INVERSION OF MT, SEISMIC, AND DC DATA

Saurabh Kumar VERMA, Ajay MANGLIK (National Geophysical Research Institute, Hyderabad)

A numerical scheme is developed to jointly invert the seismic, MT, and DC electric data. The algorithm has the option of performing individual or joint inversion of any combination of: seismic refraction and reflection, amplitude and phase of MT fields, and DC resistivity data for any electrode configuration. For difficult targets like sandwiched low velocity layer or a thin resistive layer below a conducting overburden, examples are presented to demonstrate that the ambiguity in interpretation is significantly reduced in case of joint inversion. The range of possible solutions is increasingly constrained as more number of data sets is included. This is found to be valid even for noisy data with some vital data points missing. Efficacy of the algorithm is also demonstrated on data relating to: 1) detection of low velocity sediments below a thick layer (~ 1 km) of high velocity basalts, and 2) location of sea water - fresh water interface at shallow depths ($<$ 50 m) in coastal areas.

GAI.10/09A/A11-008   1115

APPROXIMATE JOINT INVERSION OF DC GEOELECTRIC AND REFRACTION SEISMIC DATA

Tamas ORMOS[1], Michael DOBROKA[1], Akos GYULAI[1], Lothar DRESEN[2] ([1]Department of Geophysics, University of Miskolc, [2]Institute of Geology, Mineralogy and Geophysics, Ruhr University, Bochum)

One of the most important possibilities to reduce or abolish the uncertainty of measured VES data, occurring in a single inversion, is known as the joint inversion method. Many joint inversion schemes use 1D forward modelling in the integrated interpretation of various geophysical data. In extending the joint inversion approach to the investigation of 2D structures the discretization of the model parameters and the appropriate choice of the forward modelling procedure play very important role. This problem is closely related to the forward modelling algorithm, used in the inversion procedure. In the paper a seismic-geoelectric joint inversion method is proposed for the investigation of two dimensional near-surface geological structures. Assuming the model being layer-wise laterally inhomogeneous with curved boundaries, a quick ray tracing algorithm is used for the calculation of refraction seismic traveltime data (Ormos, 2002). For the above mentioned reasons we use in the geoelectric forward modeling the locally 1D approximation with model parameters given by the Generalized Series Expansion method. This means, that in calculating the apparent resistivities -at the xj measurement point- the (weighted) integral mean of the laterally varying thickness- and resistivity functions are used as local (quasi 1D) model parameters (Kis, 2001). The boundary surfaces and resistivities are written in the form of series expansion, the inversion algorithms are formulated for the expansion coefficients and the petrophysical parameters, as unknowns. The joint inversion method is tested using both synthetic and field data. The numerical examples show, that the method is quick and stable. It is shown, that relative to the independent geoelectric and refraction seismic inversion procedures, the joint gives better parameter estimation. The joint inversion of geoelectric and refraction seismic field data gives highly reliable and acceptable results demonstrating the validity of the (GSE) approximation used in the geoelectric forward modelling procedure. Ormos, T., 2002. Inversion of refracted travel-times for near-surface investigations, D-25, EAGE 64th Conference and Exhibition – Florence, Italy, 27-30 May, 2002 Kis, M., 2002. Generalized Series Expansion (GSE) used in DC geoelectric – seismic joint inversion. J. Applied Geophysics, 50, 401-416

GAI.10/09A/A11-009   1130

JOINT INVERSION OF GEOELECTRIC- AND SURFACE WAVE SEISMIC DISPERSION DATA

Michael DOBROKA (Department of Geophysics, University of Miskolc)

In the field of engineering and environmental geophysics, near-surface structures are traditionally explored by seismic and geoelectric methods. In order to overcome the ambiguity and non-uniqueness problems inherent in the independent inversion algorithms joint inversion methods are often applied. It was proved by various investigators, that – compared to independent inversion - the joint inversion methods give better parameter estimation in a more stable iterative procedure. In the paper the validity of this statement is extended to the joint inversion of surface wave dispersion data (group velocities) and DC geoelectric apparent resistivities. The laterally varying model parameters (thickness, body wave velocities and specific resistivity) are discretized using series expansion in terms of appropriately chosen base functions. The seismic guided waves are assumed to propagate along the dip direction of the 2D   model while the and geoelectric measurement arrays are assumed to be parallel with the strike direction. The inversion algorithm proposed in this paper uses accurate forward modelling procedure in the calculation of the frequency dependent group velocity of the guided waves (1st order WKB approximation), while in the calculation of theoretical apparent resistivity data 1D approximation is used with the local value of the discretized thickness and, resistivity functions. The inversion algorithm is tested in the special case when the petrophysical parameters are constant and the thicknesses are functions of the lateral coordinates. In the numerical tests geoelectric data sets calculated by means of an FD method are used, while the dispersion data are calculated in the WKB approximation. Two inversion methods are used throughout the paper minimizing the L2 and the L1 norm of the vector of difference between the measured and calculated data, respectively. In the later case the method of Iteratively Reweighted Least Squares (IRLS) is applied. The inversion results are qualified in both the data and model spaces. A comparison is shown between the individual and joint inversion and also between the L2 and L1 inversion methods. It is proved, that the approximate joint inversion procedure is stable and accurate. The non-uniqueness and internal ambiguity problems can sufficiently be reduced by the use of seismic- geoelectric joint inversion. The joint inversion algorithms give much better parameter estimation in comparison with the independent evaluation (inversion) of the data sets measured at various measurement arrays.

SOLUTIONS OF THE INHERENT PROBLEM OF THE EQUIVALENCE IN DIRECT CURRENT RESISTIVITY AND ELECTROMAGNETIC METHODS THROUGH GLOBAL OPTIMIZATION AND JOINT INVERSION BY SUCCESSIVE REFINEMENT OF MODEL SPACE

Shashi Prakash SHARMA[1], Saurabh Kumar VERMA[2] ([1]Department of Geology and Geophysics, IIT, Kharagpur, 721302, India, [2]National Geophysical Research Institute, Uppal Road, Hyderabad, 721302, India)

The problem of equivalence for the DC resistivity and electromagnetic methods for a thin resistive and conducting layer is well known. Attempts have been made in the past to resolve the problem of equivalence through joint inversion. However, it still remains an unresolved problem in electrical and EM geophysics. In the present study, effort is made to reduce the non-uniqueness due to equivalence using global optimization and joint inversion by successive refinement of the model space. A number of solutions derived using very fast simulated annealing (VFSA) global inversion that fit the observation equally well, follow the physical principle and show a definite trend. Model data from simply defined mean model of various VFSA solutions does not necessarily fit the observations. Study of multiple models satisfying equivalence show a definite trend. This trend is ρ_2/h_2=constant and $\rho_2 \times h_2$=constant for conductive and resistive layer, respectively. Former representing a straight line while latter one represents rotated branch of a hyperbola. Logarithmic transformations of both represent straight lines such that mean model fit the observation always. Therefore, the mean model must be defined according to the trend of the non-uniqueness. The mean model defined by multiple VFSA solutions shows extremely large uncertainty (almost 100%) in the final solution after inversion of individual data sets. Uncertainty associated with the intermediate resistive and conducting layers is also very high after global optimization and joint inversion. In order to reduce the large uncertainty associated with the intermediate layer, the global optimization is performed again by reducing and redefining the search limits of model parameters according to the uncertainty in the solution. The new minimum and maximum limits are obtained from the uncertainty in the previous iteration. Though the misfit error reduces in the solution after successive refinement of the model space in individual inversion, it is observed that the mean model drifts away from the true model. However, successive refinement of the model space using global optimization and joint inversion of DC resistivity and EM data reduces uncertainty to a very low level in 4 to 5 iterations. This approach works very well in resolving the problems of equivalence for resistive as well as for conducting layers.

SIMULTANEOUS INVERSION OF ELECTRIC AND MT DATA IN 1-D SITUATIONS USING MCMC METHODS

Michel MENVIELLE[1], Michel ROUSSIGNOL[2], Jean-Jacques SCHOTT[3] ([1]CETP, [2]EQUIPE D'ANALYSE ET DE MATHÉMATIQUES APPLIQUÉES, UNIVERSITÉ DE MARNE LA VALLÉE, FRANCE., [3]EOST, STRASBOURG, FRANCE)

In the Bayesian approach, the inverse problem solution can be obtained from a posteriori probability distribution of the model given the data and a priori information on model parameters. Stochastic algorithms based upon MCMC (Monte carlo Markov Chain) methods have already been developed to solve the Bayesian inverse problems in both electric and MT 1-D situations. The domain under study is divided into a large number of thin horizontal homogeneous layers whose thickness is fixed, and the model parameters are the conductivity of each layer. We use an a priori law of the parameters which favour smooth models. For each layer, the a priori and a posteriori laws are digitised over a limited set of conductivity values. The Markov chain relies on updating the model parameters during successive scanning of the domain under study. For each step of the scanning, the conductivity is updated in one layer given the actual value of the conductivity in the other layers. Thus we designed an ergodic Markov chain, the invariant law of which is the a posteriori law of the parameters, provided the forward problem is completely solved at each step. The a posteriori marginal probability distributions are estimated from the simulated successive values of the Markov Chain. We present an application of this MCMC algorithm to the simultaneous inversion of electric and magnetotelluric data.

GAI.10/09A/A11-012   1215

JOINT INVERSION OF MAGNETOTELLURIC AND SEISMIC DATA FROM SOUTHERN GRANULITE TERRAIN OF THE INDIAN SHIELD

A. MANGLIK, K. NAGANJANEYULU, K. SAIN, T. HARINARAYANA, V. VIJAYA RAO, S.K. VERMA (National Geophysical Research Institute)

An integrated geophysical, geological study of the Southern Granulite Terrain (SGT) of the Indian shield was carried out along the Kuppam- Palani transect in order to delineate the crustal structure and understand the evolution of this Proterozoic crust. This 300-km long transect was covered by deep seismic reflection and refraction, and wide-band magnetotellurics studies besides other geophysical methods. The results indicate presence of a thick mid- crustal low velocity and electrically conducting layer. In the present study, a segment of this profile is selected where both MT and seismic data indicated layered-structure model. Individual inversions of these data sets for wide ranging initial guess models yield different results emphasizing the ambiguity of obtained models. Joint inversion of the two data sets leads to reduction of the range of this ambiguity.

THREE-DIMENSIONAL ELECTROMAGNETIC MODELING BASED ON THE CONTRACTION INTEGRAL EQUATION METHOD

Michael S. ZHDANOV, Gabor HURSAN (Department of Geology and Geophysics, University of Utah)

The integral equation method has been proven to be an efficient tool to model three-dimensional electromagnetic problems. Due to the full linear system to be solved, the method has been considered effective only in the case of models consisting of a strongly limited number of cells. However, recent advances in matrix storage and multiplication issues facilitate the modeling of horizontally large structures.Iterative methods are the most feasible techniques for obtaining accurate solutions for such problems. In this paper we demonstrate that the convergence of iterative methods can be improved significantly, if the original integral equation is replaced by an equation based on the modified Green´s operator with the norm less or equal to one. That is why we call this technique the Contraction Integral Equation (CIE) method. We demonstrate that application of the modified Green´s operator can be treated as a preconditioning of the original problem. We have performed a

A

comparative study of the convergence of different iterative solvers applied to the original and contraction integral equations. The results show that the most effective solvers are the BIGGSTAB, QMRCGSTAB, and CGMRES algorithms, equipped with preconditioning based on the CIE method.The high convergence rate of the iterative methods applied to the contraction integral equation is based on the fact that this new equation is the preconditioned form of the conventional integral equation with the preconditioning matrices determined by the conductivity distribution within the electromagnetic model. This form of the preconditioners is based on the fundamental radiation properties of the electromagnetic field, expressed by the energy inequality, which has a clear physical interpretation: the total energy of the anomalous electromagnetic field radiated outside the domain with the anomalous conductivity is always non-negative. This physical property of the electromagnetic field provides the mathematical convergence property of the iterative methods with the new preconditioners introduced in this paper.

GAI.10/09P/A11-002   1415

THREE-DIMENSIONAL INVERSION OF VERY LOW FREQUENCY (VLF) ELECTROMAGNETIC DATA

Shashi Prakash SHARMA (Department of Geology and Geophysics, IIT, Kharagpur, 721302, India)

Three-dimensional inversion of VLF and VLF-R data measured along several profiles over an isolated conducting structure is considered. Generally numerical modeling and inversion of VLF data are performed considering 2-D structures where subsurface models are assumed on the basis of equivalent current density cross section. In the present study, equivalent current density cross-section over a 3-D structure is studied. The study shows that 2-D current density cross section over 3-D structure yields information useful to construct the subsurface model. These models are described using a set of variables in terms of geometrical and physical parameters. Various model parameters are then optimized (parametric inversion) to obtain best estimates that fit the observation. Apparent resistivity and phase data from E-polarization are used in inversion. The results show that the models thus obtained can also fit the real and imaginary anomalies. A number of models where profiles may or may not be perpendicular to the geological strike are inverted. Data from both E- and H-polarization are inverted together for a complex model that has azimuth as well as dip. Synthetic, noise-free, and noisy data from a number of models are inverted to show the efficacy of the approach.

GLOBAL-SCALE ELECTROMAGNETIC INDUCTION: 3-D TEST COMPUTATIONS AND THE RESPONSE OF A REALISTIC STRUCTURE

Ryokei YOSHIMURA, Naoto OSHIMAN (Research Center for Earthquake Prediction, Disaster Prevention Research Institute, Kyoto University)

We provide a new forward simulator based on an edge element finite element method (FEM) for calculating electromagnetic induction responses in a 3-D conducting sphere excited by an external source current for a variety of frequencies. The formulation is in terms of the magnetic vector potential. The edge element approach used in our simulator assigns the degrees of freedom to the edges rather than to the nodes of the element. In other words, the unknowns are the tangential components of the magnetic vector potential along the edges of the element. This edge element strictly satisfies the discontinuity of the normal boundary conditions across a material interface without considering the enforced normal boundary conditions that are usually practiced in a nodal element FEM. We also propose a new and efficient algorithm for mesh generation. The reason why we developed the algorithm is that little has been reported on tetrahedralization of the 3-D domain adopted to analyze geoscientific problems, although mesh generation is an essential pre-requisite for numerical solution. In comparison with the previous mesh generators, the algorithm presented here has an advantage that the generated tetrahedral element's shape is more appropriate for numerical analyses, especially solutions with the FEM. In order to verify our simulation code, we compare our results with those of other solvers for several test computations, corresponding to azimuthally symmetric and asymmetric thin shell models and a fully 3-D model. As a consequence, the test computations verify our formulation and simulation code, and derive the properties of our simulator. Finally, we plan to apply our code to calculate the response of a realistic mid-mantle structure.

GAI.10/09P/A11-004   1445

PROPERTIES OF THE TIME DOMAIN SURFACE GEOELECTRIC MODELED USING 3D EARTH MODEL AND REALISTIC IONOSPHERIC SOURCE CURRENT

Antti A. PULKKINEN[1], Martin ENGELS[2], Ari VILJANEN[1], BEAR WG[3] ([1]Finnish Meteorological Institute, [2]University of Uppsala, [3]project leader: Toivo Korja, Geological Survey of Finland)

Geomagnetically induced currents (GIC) flowing in technological systems on the ground are known as ground effects of space weather. The primary driver of these currents is the surface geoelectric field which in turn is produced by rapidly varying ionospheric currents. The knowledge about the behaviour of the ionospheric source current and the surface geoelectric field is of great interest when trying to understand the GIC, and the induction phenomena in general. Traditional way to investigate GIC-related geoelectric fields is to use simplified earth models (e.g. 1D) or/and simplified ionospheric source models (e.g. line current and uniform current sheet). Although simplified models have provided valuable knwoledge, the next natural step is to move toward more realistic Earth and ionospheric current models. In this paper, we first derive ionospheric equivalent currents using novel Spherical Elementary Current System method and the magnetic data from about 70 magnetometer sites of the BEAR experiment (June-July 1998). Fourier-transformed time series of ionospheric currents are then fed to the volume 3D code that uses crustal conductivity model based on all available data of the whole Fennoscandian Shield and surrounding areas. 3D code is run for relevant frequencies and the time domain geoelectric fields at the Earth´s surface obtained via inverse Fourier-transforms are analyzed.

INVERSION OF TDEM DATA IN POLARIZED AND SUPERPARAMAGNETIC MEDUM

Pavel O. BARSUKOV, Edouard B. FAINBERG, Eugeny O. KHABENSKY (Applied Electromagnetic Research, the Netherlands)

 1D inversion program for time domain electromagnetic (TDEM) data registered in geological medium characterized by frequency dependence of electrical conductivity, dielectric and magnetic permeability is developed. The inversion algorithms are based on the direct problem solution in layered section with electromagnetic parameters which are complex functions of frequency. The models of frequency dispersion developed by Debye, Cola-Cola, Davidson and Neel in any combination for each analyzed layer of rocks are admitted in the program. Inversion is carried out by purposive enumeration of the layers´ parameters by minimization the functional of experimental and theoretical data misfit. Efficiency of this

approach is shown by the examples of interpretation of experimental TDEM data containing single and multiple changes of a sign of the medium response (program TEM-RESEARCHER). The dispersion parameters of the medium received in result of inversion are used for mineral research, mapping of the environmental contaminations and tectonic dislocations of rocks as well.

GAI.10/09P/A11-006   1515

DERIVING MANTLE CONDUCTIVITY-DEPTH PROFILES FROM REGIONAL HARMONIC ANALYSIS OF GEOMAGNETIC VARIATIONS AT AURORAL OVALS

J. Miquel TORTA[1], Angelo DE SANTIS[2], Lluis R. GAYA-PIQUE[2], Santiago MARSAL[1] ([1]Observatori de l'Ebre, CSIC-URL, 43520 Roquetes. SPAIN, [2]Istituto Nazionale di Geofisica e Vulcanologia, Rome, Italy)

Deep electromagnetic sounding of the Earth can be obtained from thedetermination of an inductive response transfer function from a set of harmonic coefficients representing some measured geomagnetic field variations at or near the surface. Conductivity profile of the average Earth can be deduced from global analyses of the geomagnetic field variations. A reliable way to make regional estimations goes through isolating the distinct field variation over the restricted region by means of a tool that allow separating the external source field from the internally induced one. But, any regional method that is supposed to fit fields with intrinsic wavelengths much larger than the area covering the measurements suffers from an improperly external-internal separation. However, there are some conditions in which it is possible to carry out an analysis of some geomagnetic variations and rigorously separate internal and external fields, i.e. in those cases in which the area of existence of the variations is somewhat coincident with the region defining the analysis; or whensome regional part of the global source field can be separated, because of its independence or symmetry, from the remainder of the variation source. In this work we present some applications of the method of Spherical Cap harmonic Analysis to polar cap and auroral fields which, in turn, present rather complex structures, and so more suitable to be fitted by inherently short wavelength basis functions, so that information about the mantle conductivity beneath the Arctic and the Antarctic can be readably extracted.

TIME-DOMAIN INVERSION FOR THE RADIAL ELECTRICAL CONDUCTIVITY DISTRIBUTION OF THE EARTH'S MANTLE

Yozo HAMANO (Department of Earth and Planetary Science, Universisty of Tokyo)

A new time domain inversion method was applied to obtain a global radial distribution of the electrical conductivity of the Earth's mantle. In this method, sequential data sets of hourly mean values during a large magnetic storm from 57 geomagnetic observatories were used to separate the externally generated field and the induced field based on the spherical harmonic analysis. The separated external field is dominated by P10 component during the initial stage of the magnetic storm, but P21 component becomes significant in the later stage. As for the induced field, the self-induce field is dominant in degree 1 and degree 2 components, whereas the higher components (n >2) were largely contaminated by the secondary field caused by the interaction of the P10 source field and the strong surface heterogeneity due to the distribution of oceans and lands. Relative importance of the self-induced field and the coupled fields in each harmonic component was estimated by the forward calculation of the induction process for the 3-D heterogeneous earth (Hamano, 2002), in which the surface conductivity heterogeneity was assigned based on the surface topography of the earth. The result indicates that the degree 1 and 2 components are mainly due to the self-induced field and the secondary fields are negligibly small. On the other hand, in the higher degree components, coupled components are dominant during the initial stage of the magnetic storm. Hence, for the radial distribution estimate, the low degree components were used, although the higher degree component become important for the determination of the conductivity heterogeneity of the deep mantle. For the inversion, step response of the induced field (time variation of the internal field corresponding to the abrupt change of the external field), were first obtained by combining the external and the internal field. Then, the observed step responses were compared with the theoretical response function of a uniform sphere (Chapman and Bartels, 1940) to obtain the penetration depth, d(t), and the average conductivity to the depth, s(t), as a function of time. The relation, s(t) - d(t), gives the radial conductivity sstructure s(d). Since the present approach can utilize the signals with the time range between 1 hour and several days, the method is more sensitive to the mid-mantle structure (400 km - 1000 km) compared to the previous frequency domain approachs. It is also to be noted that the present approach can explicitly take into account the influence of the surface heterogeneity on the response functions.

ELECTRICAL AND GPR TOMOGRAPHIES FOR ARCHAEOLOGICAL INVESTIGATIONS AT MIT-RAHEINA VILLAGE, GIZA, EGYPT

Abdel- Rady Ghareeb HASSANEEN[1], Salah Sherif OSMAN[2], Mohamed Abdel - Aal ABD - ALLAH[3], Fathy Ahmed SHAABAN[4] ([1]Prof. of Geophysics and Head of the Geomagnetic and Geoelectrical Dept. National research Institute of Astronomy and Geophysics, Helwan, Cairo, Egypt., [2]Assistant Prof. of Geophysics, [3]Lecturer of Geophysics, [4]Lecturer of Geophysics)

This work aims to investigate the near-surface sedimentary cover for tracingthe buried archaeological relics, at Mit-Raheina village, Giza, Egypt. Resistance scanning and GPR profiles have been conducted in the investigated area. Resistance survey have been conducted, using the RM15 Resistance Meter (from the Geoscan Research Insititute, England), at Tell El-Rabi'a (behind Hathour Temple). A total number of 12 square grids, with grid length of 20 m, are conducted. The field data are processed and illustrated using the GEOPLOT software. Sixty-five detailed GPR profiles were measured at Tell El-Rabi'a using the Surface Interface Radar, SIR-2000 instrument, and utilizing a 400 MHz antenna with a time window 100 ns.Two Way Time (TWT), 38 profiles are carried out east to Hathour temple, each profile has a length of 60 m with profiles apart of 1 m and 27 profiles are carried out north to the temple, each of them has a length of 40 m and profiles apart of 1 m. The analysis of the radar sections and the resistance measurements with the available excavation data allowed for identification and constructions of the shape and extension of

the expected archaeological targets beneath the earth surface.

GEOELECTRICAL STUDY TO DELINEATE THE EFFECT OF GROUNDWATER INCREMENT IN ABU-SIR ARCHAEOLOGICAL AREA, EL- GIZA, EGYPT

Abdel - Rady Ghareeb HASSANEEN[1], El-Said Ahmed EL-SAYED[2], Mamdouh Mohamed SOLIMAN[3] ([1]Prof. of Geophysics and Head of the Geomagnetic and Geoelectrical Dept. National Research Institute of Astronomy and Geophysics, Helwan, Cairo, Egypt., [2]assistant Prof. of geophysics., [3]assistant Lecturer of geophysics)

Abu-Sir area has a great archaeological importance whereas, it includes the Sun Temple, three famous archaeological Pyramids, and many other tombs. The present study is concerned with mapping the groundwater aquifers, delineating the litho-facies distribution and the structural controls, and for studying the characteristics of the groundwater in Abu-Sir archaeological area. In the geoelectrical resistivity work, 45 VESes using Schlumberger configuration were carried out. In a primary step to interpret the present data qualitatively, the apparent resistivity data are used to construct iso-apparent resistivity maps and sections. From the qualitative interpretation, it is concluded that, the resistivity values increase with increasing AB/2 reflecting the presence of two bearing water zones (shallow and deep aquifers). The thicknesses of these aquifers increase to the east of the area under investigation and decrease gradually to the west of the area. The apparent resistivity data is processed and interpreted quantitatively using Zohdy (1989) and Resist (Velpen, 1988) programs. The interpreted resistivity data are used in constructing twelve geoelectrical cross-sections (two are given), two iso-pach maps for the two upper layers (zone A and B) and water level map for the deep aquifer surface (zone C). According to these cross-sections and maps, the area under investigation is divided into four geoelectrical zones. The upper zone has a thickness varying from 4 to 19 m and consists mainly of sandy gravel, while the second zone varies in thickness from 15 to 40m and varies in lithology from clay to sandy clay, and is underlain by a sandy zone intercalated with clay lenses having a thickness of about 50m. The fourth zone is a very high resistive zone, which is referred to limestone and marly limestone equiclude. It is also appeared from the groundwater map constructed based on the resistivity data and in the light of the previous hydrographs for the groundwater wells in and near the area under study that, there is slightly decrease in the groundwater level after the construction of the High Dam.

MAPPING OF BURIED ARCHAEOLOGICAL RELICS USING GPR SURVEY AT THE ISIS TEMPLE AREA, BAHBEIT EL-HEGARA, EGYPT

Fathy Ahmed SHAABAN[1], Fouad Fawzy SHAABAN[2], Abbas Mohamed ABBAS[3], Abdel Aleem Hassan EL-ESSAWY[4] ([1]Lecturer of Geophysics, National Rsearch Institute of astronomy and geophysics, Helwan, Cairo,Egypt., [2]Professor of applied Geophysics, Geology Dept., Fac. of science, Mansoura Univ. Egypy, [3]Lecturer of Geophysics, National Rsearch Institute of astronomy and geophysics, Helwan, Cairo,Egypt., [4]Geophysicst, Schlumbeger company)

The Interpretation of ground penetrating radar (GPR) surveying data on the archaeological site of Isis temple of Bahbeit El-Hegara area helped in tracing and mapping buried relics of that temple. Sixty-three GPR profiles were conducted at the southern and eastern parts of the temple area using the SIR (Surface Interface Radar) -2000 instrument and 400 MHZ antenna with time window of 100 ns. A preliminary GPR profile was conducted on a partially buried granitic block stone of the destroyed temple for subsequent calibration and interpretation of the GPR sections and for the dielectric constant and velocity determination. The field GPR data are processed by using the Radan and Reflex programs. Analysis and interpretation of the GPR sections reveal anomalous relics of different shapes and dimensions buried at depths ranging from 1 to 5 m below the ground surface. These relics are either irregular stone blocks or regular building structures (probably walls and columns of the destroyed temple). On the other hand, the wave amplitude time slices were constructed illustrates the subsurface locations and extension of these delineated archaeological relics in the study area.

GEOELECTRIC STRUCTURE ACROSS NARMADA-SON LINEAMENT ZONE, CENTRAL INDIA, FROM 2-D MODELING RESULTS

Bantu Prasanta Kumar PATRO, Harinarayana T., Sastry R.S., Madhusudan Rao, Manoj C., Naganjaneyulu K., Sarma S.V.S. (National Geophysical Research Institute)

Magnetotelluric studies have been carried out with 25 soundings along NNE-SSW trending traverse from Edlabad-Khandwa across Narmada-son lineament (NSL), an important tectonic zone in peninsular India. The 130 km long traverse also passes through intense seismic tremor activity near Khandwa. The data were subjected to two different 2D inversion schemes- RRI and Occam. For better resolution, modelling of the data was carried out in two steps- first with the high frequency part of the data to get the shallow section and then with the data for the total frequency range. The model for the shallow section has brought out moderately resistive layer (30-150 Ohm.m) representing the exposed Deccan trap layer overlying a conductive layer (10-30 Ohm.m) corresponding to the subtrappean Gondwana sediments. The thickness of this subtrappean sediments amounts to as much as 2 km in the northern half of the profile. Further, the model has brought out well defined vertical conductive features, spatially coincide with Gavligarh, Tapti, Barwani-Sukta and Narmada south faults. The high resistive upper crust is relatively thick towards the southern end and tends to become thinner in the middle of the traverse. The lower crustal segment is conductive over a major part of the profile. The subsurface model integrated with the available regional gravity together with constraints from the nearby Ujjan-Mohan DSS traverse, provided a better constrained crustal structure for the region. The relation of the crustal model to the seismotectonic significance of the NSL region is discussed.

3-D MODELLING AND ANALYSIS OF THE DST C-RESPONSES IN THE NORTH PACIFIC OCEAN REGION, REVISITED

Alexei KUVSHINOV[1], Hisashi UTADA[2], Dmitry AVDEEV[1], Takao KOYAMA[3] ([1]Geoelectromagnetic Research Institute, Russian Academy of Sciences, 142190, Troitsk, Moscow region, Russia, [2]Earthquake Research Institute, University of Tokyo, 1-1-1 Yayoi, Bunkyo-ku, Tokyo 113-0032, Japan, [3]Japan Marine Science and Technology Center, Natsushima, 2-15, Yokosuka, 237-0061, Japan)

We have performed detailed 3-D simulations in the model with a realisticinhomogeneous surface layer in order to understand, which one-dimensional 1-D upper mantlemodel beneath North Pacific Ocean from a bunch of those published in the lastdecade, is in a better agreement with a majority of available experimental data.Our main finding is that there exists persistent disagreement between experimental and 3-D modelled C-responses when

1-D sections ofLizarralde et al. (1995), Semenov (1998) or Neal et al. (2000) are consideredas the upper mantle sections. Our 3-D model studies and reinterpretation of theexperimental data confirms the inference of Utada et al. (2002) that uppermantle beneath North Pacific Ocean in depth range down to 400 km is much moreresistive than it was guessed before. In particular our 1-D upper mantle modelsdoes not reveal astenosphere conducting layer. While 3-D modellings it was detected that there exists a systematic shiftof experimental GDS C-responses at Honolulu observatory compared with theexperimental C-responses at another observatories. It is still unclear whatis the reason of such a shift. At least 3-D simulations in the model of theinhomogeneous surface layer even at a very detailed grid of 0.3°×0.3° don'sexhibit notable ocean effect in the GDS C-responses at this site. An attempt has been made to reduce the misfit between experimental andmodelled C-responses by incorporating into 3-D model the inhomogeneouslithosphere and upper mantle. However we could observe only slight changes inthe behaviour of the model responses, because the ocean has much strongerinduction effect than deep mantle heterogeneities. Routine simulations in realistic 3-D models became possible due to novel3-D spherical forward solution that is also presented in this contribution.The solution combines modified iterative-dissipative method with Krylov subspace iteration and grid detalization scheme, and allows one to computeefficiently the EM fields in full 3-D spherical models with very high lateralcontrasts of conductivity and at very dense grids.

ANTENNA POLARIZATION EFFECT IN TDEM

Pavel O. BARSUKOV, Edouard B. FAINBERG, Eugeny O. KHABENSKY (Geoelectromagnetic Research Institute RAS)

It is well known that sometimes TDEM responses in coincided antennas change a sign, forming negative anomalies. This phenomenon is usually associated with complex, frequency dependent resistance of rocks. However in some cases frequency dispersion cannot explain the features of really measured signals. For example, at late stages of responses the negative signal attenuates in time more slowly than ~1/t and depends on resistance of antenna´s cable. On the basis of theoretical analysis of EM-field of antennas with dispersive capacity and resistance, laying on the surface of 1D layered medium with frequency dependent dielectric permeability, it is established, that at axisymmetrical excitation of magnetic field there are both vertical and radial components of an electric field, and signal decay in time with the speed depending on relaxation time of dielectric permeability of medium. The amplitude of the signal is proportional to a square of resistance of the antenna´s wire and their capacity. This phenomenon was confirmed with numerous experiments and named as Antenna Polarization effect (AP-effect or AP). AP-effect makes it possible to explain registered negative TDEM anomalies which amplitudes depend on resistance of antenna´s wire, their location above a surface of the ground, humidity of ground and air etc., abnormal slow decay in time of negative TDEM signals both in coincided and in loop-in-loop antennas.

ON THE UNIQUENESS OF THE INVERSE PROBLEM SOLUTION FOR METHOD SQ-VARIATIONS

Peter S. MARTYSHKO, Peter S. MARTYSHKO, Valentin A. PYANKOV (Institute For Geophysics)

As field magnetization it is suggested to use a field of Sq-variations.The research of effects of a field magnetization with the help of these variations is ofinterest in connection with a large deep of penetration of the field (that isnot so solid for an artificial source), regular occurrence ofSq-variations and their wide circulation. For depths in the firstkilometers the field magnetization field of Sq-variations practically issimilar.The Sq-variations are generated by system of electrical currents in the toplayers of an atmosphere (ionosphere). General distribution ofvectors of variations to the earth surface depends on the fact that thesystem of currents, adequate for Sq-variations, embraces an arc (30) on a midday meridian and remains motionless in space between theEarth and Sun. The observer, rotating round this system, fixes during 24 hours all values of a vector of the intensity of the field, caused bythe currents. Thus, we have a situation, similar tocontinuous moving of a source of a primary magnetization field.Therefore it is of interest to investigate questions ofuniqueness of the inverse problem solution of magnetic exploration incase of a field magnetization by a similar field, continuously changing thedirection. We showed the possibility of determinationof parameters of the object in the form of an elliptic cylinder from resultsof monitoring of effects of a field magnetization by a field ofSq-variations. On a practical example we illustrated the opportunity of determinationof parameters of an anomaly forming body on measurements data of a magneticfield, induced by Sq- variations. As a result of interpretation a basic opportunity of determination ofthe unique solution of a nonlinear inverse problem of a method of a fieldmagnetization the rotating field of Sq-variations on data of synchronousdifferential supervision of the module of a complete vector T of ageomagnetic field is shown. The offered approach - methodical basis foroperative interpretation of magnetic anomalies has, in comparison withearlier existing methods, the following advantages:a) With the help of a powerful source of a similar rotating fieldmagnetization field (the Sq-variation) is possible essentially to increase adeep of a method of a field magnetization and to lower its labor input;b) Application of the new interpretational apparatus allows simultaneouslyto determine boundary and magnetic susceptibility of abnormal object, that within the framework of a method of variations was considered problematic.

CHARACTERIZATION OF GEOTHERMAL RESERVOIR AROUND A HOT SPRING THROUGH INTEGRATED GEOPHYSICAL AND GEOCHEMICAL STUDIES

Shashi Prakash SHARMA (Department of Geology and Geophysics, IIT, Kharagpur, 721302, India)

Geoelectrical, very low frequency (VLF) EM and ground magnetic surveys are carried out to characterize the geothermal reservoir around a hot spring in Nayagarh, Orissa, India. Vertical electrical sounding (VES) studies in the area reveal the presence of two to four prominent litho units. The weathered and fractured litho units constitute the main aquifer system. The results of geophysical survey coupled with the geochemical studies and well inventory show venting of thermal water into the regional aquifer system through the fractured and weathered rocks. As a result, fluoride contamination is occurring in villages around the hot spring. Fluoride concentration is observed to be very high in both the hot spring and the groundwater of Singhpur village compared to those in surrounding areas. Spatial distribution of apparent resistivities at different electrode spacings indicates the presence of a low apparent resistivity zone encompassing the hot spring and the fluoride contaminated villages such as Singhpur and Sagaragan. Fluoride concentrations of groundwater and hot spring water show an inverse relation with the apparent resistivity of the formation at different electrode spacings. Finally, detailed VLF and ground magnetic survey is carried out to find the fractures in the crystalline rocks and their direction to assess the movement of contaminated groundwater.

ANALYSIS OF THE POSSIBILITIES OF LOCAL MAGNETOVARIATIONAL SOUNDING

Pavel Yu PUSHKAREV, Mark N. BERDICHEVSKY, Vladimir I. DMITRIEV, Nina S. GOLUBTSOVA (Geophysical Department, Moscow University)

One of the most troublesome problems of magnetotelluric explorations is the correction of near-surface distortions. To avoid this difficulty, we turn to the local magnetovariational sounding, employing the magnetic field. It is well known that near-surface magnetic distortions attenuate with lowering frequency. Until recent times the interpretation of magnetovariational anomalies was constrained because of the insufficient understanding of its potentials. We think that the very important event was proof by professor Dmitriev of the uniqueness theorem for 2D magnetovariational inverse problem. This allows us to treat the magnetovariational sounding with its freedom from near-surface distortions at low frequencies as a base method of deep geoelectrics. A number of experiments involving 2D and 3D modeling and 2D inversion were performed in order to study the potentials and frontiers of the local magnetovariational sounding. Models containing several conductive and resistive bodies have been considered and the resolution of the magnetovariational sounding has been studied. It was shown that single conductive bodies manifest themselves separately if the distance between them considerably exceeds their depth. Criteria of structural quasi-two-dimensionality have been derived. It was shown that conductive and resistive three-dimensional structures allow for two-dimensional approximation of magnetovariational indicators if the aspect-ratio of the structures exceeds 10. The methodology of deep electromagnetic investigations combining the local magnetovariational sounding (basic information) with the magnetotelluric sounding (detailed information) has been considered. We suppose that the most efficient approach to the inverse multicriterial magnetotelluric inverse problem may be constructed using a sequence of partial inversions taking into account the different sensitivity and different robustness of magnetovariational and magnetotelluric indicators. Using this approach, several successful inversions of synthetic and field data have been performed.

TWO-DIMENSIONAL MAGNETOTELLURIC INVERSION USING MONTE CARLO MARKOV CHAIN ALGORITHM

Nugroho Dwi HANANTO[1], Djedi Setyo WIDARTO[1], Hendra GRANDIS[2] ([1]Research Center for Geotechnology, Indonesian Insitute of Sciences, [2]Department of Geophysics and Meteorology, Institut Teknologi Bandung)

This paper describes the integration of two-dimensional magnetotelluric forward modeling into an inversion method based on a stochastic Monte Carlo Markov Chain (MCMC) algorithm. Effective exploration of model space is performed using biased sampler that is believed to have an ability to avoid local minima entrapment that frequently encountered in highly non-linear inversion problem. The Markov Chain relies on updating the model parameters during successive scanning of the domain under study. For each step of the scanning, the conductivity is updated in one element given the actual value of the conductivity in the other element. Thus we designed an ergodic Markov chain, the invariant distribution of which is the a posteriori distribution of the parameters, provided the forward problem is completely solved at each step. Results from inversion of synthetic MT data show that the algorithm can reasonably resolve the true structure. Effectiveness and limitations of the proposed inversion method is diccused with reference to the synthetic data inversions.

A FAST APPROXIMATE INVERSION PROCEDURE TO INTERPRET MAGNETOTELLURIC DATA

Erno PRÁCSER[1], Michael DOBROKA[2], Márta KIS[1] ([1]Eötvös Loránd Geophysical Institute, Budapest, [2]Department of Geophysics, University of Miskolc)

In the presented simultaneous inversion algorithm a quick forward modeling is applied, which is approximate in the sense that the predicted data are calculated by means of formulae given for 1D geological models. In order to improve the often used 1D forward modeling approximation, the integral mean value of the horizontally changing model parameters (calculated along an appropriately defined interval) is introduced for giving a more complete lateral sight. Optimizing this interval and appropriately choosing the weight function, a new tool serves for decreasing the difference between 1D and 2D interpretation in the process. The approximate inversion method is tested by using synthetic and field data. During the numerical investigations a 2D model is defined and the synthetic data sets are generated by applying a real 2D forward modeling code. In order to simulate real data sets 1% random noise is added to the calculated data. A comparison is made between the results of a real 2D inversion procedure and the presented approximate inversion algorithm. It is shown, that the presented algorithm is quick, stable and accurate enough for practical work. Its reliability is demonstrated by using it in interpreting in-situ measured data. Using the approximate inversion procedure a problem –often arising in solving 2D inversion problems - can be answered: the higher reliability and stability of the simultaneous and/or joint inversion algorithms are not always achievable in case of more complicated geological structures. In order to find acceptable inversion results it is very important to use appropriate discretization method. Another important factor in choosing the discretization and the inversion methods is the computation time. Taking this into account -as a reasonable compromise- it is often useful to reduce the number of unknowns (in order to ensure the accurate and stable parameter estimation). Our results show, that the WGSE inversion algorithm can be considered as a good candidate to realise this compromise with acceptable accuracy and cost effective calculation speed.

SOME PROBLEMS APPLYING THE 3D MODELING SCHEME TO PRACTICAL DATA

Elena Yu. FOMENKO[1], Tohru MOGI[2] ([1]Moscow State University, Moscow, Russia, [2]Institute of Seismology and Volcanology, Sapporo, Japan)

We applied a forward and inverse modeling scheme for CSMT and MT 3D data to the Usu volcanic area, Japan, to clear a resistivity structure. The Usu is an active volcanic area covered mostly by recent volcanic rock (lava or ocrastics). It is located near Usu-Shinzan fault. 2D-model in the part of this area was investigated by Ogawa et al., 1999 and Ballestracci and Nishida, 1987 (AMT data). The field data contained amplitudes and phases of impedance at 25 CSMT sites in the far zone (frequencies were in the range 0.6 - 5000 Hz) and 10 MT sites (0.0005 - 320 Hz). The data were essentially 3D and noisy. The impedances were obtained from measured Ens-Hew (Zxy) and Eew-Hns (Zyx). At first the data were smoothed and cut. Then 1D-inverse modeling scheme was applied both to the impedance amplitudes and phases taking in account the topography structure at each CSMT and MT site. Because data were essentially 3D, we used the invariant of impedance $Zinv = sqrt(Zxx*Zyy – Zxy*Zyx)$ and corresponding Rinv. Then we constructed 3D resistivity model.

At first the average algorithm was used to calculate apparent resistivity values at each Z-level for the given sites (1D). Second, the interpolation was applied in the central part of sites to convert irregular data grid to the non-uniform rectangular one at each Z-level, the extrapolation in the blank of data areas was made by using method of the nearest neighbor. The special areas (the sea, the lake Toya) were added to the 3D model manually. The constructed 3D resistivity model based on 1D-inversion data was investigated by using 3D forward modeling code based on 3D staggered grid finite difference approximation of the electrical field in the Maxwell equations (E. Fomenko, T. Mogi, 1999, 2002). This code was applied to the linear system of 380,000 * 3 equations (for Ex, Ey, Ez) to calculate Rapp amplitudes and phases at the 91 frequencies (9 decades). The relative error of stopping iterative process for the relative residual r/r_0 and divergence of the electric current $DivJ / |J|$ was less than 1.E-6. Simulation was carried out at the PC with Pentium-III CPU, 500 MHz, 512 MB RAM. The calculation required from 20 minutes to 3 hours depending on frequency. Finally we obtained a 3D resistivity model of the USU area up to 5 km depth including topography, the spacing of sites were 100 m. After comparison 1D and 3D Rapp-inv the correction of 3D-reristivity model was made. Finally the difference between 1D, 3D and the field data Rapp were not less than 10-15%.

IDENTIFICATION AND LOCALIZATION OF ARCHEOLOGICAL OBJECTS IN MAGNETIC SURVEY BY COMPLEX WAVELET ANALYSIS

Ginette SARACCO[1], Pierre-Etienne MATHE[1], Frederique MOREAU[2], Daniel HERMITTE[1] ([1]CNRS-UMR 6635, CEREGE, Department of Geophysics, Aix-en-Pce, [2]CNRS-UMR 6118, Geosciences-Rennes)

We want to detect and localized buried structures like antik ovens from magnetic measurements performed on the Fox-Amphoux site (France). A well-know method to localize in depth sources,responsible of potential anomalies measured at the ground surface (magnetic or electric), is the real continuous wavelet transform (WT), with the Poisson analyzing wavelet. This wavelet is real by definition. We have here applied a position-scale analysis from complex analyzing wavelet to use complementary information carried by the phase of the wavelet transform. Complex wavelets are built by Hilbert transforms of the Poisson or derivative of the Poisson analyzing wavelet. We show that the phase of the WT provides additional information on the geometric and total magnetic inclination of potential sources, as the modulus allows to characterize their depth and heterogeneity degree. The phase compared to the modulus, is more stable in presence of noise and we can defined it, independently of the low level of energy of the signal. In this sense, information carried by the phase is more efficient to detect small objects or to separate close sources. Conjointly, a rock magnetic study including susceptibility and magnetisations (induced or remanent) measurements give a better constrain on the magnetic parameters we want to extract.

COMPARISON OF 2-D AND 3-D MODELLING OF THE MT RESPONSE ALONG TRAVERSES IN COMPLLEX TECTONIC REGIONS OF INDIA

Nandini Nityananda NAGARAJAN[1], Praveena M.[1], S.G. GOKARN[2] ([1]National Geophysical Research Institute, [2]Indian Institute of Geomagnetism, Mumbai, India, 400 005.)

Two magnetotelluric traverses across tectonically complex regions, viz.; Narmada-Son Lineament (NSL) zone and the NW Himalaya were chosen to model using both 2-d forward modelling, incorporating topography where necessary and 3-d modelling with updated finite difference schemes. Effects of the boundary conditions on the responses were also obtained. Results for the NSL zone, indicate that the structures are significantly limited in depth when 3-d model responses are compared to the actual data. In the case of the NW Himalayan traverse, the topography was included in the 2-d model only. Even this exercise increased the complexity of the model significantly and responses for a relatively simple sub-surface structure were obtained. This is compared with the inversion of MT data along this traverse.

3-D ELECTRICAL AND ELECTROMAGNETIC MODELING OF A KIMBERLITE PIPE

Saurabh Kumar VERMA, Kushal Pal SINGH, K.P. PANTULU (National Geophysical Research Institute, Hyderabad)

Due to the presence of clayey minerals, the topmost regions of weathered kimberlites are often very good conductors. Such kimberlites provide good electrical/EM response even if they are concealed by an overburden layer. Considering a representative 3-D electrical model, DC electrical and multi-frequency EM responses are computed to study the role of various parameters like: overburden thickness and conductivity, conductivities of the pipe and host medium, size of the conductive pipe, etc. The study provides useful information on selecting optimum survey parameters for electrical and EM exploration of weathered kimberlite pipes.A field example from south India, considering DC electrical, multi-frequency and time-domain EM responses of a weathered kimberlite buried under a cover of black cotton soil, is presented. Three dimensional modeling of electrical and frequency EM data is done to compare the parameters of the kimberlite body as obtained by the two methods. Image sections based on frequency and time-domain EM responses reveal that the latter are comparatively less noisy. It is also found that the time domain EM response provides better resolution of the weathered kimberlite to a greater depth as compared to the frequency EM response.

DEEP CRUSTAL IMPLICATIONS OF ELECTRICAL CONDUCTIVITY ON THE NORTHERN EDGE OF THE CONGO CRATON FROM AUDIO MAGNETOTELLURIC SOUNDINGS IN THE ABONG-MBANG/AKONOLING REGION, CAMEROON(CENTRAL AFRICA)

Théophile Mbarga NDOUGSA, MBOM ABANE. S. (Department of Physics, Advanced Teachers Training College, University of Yaounde I)

Audio magnetotelluric (AMT) soundings have been carried out in the region of Abong-Mbang/Akonolinga (Cameroon Republic), along two profiles running approximatively N-S each, over 35-40 km length. The station are located so as to cover laterally the extreme zones E and W of a vast region characterized by a remarkable E-W gravity anomaly. The principal directions along which the measurements were made, were determined by a rotation method with a scalar M.T instrument. The frequency range employed in this instrument is 4.1 to 2300 Hz, which in view of the large resistivities value of the metamorphic terrains encountered, is able to sound great depths. The analysis and interpretation of data reveal the existence of an extensive deep E-W fault, the Abong-Mbang fault. The resulting geoelectric model appears to be that of a structure of grabens and horsts in the basement, resulting from tectonic vertical movements reaching 3 km at Abong-Mbang.

This study is a preliminary report on a vast geophysical investigation on the deep structures on the border of the Congo Craton in Cameroon.

GAI.10/09P/D-017   Poster   1615-136

DETERMINATION OF A TECTONIC NODE FROM THE INTERFERENCE OF STRUCTURAL DIRECTIONS ON THE BORDER OF THE CONGO CRATON AYOS REGION CAMEROON, BY USING THE AUDIO MAGNETOTELLURIC METHOD

Mbom Abane S.[1], Ndougsa Mbarga T.[1], Manguelle-Dicoum E.[2] ([1]Department of Physics, Advanced Teachers Training College, University of Yaounde I, [2]Department of Physics, Faculty of Science, University of Yaounde I)

The northern border of the Congo Craton shows important tectonic structures characterized by striking gravity anomalies, which remain to be precisely delineated. The existence of a major faulted structure known as the Abong-Mbang fault, has already been revealed along the 46°N latitude, thanks to a remarkable correlation between the gravimetric and the geoelectric signatures produced by it. The audio magnetotelluric (A.M.T) method has been used in a preliminary investigation of structures transversal to those suggested by the gravity map in the Abong-Mbang/Akonolinga region. Soundings in the Ayos zone give evidence of two structural directions, ENE-WSW and NNW-SSE, and confirm the continuity of the major E-W tectonic structure prevailing at Abong-Mbang/Akonolinga. Analysis and interpretation of the data enabled us to characterize these tectonic structures as concording with those of the North Equatorial Pan African Chain.The present study reveals the existence of a major structural interference zone, the Ayos tectonic node, which requires further geophysical study.

REALTIME GLOBAL MAPPING OF LIGHTNING USING WIDELY SPACED VLF RECEIVERS

Craig J. RODGER[1], Richard L. DOWDEN[2] ([1]Department of Physics, University of Otago, [2]Low Frequency Electromagnetic Research)

An experimental network of six radio receivers operating at Very Low Frequency (VLF; 3-30 kHz), stretching from Australasia to Japan, has been in operation since early 2002. Propagation at these very long electromagnetic wavelengths (up to 100 km) allows lightning strokes to be located in real time at up to 10,000 km from the receivers with a location accuracy that is estimated to be a few kilometres. True global mapping of lightning from widely spaced (a few Mm) ground-based receivers requires the use of frequencies below about 30 kHz. Lightning impulses in this frequency range suffer low propagation attenuation, and hence propagation in the Earth-ionosphere waveguide is possible over global distances. At each receiver site, some tens of lightning impulses (″sferics″) are received each second. Propagation of the impulses inside the waveguide formed by the Earth and the lower boundary of the ionosphere disperses the impulses into wave trains. the first millisecond of which is processed to determine the time of arrival. These times of arrival are transmitted to a central station in Dunedin, New Zealand, for determining the lightning stroke location. The network is being expanded from the current 7 lightning receiver´s located in the Western Pacific to ~16 receiver stations in locations spanning the whole world. All receiver stations are based on university campuses and consist of a short (1.5 m) whip antenna, GPS receiver and VLF receivers, plus a processing computer connected to the Internet. All our current and planned TOGA sites are in built-up areas unsuitable for use of magnetic loop antennas at VLF due to man-made noise such as power line harmonics which would dominate over the sferic magnetic field. This is not the case for the vertical electric field of the lightning impulses. The antenna´s are mounted on ferro-concrete buildings, which are poor conductors at VLF and thus remain at ground potential, shielding the antenna from man-made electric noise generated within them. The processing of the lightning impulses at each receiver station is being upgraded to determine the signals time of group arrival (TOGA) rather than the threshold-based time of arrival. This will compensate for the dispersion of the lightning impulse, and increase the accuracy of the lightning locations determined by the network. A worldwide lightning detection network has a wide number of scientific and commercial applications, including those related to the studies of worldwide red sprite and elve observations. Current operation of the network is concentrated on Australasia and the Western Pacific area. The role of lightning in starting wildfires is being investigated in cooperation with Murdoch University and the Western Australian Government, and is partly funded by the Australian Research Council.

ULF/ELF INTERFEROMETRY

Martin FUELLEKRUG (Institut fuer Geophysik/Frankfurt am Main)

The electromagnetic radiation from naturalatmospheric sources is recorded in theULF/ELF frequency range from 1-200 Hzwith a local magnetometer array. This array is used for beam forming of ULF/ELF radiation and for the developmentrol noise reduction processing schemes, since thenatural atmospheric electromagnetic radiation inthe ULF/ELF frequency range is highly correlatedon the local scale. The accuracy of the interferometeris tested prior to deployment for the arrival angleand the velocity. During the experiment, both parameters are recorded on a continous basis and the temporal averaging results in a mean behaviourof the natural electromagnetic fields. Individual arrival angles are related to individual lightning flashes in the vincinity. The measured wave propagation velocities result from the continuous modification of the ionospheric D-layer and yields important information on local and short term ionospheric disturbances.

RELATIONSHIP BETWEEN GLOBAL LIGHTNING ACTIVITIES AND CHANGES IN THE SPECTRAL POWERS IN THE SCHUMANN RESONANCE BANDS

SATO MITSUTERU, Hiroshi FUKUNISHI (Department Geophysics, Tohoku University)

In order to identify the relationship between global lightning activities and changes in the spectral powers of the Schumann resonance (SR) bands, we have analyzed ELF magnetic field waveform data in the frequency range of 1-100 Hz obtained at Syowa station (69.0° S, 39.6° E) in Antarctica and Onagawa observatory (38.4° N, 141.5° E) in Japan. First, we have calculated dynamic spectra of the Syowa ELF data for both the geomagnetic north-south (H) and the east-west (D) component over the period between February 2000 and January 2002. Then, powers of first three SR modes at 8, 14, 20 Hz are extracted from each of the H- and D-component dynamic spectra as an indicator of global lightning activity. It is found that the SR power levels in the H-component are maximum for the time intervals of 5-13 UT and 18-01 UT from May to September. On the other hand, the SR power levels in the D-component are maximum for the time interval of 13-18 UT from September to May. It is found that these diurnal and seasonal variations of the SR power are caused by the latitudinal and longitudinal distributions of major lightning source regions located in North America, South America, Africa and South-East Asia. Power spectra of the SR power variations are calculated by the maximum entropy method. It is found that the power spectra show a distinct peak at ~27 days. Cross spectral analysis is made between the variations of SR power and each of the variations of F10.7 index, cosmic ray flux, sunspot number, relativistic electron and ion fluxes observed by the GOES-8 satellite, Kp index, and DST index. It is found that all these parameters have a distinct spectral peak around 27-32 days. However, coherence between variations of the SR power and other parameters are less than 0.3 in all cases. Using ELF magnetic field data obtained at Onagawa observatory for the period between October 2001 and January 2002, dynamic spectra and powers of first three SR modes are also calculated. Power spectra of changing SR levels at Onagawa also show a clear spectral peak at ~27 days. Coherence between the activity changes at Syowa and those at Onagawa is estimated to be 0.9. All these facts may imply that the changes in SR power are not due to the modulation of the upper reflection boundary at ~80 km altitude in the Earth-ionosphere cavity but due to that of the lightning activities themselves. Possible mechanisms of the 27-day modulation for global lightning activities will be discussed.

SPRITE-LIGHTNING STATISTICS, CLOUDTOP TEMPERATURES AND THE MESOSPHERIC BREAKDOWN ELECTRIC FIELD

Fernanda T. SÃO SABBAS (Physics Department, University of Alaska Fairbanks)

A detailed statistical analysis of the temporal and spatial relationships between lightning and sprites shows that the distribution of time intervals between sprites and parent +CGs, centered in 10-20 ms, appears to characterize the time scale for the development of an individual electron avalanche into a streamer between ~70-85 km altitude, as given in the *Pasko et al.* [1998] model. Within the same analysis, the distribution of the distance between sprites and parent +CGs showed that sprites have the tendency to occur within 50 km lateral displacement from the CG, consistent with results previously reported by *Wescott et al.* [1998] and *Lyons* [1996]. Also studied was the relationship between IR cloudtop temperatures of the sprite-generating thunderstorm, as derived from GOES-8 satellite images, and lightning/sprite activity. The maximum sprite and -CG production of the system were simultaneously achieved at the time of maximum contiguous cloud cover of the coldest region ($T_c < -52°$ C), ~ 2 hr before the system reached its maximum extent. It is suggested that the total -CG activity and dynamical development of the thunderstorm may be more tightly correlated with sprite activity than has previously been reported. This work establishes basic steps towards the development of a methodology to investigate sprite occurrence based on satellite images by themselves. This would permit studies of sprites in regions where ground lightning data is not available. In addition, a numerical simulation of electric breakdown conditions of the mesosphere based on the quasi-electrostatic model of *Pasko et al.* [1997] was performed. Inhomogeneities in the atmospheric conductivity were introduced in order to explain the lateral displacement of the sprite from the parent lightning discharge.

GAII.04/07A/A08-005   1015

OBSERVATION OF SPRITES OVER THE SEA OF JAPAN AND CONDITIONS FOR LIGHTNING-INDUCED SPRITES IN WINTER

Masashi HAYAKAWA[1], T. NAKAMURA[1], Y. HOBARA[2], E. WILLIAMS[3] ([1]Department of Electro-Engineering , University of Electro-Communications, [2]) Laboratoire de Physique et Chimie de Environnement, CNRS, [3]) Parsons Laboratory, Massachusetts Institute of Technology,)

We have succeeded in observing sprites for winter lightning in the Hokuriku area (Japan Sea side) of Japan in the winter of 2001/2002. The optical results on three days are compared with the corresponding characteristics of parent (causative) lightning with particular attention to the significant differences between Hokuriku winter lightning and the more widely studied continental lightning. Despite significant differences with Hokuriku winter lightning, we have found nearly the same sprite properties as already observed in the U.S. continent with a few significant differences. Then, we have also discussed the criteria for sprite occurrence. Specifically, two similar criteria are found : (1) cloud-to-ground discharges of positive polarity and (2) the presence of a certain threshold in vertical charge moment (200-300C•km)(roughly consistent with that for the U.S. continent). Mesoscale convective systems are not necessary to store the charge necessary for sprites, but the parent Hokuriku winter clouds are substantially larger in area than ordinary summer thunderclouds. However, there may exit another condition such as clustering or self-organizing effect of thunderclouds for sprite production.

GAII.04/07A/A08-006   Invited   1050

LOW-LIGHT VIDEO AND ELF OBSERVATIONS OF SPRITES ABOVE HAITI/DOMINICAN REPUBLIC THUNDERSTORMS

Victor PASKO[1], Steve CUMMER[2], Mark STANLEY[3], John MATHEWS[1], Umran INAN[4], Troy WOOD[4], Earle WILLIAMS[5], Robert BOLDI[5], Mitsuteru SATO[6], Yukihiro TAKAHASHI[6] ([1]Penn State University, University Park, PA 16802, USA, [2]Duke University, Durham, NC 27708, USA, [3]Los Alamos National Laboratory, Los Alamos, NM 87545, USA, [4]Stanford University, Stanford, CA 94305, USA, [5]Massachusetts Institute of Technology, Cambridge, MA 02139, USA, [6] Tohoku University, Aramaki-aoba, Sendai 980-8578, Japan)

In August-September 2001 an experimental campaign has been conducted in Puerto Rico to perform correlative studies of lightning and lightning-induced ionospheric effects. The campaign, which was sponsored by a Small Grant for Exploratory Research from the National Science Foundation to Penn State University, had a broad range of scientific goals including studies ionospheric effects of thunderstorms, studies of VHF-quiet positive leaders

A

and studies of large scale optical phenomena above ocean thunderstorms in tropics. As part of this program we conducted night time video recordings of lightning and large scale luminous phenomena above thunderstorms using a SONY DCR TRV 730 CCD video camera equipped with a blue extended ITT Night Vision GEN III NQ 6010 intensifier with 40 deg field of view. The intensifier provided a monochrome (predominantly green) image output. The video system was deployed at the Lidar Laboratory on the grounds of Arecibo Observatory, Puerto Rico (18.247 deg N, 66.754 deg W, elevation 305 m above the sea level). We report here low-light video and ELF recordings of 8 sprite events observed above a Haiti/Dominican Republic thunderstorm from Arecibo Observatory, Puerto Rico between 01:10 and 02:51 UT on September 3, 2001. The sprite producing thunderstorm system was located approximately 700 km from the observational site and had the cloud area exceeding 10^4 km^2. Morphological features of the observed events closely resemble those observed in other parts of the globe and include, in particular, isolated columns, groups of two or more columns, `dancing sprites´, and small impulsive glows confined to higher altitudes. ELF recordings, performed at Duke University, at Rhode Island MIT site, and at Palmer (Stanford University) and Syowa (Tohoku University) Antarctic stations, identified the 7 of the observed events as to be clearly associated with positive cloud to ground lightning discharges (+CGs) involving the vertical charge moment changes ranging between +143 C km to +2520 C km. The observed QL=143 C km for the weakest sprite event is consistent with the experimentally established 120 C km minimum lightning charge moment change required for the initiation of a sprite [Hu et al., GRL, 29, 10.1029/2001GL014593, 2002]. One sprite event (02:05:49.561 UT) was confirmed in ELF records collected at all four observational sites as being produced by an impulsive CG lightning with negative polarity. The associated vertical charge moment change was estimated to be -278 C km in 1.2 ms.

GAII.04/07A/A08-007   Invited   **1110**

GIGANTIC JETS BETWEEN A THUNDERCLOUD AND THE E-LAYER IONOSPHERE*

Rue-Ron HSU[1], H.T. SU[1], Alfred B. CHEN[1], W.S. HSIAO[1], Y.C. WANG[1], L.C. LEE[2], M. SATO[3], H. FUKUNISHI[3] ([1]Department of Physics, National Cheng Kung University, [2]National Space Program Office, [3]Department of Geophysics, Tohoku University)

During Taiwan 2002 summer sprites campaign, five gigantic jets were observed above an oceanic thunderstorm, which wasraging near Luzon Island, Philippines on 22 July 2002. The morphology of thesejets of was a hybrid of sprites and blue jets, which have a tree-like or acarrot-like top but all have a blue jet-like body. The luminous period of thesejets lasted from 300 ms to 500 ms, which is longer than typical sprites but isshorter than that of the gigantic jets observed by Pasko et al. in 2001 [Paskoet al., 2002]. At the fully developed stage, these jets extended from cloud topat 16 km to the E-layer ionosphere at 95 km. The luminous lengths were nearly80 km, the lateral radius at the top of the jet was ~20 km, and the estimatedilluminating volume was approximately 32,000 km^3. From the existing lightning data, nocloud-to-ground strokes were found to be associated with these jets. However,Syowa station in Antarctica and Onagawa station in Japan both detectedunmistakable signatures of these events in the ELF band. Thus it is highlyprobable that these gigantic jets were not CG-induced events, and they possiblyare true lightning between a thundercloud and the ionosphere. In the talk, thedynamic behaviors, the ELF signatures, and the possible generating mechanism ofthese gigantic jets will be presented and discussed. TELESCOPIC IMAGING OF UPPER ATMOSPHERIC LIGHTNING-RELATED STREAMERS AND DIFFUSE GLOW

Elizabeth A. GERKEN, Umran S. INAN (Electrical Engineering, Stanford University)

Telescopic imaging shows that decameter-scale structure in luminous lightning-related electrical discharges above thunderclouds covers a wide range of morphologies and time scales. The Stanford University telescopic imager observed hundreds of sprites during deployments in New Mexico and Colorado in the summers of 1998-2000. The telescopic imaging system consists of a ¯41 cm diameter, f/4.5 reflecting telescope with an intensified CCD camera attached to its eyepiece, a bore-sighted wide field of view (FOV) camera mounted on its top, and both telescopic and wide field of view photometers. Electromagnetic signatures of causative lightning discharges known as radio atmospherics (or sferics) were recorded using crossed-loop magnetic antennas and ELF/VLF receiving systems located at Stanford and in Colorado. Certain categories of structures have been found to occur such as upward and downward branching, beading, propagating diffuse glow striations and streamer/diffuse glow transition regions. Propagating diffuse glow striations are observed to move slowly and are similar to the phenomenon observed in glow discharge tubes. A transition region between streamer formation and diffuse glow is observed at ¯80km altitude. Faint positive streamers are observed at the base of large bright sprites. Some sprites having branching positive streamers and non-branching negative streamers may be double-headed streamers initiated from plasma enhancements. While many streamers move at velocities greater than the time resolution of regular video rate imaging, some have been found to move as slowly as 10Λ4 m/s. Beads at the base of columns can glow for over 100ms while slowly drifting upward.

GAII.04/07A/A08-009   Invited   **1150**

SPRITES, ELVES AND OTHER TRANSIENT LUMINOUS EVENTS (TLES) OBSERVED FROM THE SPACE SHUTTLE COLUMBIA DURING THE MEDITERRANEAN ISRAELI DUST EXPERIMENT

Yoav Y. YAIR, Colin PRICE, Peter ISRAELEVITCH, Meir MOALEM, Adam DEVIR, Joachim JOSEPH, Zev LEVIN, Ilan KOREN, Mustafa ASFUR (Department of Life and Natural Sciences, The Open University of Israel)

The Mediterranean Israeli Dust Experiment (MEIDEX) flew on-board the space shuttle Columbia in January 2003. During the night-side of 29 shuttle orbits there were dedicated observations of the Earth's limb, above forecasted areas of active thunderstorms. This was accomplished with a Xybion IMC-201 multispectral camera (860nm, 665nm, 380nm, 470nm), guided by the astronauts toward the storms with intent of capturing Sprites, Elves and Jets. Two VLF/ELF sites in Israel were simultaneously used to collect electromagnetic data, together with stations in Hungary, USA, Antarctica and Japan. The astronauts collected more than 9 hours of data, of which 7 hours were transmitted to the ground and saved. Initial analysis of the data from space shows many TLEs in the mesosphere above thunderstorms in Africa, Australia and the Pacific Ocean. Calculated heights, energies and dimensions will be presented. A possible relation with meteors that were observed in close proximity to the TLEs will be discussed.

GAII.04/07P/A08-001   Invited   **1400**

COMPARISON OF TEMPORAL DECAYS OF DYNAMIC AND STATIONARYSPRITE FEATURES BASED ON 1-MS RESOLUTION OBSERVATIONS OF SPRITES

Dana MOUDRY, Hans C. STENBAEK-NIELSEN, Dave D. SENTMAN (Geophysical Institute, Univ of Alaska Fairbanks)

A 1-ms resolution high speed imager deployed to Wyoming in the summerof 1999 by the Geophysical Institute at the University of AlaskaFairbanks provided good imagery of lightning-induced optical emissionsin the upper atmosphere, such as multiple types of sprites, halos andelves (Stenbaek-Nielsen et al. 2000). The sprite images obtained onAugust 18, 1999 indicate that sprites are composed both of dynamicalfeatures previously identified - downward propagating tendrils andupward propagating branches (Stanley et al. 1999; Takahashi etal. 1996), and also of stationary features, such as columns, beadswithin the sprite body, and puffs above branches (Moudry et al. 2002).We compare the brightness decay of the individual sprite features witheach other, with halos, and with an area-averaged brightnessdecay. The area-averaged brightness decay is more representative ofreal photometers. The comparison is made in order to find which spritefeatures may be responsible for the dominant photometer signal. Weobtain the brightness decay curve by choosing areas on the 1-ms imageswhich are fully within a particular stationary or dynamic spritefeature. The values of pixels within these areas are added toconstruct signal from an imaginary photometer that would have theequivalent field of view as the chosen region. The stationary spritefeatures decay slower than dynamic sprite features, which in somecases resemble the decay of sprite halos. These characteristics areimportant for interpretation of photometers whose field of viewincludes more than one sprite feature.References:Moudry et al., Eos Trans. AGU, 83(47), Fall Meet. THE SPECTROSCOPY AND ENERGETICS OF RED SPRITES

Jeff Stanley MORRILL (E. O. Hulburt Center for Space Research, Naval Research Laboratory)

During the past decade, the study of red sprites has evolved from the observation of their general physical properties and application of relatively simple models to detailed research into the fundamental nature of the morphology, chemistry, and energetics of this highly dynamic phenomenon. Spectroscopy is one area that has provided significant information on the energetics and chemistry of sprites. This includes observations from video spectrographs and narrow-band imaging and photometry. This talk will review spectroscopic and photometric observations and present recent results on ionization and electron energetics observed in sprites.

GAII.04/07P/A08-003   **1450**

MINIMUM ELECTRIC FIELDS REQUIRED FOR PROPAGATION OF POSITIVE AND NEGATIVE STREAMERS IN SPRITES

Ningyu LIU, Victor P. PASKO (Department of Electrical Engineering, Penn State University)

Recent telescopic imaging of sprites revealed an amazing variety of generally vertical fine structure with transverse spatial scales ranging from tens to a few hundreds of meters [e.g., Gerken et al., GRL, 27, 2637, 2000]. The appearance of the fine structure in sprites has been interpreted in terms of positive and negative streamer coronas, which are considered as scaled analogs of small scale streamers, which exist at high atmospheric pressures at ground level [e.g., Pasko et al., GRL, 25, 2123, 1998; Raizer et al., J. Phys. D Appl. Phys., 31, 3225, 1998].One of the important questions of the current sprite research, which directly relates to the evaluation of the total volumes of atmosphere affected by this phenomena and possible role of sprites in establishing a direct path of electrical contact between the tropospheric and mesospheric/lower ionospheric regions, is related to the determination of the minimum electric fields required for the propagation of streamers in air at different pressures. The minimum field required for the propagation of positive streamers in air at ground pressure has been extensively documented experimentally and usually stays close to the value 4.4 kV/cm [Allen and Ghaffar, J. Phys. D Appl. Phys., 28, 331, 1995], in agreement with recent results of numerical simulations of positive streamers [Babaeva and Naidis, IEEE Trans. Plasma Sci., 25, 375, 1997; Morrow and Lowke, J. Phys. D Appl. Phys., 30, 614, 1997]. The information about the absolute value of the similar field for the negative streamers at present is very limited. The existing sources indicate that this field is a factor of 2-3 higher than the corresponding field for the positive streamers [e.g., Raizer, Gas Discharge Physics, 1991, p. 361; Babaeva and Naidis, 1997]. We note that although from the streamer similarity laws one generally would expect the minimum fields required for streamer propagation to scale with altitude proportionally to the air neutral density N, the actual scaling for the altitude range of sprites has not yet been verified experimentally, and a limited amount of data currently available in the literature [Griffiths and Phelps, Q.J.R. Meteorol. Soc., 102, 419, 1976; Bazelyan and Raizer, Spark Discharge, 1998, p. 216] indicate possible deviations from the N scaling. A new two-dimensional model has recently been developed at Penn State for studies of dynamics of streamers for a wide range of air pressures corresponding to streamer dominated regions of sprites [Liu et al., Eos. Trans. AGU, Fall Meet. Suppl., 83, F137, 2002]. The model utilizes a modified Scharfetter-Gummel algorithm for solution of electron convection-diffusion equation [Kulikovsky, J. Comput. Phys., 119, 149, 1995] and accounts for effects of photoionization on the streamer dynamics [e.g., Kulikovsky, J. Phys. D: Appl. Phys., 33, 1514, 2000, and references therein]. In this talk we will discuss conditions required for the propagation of streamers in air at different pressures and will present corresponding results from the [Liu et al., 2002] model documenting the minimum electric field magnitudes required for the propagation of positive and negative streamers at sprite altitudes.

FULL WAVE ANALYSIS OF ELVES CREATED BY LIGHTNING-GENERATED EMP

Satoshi YAGITANI, Isamu NAGANO, Kazutoshi MIYAMURA, Satoshi MAKINO, Yoichi NAKAMURA (Graduate School of Natural Science and Technology, Kanazawa University)

Intense electromagnetic pulses (EMPs) radiated from lightningdischarges interact with the ionosphere and create the transientoptical flashes above thunderstorms referred to as elves at altitudesabove 80 km. Corresponding to the EMP propagation up through theionosphere, elves expand quasi-toroidally up to a few hundreds of kmwithin 1 millisecond after lightning discharges. So far, severalstudies have modeled the EMP-ionosphere interaction to explain

theobserved temporal and spatial aspects of elves with the unmagnetizedionospheric model. In this study, to investigate more exact spatialand temporal structures of elves, we calculate the propagation oflightning-generated EMPs in the magnetized ionosphere on the basis ofa full wave analysis. Combining the full wave analysis with spatial and temporal Fourieranalysis, we calculate rigorously the temporal and spatial evolutionof a lightning-radiated EMP in a horizontally stratified magnetizedionosphere, free space and the ground. Actually in the creation ofelves, the intense EMP first heats the ionosphere to enhance electrondensity and collision frequency there, which should then decay the EMPenergy. The full wave analysis, however, cannot treat such temporalchanges in ionospheric parameters because it is based on the solutionof the linear wave equations in a temporally invariant cold plasma.Here, we approximately incorporate such an effect into the calculationby modifying the EMP propagation in the ionosphere, where the EMP,while going up through the heated region, is equivalently attenuatedby the increase in the collision frequency. On the basis of thecalculated evolution of the EMP, we evaluate the intensity ofionospheric optical emissions (elves) due to the first positive bandof N2 excited by the EMP. With a midlatitude nighttime ionospheric model and a +CG lightningdischarge of 200 kA, calculated results show that the temporal andspatial evolution of elves is quite consistent with the so-farobserved behavior of actual elves. It should be noted here that inthis case the luminous ring of elves has the appreciable asymmetry inthe north-south direction, which is caused by the whistler-modepropagation of the EMP along the geomagnetic field line. On the otherhand, a more powerful lightning discharge radiates a more intense EMP,which furthermore enhances the ionospheric collision frequency. Withsuch an over-enhanced collision frequency which is much higher thanthe electron cyclotron frequency, the whistler mode propagation of theEMP becomes impossible, so that the horizontal structure of the elvesring becomes more or less isotropic, as in the case of theunmagnetized ionosphere.

GAII.04/07P/A08-005   Invited   1540

THE RESULTS FROM THE 1999 SPRITES BALLOON CAMPAIGN

Edgar Andrew BERING, III[1], Lekhnath BHUSAL[1], James R. BENBROOK[1], Jonathon A. GARRETT[1], Amy M.P.JACKSON[1], Eugene M. WESCOTT[2], Dana R. MOUDRY[2], Davis D. SENTMAN[2], Hans C. STENBAEK-NIELSEN[2], Walter A. LYONS[3] ([1]Department of Physics, University of Houston, [2]Geophysical Institute, University of Alaska, Fairbanks, Alaska, USA, [3]FMA Research, Inc., Yucca Ridge Field Station, 46050 Weld County Road 13, Ft. Collins CO 80524, USA)

A balloon campaign was conducted in summer, 1999, to measure the stratospheric electromagnetic fields associated with sprites. This paper will summarize some of the salient results this work. The balloon payloads were instrumented with electric field detectors, magnetometers, an upward looking photometer, and other instruments. Ground observations for detection of sprites included low light level TV (LLTV) observations from three sites, Jelm Mt., WY, Bear Mt., SD, and Yucca Ridge, CO. The disagreements between models and these data will be discussed. The all-sky upward looking photometer data was examined by checking the trace at the times of cloud to ground (CG) strokes reported by the US National Lightning Detection Network (NLDN) to find transient luminous events (TLE's) that were missed visually. In total numbers, the number of -CG TLE's (presumably all halos) predominates over the number of +CG TLE´s. 3602 events were analyzed in 4.1 hours of storm time. Threshold current moments of ~50 kA-km for the positive cloud to ground (+CG) TLE's and ~-5 kA-km for negative cloud to ground (-CG) TLE'S are found. Inclusion of the -CG events that are not seen from the ground raises mesospheric power input estimates by a factor of ~5-7. Including the mesospheric effect of CG´s not associated with TLE's increases this estimate by a factor of 20.

GAII.04/07P/A08-006   Invited   1605

ELECTRODYNAMICS OVER SPRITE PRODUCING STORMS

Robert H. HOLZWORTH[1], Michael P. MCCARTHJY[1], Timothy M. CHINOWSKY[1], Jeremy N. THOMAS[1], Michael J. TAYLOR[2], Dominique PAUTET[2], Osmar PINTO, JR.[3], Iara PINTO[3] ([1]Earth and Space Sciences, University of Washington, [2]CASS, Utah State University, [3]DGE/INPE)

We present the latest results from a balloon campaign to measure electrodynamic, optical and X-ray properties of the middle atmosphere over sprite producing storms. The first flight was launched on 6 December 2002 from Cachoeira Paulista, Brazil during a period of active thunderstorms. The balloon floated within 50 km of 279 lightning network cataloged strokes and within 50 to 100 km of another 379 network detected strokes. The instrumentation consisted of optical flash detectors, x-ray spectrometers, and vector electric and magnetic field probes covering the frequency range from DC to 10 kHz. Two different electric field instruments were used in order to cover a wide dynamic range of 0.001 to 250 V/m. By the time of this presentation we expect to have had other successful balloon flights, now scheduled for Feb/Mar 03. Following the Sprite99 campaign (Bering, University of Houston), this campaign is the second effort to make near measurements of conductivity, the quasi-static electric field environment, and electromagnetic changes at sprite-producing thunderstorms. During preparations for the first flight in December 02 we made the first images of sprites from both the ground and airborne in Brazil. During that balloon flight we detected electric field transients related to both positive and negative strokes exceeding 100 V/m (largest detected was > 240 V/m). Interestingly the horizontal electric field component was about two times the magnitude of the vertical component.

STUDIES ON HYBRID TWEEK MODE WAVE

Koji KAWAKITA, Takeo YOSHINO (Graduate School of Electrical Engineering, Fukui University of Technology)

The author investigated the radiation mechanism of the hybrid tweek wave by means of the data observed at Awara Space EM Phenomena Observatory of Fukui Univ. of Tech. between 1997 and 2000. Usual tweek wave has the guided mode propagation in wave guide consisting of the earth surface and the bottom region of ionosphere. It has a lower cutoff frequency produced by the dominant mode of wave-guide propagation characteristics at around 1.8 kHz. However, an unusual tweek wave propagates until zero order mode wave extended under the dominant cutoff frequency of usual tweek waves. The author accepted the name of the waves as Hybrid tweek mode wave.In our analysis results, we referred that the occurrence number ratio and the propagation distance of the hybrid tweek mode wave are tendency to affect with the geomagnetic activity. We found the most greatest radiated region of the hybrid tweek mode wave is tendency to concentrate in the geomagnetic 0 degrees dip.And we could obtain the analysis results of determination of source area of the Hybrid tweek wave is concentrated in the region of Borneo and New Guinea area. Accordingly, we considered the excitation characteristics of E.L.F. range (500 Hz) with the vertical components against a plane of the ionosphere by using of the Full wave analysis.At the n=0 mode propagation in the E.L.F. range, the analysing results is shown similar to the terrestrial wave-guide boundaries in the geomagnetic 0 degrees dip surrounded by the perfect conductors. And it is very difficult to apply to the E.L.F. electromagnetic wave components of the hybrid tweek mode wave which propagate to the all directions covered a wide range between the ionosphere and the ground by means of only the terrestrial wave-

guide mode theory.Therefore, we considered the refer to the feasible different propagation mode theory in which E.L.F. wave components has widely propagation path which are not depended on the wave-guide mode theory. As physical image of the Hybrid tweek mode wave propagation, the E.L.F. wave lower than cut-off frequency of the terrestrial dominant mode horizontally propagate along the boundary between the bottom of ionosphere and air as the surface mode, and the another natural radio wave components which higher than cut-off frequency propagate under the multi-reflections between the bottom of ionosphere and ground of the earth followed the waveguide mode theory. This consideration means that the Hybrid tweek mode wave may be compared to ˝Hybrid propagation˝ which have both propagation mode of the surface mode and the waveguide mode. In analysis data, we considered the propagaion characteristics in cases of the Hybrid tweek mode wave for E.L.F. wave propagate horizontally along the boundary between the bottom of ionosephre and air by surface mode. Although we could not progress into details about the propagation characteristics on E.L.F. electromagnetic wave which propagate by the surface mode propagation, We attempted to calculate the attenuation coefficients of the surface mode E.L.F. electromagnetic waves which are excited in the horizontal direction against plane of the ionosphere.

SPATIAL SELECTIVITY OF THUNDERSTORM ACTIVITY (IMPACT OF LITHOSPHERE)

Igor Ivanovich ROKITYANSKY (Institute of magnetism)

In Ukraine, about 500 meteorological stations were in operation during second half of XX century, covering rather uniformly all the territory with typical spacing between stations 20 - 30 km. Thunderstorms were fixed by visual observations in an area around the station with radius approx. 10 km. Taking into account typical dimensions of thunderstorm clouds, we can expect that essential part of thunderstorms have been recorded. Annual quantity of thunderstorms observed at every station was used as initial data, this quantity averaged over several years (1986-1994) was termed as thunderstorm activity (TSA). The activity varied from 2 to 50, being for majority of stations in interval 20 - 30. Anomalous low TSA (<10) was observed at 28 stations and what is interesting this stations have a tendency to be arranged along several curve lines, some of them are rather long (up to 200 km). And three long lines of decreased TSA turns out to diverge from Chernobyl.. When the processing of Ukrainian data was extended to earlier years (i.e. before 1986 - the year, when Chernobyl catastrophe happened), the picture of TSA anomalies turned out to be rather different. It lead to suggestion: Chernobyl catastrophe changed distribution of TSA. It can be explained as follows: radioactivity changes the conductivity of the air and than the conditions of thunderstorm/lightning formation. Comparison of TSA with geophysical, geological and geomorphological data does not reveal any significant correlation.. In some books, it is written that TSA has anomalies over prominent geological structures, especially over deep faults, but no quantitative characteristics are given. Quantitative data were received in Siberia. Electrical power lines´ pillars there were made usually of wood. Lightning strokes destroyed the pillars. Some pillars are frequently undergo lightning strokes, some - not frequently, some - never. The last ones are clustered into narrow strips, the first two are formed wide areas. It is exactly as were observed in Ukraine. This results suggest that thunderstorm/lightning spatial selectivity manifests some environmental characteristics of lithosphere origin, the most probable of which are: 1) Earth´s conductivity which is very variable spatially, but not temporary, 2) Gases emanations from the Earth interior which are very variable both spatially and temporally. They (especially radioactive ones) influence electrical conductivity and other properties of the atmosphere from near the surface to ionosphere strata (which is manifested by earthquakes' precursor study) that should influence both the lightning discharge and thunderstorm cloud formation. Spatial ground selectivity of thunderstorm/lightning activity (lithosphere factor) is the essential aspect in the global electrical circuit study. Lightning spatial selectivity can and should be studied using the data of ground-based long-range detection systems (ZEUS in Europe) as well as satellite data.

THIN WIRE REPRESENTATION OF A VERTICAL CONDUCTOR AND ANALYSIS OF ITS SURGE RESPONSE

Osman Md GONI, Hideomi TAKAHASHI, Eiji KANEKO (University of the Ryukyus)

The steel tower surge impedance is one of the basic parameters forthe anti-lightning design. Therefore, since Jordan, a lot ofexperiments and theories are proposed, however, there are noestablished theories. This is the stumper which is known as ``thevertical conductor problem´´ in the present-day electricengineering. In surge simulations, accurate modeling of a thin wire isnecessary to represent transmission wires and steel frames of abuilding. Comparing the theories of FDTD and MoM, the former ismore advantageous to handle 3-D currents in an imperfectlyconducting medium . On the other hand, the later is moreadvantageous to accurately represent the thin wire(˝thin wire˝ isdefined as a conductive wire of which the radius is smaller thanthe size of a discretized cell used in FDTD and segment length orwavelength in case with MoM.As for surge impedance on a tower model of a vertical conductor,we have a theoretical formula byLundholm. The theory of Lundholm looks like to be a perfecttheory, however, this formula does not coincide with theexperimental results. Thus, there is the strange situation thatthe Jordan´s formula of the wrong theory agrees with theexperiments more correctly. Hara et al. derived experimentalformula.Moreover, one of the authors proposed a theoretical formula ofsurge impedance; considering the existence of ground surface, and withoutground surface. The former formula is very similar to the experimentalformula of Hara et al..In this research, these theoretical formulas of surge impedanceare examined by the simulation analysis of vertical conductor withthe help of Numerical Electromagnetic Code (NEC-2) and theexperimental results of that. In the measurement at an actualtower, however, it is difficult to stretch a current lead wirevertically from the tower top, where the current lead wire acts asa vertical lightning channel. Measurements on reduced-scale modelsare more economical than those on full-sized towers, and areflexible in setting up various experimental arrangements. It is,however, not easy to maintain the accuracy of the measurement,since the geometrical size of the measuring devices is largerelative to the measured system. The simulation and experimentalanalysis of surge response are carried out in the severalarrangements of the current lead wire and the current source. In all thecases, the voltage measuring wire is placed at the perpendicularto the current lead wire. Each of the arrangement of the currentlead wire affects the measured surge impedance of the verticalconductor and these will be explained in this research in detail.The experimental set upof the model to be analyzed in this paper is verified with thesimulation result of the equivalent circuit model by the EMTP.Finally, this paper also shows a comparison study of FDTD methodMoM for the calculations of the surge inpedances of the verticalconductor.

PROJECT OF MICROSATELLITE TARANIS

Elisabeth BLANC, Taranis team (Commissariat Energie Atomique, Laboratoire de Detection et de Geophysique)

Strong interactions between the middle and upper regions of the atmosphere and ionosphere are manifested by light emission in the middle and upper atmosphere, known as sprites and elves, gamma radiation of atmospheric origin, electromagnetic emissions recently observed above atmospheric storms. This direct coupling between active storm cells, the thermosphere and the ionosphere - and the considerable energies involved - gives rise to processes unsuspected until now regarding space plasmas as well as the chemistry and dynamics of the middle atmosphere. The electromagnetic and particle emissions could derive from the run away relativistic electrons initiated by the impact of cosmic rays on storm cells. These processes can have a significant effect on the Earth´s magnetosphere, in particular by modifying the source terms and loss of the radiation belts. The microsatellite Taranis (Tool for the Analysis of RAdiations from lightNIngs and Sprites) proposes to study the coupling between atmosphere, ionosphere and magnetosphere during atmospheric storms. This has to be carried on a local and global scale in order to understand the physical mechanisms responsible for the impulsive transfers of energy between the neutral atmosphere and plasmas of the ionosphere and magnetosphere. The final goal is to establish the impact of these processes on the Earth´s environment.The purpose of this presentation is to describe in a first part the project Taranis, his scientific objectives, the mission and the scientific payload. In a second part the first results of the experiment LSO (Lightning and Sprite Observations), on board of the International Space Station, will be presented. LSO is composed of two micro-cameras, fixed on a ISS window for observations at the horizon or at the nadir. One camera is equipped with a filter and measures the emissions from earth in a specific spectral window, the second works in the visible. The measurements allow the identification of sprites and lightning from space at the nadir. This measurement concept will be used for the camera observations in the future micro-satellite Taranis.

ON THE DYNAMICS OF THE NORTH-SOUTH SEASONAL MIGRATION OF GLOBAL LIGHTNING

Gabriella SATORI (Geodetic and Geophysical Research Institute, Csatkai u. 6-8., H-9400 Sopron, Hungary)

The daily Schumann resonance (SR) frequency patterns are mainly determined by the lightning source-observer configuration. Four basic types of daily frequency patterns have been distinguished corresponding to the four seasons observed for each SR mode at Nagycenk, Hungary. The number of days with similar daily frequency patterns (characteristic for a season) were very different. The similar daily frequency patterns (I. type) have been observed during 160-165 consecutive days from the beginning of November to the first part of April in any year of SR observations at Nagycenk. This means that the position of global lightning, centered on the tropics and the Southern Hemisphere in these months, is rather stable with respect to the observer. The northward migration of lightning in the next season is very fast as only about 40-50 daily frequency patterns show similar characters (II. type) in the months April and May. The number of days with the daily frequency pattern of III. type is 90-100 covering the three summer months (June, July, August) in the Northern hemisphere. The migration of lightning is slower southward than in the opposite direction and it takes about 60-70 days as indicated by the daily frequency patterns of IV. type characteristic mainly in September-October. The dynamics of the north-south migration deduced from SR observations was compared with the dynamics of the mean land surface temperature variations measured in those latitudes of the Northern and Southern hemisphere lands where lightnings mainly occur and in the tropical Pacific. The temperature reaches the highest values and remains very stable in the south tropical Pacific for a rather long period just when the diurnal frequency pattern of I.type can be observed. "Cooling" (only about 1-2 degree C) occurs here in April when global lightning starts its migration to the Northern hemisphere as indicated by SR measurements. Duration of the migration back to the Southern hemisphere coincides with the warming up period in the south tropical Pacific and doesn't fit properly the warming up time in the Southern hemisphere lands. It seems that the dynamics of the north-south lightning migration follows oceanic (Pacific) thermodynamical properties in spite of the fact that the global lightning is mainly concentrated on the lands. This result is in accordance with the meridional redistribution of global lightning as a response to the temperature variations in the tropical Pacific on the ENSO time scale (Sátori and Zieger, 1999)

LIGHTNING LOCATION WITH A SINGLE VLF EM RECEIVER

Isamu NAGANO, Satoshi YAGITANI, Hisao KOMONMAE (Graduate School of Natural Science and Technology, Kanazawa University)

VLF radio pulses (spherics) generated by lightning discharges havebeen used to detect the locations of the discharges. As seen in theU.S. national lightning detection network (NLDN), one of the widelyused systems utilizes the VLF receivers placed at a couple of stationsto perform the direction finding and the time-of-arrival measurementsof spherics. Such a system, however, requires to construct anexpensive network of synchronized multiple electromagnetic sensorsinstalled at different sites over a wide area. In this work, we havedeveloped a simple and cheap system with just a single VLFelectromagnetic (EM) receiver to locate lightning discharges, whichcan determine both the direction and range of each lightning returnstroke. With this system, we observe wave forms of two horizontal magneticfields and of one vertical electric field of VLF spherics. The waveform of each VLF spheric usually consists of a couple of sequentialpulses. The first pulse comes directly from a lightning returnstroke, and is used for the direction finding of the stroke. Thesecond and later pulses represent the multiple reflections of thefirst pulse between the ionosphere and the ground. The difference inthe time-of-arrival of each set of adjacent pulses is determined bythe difference in their multi-hop propagation path lengths in theEarth-ionosphere waveguide. By using the time-of-arrival differencesbetween two or more pulses, we can inversely estimate both thereflection height of the ionosphere and the range of the lightningstroke. In our developed system two orthogonal horizontal magnetic componentsand one vertical electric component of spherics are measured with twosets of loop antennas and a vertical wire dipole antenna,respectively. Their wave forms are band-limited between 1

and 14 kHzand then digitized, where the whole wave forms of individual sphericcan be automatically recorded. By extracting a sequence of pulsesfrom each of the recorded spheric wave forms, the system calculatesthe direction and range of the corresponding lightning stroke. With this system installed at Kanazawa University, we have so faracquired thousands of lightning-generated spherics, including the +CGstrokes in winter (characteristic of Japanese Hokuriku Region aroundKanazawa) as well as the -CG lightning strokes in other seasons.Compared with the lightning location data provided by a local powercompany (which makes use of the conventional system with a couple ofreceivers set at different stations), it is confirmed that our systemcan locate each of the lightning strokes within several hundred kmwith fairly good accuracy. We are planning to apply this technique todevelop a portable lightning detector carried, for example, byairplanes or ships cruising over remote areas with no lightningdetection networks available.

A DEVELOPMENT OF OBSERVATION SYSTEM AND INITIAL RESULTS FOR THE SIMULTANEOUS MEASUREMENT OF SPRITES AND HORIZONTAL ELECTRIC CURRENTS IN THE LIGHTNING DISCHARGE

Atsushi OHKUBO[1], Hiroshi FUKUNISHI[1], Yukihiro TAKAHASHI[1], Isamu NAGANO[2] ([1]Department of Geophysics, Tohoku University, [2]Department of Infomations and Systems Engineering, Kanazawa University)

Sprites are atmospheric luminous events induced by cloud-to-ground discharges (CGs) at the altitude of 50-90 km, which are considered generated by quasi-electrostatic field caused by the CG. There are still many open questions on the occurrence and the generation mechanism of sprites and related phenomena. For example, what determine the horizontal distributions of sprite streamers and various sprite occurrence time lags from the parent CG. Horizontal electric current in intra-cloud discharge, cloud-to-cloud discharge and as a horizontal component of cloud-to-ground discharge are thought to be an explanation for these issues as suggested by some authors (ex. Cho et al., 2001; Bell et al., 1997). However, simultaneous observations of sprites and horizontal electric currents associated with lightning discharges have not been carried out up to now.In order to investigate the role of horizontal electric currents in sprite generation mechanism, we have developed a three-component dipole antenna system for an electric field measurement of sferics. These three electric field antennas are oriented in vertical, north-south and east-west directions, respectively. We operated this antenna system with two horizontal loop antennas for magnetic field at Iitate observatory, Fukushima (37.7°N,140.7°E) in January 2003. On the other hand, we observed sprites by an image-intensified CCD imager and a multi-anode array photometer at the observatory. Further, we employed another two horizontal loop antenna system at Yamanashi Prefectural Science Center (35.40°N,138.40°E), to determine the CG locations. The frequency range of electric field antenna system are from 10 Hz to 30 kHz and that of magnetic field antenna system are 1 to 30 kHz, covering VLF range in which sferics have the highest spectral power. The electric and magnetic field data of sferics are recorded in the audio channels of VHS videotape.We will present the detail description of the new system and initial observational results. Especially we will discuss about the identification of horizontal electric currents in lightning discharges.

INVESTIGATION OF WINTERTIME SPRITES AND THEIR PARENT THUNDERSTORM SYSTEMS IN JAPAN

Toru ADACHI, Hiroshi FUKUNISHI, Yukihiro TAKAHASHI (Department of Geophysics, Tohoku University)

Sprites are transient luminous events at the altitude of the mesosphere induced by cloud-to-ground discharges. To investigate the relationship between the sprites and their parent thunderstorm systems in winter of Japan, we have carried out the Wintertime Sprite Campaign for four winter seasons since 1998. During these periods, we captured 55 sprites with two multi-anode array photometers (MAPs), image intensified CCD cameras (IICCDs) and VLF sferics receivers. Each MAP has 16 channels arrayed in vertical and time resolution of 50 μs, which enables us to detect the rapid vertical motion of sprites. The result of data analysis demonstrates that winter sprites occurred above both the Sea of Japan and the Pacific Ocean. However, the characteristics of sprites observed in these two regions are different. That is, columniform sprites are observed above the Sea of Japan, while carrot sprites are observed above the Pacific Ocean. By combining the sprite data with GMS satellite infrared images, temperature profiles obtained from the observation of Rawinsonde or the MSISE-90 model and ground-based radar precipitation maps, we found that sprites above the Sea of Japan usually occur just above cold fronts. In minor cases, however, sprites occur after cold fronts have reached the Pacific Ocean. In both cases, it is likely that precipitation particles play an important role for sprite generation.Further, we classify winter sprites based on their occurrence regions, meteorological conditions, the characteristics of parent thunderstorms and cloud-to-ground discharges.

GAII.04/09A/D-005 — Poster — 0830-141

SPRITES OBSERVATION IN NORTHERN SCANDINAVIA

Yukihiro TAKAHASHI[1], Mitsuteru SATO[1], Satonori NOZAWA[2], Hiroshi FUKUNISHI[1], Ryoichi FUJII[2] ([1]Department of Geophysics, Tohoku University, [2]Solar-Terrestrial Environment Laboratory, Nagoya University)

It has been well known that the summer thunderstorm that has a large horizontal extent and a fairly high cloud top sometimes produce sprites and elves, transient luminous emissions induced by cloud to ground (CG) lightning discharges. Large amounts of charge removal by positive CG which often take place in a big thunderstorm are thought to be a requirement for sprites. However, in 1998 activities of sprites and elves were discovered in the west coast of Japan when a cold front passed over Japan. Now it has been recognized that these emissions occasionally appear also in the Pacific Ocean around Japan in wintertime. These facts strongly imply some occurrence of sprites and elves in other areas, such as Northern Scandinavia where positive CGs are observed in wintertime like as in the west coast of Japan. If we can detect sprites and/or elves in the polar region, the interaction between the lightning-induced phenomena and the polar ionosphere/magnetosphere would be quite interesting. Computer simulation study shows an electron density enhancement by ~10 times associated with elves, suggesting a modulation of ionospheric currents. If the internal quasi DC current in sprite connects to filed aligned current in the magnetosphere, an appearing aurora feature might be modified. Further, it is predicted that sprite-related CGs can make upward runway electrons which incident into the magnetosphere. In order to search and investigate sprites and elves occurring in Scandinavia, we installed an image-intensified CCD camera at ESRANGE, Kiruna, Sweden in November 2002. The camera directed to the northwest covers 30 degree horizontally and its gain is adjusted automatically. The data are recorded in D-VHS videotapes. Actual operation of the camera and video recorder is conducted from Japan by an internet-controlled power supply, according to the weather information on web pages. Lightning data including location and peak current are provided by a Swedish company. Combining sprites and elves images with

EISCAT, ground-based magnetometer , and polar orbiting satellite data, we will examine the physical interactions between sprites/elves and the ionosphere/magnetosphere in detail.

GAII.04/09A/D-006   Poster   0830-142

NUMERICAL MODELING OF SPRITES FOR THEIR ENERGETICS AND CHEMICAL EFFECTS ON THE MIDDLE ATMOSPHERE

Yasutaka HIRAKI[1], Lizhu TONG[2], Hiroshi FUKUNISHI[1], Ken-ichi NANBU[2], Yukihiro TAKAHASHI[1], Yasuko KASAI[3] ([1]Department of Geophysics, Tohoku University, [2]Institute of Fluid Science, Tohoku University, [3]Communications Research Laboratory)

Using our newly developed field and particle model, we have performed numerical simulations on the energetics and dynamics of sprites. In addition to ionization, dissociation and excitation processes, photoionization processes due to EUV emission, which are caused by high-energy electrons, are included in our model. We derived the non-Maxwellian energy distribution function of electrons accelerated by a large electric field in the middle atmosphere above thunderstorms. The temperatures of electrons can be estimated and are compared with the results of previous observations. Temporal evolution of optical emissions is also discussed, focusing our attention on the effect of photoionization processes, and the results are compared with observations. Further, we have investigated the chemical effects of sprites on ions and neutral species. Our preliminary results presented in the AGU Fall meeting in December 2002 are examined in details, using our particle simulation code. We estimated the total amount of ions and atomic neutrals produced by each sprite event. By substituting the calculated production rates of these particles into a 1-D chemical transport model, we will discuss the effect of sprites on the mesospheric ozone chemistry.

THE EFFECTS OF THE THUNDERCLOUD OF REVERSE ELECTRIC POLARITY ON THENIGHTTIME E REGION IONOSPHERE

Vitalii P. KI M, Valerii V. HEGAI (IZMIRAN, Troitsk, Moscow Region, 142190 Russia)

The large thunderclouds of reverse polarity, with the negatively-chargedupper part and the positively-charged bottom part, are frequently associatedwith intense upward electric discharges accompanied by sprites, elves, andblue jets. In this paper, we have modeled the effects exerted by the quasi-static electric field of the thundercloud of reverse electric polarity on the nighttime E region ionosphere. Calculations are made with and without allowance for thepresence of metal ions. The results show that the electron density substantially increases in the middle part of the E region over the thundercloud. If the background ionospheric plasma contains a minor admixture of metal ions, the sporadic Es layer can be formed at about 120-km altitude.

GLOBAL ASSIMILATION OF IONOSPHERIC MEASUREMENTS (GAIM)

Robert W. SCHUNK[1], Ludger SCHERLIESS[1], Jan J. SOJKA[1], Donald C. THOMPSON[1], David N.ANDERSON[2], Mihail CODRESCU[2], Cliff MINTER[2], Timothy J. FULLER-ROWELL[2], Roderick A. HEELIS[3], Marc HAIRSTON[3], Bruce M. HOWE[4] ([1]Center for Atmospheric and Space Sciences, Utah State University, Logan, UT 84322-4405, [2]NOAA/Space Environment Center, Department of Commerce, 325 Broadway, Boulder, CO 84303., [3]W B Hanson Center for Space Sciences, University of Texas at Dallas, PO Box 830688, MS F022, Richardson, TX 75083-0688, [4]Applied Physics Laboratory, University of Washington, 1013 NE 40th Street, Seattle, WA 98105.)

The ionosphere is a highly dynamic medium that can vary significantly from day to day and from hour to hour at a given location, and these variations can have detrimental effects on military and civilian systems. In an effort to minimize or circumvent the detrimental effects, a physics-based data assimilation model of the ionosphere and neutral atmosphere is under development with funding from the Multi-Disciplinary University Research Initiative (MURI) program. Two university consortia are involved, with Utah State University (USU) and University of Southern California (USC) as the lead institutions. When completed, the GAIM model will provide specifications and forecasts on a spatial grid that can be global, regional, or local (50 km x 50 km). GAIM will use a physics-based ionosphere-plasmasphere-polar wind model and a Kalman filter as a basis for assimilating a diverse set of real-time (or near real-time) measurements. Some of the data to be assimilated include in situ density measurements from satellites, ionosonde electron density profiles, occultation data, ground-based GPS TECs, TECs between ground stations and LEO satellites with radio beacons, and line-of-sight UV emissions from selected satellites. The resulting specifications and forecasts will be in the form of 3-dimensional electron density distributions from 90 km to geosynchronous altitude (35,000 km). Auxiliary parameters will also be available, including N_mF_2, h_mF_2, N_mE, h_mE, and slant and vertical TEC. In addition, GAIM will provide global distributions for the ionospheric drivers (neutral winds and densities, magnetospheric and equatorial electric fields, and particle precipitation patterns), and in its specification mode, it will provide quantitative estimates for the accuracy of the reconstructed ionospheric densities. The overall program involves model construction, data quality assessment, data assimilation, construction of an executive system to automatically run the model, validation, and science. An initial form of GAIM already exists and recent results from the USU consortium will be presented. Also, there will be a discussion of the real-time data sources that will become available during the coming decade.

GAII.05/07A/D-002   Poster   0830-018

HE+ DENSITY ISS-B SATELLITE DATA IN EMPIRICAL AND STATISTICAL TOPSIDE IONOSPHERE SIMULATION

Larissa SIDOROVA (Institute of Terrestrial Magnetism, Ionosphere and Radiowave Propagation, Troitsk, Moscow region, 142190, RUSSIA, E-mail: lsid@izmiran.rssi.ru)

As repeatedly pointed early, there are serious shortcomings in the International Reference Ionosphere model (IRI) especially in upper topside and at high solar activity. The topside He+ density profiles, obtained at ~ 1100 km heights during 1978-1979 years (high solar

---

activity period) on ISS-b satellite data, were compared with IRI model data. The comparison reveals the large discrepancy in the regions of the low and, especially, middle latitudes, where the diurnal and seasonal He+ density profiles are overestimated in IRI by a factor of 10 and more. It seems the prominent feature of the topside ionosphere, as mid-latitude He+ density trough, LIT, is reflected in IRI topside model hardly. The present study deals with He+ density topside modeling at middle and low latitudes at high solar activity period. Since only He+ density was regularly measured onboard of ISS-b, He+ density profiles were under consideration. Mid-latitude He+ density troughs, LIT, and other distinct structure as He+ density subtroughs, located equatorward than LIT, are studied. The obtained He+ density characteristics are used for empirical and statistical simulation. (a) The He+ density profiles as functions of local time, season and longitude were obtained as empirical topside data in the different latitudinal areas. (b) The LIT occurrence statistics as function of local time, season, longitude and Kp activity was produced. For example, by day the He+ density LITs are seen more often in summer (P~ 30%) than in winter (P~ 5 to10%). At night they do quite often occur in winter (P~ 40 to 60%) than in summer (P~ 35 to 55%). LIT probability is weakly dependent on magnetic activity. (c) The He+ density subtrough occurrence statistics as function of local time, latitude and season was obtained and mapped. Subtroughs are less frequent phenomena than LITs, but they are more frequent than it was expected from the literature analysis. So, according to ISS-b data, they were revealed in ~ 570 cases in ~ 4000 passes in a very broad latitudinal interval (25-58˚Λ). For example, by day the subtroughs are observed rather seldom but stable in summer (P~ 7 to 12%) and only in exclusive cases in winter. They are more often observed under nighttime conditions in winter (P ~ 30%) than in summer (P ~ 5-10%). Obtained empirical topside data and statistics could be very useful for further IRI development. For example, topside statistics is possible to use as empirical description in the IRI prediction scheme like the spread F occurrence statistics is used.

GAII.05/07A/D-003   Poster   0830-019

SPECIFICATION AND PREDICTION OF DYNAMIC PROCESS IN IONOSPHERE

Jian-shan GUO, Jiankui SHI, She-ping SHANG, Manlian ZHANG, Xigui LUO, Hong ZHENG (Laboratory for Space Weather,Center for Space Science and Applied Research, Chinese Academy of Sciences)

Specification and prediction of ionospheric weather are the key scientific pursuits of ionospheric physicists. However, not any arbitrary combination of a dynamic process and an observation system possesses possibility of specification and prediction for the dynamic process. Specification and prediction are essentially the state estimations of the dynamic process for current and beyond current time respectively from observation available at current time. This estimation procedure largely based on a random dynamic system, which consists of dynamic process, observation system and optimal estimation procedure. We attempt to give a complete framework in this paper under which the specification and prediction procedure carries through. Based on the procedure, the observability, the spesificatability and the predictability of the dynamic process are discussed. We discuss some crucial issues as follows: modeling a specific dynamic process in the ionosphere as a random dynamic system in state space; state and its uncertainty estimation for the dynamic process; the observability of an observation system, the specificatability and predictability of the dynamic process. As an example, a second order dynamic system is discussed in a specific manner to illustrate the specification and prediction procedure, ranging from modeling the system, specification, prediction and their uncertainty calculation. The analysis shows that the key issue of specification and prediction are the state and parameter estimation for the dynamic process. Suppose the state and parameter of a dynamic process s(t+a) are estimated by output g(t) of the random dynamic system, the estimations are the specification as a=0, the prediction as a>0, and interpolation as a<0. The specificatability and predictability are determined by the possibility of retrieval of s(t+a) from g(t) as a=0 and a >0 respectively, and quantitatively defined by observable and controllable matrix of the system. The estimation technique, due to its optimization and integration features, could obtain better accurate results than those obtained by dynamic process, measurement or their statistical analysis alone. More attention for dynamic estimation procedure creation should be paid to transition matrix finding, which is usually not easy for practical ionospheric weather system. High performance computing hardware and software studies should be promoted further so as to meet the requirement of large storage and extensive computation in the optimal estimation. The random dynamic system discussed in the paper is in a very general form, so the main results are applicable to other dynamic fields such as atmosphere, space and geophysics in case of without difficulty for modeling the dynamic process in state space. The discussion in this paper is appropriate for the static or steady state or transition process of dynamic system. Many phenomena in atmosphere and space environment are unstable and chaos, so the dynamic study should include and integrate these two branches of learning. PLASMA TEMPERATURES FROM ACTIVE

Ludmila TRISKOVA[1], Vladimir TRUHLIK[1], Jan SMILAUER[1], Nella SMIRNOVA[2] ([1]Department of Upper Atmosphere, Institute of Armospheric Physics ASCR, [2]Space Research Institute, Russian Academy of Sciences)

Ion temperature (Ti) and related electron temperature (Te) distributions have been analyzed on the base of data measured by Radiofrequency Probe and Retarding Potential Analyzer onboard the main satellite of the ACTIVE mission (Intercosmos 24, perigee 500 km, apogee 2500 km, inclination 83 deg). Results from the period 1989-1991 have been analyzed. About 200000 I-V characteristics were evaluated so far. For each Ti value corresponding Te (from radiofrequency probe) was assigned. Only temperatures from intervals with both Ti and Te available were processed. Consistency of the obtained data is discussed. Measured Ti is compared with that modeled by IRI2001 (International Reference Ionosphere). Millstone Hill incoherent scatter results are also shown. At the altitude of 550km the measured Ti data and IRI model are in agreement, and both are relatively close to the Millstone-Hill ISR model. At higher altitudes during the daytime the IRI values are systematically higher than the measured Ti.

THE ASSIMILATION OF GROUND AND SPACE GPS TEC MEASUREMENTS IN THE GLOBAL ASSIMILATIVE IONOSPHERE MODEL (GAIM)

George A. HAJJ[1], Xiaoqing PI[1], Gary ROSEN[1], Paul STRUAS[2], Chunming WANG[1], Brian WILSON[3] ([1]University of Southern California, [2]Aerospace Corporation, [3]Jet Propulsion Laboratory)

As the number of ground and space-based receivers tracking the global positioning system (GPS) steadily increases, and ionospheric remote sensing data such as measurements of airglow become available, it is becoming possible to monitor changes in the ionosphere

continuously and on a global scale with unprecedented accuracy and reliability. This is best achieved by means of data assimilation using a 4-dimensional (4DVAR) scheme or a recursive statistical estimation approach such as the Kalman filter. Our presentation will review the development of a Global Assimilative Ionospheric Model (GAIM) at the University of Southern California and the Jet Propulsion Laboratory capable of assimilating various types of data including ground and flight GPS total electron content (TEC), ionosondes and airglow measurements. The recursive estimation technique is used to the determination of electron density with a relatively short data assimilation cycle of ~15 minutes. The 4DVAR technique is used to estimate the ionospheric driving forces with a longer data assimilation cycle of ~ 2 hours. The optimized ionospheric state variables and driving forces are then used in the forward model to produce new forecasts for ionospheric variables. The evaluation of either approach is first made through Observation System Simulation Experiments (OSSE) in which simulated measurements derived from forward model output are used. Our presentation will describe GAIM and examine its analyses by assimilating GPS TEC data from nearly 100 global ground stations and the currently operating GPS flight experiments, CHAMP, SAC-C, GRACE and IOX. A series of GAIM retrievals will be presented and validated by comparisons to: vertical TEC data from the TOPEX altimeter, UV measurements, slant TEC data from ground GPS sites not used in the assimilation, and a global network of ionosondes.

GAII.05/07A/D-006   Poster   0830-022

ESTIMATION OF IONOSPHERIC DYNAMICAL DRIVERS USING A GLOBAL ASSIMILATIVE IONOSPHERIC MODEL

Xiaoqing PI[1], Chunming WANG[2], George A. HAJJ[1], Gary ROSEN[2], Brian D. WILSON[1] ([1]Jet Propulsion Laboratory, California Institute of Technology, [2]University of Southern California)

A global assimilative ionospheric model (GAIM) has been developed by the consortium of University of Southern California and Jet Propulsion Laboratory. The model is capable of assimilating various types of ionospheric measurements, such as line-of-sight total electron content (TEC) and satellite limb scans of ultraviolet airglow emission, to optimize the modeling of ionospheric volume densities. Among the assimilation techniques developed with GAIM, a 4-dimensional variational (4DVAR) approach allows the estimation of model drivers that satisfies the requirements of minimizing the difference between observations and model predictions on regional and global scales. Observation system simulation experiments (OSSE) have been conducted with the global positioning system (GPS) and the IGS global ground-based network. The experiment results show that using GAIM and the 4DVAR technique with the existing GPS observation system, it is promising to solve for simultaneously zonal electric field and thermospheric meridional wind that play key roles in the evolution of equatorial spread-F irregularities. Validation of the assimilative modeling techniques is also conducted in the Pacific and South America regions with multi-diagnostic observation techniques. The framework of the validation effort and preliminary results will be presented at the meeting.

SOLAR WIND DRIVEN RADIATION BELT RESPONSE FUNCTIONS: DATA ASSIMILATION METHODS FOR CHARACTERIZING RADIATION BELT DYNAMICS

E. Josh RIGLER[1], Daniel N. BAKER[1], Dimitris VASSILIADIS[2] ([1]LASP/Univ. of Colorado at Boulder, [2]Goddard Space Flight Center)

Characterizations of radiation belt dynamics using linear prediction filters (LPFs) were first published by Nagai (1988) and Baker et al. (1990). These studies focused primarily on short-term predictions of daily-averaged radiation fluxes at geostationary orbit using global magnetospheric indices and the speed of the solar wind impinging on the earth's magnetosphere. More recent work by Moorer and Baker (2000) focused on 4-dimensional data assimilation methods to specify with very high accuracy the outer radiation belt fluxes at all spatial locations. Using solar wind data from the NSSDC OMNI database and SAMPEX 2-6 MeV omnidirectional electron fluxes at various magnetic L-shells, new analyses have used multi-input, adaptive local-linear response functions to describe the evolving response of relativistic radiation belt electrons to solar wind input. Physical interpretations and implications can be gleaned by applying this powerful data analysis technique. This can include a partial separation of adiabatic and non-adiabatic responses to changing solar wind conditions. Extension of present methods holds the hope of ingesting data from numerous operational spacecraft in real time and subsequently specifying (or forecasting) radiation properties at any chosen point in the Earth's magnetosphere.

MAGNETOSPHERIC DATA ASSIMILATION

Joachim RAEDER (IGPP, University of California)

Data assimilation (DA), that is, the ingestion of data into large-scale numerical models was first introduced intonumerical weather prediction models in order to overcomethe problem of insufficient data for model initialization.It is now a standard procedure that is used in allcontemporary forecast models. Following the success in atmospheric models, DA has been introducedinto oceanic, and most recently into ionosphericspecification and forecast models. No serious attempthas yet been made to incorporate DA techniquesinto global magnetospheric models. The prime reason isthe lack of sufficient data. However, there are also otherissues. While DA in the before mentionedareas primarily addresses an initialization problem, themagnetosphere is much more a driven system with relativelyshort memory. The magnetosphere is also characterizedby discontinuous field variables and other constraints,such as the requirement that divergence of the magnetic field vanishes. These issues make the application of standardDA procdures difficult. In this talk I shalloutline the problems that lie ahead of us to introduceDA into global magnetosphere models and possible pathwaysfor a successful DA implementation.

IONOSPHERIC DATA ASSIMILATION IN GAIM

Ludger SCHERLIESS, Robert W. SCHUNK, Jan J. SOJKA, Donald C. THOMPSON (Center for Atmospheric and Space Sciences)

With the significant increase in thenumber of ionospheric observations that will becomeavailable overthe next decade, ionospheric data assimilation will provide a powerful tooltoward an improved specification and forecasting of the global ionosphere,with an unprecedented accuracy and reliability.A physics-based data assimilation model of the ionosphere is underdevelopment as the central part of a DoD MURI funded program called GAIM(Global Assimilation of IonosphericMeasurements).The goal of this effort will be the development of an operational ionosphericassimilation model that will provide specifications and forecasts on spatial gridsthat can be global, regional, or local (50 km x 50 km). Thespecification/forecast will be in the form of 3-dimensional electron densitydistributions from 90 km to geosynchronous altitudes (35,000 km).GAIM will use a physics-based ionosphere-plasmasphere model and a Kalman filteras a basis for assimilating a diverse set of real-time (or near-realtime)measurements.In addition, to the physics-based Kalman filter, we have developeda Gauss-Markov Kalman filter model. For both of these models, we have assimilatedseveral data types, including in situ electron density measurements from DMSPsatellites, bottomside electron density profiles from the Air Force network ofdigisondes, GPS-TEC from a global network of more than 100 ground stations,and GPS-TEC from more than 300 stations in the CORS network (over the U.S.).In this paper we give an update on the model development andpresent initial results from the two models and a validationusing independent data sources.

NEW DATA SOURCES TO DRIVE AN ASSIMILATING MODEL FOR THE IONOSPHERE

Robert P. MCCOY (Code 321SR, Office of Naval Research)

Existing operational models used to specify and forecast the global ionospheric electron density are either empirical or climatological and do not use data assimilation techniques. This is due to the relatively small amounts of data that have been routinely available. Ionospheric data types used operationally include a few ground-based digisondes, in-situ plasma data on weather satellites and total electron content (TEC) measurements using about three dozen land-based dual frequency GPS receivers. The sum of these measurements is small compared to the five million+ measurements assimilated daily into meteorological forecast models. This situation is about to change dramatically when the Defense Meteorological Satellite Program (DMSP) begins launching its next block of weather satellites (currently scheduled for Spring 2003). Each satellite will have a pair of ultraviolet spectrographs to produce images of ionospheric airglow in the both the limb and nadir cross-track directions. These images will be used to infer electron density profiles and nadir TEC measurements along the satellite orbits and should yield more than a million electron column measurements per day. Additional new ionospheric data sources, which should be routinely available in the near future, include GPS occultation measurements (e.g. COSMIC constellation) and computerized ionospheric tomography (CIT) using the existing Transit (and similar) dual frequency UHF radio beacons on low Earth orbiting satellites. With these new and large data sets in mind, the Office of Naval Research (ONR) is sponsoring the development of an assimilating model for the ionosphere. The sponsorship is in collaboration with the Director Defense Research and Engineering and the Air Force Office of Scientific Research. This new model will assimilate these data and other potential new data sources including a geosynchronous ultraviolet ionospheric imager currently under development.

GAII.05/08A/A15-005   1040

VALIDATION OF A GLOBAL IONOSPHERIC DATA ASSIMILATION MODEL

Brian D. WILSON[1], George HAJJ[1], Chunming WANG[2], Xiaoqing PI[1], Gary ROSEN[2] ([1]Jet Propulsion Laboratory, Caltech, [2]Dept. of Mathematics, University of Southern California)

As the number of ground and space-based receivers tracking the global positioning system (GPS) steadily increases, and the quantity of other ionospheric remote sensing data such as measurements of airglow also increases, it is becoming possible to monitor changes in the ionosphere continuously and on a global scale with unprecedented accuracy and reliability. However, in order to make effective use of such a large volume of data for both ionospheric specification and forecast, it is important to develop a data- driven ionospheric model that is consistent with the underlying physical principles governing ionosphere dynamics. A fully 3-dimensional Global Assimilative Ionosphere Model (GAIM) is currently being developed by a joint University of Southern California and Jet Propulsion Laboratory team. GAIM uses a first-principles ionospheric physics model (˝forward˝ model) and Kalman filtering and 4DVAR techniques to not only solve for densities on a 3D grid but also estimate key driving forces which are inputs to the theoretical model, such as the ExB drift, neutral wind, and production terms. The driving forces are estimated using an ˝adjoint equation˝ to compute the required partial derivatives, thereby greatly reducing the computational demands compared to other techniques. For estimation of the grid densities, GAIM uses an approximate Kalman filter implementation in which the portions of the covariance matrix that are retained (the off-diagonal elements) are determined by assumed but physical correlation lengths in the ionosphere. By selecting how sparse or full the covariance matrix is over repeated Kalman filter runs, one can fully investigate the tradeoff between estimation accuracy and computational speed. Although GAIM will ultimately use multiple datatypes and many data sources, we have performed a first study of quantitative accuracy by ingesting GPS-derived TEC observations from ground and space-based receivers and nighttime UV radiance data from the LORAAS limb scanner on ARGOS, and then comparing the retrieved density field to independent ionospheric observations. A series of such GAIM retrievals will be presented and validated by comparisons to: vertical TEC data from the TOPEX altimeter, slant TEC data from ground GPS sites that were not included in the assimilation runs, and global ionosonde data (F0F2, HMF2, and bottom-side profiles where available). By presenting animated movies of the GAIM densities and vertical TEC maps, and their errors computed as differences from the independent observations, we will demonstrate the reasonableness and physicality of the climatology derived from the GAIM forward model, examine the consistency of the GPS and UV datatypes, and characterize the quantitative accuracy of the ionospheric ˝weather˝ specification provided by the assimilation retrievals.

GAII.05/08A/A15-006   1100

IONOSPHERE SOUNDING BY GPS MEASUREMENTS ON CHAMP

Norbert JAKOWSKI[1], Stefan HEISE[2], Konstantin TSYBULYA[1], Andreas WEHRENPFENNIG[3] ([1]Deutsches Zentrum fuer Luft- und Raumfahrt (DLR), Institut fuer Kommunikation und Navigation, [2]GeoForschungsZentrum Potsdam (GFZ), Division 1, Telegrafenberg, Potsdam , Germany, [3]Fachhochschule Neubrandenburg, Neubrandenburg, Germany)

GPS measurements onboard the German CHAMP (CHAllenging Minisatellite Payload) satellite provide a good possibility for operational sounding the ionosphere on global scale. Both the radio occultation measurements and the navigation measurements made by using the upward looking GPS antenna have a big potential to reconstruct the spatial and temporal distribution of the electron density in the ionosphere. To fulfill operational requirements, the Ionospheric Radio Occultation (IRO) data are processed in a automatically working processing unit that provides electron density profiles within 3 hours after data dump from CHAMP. More than 50000 vertical electron density profiles have been obtained since the beginning of ionospheric radio occultation (IRO) measurements on 11 April 2001 by using a model assisted retrieval technique. Although comprehensive validation work is not yet finished, IRO data products are made available to the international science community via the ISDC of the GFZ Potsdam. At present about 150 electron density profiles from global scale are retrieved by the processing system. Recent validation results are reported. To obtain a more comprehensive view on the spatial and temporal electron density distribution, the 0.1 Hz sampled dual frequency navigation measurements are used to derive the total electron content (TEC) along the ray paths between the CHAMP and GPS satellites. After assimilating these integral measurements into the Parameterized Ionospheric Model (PIM) of local electron density it is possible to reconstruct the spatial electron density distribution close to the CHAMP orbit plane. This technique has also the capability to run in an operational mode for providing near-real-time data into forecast models for space weather applications.

AN ON-LINE DATABASE FOR IONOSPHERIC THERMAL PLASMA DATA FROM DMSP

Marc R. HAIRSTON, William R. COLEY, R.A. HEELIS (Center for Space Sciences, University of Texas at Dallas)

Since 1987 the polar orbiting meteorological satellites in the DMSP program have carried a package of instruments for measuring parameters of the thermal plasma in the topside ionosphere (~840 km). This instrument package (known as SSIES) measures all three components of the bulk flow of the plasma, the ion and electron temperatures, the total plasma density and the fractional composition of O+, H+ and He+. To date eight satellites (DMSP F8 through DMSP F15) have flown with the SSIES package on board returning a total of over 45 satellite-years of data which span one and a half solar cycles. This database provides a tremendous scientific resource for the ionospheric community and numerous research projects and papers have already been based on these data. However it usefulness has been limited because of the sheer volume of data and the difficulty in distributing these data easily to the community. To solve this, we have set up a web-based distribution service of a subset of these data covering the past solar maximum period of 2000 through 2002. (The URL is **http://cindispace.utdallas.edu/DMSP/**) This talk will outline the scope and usefulness of these data as inputs to various models and data assimilation routines. Emphasis will be placed on the automatic evaluation of the data quality in order to prevent bad data from being used in models or data assimilation routines. In addition the talk will cover the current state of the data distribution service and our plans to expand it to encompass both the historical data (back to 1987) and the ongoing acquisition of new data from the operational DMSP spacecraft.

GAII.05/08A/A15-008   1150

VALIDATION OF THE IONOSPHERIC DATA ASSIMILATION THREE DIMENSIONAL (IDA3D) ALGORITHM

Trevor W. GARNER, Gary S. BUST, Thomas L. GAUSSIRAN II (ARL:UT)

Ionospheric tomography has been used for several years to create large-scale electron density maps for GPS or radio beacon TEC data. Recently, the computerized ionospheric tomography (CIT) algorithm [Bust et al., *Int. J. Imag. Syst. Technol., 5*, 160, 1994] has been adapted into the Ionospheric Data Assimilation Three Dimensional (IDA3D) algorithm. IDA3D is a data assimilation algorithm, which incorporates all available electron density and electron content observations into a coherent picture of the synoptic or global scale ionosphere. IDA3D primarily uses slant total electron content (TEC) measurements from available GPS ground sites and radio beacon receiver arrays operated by the Applied Research Laboratories, The University of Texas at Austin (ARL:UT), but can easily use peak electron density measurements from digasondes, electron density profiles from incoherent scatter radar and satellite-based GPS-occulation measurements of the topside TEC. This study compares different electron density maps for the same time period. Individual maps are created for each data set and combination of data sets (for a total of thirty maps), and compared to those observations that not used in a given map. By comparing the IDA3D maps to withheld observations, this study determines the validity of IDA3D, the usefulness of a given data set, and regions where more observations are needed.

GAII.05/08A/A15-009   1210

SPLINE-BASED EMPIRICAL MODEL OF HIGH-LATITUDE IONOSPHERIC POTENTIAL

Satoshi TAGUCHI (University of Electro-Communications, Japan)

During a couple of decades the characteristics of the high-latitude ionospheric convection have been understood well, and now several empirical models exist which cover a broad range of solar wind conditions. While these existing models predict some situations well, it appears that they do not show satisfactory reproduction in particular for the convection during positive IMF Bz, and for the one during a substorm including its development. For this kind of situations, the convection tends to be intensified in a relatively small region, and if the location of such convection is affected by an unknown parameter or with a time scale that is out of range considered for the modeling, the convection structure may be smoothed out in the model. In this study, an empirical potential model presented in which a potential structure having a latitudinal scale of down to about 500 km can be reproduced reasonably. We took the potential zero and peaks from each of about 2500 pass of DE 2, focusing on the above scale, and obtained empirical relations for the location and magnitude of these potentials with the IMF magnitude or solar wind electric field for each 30 degree IMF clock angle and 3 hr MLT bin. Then, we created a potential distribution for each condition using a data interpolation technique with spline. This modeling for positive IMF Bz shows that a reverse convection pattern appears in a broader range of IMF conditions than the one given by the existing convection models, and that the potential magnitude can be larger by a factor of 1.5. For substorms, a phase-dependent model was made in which the development of potential during a substorm as well as the IMF dependence can be represented, by categorizing DE 2 substorm passes into several groups in terms of AL index development. The potential model shows that early in the expansion phase, the positive potential that usually occurs in the postmidnight sector, starts to enter the poleward side of the negative premidnight potential, leading to the development of a distorted pattern. At the substorm maximum, the negative premidnight potential occurs at higher latitudes than in earlier stages, leading to a pronounced Harang discontinuity. Details of relations of the potential variations with IMF, which are used in the model construction, will be presented, and possibility of the prediction of potential maps for extremely large IMF with the extrapolation of these relations will be also discussed.

GAII.05/08P/A15-001   1400

RADIO AND OPTICAL MEASUREMENT OF THE IONOSPHERE WITH OBSERVATIONAL NETWORKS IN JAPAN

Akinori SAITO[1], S. FUKAO[2], M. YAMAMOTO[2], K. SHIOKAWA[3], Y. OTSUKA[3], M. KUBOTA[4], T. OGAWA[3] ([1]Department of Geophysics, Kyoto University, [2]Radio Science Center for Space and Atmosphere, Kyoto University, [3]Solar-Terrestrial Environment Laboratory, Nagoya University, [4]Communications Research Laboratory)

Observational networks of GPS receivers, all-sky imagers, ionosondes and magnenetometers are continuously operated in Japan and provide a large data set on the Ionosphere-Thermosphere-Magnetosphere system in the midlatitude region. The GPS network of Geographical Survey Institute and the all-sky imager network of Nagoya University can measure the 2-D horizontal structures of the ionosphere, which cannot be detected with classical observational techniques, such as ionosonde. Combination of the two-dimensional measurements by these networks and the vertical measurements by the ionosonde network, the MU radar and occultation by satellite-borne GPS receivers enable to observe three-dimensional structures of the ionospheric electron density and its temporal variations. Measurements of the other physical parameters, such as the electric field, the neutral wind, and the electric current by the MU radar, coherent radars, Fabry-Perot interferometers and magnetometers are also important to clarify physical mechanisms that create the structures of the ionospheric electron density. The F-region Radio and Optical measurement of Nighttime TID (FRONT) campaign demonstrated the advantage of these cluster of the observational instruments in Japan to study ionospheric phenomena. In this campaign, about 1,000 of GPS receivers, five of all-sky CCD imagers, two of Fabry-Perot interferometers, the MU radar, and ionosonde network was operated to investigate the physical mechanism of the medium-scale traveling ionospheric disturbances (MSTIDs) in the nighttime ionosphere. The MU radar observed the electron density profile in its incoherent scatter mode, and 3-m scale field-aligned irregularities (FAIs) in its coherent scatter mode. Comparison of the total electron content detected by the GPS receiver network and the 630nm band airglow detected by the all-sky camera network clarified that the modulation of the ionosphere by MSTIDs occurs mainly on the bottomside of the ionosphere. FAIs were found to embed in a certain phase of MSTIDs measured by the GPS network. This indicates that the polarization electric field is generated inside MSTIDs and causes small-scale plasma instabilities. The continuous observation of the GPS network and the optical instrument network in Japan has observed the equatorial anomaly and plasma bubbles besides TIDs under various conditions of the geomagnetic activity, local time and season. Comparison of these observational results detected by multi-instruments with IRI model and physical models reveals the physical mechanisms that determine behaviors of the ionosphere at low- and mid-latitudes.

GAII.05/08P/A15-002   1430

INCOHERENT SCATTER RADAR DATA AND FUTURE POSSIBILITIES FOR FURTHER EXTENDED REAL-TIME DATA AVAILABILITY

Anthony VAN EYKEN[1], John HOLT[2] ([1]EISCAT Scientific Association, [2]MIT Haystack Observatory)

Incoherent scatter radars have been operating for 40 years and continue to provide the most detailed ionospheric data available from the ground. While operational constraints have normally restricted incoherent scatter to relatively short duration data sets, recent developments in radar hardware, coding techniques, data processing and data distribution make the recording of extended datasets both practical and valuable. Both the EISCAT Svalbard Radar and Millstone Hill Radar have been developing the infrastructure to support long experiments and can already handle programmes with durations exceeding four weeks. Long duration experiments provide possibilities to study phenomena not normally accessible to these facilities and also provide datasets applicable to comparison with many ionospheric and atmospheric models. Using examples from recent extended operations, we illustrate how the ready availability of fully analysed data through WWW-based database tools allows these facilities to be easily exploited by a wide user community.

GAII.05/08P/A15-003   1500

OPTIMAL INTERPOLATION (OI) ANALYSIS OF HIGH-LATITUDE IONOSPHERIC ELECTRODYNAMIC VARIABLESUSING EOF BASES AND MAXIMUM LIKELIHOOD METHOD FOR ERROR COVARIANCE ESTIMATION: JANUARY 9-11, 1997

Tomoko MATSUO, Arthur D. RICHMOND, Gang LU (HAO/NCAR)

The Assimilative Mapping of Ionospheric Electrodynamics (AMIE) procedure, developed by *Richmond and Kamide* [1988], carries out an objective multivariate functional analysis of high-latitude ionospheric electrodynamic variables: electric fields, electric potential, ionospheric currents, and magnetic field perturbations. The scheme is essentially based on Optimal Interpolation (OI) theory [e.g., *Lorenc*}, 1986]. In the current AMIE procedure, each variable is presumed to be expanded in a series of *I* basis functions, which are chosen as modified spherical harmonic functions. For the problems to which the AMIE procedure is usually applied the size of state vector (*I ~ 244*) is smaller than the size of observation vector (300 to 1000).In this study some technical improvements upon the traditional implementation of the OI method are demonstrated for the storm period of January 9-11, 1997.One of the improvements is to use the set of 11 Empirical Orthogonal Functions (EOFs) of *Matsuo et al.* [2002] as basis functions (*I* = 11). This extension incorporates realistic spatial coherence of the electric field on large scales into the analysis and also reduces the background error covariance to a diagonal matrix.Furthermore, both observational and background error covariances are parameterized with respect to 4 free parameters, and these parameters are estimated at each analysis time-step using the maximum-likelihood method [*Dee*, 1995].As has been demonstrated by *Dee* [1995], the error covariance parameter estimation can be performed in the innovation covariance space by matching a covariance model to the actual innovation vector. As the size of the problem is relatively small, on-line covariance parameter estimation is feasible.In this way the state dependence of the background error covariance is incorporated systematically into theprocedure without resorting to a dynamic data assimilation methodology such as Kalman-filter.

RTAMIE STATISTICAL VALIDATION RESULTS

Aaron J. RIDLEY[1], Eric KIHN[2] ([1]Center for Space Environment Research, University of Michigan, [2]NGDC/NOAA, Boulder, CO)

We present results from a validation study of the assimilative mapping ofionospheric electrodynamics (AMIE) technique and the real-time versionof AMIE. The validation consists of comparing AMIE calculations of particleprecipitation and Hall conductances to DMSP J4 data. We will present2 years worth of AMIE results (1997-1998) and statistical comparisons between the data and measurements. It is found that when there is verylittle data in a sector, the AMIE technique relies heavily upon the backgroundmodel, such that the differences between AMIE and DMSP are the same asthe differences between the statistical model and DMSP. As more datais included, the agreement differences between AMIE and DMSP increases.This increase is quantified as a function of magnetic local time and activitylevel. In addition, statistical comparisions between the background modeland the DMSP data are presented.

GAII.05/08P/A15-005   1600

CIRCUM-PAN PACIFIC MAGNETOMETER NETWORK OBSERVATIONS FOR STUDY OF IONOSPHERE-THERMOSPHERE-MAGNETOSPHERE COUPLING SYSTEM

Kiyohumi YUMOTO, the CPMN Group (Space Environment Research Center, Kyushu University, Japan)

In order to understand couplings of the magnetosphere-thermosphere-ionosphere system, the STP group in Kyushu University, Japan is conducting the Circum-pan Pacific Magnetometer Network (CPMN) observations at 54 stations in the world. Especially, by using the magnetic data from the CPMN stations along the 210 magnetic meridians, we are making global patterns of the equivalent ionospheric current, which show a clear seasonal variation of Sq current patterns and couplings of the Sq dynamo current system at middle- and low- latitudes and the ionospheric and field-aligned current (FAC) system in the auroral region. We are also developing a simulation code, which can calculate a global distribution of ionspheric current vectors generated by the Sq dynamo in the thin model ionosphere and by the Region 1 and 2 FAC model in the auroral region. We used the two-dimensional model called ´thin shell model´ in order to simulate the Sq current system. This model reproduces well the ionospheric current, if the equator vicinity is excluded. In the equatorial region, the vertical electric current which can not be expressed in ´thin shell model´ exists. Then, the new conductivity model at the equatorial latitude was made to add the effect of vertical electric current in the equatorial region, and global ionospheric current was simulated. The conductivity and current density model in the Region 1 and 2 in the polar region are a function of the magnetic activity. Although more realistic neutral wind model in the lower latitude region, conductivity models at the equatorial and auroral latitudes, and FAC patterns in the auroral region are desired, in the near future we may establish the data assimilation technique for the Ionosphere-Thermosphere-Magnetosphere system by comparing the ground-based network observations and the simulation results.

IONOSPHERIC DATABASE IN EU COST 271 ACTION- EFFECTS OF THE UPPERATMOSPHERE ON TERRESTRIAL AND EARTH-SPACE COMMUNICATIONSINCLUDING EUROPEAN REAL-TIME IONOSONDE NETWORK

Bruno ZOLESI[1], Ljiljana CANDER[2] ([1]Istituto Nazionale di Geofisica e Vulcanologia, [2]Rutherford Appleton Laboratory)

The ability to monitor, specify and forecast the impact of the variability of the space environment on terrestrial and Earth-space and satellite to satellitecommunications significantly depend on data sources, data quality and data assimilation modelling. The EU COST (Co-operation in the field of Scientific and Technical Research) Action 271 on Effects of the Upper Atmosphere on Terrestrial and Earth-Space Communications (EACOS) is aresearch program that provides scientific context to study: (a) Impact of the variability of the space environment on communications; (b) Assessmentof space plasma effects for satellite applications; (c) Ionospheric effects on terrestrial communications; and (d) Space plasma effects on Earth-space are described and the most significant results of different working groups reviewed. Two important components of this action are a unified database of detailed ionospheric vertical sounding observations from across Europe and European real-time ionosonde network. This paper presents a review of current ionospheric database status and focus on its application in modelling and forecasting studies.

GAII.05/08P/A15-007   1700

REAL DATA ASSIMILATION INTO SATELLITE-BASED EMPIRICAL MODELS OF HIGH-LATITUDE IONOSPHERIC ELECTRODYNAMICS FOR EMULATION OF QUASI-SYNOPTIC OBSERVATIONS

Vladimir PAPITASHVILI[1], Daniel WEIMER[2], Freddy CHRISTIANSEN[3], Frederick RICH[4] ([1]SPRL, University of Michigan, [2]Mission Research Corporation, [3]Danish Meteorological Institute, [4]U.S. Air Force Research Laboratory)

Although ample data from various ground instruments and satellite missions allow us to study ionospheric electrodynamics globally and instantaneously in both the sunlit and dark polar caps, little is available for the day-to-day collection of synoptic observations in 'Geospace' needed for constraining of physics-based models of the near-Earth environment to reality. Here we report on a series of new empirical models of ionospheric convection and field-aligned currents constructed separately for both the northern and southern polar regions from the satellite-based data (DE 2, DMSP, Ørsted, and CHAMP). These models are parameterized by the IMF strength and 'clock angle' direction, as well as by the Earth´s dipole tilt; they are constrained to the quiet and moderately disturbed conditions but not to geomagnetic storms. In this study, we tried to develop a technique which would modify our modeled patterns (for the given IMF parameters and season) by assimilating available satellite passes (from one to a few) into the pattern. (This approach is similar to the AMIE technique but it does not utilize ground-based data.) The outcome of that assimilation is a series of emulated 'synoptic observations' over high latitudes sampled by a cadence of the available satellite passes. This allows us to capture quasi-synoptic time series of various ionospheric parameters, which we believe can then be digested into the MHD codes for the adjustment of code's regimes for various 'space weather' conditions. The proposed technique requires a unified approach in modeling of the high-latitude ionospheric electrodynamics from various data sources.

IONOSPHERIC DATA FUSION ALGORITHMS FOR SATELLITE BASED IONOSPHERIC SENSORS

Robert E. DANIELL[1], Douglas J. STRICKLAND[2] ([1]Boston Office, Computational Physics, Inc., [2]Computational Physics, Inc.)

We are in the process of developing data fusion algorithms intended to produce ionospheric specifications in the low latitude, midlatitude, and auroral regions using a wide variety of *in situ* and remote sensing data from space based platforms. The data to be ˝fused˝ include

thermal plasma properties (e.g., electron density, ion composition, electron and ion temperature), slant TEC (from GPS occultation sensors, beacons, and radar altimeters), topside electron density profiles (EDPs) from topside sounders, and UV radiances (day, night, and aurora; disk and limb) from FUV and EUV imagers. Because the UV radiances come in the form of both disk and limb images, they are potentially extremely important sources of information. For example, at night images of the 135.6 nm line of atomic oxygen (whether disk or limb) can be converted to integrals of n_e^2 along the line of sight. In the daytime, photoelectron excitation of atomic oxygen greatly exceeds the recombination source (except in the low latitude region where the ionosphere is frequently lifted above the main dayglow emitting layer) making ionospheric information indirect, but still potentially useful. In the aurora, the FUV emissions from atomic oxygen and molecular nitrogen provide information on the energy flux and hardness of the electron and ion spectra that produce the auroral displays. These can be used to estimate the electron density in the auroral *E*-layer. The data obtained from this wide variety of sensors and measurement techniques is of variable quality and is unevenly distributed in both space and time, but the objective is to produce ionospheric specifications throughout the region visible to the UV imagers. We will present the results of a study of various three dimensional ionospheric reconstruction techniques (based on various optimal estimation methods) capable of ingesting this data and producing the desired ionospheric specifications. The study is based on simulations of both the data sources and generic sensor models, designed to be as realistic as possible. For example the thermospheric and ionospheric models will be modified (˝by hand˝) to simulate traveling ionospheric disturbances (TIDs) so that the effect of this phenomenon on algorithm performance can be judged. Our goal is to select from the candidate algorithms those that are accurate, compact, fast, and robust under realistic conditions, and which degrade gracefully when the various data sources are absent. We also hope the study can be used as a test bed for various configurations of space environment sensors.

GAII.05/08P/A15-009   1740

IMPROVEMENTS IN GLOBAL IONOSPHERIC SPECIFICATION USING IONOSPHERIC OCCULTATION MEASUREMENTS

Phillip Charles ANDERSON[1], Paul R. STRAUS[1], Ludger SCHERLIESS[2], Robert W. SCHUNK[2], Jan J. SOJKA[2] ([1]Space Science Applications Laboratory, The Aerospace Corporation, Los Angeles, CA, [2]Center for Atmospheric and Space Sciences, Utah State University, Logan, UT)

GPS occultation measurements are a new and valuable tool for providing global information about the ionospheric structure to assimilative ionospheric models. One low-Earth orbiting satellite with a single GPS antenna makes measurements of ~500 occultations a day. These measurements provide a global specification of the ionosphere never before available. We will be reporting the results of the first large scale study to incorporate these measurements into an assimilative ionospheric model, specifically the GAIM model. GAIM (Global Assimilation of Ionospheric Measurements) uses a Kalman filter to assimilate various types of ionospheric data such as slant path total electron content (TEC) measurements made by GPS occultation receivers, ionosonde data, and satellite-based in-situ electron density measurements. We will report on the improvement of GAIM achieved with the inclusion of the occultation measurements during selected space weather events. The occultation measurements will be provided by the PICOSat (Polymer Battery Experiment/Ionospheric Occultation Experiment/Coherent Electro Magnetic Radio Tomography/Optical Precision Platform Experiment - Satellite), CHAMP (Challenging Minisatellite Payload for Geophysical Research and Application), and SAC-C (Satelite de Aplicaciones Cientificas) spacecraft. Modeling parameters tested will include the accuracy of the ionospheric density profiles and the drivers responsible for the development of ionospheric structure such as the ionospheric electric fields.

LOW AND MID LATITUDS

GAII.06/09A/A10-001   0900

OCCURRENCE AND SPECTRAL CHARACTERISTICS OF IONOSPHERIC IRREGULARITIES DERIVED FROM ROCSAT-1 OBSERVATIONS

Huey-Ching YEH[1], S.-Y. SU[1], R.A. HEELIS[2], H.-H. HO[1], K.-Y. CHEN[1], C.-H. LIU[1] ([1]Institute of Space Science, National Central University, [2]William B. Hanson Center for Space Sciences, The University of Texas at Dallas)

A large set of F-region ionospheric irregularities at low latitudes has been detected by the Ionospheric Plasma and Electrodynamics Instrument (IPEI) onboard the ROCSAT-1 satellite since early 1999. Over the passing four years IPEI has been collecting data by alternating operations of the NORMAL mode with a sampling rate of 32 Hz and the FAST/AUTO mode with a sampling rate of 1024 Hz at 100% duty cycle. The simultaneously high resolution data of ion density and the two cross-track ion velocity components allow us, never before from satellite ion drift data, to study the spectral characteristics of the irregularities to the smallest scale of 15 m along the satellite track. Here, we report some statistical features of these irregularities. In particular we show how their occurrences vary with local time, longitude (geomagnetic field configuration), season, as well as the evolution of storm-time disturbed electric fields. We present the threshold values of density gradients along the satellite path and of upward ion drift enhancement, which might be considered as the precursor signatures for the prediction of post sunset irregularities. Furthermore, in the efforts to identify the underlying processes (instabilities) that control the evolution of irregularity structures, we investigate the detailed spectral features such as spectral index, wavelengths of spectral breaks that differentiate various wave modes, and the correlation between density and velocity spectra for various types of irregularity. As an example, we present the comparisons of these spectral features between those of fast rising bubbles and those of descending or fossil bubbles, which are chosen to approximately represent the growing and the decaying stages of irregularity structures.

GAII.06/09A/A10-002   0920

SIMULTANEOUS RADAR OBSERVATIONS OF THE EQUATORIAL SPREAD F AT 18 MHZ AT THE EQUATOR AND AT 53 MHZ AT OFF THE EQUATOR OVER INDIA

Amit Kumar PATRA, D. TIWARI, Sripathi S., Rao P.B., Sridhran R., Devasia C.V, Viswanathan K.S., Subbarao K.S.V., Sekar R., Kherani E. (National MST Radar Facility)

In this paper, we present simultaneous observations of equatorial spread F on several nights made using the 18 MHz radar at Trivandrum, an equatorial station and 53 MHz radar observations at Gadanki, an off equatorial station. It may be mentioned that a good part of the F region over these two locations are well connected through the magnetic field lines. We present the morphology of ESF irregularities and characteristic differences of the two scales of irregularities observed at the two locations. For example, we have not observed more than 3 plumes and no post-midnight plumes at 18 MHz while multiple plumes have been observed at 53 MHz. Bottomside irregularities at Trivandrum are found to be weak and they are very rare at Gadanki. The observed velocities at 18 MHz are found to be remarkably less than that observed at 53 MHz. Taking advantage of the locations of the two radar systems, we have also studied the mapping efficiency in the spread F structures and velocity fields. Mapping efficiency is found to decrease with decreasing periods (proportional to wavelength). The results are discussed in the light of present understanding of the ESF irregularities at different scale sizes. We also discuss on the mapping of the structures and coupling between the equatorial and low latitude.

GAII.06/09A/A10-003   0935

SIMULTANEOUS STUDY OF LARGE SCALE GRADIENT-DRIFT AND RAYLEIGH-TAYLOR INSTABILITY IN THE NIGHT-TIME EQUATORIAL IONOSPHERE

Esfhan Alam KHERANI (Post-doc fellow, Planetary and Space Science division, Physical Research Laboratory)

This is an attempt to explain the large scale (~100 km) towering structures observed by VHF radars in the equatorial E region. In order to know the possible cause for such structures, the numerical simulation of Gradient drift instability (GDI) in the E region and Rayleigh-Taylor instability (RTI) in the F region are simultaneously performed for night-time equatorial ionosphere. In contrast to the present believe, the investigation reveals that the fringe-field associated with the RTI is inefficient to produce any structures in the E region. On the other hand, it is found that the GDI can excite the large scales in the E region itself. These scales develop as the towering structures and penetrate into the lower boundary of the F region. Though the local linear theory of GDI does not predict growth for such large scales, the non-local linear theory with proper altitude variation of scale height may provide the answer for growth of such scales.

GAII.06/09A/A10-004   0950

THE TOPSIDE IONOSPHERE HE+ DENSITY SUBTROUGHS AS IRREGULARITIES OF THE BUBBLE ORIGIN

Larissa SIDOROVA (Institute of Terrestrial Magnetism, Ionosphere and Radiowave Propagation, Troitsk, Moscow region, 142190, RUSSIA, E-mail: lsid@izmiran.rssi.ru)

The comparison of the topside ionosphere He+ density subtrough statistics (LT/month) with the similar statistics for equatorial F-spread (ESF) over the Brazilian and Peruvian regions for the same solar activity period shows the surprising coincidence in the most features. The He+ density subtroughs as irregular structure of the topside ionosphere, occurred equatorward of the light ion trough, were studied on ISS-b satellite data (1978-79). They were detected in ~ 570 cases in ~ 4000 passes at ~ 1100 km heights over mid- and low-latitude ionosphere (25-58°Λ) during high/maximum solar activity period. One group of the subtroughs, mainly revealed at latitudes of L=2-4 and being in dependence on geomagnetic activity, demonstrates a distinct storm-time nature. Apparently, this group could be created by so-called «plasmatails» mechanism. But another group of the subtroughs, revealed deeply inside of the plasmasphere at L~ 1.3-3, does not depend on geomagnetic activity practically at all. These subtroughs of «non-disturbed origin» show the above-mentioned similarity with ESF phenomena. They mostly occur in the evening-night sector (18-05 LT) in period from October till May like ESFs (or bubbles). Monthly mean subtrough occurrence probability, plotted in local time versus month and averaged on longitudes, shows the distinct December solstice maximum and equinoctial maxima like the ESF occurrence probability plot at the Brazilian and Peruvian longitudes for the same solar maximum years. Hence, the He+ density subtroughs and ESFs may be considered as phenomena of the same bubble origin, since ESF is often associated with plasma bubbles, produced by Rayleigh-Taylor instability mechanism. As it is known from plasma bubble dynamics, the bubbles could display themselves as plasma density depletions at latitudes far from equator. Bubbles, upward lifting to plasmasphere heights, tend to extend along magnetic field tubes. So extended bubbles, looked like «banana», reach by own end(s) the more low (ionosphere) heights and tend to latitudes away from equator. Probably, the obtained He+ density subtroughs occur at the topside ionosphere heights by the same way.

GAII.06/09A/A10-005   1005

SEASONAL VARIATIONS IN THE SPATIAL STRUCTURE OF EQUATORIAL SPREAD F IRREGULARITIES

Archana BHATTACHARYYA, Bharati ENGAVALE, Krishnamoorthy JEEVA (Indian Institute of Geomagnetism)

Evolution of spatial structure in the Equatorial Spread F (ESF) irregularities determines the distribution of coherence (50% de-correlation) scale lengths found in the ground scintillation patterns produced by the scattering of radio waves by these irregularities. Scintillation data usually consists of a time series of amplitude or intensity fluctuations recorded by a receiver as the ground scintillation pattern drifts across the receiver. Hence, the spatial scales in the ground scintillation pattern are converted into temporal scales and an estimate of the drift speed of the scintillation pattern is required in order to derive the coherence scale length of the ground scintillation pattern for a particular interval of the scintillation event. The drift speed varies throughout the course of a scintillation event, with rapid variations in the initial stages of ESF development, due to the perturbation electric field associated with the Rayleigh-Taylor instability, and generally slower variations after 22 LT when the irregularities simply drift with the ambient plasma. A recently developed method is used to circumvent the problem presented by a varying drift speed, in obtaining the distribution of coherence scale lengths in the ground scintillation pattern from spaced receiver measurements of amplitude scintillations on a 251 MHz signal transmitted from a geostationary satellite and recorded at an equatorial station. The distribution of coherence scale lengths obtained during the period June 2001 to July 2002 shows distinct seasonal variations in the evolution of spatial structure in the ESF irregularities. The shortest coherence scale lengths are obtained in the month of August 2001. Distinctly shorter coherence scale lengths are obtained in September – October 2001, as compared to March – April 2002. Presence of shorter scale lengths in

the ground scintillation pattern does not necessarily imply the presence of shorter scale length irregularities. In the strong scintillation regime, theoretical calculations show that on the contrary, short spatial scale lengths in the scintillation pattern may occur due to focusing of the radio waves by irregularities with steeper power-law spectra, which indicate absence of short scale length irregularities. Seasonal variations in the power spectrum of the irregularities is explained in terms of differences in the height of the night-time F-region, as deduced from the drift speed of irregularities derived from the data. A possible precursory role of the daytime electrojet strength in the evolution of spatial structure in ESF irregularities is also examined.

GAII.06/09A/A10-006   1020

ROLE THE MAGNETOSPHERIC AND IONOSPHERIC CURRENTS IN GENERATION OF THE EQUATORIAL F LAYER IRREGULARITIES DURING MAGNETIC STORMS

Lilia Z. SIZOVA (Institute of terrestrial magnetism, ionosphere and radio wave propagation)

The available model of the magnetospheric ring current effects on the generation of the equatorial F layer irregularities have been hypothesized by Aarons in 1991. Since that time three basic effects of the ring current in the generation or inhibition of irregularities are much used. According to results of current statistical studies, in the literature one can see that Aarons´ criteria provide to predict near 70% of scintillations using Dst index. To amplify Aarons´ criteria or propose new criteria for better predicting of S4 and other characteristics of scintillations that is the question. The equatorial electrojet strength, Kp, Dst, AE, AU and AL indices reflected contribution of different manetospheric and ionospheric currents are examined to test geomagnetic activity effect on the generation of ionospheric irregularities producing VLF scintillations. It is shown, that additional to Aarons´ criteria, can use models explained relationship between equatorial ionospheric parameters as h'F, foF2 and equatorial geomagnetic variations with the auroral ionosphere currents and the solar wind parameters as Bz and By components of the IMF for prediction of the ionospheric scintillations. In the present phase of the experimental investigations of electron density irregularities in the ionosphere the new ways are opened up because in interaction of the solar wind-magnetosphere-ionosphere during magnetic storms have progressed greatly. From the modern point of view intensity of electric fields and currents at the Polar Regions as well as the magnetospheric ring current intensity are strong depended from variations of the IMF. The magnetospheric ring current can not directly penetrate to equatorial ionosphere. On the other hand, the equatorial scintillations can be observed in the absence of the magnetospheric ring current.

MULTI-POINT GROUND AND SATELLITE OBSERVATIONS OF NIGHTTIME MEDIUM-SCALE TRAVELING IONOSPHERIC DISTURBANCES AT MIDLATITUDES

Kazuo SHIOKAWA, Yuichi OTSUKA, Tadahiko OGAWA (Solar-Terrestrial Environment Laboratory, Nagoya University)

We review our recent results of nighttime medium-scale traveling ionospheric disturbances (MSTIDs) from multi-point airglow imaging observations in Japan, Australia, and Indonesia. The typical wavelength, velocity, period, and amplitude of MSTIDs are 100-300 km, 50-100 m/s, 0.5-1.5 h, and 5-15%, respectively. The occurrence of MSTIDs has a major peak in summer and a minor peak in winter, which is opposite to that at American sector (Arecibo). They coninuously move southwestward. From a campaign observation in the southern island (Okinawa), Japan, there seems to be a possible equatorward limit of MSTID propagation around 18 MLAT. Detailed investigation of a MSTID event of May 17, 2001 was performed using 630.0-nm and 777.4-nm airglow images, neutral wind from a Fabry-Perot interferometer, and ion drift and density data from the DMSP satellite. We found that the vertical wavelength estimated from the gravity wave dispersion relation was too small to explain the observed amplitudes of airglow intensity. On the other hand, an electric field oscillation of about 1.2 mV/m was sufficient to reproduce the observed airglow amplitudes in a simple ionospheric model. The DMSP satellite did observe oscillation of the polarization electric field correlated with the MSTID structure in the airglow image, suggesting that the polarization electric field plays an important role in the generation of MSTIDs. From conjugate airglow measurements between Japan and Australia, we found magnetic conjugacy of the MSTIDs, indicating field-aligned mapping of the electric fields between both hemispheres.

GAII.06/09A/A10-008   1110

A SURVEY OF PRESENT KNOWLEDGE OF THE UNSTABLE SPORADIC LAYERS AT MIDLATITUDE

Christos HALDOUPIS (Physics Department, University of Crete, Heraklion, Crete, Creece)

In recent years, and especially after the deployment of the MU radar in Japan,the interest in the study of midlatitude E-region coherent backscatter phenomena, that exist always in connection with unstable sporadic E layers (Es), has grown remarkably. This has become evident from the increased number of midlatitude VHF and HF coherent backscatter radar experiments and in situ rocket flights, the large number of relevant publications, and the interesting new scientific results obtained. Among the highlights of this intensive research are: 1) the observation of characteristic periodicities in backscatter with periods from a few minutes to about 30 minutes (QP echoes) which implied a dominant wave-like modulation mechanism of the midlatitude Es plasma, 2) the detection of pure Farley-Buneman waves (Type 1 echoes) which implied the existence at times of large electric fields at least an order of magnitude higher than the ambient electric fields at midlatitude, 3) the existence of large neutral winds reaching at times values higher than 150 m/s which can play a key role not only in forming Es but also in causing plasma destabilization, 4) the observation of long term periodicities in backscatter and Es occurrence with periods in the range from 2 to 10 days which implied a connection with planetary waves, and 5) the new conceptual ideas and models developed for the interpretation of the observations. This survey does not purport to give a complete account of the large volume of work done on this topic, but aims rather at presenting a synthesis of old and new experimental findings which leads to an integrated picture of our present physical understanding. In addition we update what we consider to be remaining problems that require further study.

GAII.06/09A/A10-009   1130

MORPHOLOGICAL STUDY OF THE FIELD-ALIGNED E LAYER IRREGULARITIES OBSERVED BY THE GADANKI VHF RADAR

Chen-Jeih PAN[1], P.B. RAO[1] ([1]Institute of Space Science, National Central University, [2]National MST Radar Facility, Tirupati-517502, India)

We operated the Gadanki radar on the nights (18 to 06 LT) of June 17-20, July 15-18, and August 19-22 during 1998; on the nights of August 5-12 and August 16-19during 1999. On the other hand, daytime (09 to 18 LT) observations were carried out on June 15-18, July 13-

16, and August 17-20 during 1998. The total observation periods are 161 hours for the nighttime and are 68 hours for the daytime observation. By examining the 15-day data set, we present the morphological features of the E region FAI observed by the Gadanki radar. We find:(1) There are two echoing regions: the lower region between 90 and 100 km ranges and the upper region between 105 and 120 km ranges.(2) Echoes observed in both the upper and lower regions are similar to type 2 echoes reported by other radars in the mid-latitudes.(3) Echoes of the lower region may occur in daytime as well as in nighttime. Although there is an observation break between 06 and 09 LT, noontime (11 to 14 LT) seems to be the minimum period of occurrence. QP echoes are commonly detected at the lower region no matter daytime or nighttime and are the so-called "LQP echoes". (4) The spectral characteristics of the lower region echoes differ from daytime and nighttime. The mean Doppler velocities are more variant than those of the daytime and the spectral widths are broader in the nighttime.(5) The upper region echoes appeared only in the nighttime with a maximum period between 23 and 05 LT. Typical QP echoes detected here are similar to those observed at mid-latitudes. (6) Unlike the value close to zero of the mean radial velocities of the lower E region echoes, a downward velocity is noticed at the upper E region. Both the mean Doppler velocities and the spectral widths are found larger than those of the lower regions.We also compare the features of the FAI echoes between Gadanki and Piura radars since the geomagnetic latitude of these two radars are close. Although the morphological distribution and spectral characteristics are very similar for those FAI echoes, daytime echoes and the LQP echoes are rarely reported by Piura. It is suggested that the neutral winds may play a role in this discrepancy since those echoes usually occur at the altitudes below 100 km.

GAII.06/09A/A10-010 Invited **1145**

ION THERMAL EFFECTS ON E-REGION INSTABILITIES

Meers M. OPPENHEIM, Yakov S. DIMANT (Center for Space Physics, Boston University)

The Farley-Buneman (FB) and gradient-drift instabilities frequentlycreate strong radar returns from the E-region ionosphere. The FBinstability theory, as typically applied, assumes that ions remain inisothermal equilibrium with the background neutral atmosphere. Wepresents both simulations and theoretical studies showing thatwave-driven ion heating, particularly at high altitudes within theE-region, can profoundly modify the behavior of FB instability growthand saturation. Using a fully kinetic 2-D simulation of afield-driven FB instability, we shall illustrate the importance of ionthermal effects in both the high-latitude and equatorial electrojets.For instance, when the driving field exceeds the FB instabilitythreshold field by a factor of 4 then an ion thermal instabilitydevelops in place of the FB instability. These waves grow andsaturate with characteristics different from those of FB waves and mayaccount for many observational characteristics of high latitudeirregularities. In another instance, where the driving field exceedsthe instability threshold field by a factor of 2, then FB wavesdevelop but are modified from pure FB waves due to ion thermaleffects. We shall also show how linear fluid theory of the thermallymodified FB instability can explain many features seen in thesimulations. Furthermore, by adding ion thermal effects to the FBtheory, we predict an extended altitude range in which waves will growfor a given driving field.

GAII.06/09A/A10-011 **1205**

INTERFEROMETRIC OBSERVATIONS OF E REGION FIELD-ALIGNED IRREGULARITIES WITH THE PIURA VHF RADAR

Jorge L. CHAU[1], Danny SCIPION[1], Luis A. FLORES[2] ([1]Radio Observatorio de Jicamarca, IGP, [2]Laboratorio de Fíica, Universidad de Piura)

Since 1991, we have measured echoes from *E* region field-aligned irregularities using the Piura VHF radar (~7° dip latitude, just outside the equatorial electrojet (EEJ)). These observations have been made with a monostatic (the same antenna for transmission and reception) system allowing us to get a good understanding of their diurnal and seasonal characteristics. These echoes occur mainly at night and are stronger during southern hemisphere summer months. However, we have not been able to get a good understanding of their spatial and short-term temporal characteristics with the monostatic setup, which could give us ambiguous results when, for example, coherent scatter from these irregularities arises from spatially compact regions of space rather than as volume scatter. In order to resolve this ambiguity, we have recently implemented an interferometry receiving system with multiple baselines. In this work, we will present the latest results obtained during this summer, including results from a north-south baseline (aligned with the magnetic field), and from multiple baselines in the east-west direction (transverse to the magnetic field).

GAII.06/09A/A10-012 **1225**

RECENT PROGRESS OF THE CHUNG-LI RADAR GROUP IN THE STUDY OF ES IRREGULARITIES

Yen-Hsyang CHU (Institute of Space Science, National Central University)

It has been ten years since the capability of the ionospheric observation was implemented at the Chung-Li VHF radar. In this report, we present the recent progress in the investigations of the ionospheric Es irregularities. With the interferometry technique, three-dimensional structures of the type 2 irregularities in the expected echoing region were reconstructed. It shows that the structure the type 2 irregularities may be in a form of horizontal thin layer, or well-organized clump shape, or loose cluster. The plasma structure of the type 1 irregularities is also analyzed and the results show that the zonal extent of the spatial structure of the type 1 irregularities assembled in a form of thin layer with thickness of 1-2.5 km may be as large as greater than 12 km. The beam broadening effect on type 2 radar spectrum due to the drift of the type 2 irregularities is investigated theoretically and experimentally. We find that the Doppler spectral width of the Es field-aligned type 2 irregularities is not only the function of the transverse beam drift velocity, but also related to the zonal extent of the plasma structure. The interferometry measurements support the theoretical predictions.

GAII.06/09A/A10-013 **1245**

QUASI-PERIODIC DRIFT MOTIONS OF METER-SCALE IRREGULARITIES OBSERVED AT THE CHUNG-LI VHF RADAR

Chien-Ming HUANG (Institute of Space Science, National Central Univ.)

The observations of meter-scale, field aligned irregularities made at the Chung-Li VHF radar are presented. Applying radar interferometry, the temporal and spatial variations of backscatter positions show the appearance of quasi-periodic drift motions, with wavelengths of about 10-15 km, and wave frequencies close to the Brunt-Vaisala frequency. This periodicity also reflects the so-called QP echoes shown in the RTI (range-time-intensity) plots. In-beam images of scatters are also analyzed in this paper, results show that the scattering structures are mainly organized along wave fronts. But, in some cases, the quasi-

---

point target scatters are responsible for the striations in the RTI plots.

MID-LATITUDE E-REGION IRREGULARITIES REVEALED BY THE SEEK-2 (SPORADIC-E EXPERIMENT OVER KYUSHU 2) EXPERIMENT

Mamoru YAMAMOTO, Shoichiro FUKAO (Radio Science Center for Space and Atmosphere, Kyoto University)

Ionospheric irregularities in the mid-latitude E-region has been one of the study topics for more than ten years. The epoch was the discovery of the quasi-periodic (QP) structure in the E-region FAI (Field-Aligned Irregularity) echoes observed with the MU radar in Japan. We have been extensively studying the phenomena by using HF/VHF radars, ionosondes, optical instruments, sounding rockets, and computer simulation. The QP structures appear in the E-region FAI as a reflection of modulation pattern in the Sporadic-E (Es) layers. The structures are associated with polarization electric field, which suggests strong coupling process between the ionized and neutral atmosphere. Electrodynamic coupling of different altitudes of E-region ionophsere is also an important issue together with E- and F-region coupling processes. Detailed generating mechanism of the QP echoes is, however, still unresolved. In August 2002, we conducted SEEK-2 (Sporadic-E Experiment over Kyushu 2) campaign in Japan under collaboration with many scientists from Japan, USA and Taiwan. Since the SEEK-2 follows the achievements of the first SEEK campaign in 1996, it was extended in some aspects. The SEEK-2 consists of two sounding rockets of Institute of Space and Aeronautical Sciences that include in-situ experiment of electron density, electron temperature, electric field, plasma fluctuation and waves, and geomagnetic field as before. As a new rocket experiment, we conducted rocket-beacon experiment to measure TEC (Total Electron Content) of the Es-layers, and both up-leg and down-leg releases of TMA (Tri-Methyl Aluminum) to measure the neutral winds and waves. From the ground we measured the same observation region of the rockets with two radars of 24.5MHz and 31.6MHz, ionosonde network of Japan, an MF radar, several airglow imagers, and a GPS scintillation-receiver system. We observed intense QP echoes with radars after 23 LT (= UT + 9 hours) on August 3, 2002, and launched rockets into the E-region at 2324 LT and 2339 LT. The operation of the SEEK-2 was very successful as we could select a good event for the launches. All instruments on the rockets worked fine. From preliminary data analyses we are finding that the rockets detected multi-layered Es-layers at 103, 105 and 129km altitudes, and intense electric fields that approach ± 10 mV/m. The rocket-beacon experiment measured horizontal structures of the E-region TEC. The TMA release showed rippled structures which may prove existence of wave or instability in the neutral atmosphere. We now continue efforts for further data analyses. In the presentation we will show more results from the SEEK-2, and discuss newer view of the mid-latitude E-region FAI.

GAII.06/09P/A10-002 **1420**

SEEK-2: OBSERVATIONS OF NEUTRAL WINDS AND TURBULENCE IN A REGION SPORADIC E AND QP STRUCTURE

Miguel Folkmar LARSEN[1], M. YAMAMOTO[2], R. TSUNODA[3], S. FUKAO[2] ([1]Dept of Physics,Clemson University, [2]Radio Atmospheric Science Center, Kyoto University, [3]SRI International)

A pair of rockets was launched into sporadic E conditions from Kagoshima Space Center in Japan on August 3, 2002, to measure the electric fields, electron densities, neutral winds, and other parameters in a sporadic E layer which had Quasi-Periodic (QP) radar echo structures. The neutral wind measurements were obtained from a trimethyl aluminum (TMA) chemical tracer release which covered the altitudes from approximately 85 to 120 km. The measurements show the presence of large shears and significant turbulence and wave structure along the trail, consistent with several earlier measurements. In the talk, the results from the SEEK-2 wind measurements will be presented, along with a discussion of the relationship between the new results and earlier results from measurements of winds associated with sporadic E.

SEEK2 RADIO BEACON IMAGING OF SPORADIC-E LAYERS

Paul A. BERNHARDT[1], C.A. SELCHER[2], C.S. SIEFRING[1], M. YAMAMOTO[3], S. FUKAO[3] ([1]Plasma Physics Division, Naval Research Laboratory, [2]Information Technology Division, Naval Research Laboratory, [3]Radio Atmospheric Science Center, Kyoto University, Kyoto)

During SEEK2 (Second Sporadic-E Experiment over Kyushu), two-dimensional images of Sporadic-E layers have been produced using computerized ionospheric tomography (CIT). Two rockets were launched from the Kagoshima Space Center (KSC) on August 3, 2002 at 23:24:00 JST (14:24:00 UT) and 23:39:00 JST (14:39:00 UT). Each of the two SEEK 2 rockets carried a two-frequency radio beacon that transmitted to receivers located at four ground sites. Two of the sites, Uchinoura and Taramizu were in the plane of the rocket trajectories. The rockets flew through sporadic-E layers located near 105 km altitude. The apogees of the two rockets were 151.9 and 116.6 km, respectively. The TEC measurements were obtained using differential phase from the 150 and 400 MHz carrier signals from the beacon. Because the rocket trajectory provided continuous tracking of phase absolute TEC was obtained. Data correction was required to eliminate rocket spin effects, which produced a constant differential phase, offset along with spin modulation of the phase. The latter was eliminated using a 1 Hz low pass filter. The initial data interpretation provided electron density profiles when passing through E-Layer and vertical TEC mapped to 105 km altitude along the propagation path. As the radio beacons penetrated the E-layers, sharp increases in total electron content (TEC) was observed. These data were differentiated with change in slant path to yield profiles of apparent electron density as a function of rocket altitude. With these profiles as basis functions, tomography was used to reproduce the structure of the sporadic-E layers as a function of both altitude and horizontal range along the trajectory. Two other receivers located at Tanagashima and Tasaki were located 50 km on either side of the rocket trajectory. The data from these sites will be used to determine the three-dimensional structure of the sporadic-E layers. This experiment demonstrated the utility of a rocket-borne radio beacon sensor to detect irregularities along the propagation path between the radio beacon and a network of ground receivers.

RADAR OBSERVATIONS OF FIELD-ALIGNED PLASMA IRREGULARITIES IN THE SPORADIC E EXPERIMENT OVER KYUSHU 2 (SEEK-2)

Susumu SAITO[1], Masato MARUMOTO[1], Mamoru YAMAMOTO[1], Shoichiro FUKAO[1], Roland T. TSUNODA[2] ([1]Radio Science Center for Space and Atmosphere, Kyoto University, Japan, [2]SRI International, USA)

To understand the physical processes of Quasi-Periodic (QP) echos found in the mid-latitude E region, the Sporadic E Experiment over Kyushu 2 (SEEK-2) campaign was conducted in this summer as the successive campaign of the SEEK in 1996. Two ionospheric radars were installed in Tanegashima to measure properties of field-aliinged irregularities (FAIs) as well as to determine the launch timing of two rockets into the ionosphere. Lower Thermosphere Profiler Radar (LTPR, 31.57 MHz) and Frequency Agile Radar (FAR, 24.515 MHz) were installed in Minamitane town (30.37N, 130.97E) and Nishino-omote city (30.75N, 131.03E), respectively. Strong QP echoes were observed with both the radars when the two sounding rockets were launched into the ionosphere with 15 minutes interval. From the twin radar measurements, it was infered that echoing regions were propagating in the South-West direction at about 30 m/s with spatial separations of 12 - 23 km. These results were compared with onboard measurements of of electric fields and electron densities as well as with neutral wind velocity derived from meteor echoes measured by LTPR. Interferometric measurements of fine scale structures of QP echoes by LTPR will also be presented.

GAII.06/09P/A10-005   1515

ELECTRON DENSITY IRREGULARITIES IN THE NIGHT-TIME SPORADIC-E LAYERS OBSERVED BY A SOUNDING ROCKET S-310-31 DURING THE SEEK-2 CAMPAIGN PERIOD

Hirotaka MORI[1], Koh-ichiro OYAMA[2] ([1]Communications Research Laboratory, [2]The Institute of Space and Astronautical Science)

SEEK-2 (Sporadic-E Experiment over Kyushu) was the second coordinated rocket and radar campaign conducted in August, 2002 to observe spatial structures and properties of the nighttime sporadic-E layer in the midlatitude E region over Kyushu, Japan and study the generation mechanism of the QP (Quasi-Periodic) structure of the sporadic-E layers which were previously found by the QP radar backscatter echoes. Two sounding rockets S-310-31, -32 were launched successively in 15 minutes at the same night on August 03, 2002 when the strong QP echoes were detected by a coordinated radar measurement. A fixed-bias Langmuir probe was installed on the first rocket S-310-31 launched at 23:24 JST to measure the plasma-density structure related to a sporadic-E layer. The fixed-bias probe can measure the electron current proportional to the electron density continuously by applying a fixed-bias of 5 V to a gold-plated spherical probe with a 5-cm diameter installed on top of the rocket. It has two measurement modes with different frequency bands to measure the km-scale density structure and the small-scale density irregularities generated in the structure, respectively. The rocket reached an apogee of 152km and the probe worked normally during the entire flight. The preliminary analysis of the data reveals the following results. A strong double-peak Es layer was observed at a height of 102-104 km during the upleg, and a single-peak Es layer was observed at 103 km during the downleg. Week Es layers were also found at higher altitudes separated by about 10 km during the both legs. Meter-scale irregularities were generated in the density gradient regions of these Es layers. These results will be compared with other onboard and ground measurements.

GAII.06/09P/A10-006   1530

OBSERVATION OF ELECTRON NUMBER DENSITY PROFILES AND VLF PLASMA WAVES BY USING S310 SOUNDING ROCKETS DURING THE SEEK-2 CAMPAIGN

Makoto WAKABAYASHI, Takayuki ONO (Graduate School of Science, Tohoku University)

The SEEK-2 campaign has been carried out in early August 2002 in order to study on the generation mechanism of quasi-periodic radar backscatter echoes due to field-aligned irregularities accompanied with sporadic-E layers of the mid-latitude region, including rocket experiments and ground observations. Two sounding rockets (S310-31,32) were prepared for this purpose and launched toward east from Kagoshima Space Center, at 23:24 JST(S310-31) and 23:39 JST(S310-32) on August 3, 2002. In this campaign, altitude profiles of electron number density were measured by using the Impedance Probe installed on both the rockets. The maximum electron densities of about 9x10^4/cc (for S310-31), and 2x10^5/cc (for S310-32) were measured within an altitude range of 100-105km associated by several sub peaks. On the other hand, TMA experiment on board S310-32 was carried out to observe the neutral wind velocity profile of the ionosphere. The Plasma Wave Monitor, also installed on S310-32, has detected plasma wave signatures associated with the TMA release in the sporadic-E layer. Electron density profiles showed that sporadic-E layer consists of one or two main peaks(~x10^5/cc) at 104-106km altitude and several small peaks existing above and below the main peaks. We compared their number density profiles with the results of Low Thermosphere Profiler Radar located on Minamitane and FAR on Nishinoomote. In comparison with LTPR data, peaks in the number density profiles well correspond with altitude profiles of intense echoes in the radar data. We purpose a model of 2 dimensional distribution model of sporadic-E structure. In this model, sporadic-E layer patches distribute horizontally being associated with multi-layer structure of relatively weak densities. From each weak ionization region the field-aligned irregularities are possibly generated along the magnetic field lines. On the other hand, Plasma Wave Monitor data shows generation of plasma waves associated not only with the TMA release but also with the effect of the passage through the sporadic-E layer. The present results are able to contribute to understand the mechanism of quasi-periodic echoes, and generation mechanism of TMA lightning which was found in the present rocket experiment.

GAII.06/09P/A10-007   1545

STUDY OF GENERATION OF POLARIZATION ELECTRIC FIELDS ASSOCIATED WITH A SPORADIC-E LAYER

Tatsuhiro YOKOYAMA[1], Mamoru YAMAMOTO[1], Shoichiro FUKAO[1], Robert F. PFAFF[2] ([1]Radio Science Center for Space and Atmosphere, Kyoto University, [2]NASA/Goddard Space Flight Center)

The quasi-periodic (QP) radar echoes of the ionospheric irregularitiesin the midlatitude E-region was first observed with the MU radarand studied for more than ten years.It has been revealed that the QP echoes tend to appear in the post-sunsetperiod during the summertime with periods of 2--15 minutes andgeneration of the QP echoes are correlated with sporadic-E (Es) layers.Further, from the two rocket experiment, ̋SEEK ̋ and ̋SEEK-2̋conducted in 1996 and 2002, respectively,the intence electric field of morethan 10 mV/m associated with the QP echoes was detected.Recently, the new model to explain such a largeelectric field by the internal structure of a Es layer was proposed. In the SEEK-2 campaign, we conducted the measurements ofan electric field, an electron density, a neutral wind,a horizontal distribution of Es layers, etc., at almost the same time.With a computer simulation model, we can

examine the generation ofpolarization electric fields by taking other measured parametersinto consideration.We will present the detailed results of the electric field measurementsand other related observations in the SEEK-2, and the simulation studyof generation of polarization electric fields.

GAII.06/09P/A10-008   1620

SOME ASPECTS OF SUMMERTIME LOW-ALTITUDE QUASI-PERIODIC ECHOES OBSERVED WITH THE MU RADAR

Tadahiko OGAWA[1], Yuichi OTSUKA[1], Kazuo SHIOKAWA[1], Fumiki ONOMA[1], Mamoru YAMAMOTO[2] ([1]Solar-Terrestrial Environment Laboratory, Nagoya University, [2]Radio Science Center for Space and Atmosphere, Kyoto University)

Quasi-periodic (QP) radar echoes from midlatitude sporadic E layers (Es) in the summer night were first discovered in 1989 by using the 46.5-MHz middle and upper atmosphere (MU) radar at Shigaraki, Japan. They appear at altitudes of 100-130 km, have periods of 5-20 min perhaps due to short-period atmospheric gravity waves, and are believed to be caused by field-aligned electron density irregularities generated through plasma instabilities and/or neutral turbulence. In this paper we analyze data obtained in the summer of 2002 with MU to demonstrate some new aspects of QP echoes. First, we discuss low-altitude (90-100 km) QP echoes, here referred to as the LQP echoes, that have weak echo power and low Doppler velocity. These echoes are often connected with high-altitude (100-130 km) QP echoes (referred to as the HQP echoes), that have stronger power and higher velocity, with a gap of about 5 km in altitude. This fact suggests that (1) there exist two sporadic E layers; one at higher altitudes and the other at lower altitudes in the E region to cause the HQP and LQP echoes, respectively, and (2) both echo regions are electrically coupled through the geomagnetic field. Then, a case is studied in which HQP and LQP echoes are combined without the altitude gap to produce QP striations extending from 90 to 110 km. In association with this event, the Shigaraki 557.7-nm all-sky CCD imager, which is sensitive to the airglow at around 95 km altitude, detected very turbulent airglow patterns. Interestingly, when airglow intensity increases (decreases) gradually with time, the QP echo altitudes also increase (decrease) gradually, and temporal fluctuations of the airglow intensity are well correlated to those of the QP echo structures. The MU radar detected very high Doppler velocities exceeding 100 m/s even at around 90 km for a short period, which might be due to localized, unusual high neutral winds. In this event the Shigaraki 557.7 nm Fabry-Perot interferometer observed neutral winds over Shigaraki. The hourly winds are roughly consistent with irregularity motions below 100 km that were determined from the radar observations. Thus, the event gives a good opportunity to disclose the relationship between the irregularity generation and neutral gas dynamics.

THE SPORADIC E LAYER INSTABILITY IN THE NIGHTTIME MIDLATITUDE IONOSPHERE

Russell B. COSGROVE, Roland T. TSUNODA (SRI International Center for Geospace Studies)

Recently, it has been shown that theconfiguration of a midlatitude sporadic- E (E_s) layer ata zonal wind-shear node is unstable at night. The instability isthe result of a wind-shear driven polarization process that occurswhen a plane-wave perturbation in altitude is imposed on theE_s layer. The growth rate of the instability depends on theazimuthal alignment of the plane wave distortion, a feature thatis reminiscent of the Perkins instability. The plane wave natureof the growing modes, combined with the azimuthal dependence ofthe growth rate, suggests that the instability may provide anexplanation for frontal structures observed in E_s layers,which are found to consistently adopt the same azimuthal alignmentpreferred by the instability. Simulations of the nonlinear evolution find that the instability generates significant polarization electric fields that structurethe layer; yet, the structuring saturates without destroying thelayer completely. Decreasing the wind shear decreases thepolarization electric field, and increases the evolution timescale, but otherwise does not profoundly affect the structuresthat form in the layer. Increasing the F layerconductivity, which is assumed to map perfectly to the $E_s$layer, damps the instability. These results suggest the instabilityas a possible source of the so-called quasi-periodic (QP) echoes,which are coherent radar echoes found in the nighttime midlatitudeionosphere.

KILOMETRIC PLASMA WAVES IN MIDLATITUDE SPORADIC E LAYERS

David L. HYSELL (Earth and Atmospheric Science, Cornell University)

While the primary waves associated with sporadic E layers aregenerally assumed to be produced by gradient drift instabilities,nonlocal effects would seem to preclude the growth of midlatitudegradient drift waves with kilometric scale sizes. However, at middlelatitudes, the dip in the Earth´s magnetic field and the associatedzero order field aligned conductivity gradients make the regionunstable to a kind of resistive drift instability. This instabilityproduces waves with finite parallel wavenumbers and with wavelengthsbetween a few hundred meters and a kilometer, depending on thethickness of the underlying sporadic E layer. A three-dimensionalnumerical simulation with realistic background parameters shows thatthe instability occurs in sporadic E layers which are coupled to the Fregion which dominates the conductivity on the affected field lines. Asimple linear local analysis recovers most of the importantcharacteristics of the instability. The principle nonlocal effect innature is saturation and stabilization brought about by verticalshear. Evidence that kilometric waves are found in nature will besummarized.

GAII.06/09P/A10-011   1710

THE VARIATIONS OF ES LAYER IN THE WESTERN PACIFIC REGION DURING THE SEEK-2 CAMPAIGN

Chien-Chih LEE[1], J.Y. LIU[1], C.J. PAN[1], C.H. LIU[1], W.H. TSAI[1], T. MARUYAMA[2], L. LIU[3] ([1]Institute of Space Science, National Central University, [2]Hiraiso Solar Terrestrial Research Center, Communication Research Laboratory, Ibaraki, Japan, [3]Wuhan Ionospheric Observatory, Wuhan Institute of Physics and Mathematics, The Chinese Academy of Sciences, Wuhan 430071,China)

The SEEK-2 (Sporadic E Experiment over Kyushu) campaign was carried out in July-August 2002. In this campaign, we conducted the ionospheric observation with a 5-minute time resolution at five ionosonde stations to monitor the Es layer over the western Pacific region. These five stations consist of a digisonde potable sounder (DPS) at Wuhan (30.6ºN, 114.4ºE) and four ionosondes at Chung-Li (24.9ºN, 121.1ºE), Okinawa (26.7ºN, 127.8ºE), Yamagawa(31.2ºN, 130.6ºE), and Kokobunji (35.7ºN, 139.5ºE). We deduced the maximum frequency (foEs) and the lowest virtual height (h'Es) of the Es layer and cross-compared the two parameters between these stations. Results show that the Es layer drifts in zonal (east-west) direction. Time variations of the two parameters suggest that the traveling ionospheric disturbances (TIDs) and tides to be important.

GAII.06/09P/A10-012   1725

AN EXPECTED RESPONSE OF IONOSPHERIC IRREGULARITIES GENERATED BY NEUTRAL TURBULENCE TO CHANGES IN THE TURBULENT ENERGY DISSIPATION RATE

Yurij KYZYUROV (Department of Space Plasma Physics, Main Astronomical Observatory NASU)

Results of in-situ rocket and ground-based radar experiments have clearly shown that plasma irregularities in the lower ionosphere can be induced by neutral air turbulence. One of important parameters in turbulence is the energy dissipation rate that defines the rate at which energy is generated at the larger scales, cascaded through the inertial subrange, and finally is dissipated in the viscous subrange of the turbulent spectrum. In this report an expected response of the ionospheric irregularities to changes in the turbulent energy dissipation (TED) rate is discussed. The consideration is based on an expression for the power spectral density of the irregularities that was obtained by using a macroscopic description of the ionospheric plasma. It is shown that under fixed values of ionospheric parameters corresponding to 95 km altitude, an increase in the TED rate from 0.02 to 0.2 W/kg results in changes in the rms level of relative plasma-density fluctuations from 1.5 to 2.2 % (for irregularity length-scales 10 - 1000 m) in the case of ionospheric E-region without sporadic-E layer, and from 4 to 7 % in the case of sporadic-E of 2 km thickness. It is found that changes in the shape of the irregularity spectrum may be expected too. The changes are connected with decreasing the inner scale of turbulence (Kolmogorov scale) from 7 to 3.9 m under the mentioned increase in the TED rate. Results of this report can be tested in coordinated experimental campaigns that include measurements of the irregularity spectrum and parameters of the turbulent neutral wind.

RAYLEIGH AND TSUNAMI IONOSPHERIC COMPANION WAVES

Philippe LOGNONNE[1], Philippe LOGNONNE[1], Juliette ARTRU[2], Vesna DUCIC[1], Hiroo KANAMORI[2], Makoto MURAKAMI[3] ([1]Departement de Geophysique Spatiale et Planetaire, IPGP, France, [2]Seismological Laboratory, Caltech, Pasadena, USA, [3]Geographical Survey Institute, Ibaraki, Japan)

Rayleigh surface waves and tsunamis are producing vertical oscillations of the earth surface, which propagate upward and reach the ionosphere. We report here the observation of such ionospheric waves associated to Rayleigh Surface wave and quake generated tsunamis. These waves were detected by using the dense GPS networks of Japan and California, enabling an imaging of the ionospheric TEC variations every 30 sec. In both case, images of the wave are obtained and the propagation of the wavefront is observed. We present first results in the modelling of these waves using Normal Modes summation. The Normal modes are computed by a theory which take into account the coupling between the solid earth, the ocean and the ionosphere, as well as the energy loss at high altitude due to viscous and non-linear effects. This theory allows to compute either the Earth surface velocity or the ionospheric vertical velocities, and can be used for the computation of the transfert function between the ground and the ionosphere

MILLSTONE HILL OBSERVATIONS OF COHERENT RADAR BACKSCATTER FROM THE SUB-AURORAL POLARIZATION STREAM

John C. FOSTER, Phillip J. ERICKSON, Frank D. LIND (Haystack Observatory, Massachusetts Institute of Technology)

Observations of coherent backscatter made with the Millstone Hill 440 MHz radar during strongly disturbed conditions have been used to investigate the fine-scale spatial and temporal structure of the electric field in the auroral and sub-auroral E region. Previous observations at Millstone Hill [Foster and Erickson, GRL, 2000] have demonstrated that the backscattered logarithmic power and the irregularity phase velocity are proportional to the electric field which drives the two-stream waves. A ~20 mV/m electric field threshold for the onset of the coherent echoes was observed with ~380 m/s coherent phase speed. Coherent phase speed increased linearly with increasing electric field strength at the rate 8.5 m/s per mV over the electric field range 20 mV/m - 60 mV/m. Coherent backscatter amplitude (observed outside the saturation region) increased linearly with the electric field at the rate 25 dB per 30 mV/m. Fixed-beam experiments with high spatial resolution and data recording rate have been used to characterize the sharp spatial and rapid temporal variations of the electric field strength in the region of the sub-auroral polarization stream (SAPS [Foster and Burke, EOS, 2002]). Electric field gradients exceeding 4 mV/m per km are observed at the equatorward edge of the SAPS region and 50 mV/m changes in the longitudinally-aligned regions of intense electric fields are seen in temporally-brief intensifications of SAID electric fields. Rapid (60s) azimuth scans using a variety of radar pulse patterns, combined with pulse to pulse data sampling and the sidelobe sensitivity of the Millstone Hill steerable radar to the strong coherent-scatter cross section, permit the fine structure of the coherent power, the irregularity phase velocity, and the background (F-region) electric field to be measured across a 500 km by 500 km spatial area with 10-km spatial and 10-s temporal resolution. Observations made during an intense geomagnetic storm (April 5-6, 2000, and during the development phase of a moderate-disturbance on May 24, 2000) examine the dynamic variability of the electric field structure associated with the region of stormtime particle precipitation as well as the periodic modulation of the SAPS electric field as it expands equatorward in the dusk sector E region.

GAII.06/10A/A01-002   0850

ON THE THERMOELECTRIC ORIGIN OF ELECTRIC FIELD IN THE POLARIZATION JET

Victor L. KHALIPOV[1], A.E. STEPANOV[2] ([1]Space Research Institute of Russian Academy of Sciences, [2]Institute of Cosmophysical Research and Aeronomy, Yakutsk, Russia)

Long-lasting ground based measurements of a polarization jet (PJ) by the latitudinal chain of ionospheric stations in Yakutia ($3 < L < 5$; MLT = UT + 9 h)and by 5 subauroral Russian stations and energetic ion observations by AMPTE/CCEin 1984 - 89 were analyzed. 25 cases were found when PJ was recorded simultaneously with the AMPTE/CCE observations. The data comparison shows that at least in the considered cases of strong magnetic substorms, PJ was accompanied by strong injection of ions with the energy of ~ 20 - 50 keV and intensity of ~ 106 cm^(-2)*sec^(-1)*ster^(-1)*keV^(-1). Close to the injection region in the near midnight sector no ion dispersion was observed, but in the evening sector nose events were detected. Measurements by ionosondes at different longitudes show that

the westward velocity of the front of PJ development is close to the gradient drift velocity of 20 keV ions forming nose events. Thus, the physical mechanism of PJ formation due to energetic ion injection during a strong substorm burst is experimentallyconfirmed. PJ was observed equatorward from the region of energetic ion penetration into the inner magnetosphere but not in the gap between the injected ions and plasmasheet. PJ develops almost along constant invariant latitude covering a sector from 60 to 130 degrees in longitude. This suggests that electric field responsible for the PJ formation is of thermoelectric origin. For the recorded ion energies the PJ electric field can be as high as 50 - 100 mV/m. The position of equatorial ion injection boundary in more than 180 orbits of the AMPTE/CCE satellite for different levels of geomagnetic activity is analyzed. The form of the boundary does not depend on local time and is also located along invariant latitude in sector 18.00 -02.00 MLT.

GAII.06/10A/A01-003   0905

IONOSPHERIC PLASMA STRUCTURING IN THE CUSP AND THE POLAR CAP REGION DURING ENHANCED PLASMA CONVECTION

Santimay BASU[1], Sunanda BASU[2], C.E. VALLADARES[3], R.E. SHEEHAN[3] ([1]Air Force Research Laboratory (VSBXI), [2]National Science Foundation, [3]Boston College)

The evolution of large (hundreds of km) and small scale irregularities (tens of m) of electron density in polar cap patches during their transit from the cusp to the central polar cap has been investigated from satellite scintillation, and GPS total electron content (TEC) and phase fluctuation measurements. The cusp and the central polar cap observations of irregularity structures have been made at Ny Alesund, Svalbard and Thule, Greenland, respectively, by monitoring scintillation of 250 MHz signals from satellites in highly elliptic orbits and from measurements of TEC and large scale phase fluctuations from GPS observations. The source function of patches are investigated in terms of drainage plumes through the erosion of plasmasphere during ring current events as well as in the context of injection and transport of plasma in the cusp region similar to flux transfer events. The irregularity evolution in the cusp and the central polar cap has been examined in the context of the state of the magnetosphere-ionosphere coupling as defined by the interplanetary magnetic field orientations and the SuperDARN radar observations of plasma convection. The broad spectral characteristics of scintillation recorded in the cusp region indicate the presence of electric field turbulence in this region whereas in the central polar cap the scintillation spectra remains confined over a narrow band but are shifted to higher frequencies consistent with high anti-sunward convection. It is shown that under conditions of enhanced convection when the patch becomes unstable to the gradient-drift instability it is able to retain the integrity of meso- and medium- scale irregularities as the patch convects for long periods of time over long distances of several thousand kilometers. It is shown that recent three-dimensional nonlinear simulations of the gradient drift instability with variable ExB drift and ion inertial effects reproduce the observed results on patch integrity and variable levels of leading/trailing edge asymmetry in structuring and irregularity amplitudes.

A YEAR IN REVIEW: HIGH LATITUDE IONOSPHERIC IRREGULARITY OBSERVATIONSWITH PASSIVE VHF RADAR

Melissa G. MEYER, John D. SAHR, Dawn M. GIDNER, Chucai ZHOU (University of Washington Electrical Engineering)

We operate a passive radar in the FM radio band (100 MHz frequency range) with thepurpose of studying turbulence in the high latitude ionosphere. Currently the onlyradar of its kind in the world, our system has been online almostcontinuously since November 2001. During the year 2002, we recordedE-region irregularities on 25 separate days. Here we will presentthose observations, summarizing characteristics of the data,identifying trends, and noting conditions under which theirregularities were detected. Our radar field of view covers approximately the geomagnetic latitudesfrom 56∘ up to 63∘, a region over southwestern Canada. Though oursystem is too far south to regularly study the auroral oval, it issensitive enough to detect E-region turbulence during disturbedconditions. We have detected events at ranges up to 1200 km, and asclose as 400 km; the reported Kp index during our observations has beenas low as 4.0 and as high as 7.0. We will present range-Doppler diagrams of some typical (and atypical)irregularities that we detect; we will also present summarized resultsfrom the analysis of these observations, including the Dopplercharacteristics of the echoes, the local time at which they occurred,the range at which they occurred, and their range extent, as well asinterferometric information such as transverse size and structure. Weare able to form simple images with our interferometer, and plan toshow ``movies´´ of sequential images, from which an approximatetransverse drift speed can be inferred. We will also compare our observations with those of other coherentscatter radars in the area, and provide supplementary information fromtimes of our observed irregularities from other instruments, suchas UVI images, magnetometer readings, and measurements of the solarwind, when available. We intend to demonstrate that our unique instrument providesdata of high quality which is comparable to that of other radars ofsimilar purpose and design, and which may be used as a link inunderstanding existing datasets.

WESTWARD TRAVELING SURGES IN CRNA AND OPTICAL AURORA

Pieter H. STOKER, Albertus WILSON (Unit for Space Physics, Potchefstroom University for CHE, Potchefstroom, SOUTH AFRICA)

Latitudinal and diurnal variations in auroral data show (Hartz and Brice, Planet. Space Sci. 15, 301-329, 1967) that there are two basic categories of energetic auroral electrons, the softer electrons ($<$10 keV) cause optical emissions in the E- and F-regions of the ionosphere and the harder ($>$10 keV) electrons ionize down into the D-region for cosmic radio noise absorption (CRNA). These two categories of auroral electrons were observed during the expansion phase of a magnetic substorm on the evening of May 1, 1997, from recordings of all-sky optical aurora and 64 beam imaging riometer at the Antarctic base SANAE IV (L=4.1). While the spatial absorption structure changed only slowly during the period of observation, the low level white light luminosities showed both fast localized and fast spatial fluctuations on the one second time scale. The CRNA and auroral optical emissions could therefore not have been caused by the same electron precipitating flux. This implies that there are two quite different processes, one that is related to a softer electron flux, causing a high variability in auroral optical emissions, and another process that generates a more persistent flux of harder electrons. A CRNA westward traveling surge (WTS) was observed coincident with a surge in the all-sky optical data, together with a surge in the optical data leading the CRNA WTS by ~30-50 seconds. The CRNA WTS was ribbon-like, traveling westward at a speed of 2.3 km s-1. Both the optical surge leading the CRNA WTS and the CRNA surge should have started along the velocity shear zone of the Harang discontinuity closest to the neutral line in the magnetospheric tail region. But the softer electrons, causing E- and F- region optical emissions, may have been injected onto drift paths closer to Earth than the more energetic electrons, ionizing down into the D-region for

CRNA. These harder electrons could have been accelerated for later precipitation by an increasing dawn-to-dusk electric field arising from a reconfiguration of the tail magnetic field during the expansion phase of the substorm.

GAII.06/10A/A01-006   0955

INVESTIGATIONS OF PMSE: A SURVEY OF RECENT EMPIRICAL RESULTS

Phillip B. CHILSON[1], Jürgen RÖTTGER[2] ([1]NOAA ETL and University of Colorado CIRES, [2]Max-Planck-Institut für Aeronomie)

The term Polar Mesospere Summer Echoes (PMSE) is used to describe dramaticenhancements in the radar backscattering cross-section observed during the summer months at high latitudes near the mesopause. Since the discovery of PMSE over twenty years ago, numerous experimental efforts have been undertaken in an attempt to better understand the mechanism or mechanisms responsible for their occurence. For example, numerous hours of radar observations have been completed over a wide range of operating frequenices. To investigate small-scale structures associated with PMSE, some of the radar experiments were conducted in interferometric or imaging modes. Additionally, several radar observations made in conjuction with measurements from other instruments such as lidars, rocket launches, riometers, ionospheric heaters, and satellites. In this talk we review some of the more recent experiments and discuss how they relate to prevailing theoretical models of PMSE.

MASS ESTIMATION OF FAINT METEORS FROM RADAR HEAD ECHOES COMBINED WITH OPTICAL OBSERVATIONS

Toru SATO[1], Takuji NAKAMURA[2], Shuichi TSUTSUMI[1], Masumi NISHIO[3] ([1]Department of Communications and Computer Engineering, Kyoto University, [2]Radio Science Center for Space & Atmosphere, Kyoto University, [3]Graduate School of Human and Natural Environment Sciences, The University of Tokushima)

Impacts of meteors with spacecraft are widely recognized as one ofmajor sources of possible hazard in the space environment.Although the average mass of meteor bodies is much less than artificialspace debris, relative velocity of high-speed meteors against the earthare as high as 70km/s, which far exceeds that of artificial objects.It is thus very important to establish statistics of meteors, especiallythose of the mass and velocity, along the earth´s orbit around the sunin order to make reliable data base for designing large scale spacecraftsuch as space stations. We have developed a high-sensitivity combined radar-optical systemconsisting of the MU radar, which is a high-power VHF Doppler radar, andan ICCD video camera for the purpose of studying velocity and massdistributions of faint meteors. By combining the optical magnitude andthe velocity and orbit data obtained by the radar, we can estimate themass of individual meteor body based on some empirical equations. On the other hand, as our precise radar measurements also provide thedeceleration due to atmospheric drag, it is possible to estimate themass based on the radar data alone. Although similar attempts have alreadybeen made with the data obtained with Arecibo incoherent scatter radar(Mathews et al, 2001), application of the same method resulted in a fewto several orders smaller estimates than the radar-optical estimates. We consider this difference as mainly due to the fact that the previousstudy took into account only the direct impact of atmospheric moleculesto the meteor body. Here we propose an alternate procedure of estimatingthe mass from radar data by taking the effect of deceleration due thehigh-density gas emitted from the meteor body also into account. Wederived an empirical relationship between the density of such gas andphysical parameters obtained by the radar observations so that theestimated mass agrees with the radar-optical estimates. Our procedureprovides the mass estimates based on the radar data which agree withthe radar-optical data within an order of magnitude. Since the radar has much higher sensitivity of about 15 magnitudethan the optical sensor, and is suitable for continuous observationswith automatic data analyses, it will enable us to make statistical studyof the mass distribution of faint meteors.

METEOR ECHO STUDIES USING THE NOAA HF RADAR

Lung-Chih TSAI[1], Frank Tom BERKEY[3], T.-T. HSIAO[2] ([1]Center for Space and Remote Sensing Research, National Central University, [2]Institute of Space Science, Natioanl Central Univ., [3]Space Dynamics Lab., Utah State Univ.)

 Numerous meteor-induced Es events have been observed using the Bear-Lake dynasonde (NOAA HF radar) sited at 41.9°N and 111.4°W. As a tool for meteor diagnostics, the dynasonde utilizes interferometric receiving techniques to provide high-resolution echo-location, line-of-sight Doppler velocity, and digital ionograms as routine fundamental data products (288 soundings/day). The observed duration of the meteor induced echoes at HF is several seconds, as compared to more conventional VHF meteor observations where the ionization decay time is on the order of a second. The meteor-induced Es events are most evident between the hours of local noon and late afternoon, are characterized by radio bandwidths up to several MHz and preferentially peak at ~100 km height. Determination of atmospheric motions can also be provided by measurement of coherent scattering from meteor trails. In this work, a three-dimensional velocity vector has been derived by fitting a set of a spatially distributed, wide-band echoes to the line-of-sight Doppler velocity measurements by means of the singular value decomposition technique.

PLASMA SIMULATIONS, RADAR OBSERVATIONS AND THEORY OF A NEW TYPE OFMETEOR ECHO: THE NON-SPECULAR TRAIL

Lars P. DYRUD, Meers M. OPPENHEIM, Sigrid CLOSE, Stephen HUNT, Kelly MCMILLON, Licia RAY (Center for Space Physics, Boston University)

The Earth is continuously bombarded by extraterrestrial material inmeteoric form. Since most of this mass flux is comprised of verysmall meteors (< 0.1 g), they are either undetected or measured onlyby radars. We present research that allows new ways to interpret radarobservations of a previously poorly understood type of meteor radarecho, the non-specular trail. This new understanding allowsresearchers use these non-specular meteor echos to understand both themeteor flux and its effect on the mesopause/E-region. Plasma simulations demonstrate that meteor trails are unstable togrowth of gradient-drift Farley-Buneman (GDFB) waves that becometurbulent and generate large B-field aligned irregularities (FAI).These simulations and our analysis indicate that the non-specularechos, that can extend between 5-10 km in altitude range, arereflections from plasma instability generated FAI. Simulation andmodel results can explain a number of characteristics of thesenon-specular echos. 1) The observed altitudinal extent of thetrail echos. 2) Trail diffusion in the plane perpendicular to B thatcan be up to an order of magnitude larger than expected from ambipolardiffusion. 3) A curious, approximately 20 ms delay between head

echoobservation and trail reflection. Additionally, we present modelsshowing that the specific altitude range of trail instability dependson meteor and atmospheric properties. This variability will allowresearchers to infer neutral temperature, neutral-ion collisionfrequencies, and meteoric velocity and composition in completely newways. Finally, we demonstrate some of these non-specular traildiagnostic techniques using radar observations from the ALTAIR andPiura radar facilities.

IONOSONDE OBSERVATIONS OF THE LEONID METEOR SHOWER IN NOVEMBER 2001

Takashi MARUYAMA, Hisao KATO, Maho NAKAMURA (Communications Research Laboratory)

We applied ionosondes at four stations in Japan in their rapid-operation mode to make observations every minute for 102 hours during the period of the Leonid meteor shower in November 2001. Plenty of radio echoes that look like echo traces produced by sporadic-E reflection are seen in the ionograms, and this allowed statistical analysis in a single meteor shower event including discrimination of the backscattering by meteor trails from reflection by a horizontally stratified sporadic-E layer. The radio echoes seen in the ionograms were categorized into three types. The first are spontaneous echoes which were distributed across a wide range of virtual heights; at times during the period of maximum meteor activity, there was a statistically good correlation among the echoes seen at the four stations; the echoes of this type appear to be produced by Fresnel backscattering from meteor trails. The second are also spontaneous echoes seen during the shower period but persist for several ten minutes at the same virtual height as the typical sporadic-E layer and the top frequency of these echoes decayed with time; echoes of this type are thus attributed to the reflection from a meteor-induced sporadic-E patch. Echoes of the last type appear outside the period of maximum activity of the meteor shower in the same range of virtual heights as the conventional sporadic-E layer, and there was no time correlation between such events as observed at the four stations; these events are attributed to a periodical increase in foEs which is modulated by planetary-wave activity and have no relation with the meteor shower.

LOCALIZED IONOSPHERIC PC 3-4 WAVES OBSERVED BY THE ICELAND EAST HF RADAR

Yuichi SHINKAI[1], Natsuo SATO[2], Yukimatu Sessai AKIRA[2], Toshihumi MUKAI[3], Tohru SAKURAI´, Yutaka TONEGAWA[4], Mark LESTER[5], Stephen Eric MILAN[5], Jean-Paul VILLAIN[6], George SOFKO[7], Brian James FRASER[8] ([1]Department of Polar science, Grad. Univ. Advanced Studies, [2]NIPR, [3]ISAS, [4]Tokai Univ., [5]Leicester Univ., [6]LPCE/CNRS, [7]Saskatchewan Univ., [8]Newcastle Univ.)

On 12 February 2002 the SuperDARN Iceland East radar observed very clear20mHz ULF waves during the campaign of the SuperDARN/GEOTAIL simultaneous observation that conducted to observe the Pc 3-4 range ULF wave. In this campaign, the HF radar has ran with CUTLASS ″Stereo mode″ which runs two different scan modes simultaneously, one is a high time resolution mode (3 sec)at fixed one beam and the other is a global scan mode (16 beams). The Doppler velocity data obtained by the HF radar showed very high coherency among 8 rangegates, where each range gate is about 45 km. The phase shift of this wave among 8 range gates was about 50 degree, indicating that the wavelength of this ULF wave is at least longer than 2000 km. The ground based magnetometers (IMAGE, Iceland, Finland, SAMNET in northern hemisphere, and the Davis in Antarctica) showed that the same ULF wave signatures as the HF radar with time period about 50 seconds is observed only by the magnetometer in Iceland. On the other hand, we could not fined such wave signature from other magnetometers. This result suggests that the wave is very localized phenomena.

GAII.06/10A/A01-012   1200

OBSERVATION OF SHOCK INDUCED PI-1 PULASATIONS IN TOPSIDE IONOSPHERIC PLASMA AT 600 KM ALTITUDE ON APRIL 17, 2002 STORM DAY

Su SHIN-YI[1], Chi-Kwan CHAO[2], Huey-Chin YEH[2] ([1]National Central University, Taiwan, R.O.C.; On sabbatical leave as NRC Senior Research Associate at NASA/JSC, Houston, Texas, U.S.A., [2]Institute of Space Science, National Central University, Taiwan, R.O.C.)

ROCSAT-1 orbiting at 600 km altitude observed a rare Pi-1 pulsation event in the topside ionospheric plasma during the April 17, 2002 storm period. The pulsations in the two perpendicular-to-field-line flow components begin shortly after the interplanetary shock impact on the magnetosphere. The initial response of the topside ionospheric plasma indicates that the ionosphere was compressed inward and toward the dusk side as ROCSAT-1 was located in the post-noon sector. The subsequent oscillations with a period of 19 seconds in the radial and the zonal flow components last for less than two minutes. A rotation in the oscillation polarization is noted to change from the dominant radial component to the zonal component. This rotation in the polarization axis should be caused by the non-linear coupling effect between the two components in a layered structure of the non-uniform ionospheric plasma distribution in the radial direction. The density oscillation, though responds to the shock impact with a small delay in comparison with the flow oscillations, indicates an out-of-phase oscillation with the zonal flow component. The observation will be explained with a simple MHD model.

GAII.06/10A/A01-013   1215

WAVE STRUCTURES OBSERVED IN THE IONOSPHERIC F-REGION DURING LOW AND HIGH GEOMAGNETIC ACTIVITY

Petra SAULI[1], Patrice ABRY[2], Josef BOSKA[1] ([1]Institute of Atmospheric Physics ASCR, Czech Republic, [2]Laboratoire de Physique, ENS de Lyon, France.)

The short-term ionospheric variation, in the period range 15 minutes to 4 hours, studied in time series consisting of electron densities shows clear enhancements of waves. The analysis is based on the vertical ionospheric soundings measurements at midlatitude station Pruhonice (Czech Republic, 49.9N, 14.5E). Data were collected during several campaigns and consists of vertical ionospheric sounding measurement with 5 min repetition time, that were carried out during periods of low (1996, 1997 years) and high (1991, 2001 years) Solar activity. Among random oscillations, wave-like structures are well developed. Diurnal variations of the AGW activity during period of low solar and geomagnetic activity show clear enhancement during and several hours after sunrise and sunset. Some of the observed wave structures of AGW type have significant vertical component of propagation through the ionosphere. The most probable source of these waves seems to be the Solar Terminator passages. During the periods of high Solar and geomagnetic activity (1991, 2001), the substantial intensification of AGW activity at longer and shorter periods, associated with response of the magnetosphere to the sharp increase of solar wind, was observed.

GAII.06/11P/D-001 Poster 1400-053

SIMULTANEOUS RADAR OBSERVATIONS OF THE ELECTROJET PLASMA IRREGULARITIES AT 18 AND 54.95 MHZ OVER TRIVANDRUM, INDIA

Amit Kumar PATRA[1], D. TIWARI[1], Viswanathan K.S, Jyothi N, Devasia C.V, Subbarao K.S.V, Sridharan R ([1]National MST Radar Facility, [2]Space Physics Laboratory, VSSC, Trivandrum)

Observations of electrojet plasma irregularities made using a newly established 18 MHz coherent backscatter radar at Trivandrum are presented. Also presented are the simultaneous observations of the electrojet plasma irregularities made using a collocated 54.95 MHz radar. These correspond to 8.3 m and 2.7 m scale irregularities respectively. An interesting and new aspect of these observations is that the 8.3 m irregularities have significant anisotropy in the plane perpendicular to magnetic field in contrast to that reported for 3 m irregularities. While type-1 and type-2 could be distinctly observed at 2.7 m, it is rather difficult to distinguish at 8.3 m. The type-2 velocities are found to be pretty close to each other as expected from gradient-drift instability theory. Type-1 velocities are found to be quite close to each other only at altitudes of the peak electrojet when clear type-1 echoes are noted. But spectral widths are found to be remarkably different at the two scale sizes. The ratio of spectral width corresponding to 2.7 m to that at 8.3 m is found to be close to 1.4, quite similar to that reported earlier from Jicamarca. Ratio of spectral width to mean Doppler shift for 8.3 m at times is found to be much less than unity, even for small mean Doppler shift unlike at 2.7 m. Statistical characteristics of the spectral parameters measured at the two scale sizes are also presented and a detail comparison of these parameters have been made. The above observations are studied in the light of plasma instability theories and related simulation works.

ROLE OF E-REGION CONDUCTIVITY IN THE DEVELOPMENT OF EQUATORIAL IONOSPHERIC PLASMA BUBBLES

Archana BHATTACHARYYA (Indian Institute of Geomagnetism)

It is well known that E-region conductivity has a major effect on the non-linearevolution of equatorial ionospheric plasma bubbles because field-aligned currents (FACs) couple the equatorial F-region with the conjugate E-regions. In recent years, a linear theory for the development of equatorial bubbles has beenput forward using a transmission line analogy, in which the FACs are considered to be carried by oppositely propagating Alfve´n waves that are launched in the equatorial F-region when a plasma bubble starts to grow. Here, the transmission line analogy is extended to study the effect of the conductivity ofthe conjugate E-regions on the non-linear evolution of the equatorial ionospheric bubbles. For this, a simple three mode system is considered, and a set of mode coupling equations which describe the non-linear evolution of plasma bubbles, taking into account their coupling with the conjugate E-regions through FACs, is derived. From these equations, which correspond exactly with the Lorenzequations that have been used to describe the evolution of the Rayleigh-Benard instability, a condition for unstable fixed states is derived. This condition shows that the E-region resistivity and F-region polarizability introduce another time scale in the non-linear evolution of equatorial bubbles, which is the time scale for discharging the bubbles and thus destroying the perturbation electric field. This time scale is found to be inversely proportional to the flux tube integrated E-region conductivity and directly proportional to the length of the transmission line, which depends on the height of the F-region. When this time scale is shorter than the inverse of the linear growth rate of the Rayleigh-Taylor instability in the inertial regime, the fixed states are stable. With increasing solar flux, the E-region conductivity increases and hence the onset of chaotic evolution of the equatorial bubble can only occur fora proportionate increase in the length of the transmission line such that there is no decrease in the bubble discharge time. This provides an explanation for the past observation that the threshold value of the post-sunset upward drift ofthe equatorial F-region for the generation of strong early night irregularities increases with solar flux.

ESTIMATION OF A SIZES SPECTRUM OF THE INHOMOGENEITY THE LOWER IONOSPHERE ON THE DATA OF DOPPLER PHASE-GONIOMETRIC MEASUREMENTS

Vadim Yurievich TEPLOV, Vladimir Vladimirovich BOCHKAREV, Inna Romanovna PETROVA (Department of Physics, University of Kazan)

In this work an estimation of a spectrum of the sizes of ionospheric inhomogeneity in the lower ionosphere are resulted. These estimations are received on oblique ionospheric sounding for several middle-latitude radiolines. Measurements were carried out by the method of spased reception with small base. Array antenna included 4 vertical vibrators. Diameter antenna fields is 15 m. Mode separation was carried out in frequency area on Doppler frequency shift of a signal. Continuous measurements of exact times stations signals (Moscow) and broadcasting SW-stations with frequencies in a range from 5 up to 12 MHz located in Moscow, Saint Petersburg, Ekaterinburg (Russia), and Lamperthaym and Holchirhen (Germany) have been carried out. Measurements of various frequencies signals from several transmitters simultaneously also were carried out.The size spectrum of the scattering inhomogeneity is connected to a frequency power spectrum of a radio signal integrated Fredgolm equation of 1-st type. Characteristic function of a speed field of the scattering medium is a kernel of this equation. That fact, that a speed field of a wind at heights of the lower ionosphere is essentially non-stationary represents significant difficulty. For radiolines on which measurements were carried out, the size of Doppler variations of frequency caused by regular large-scale movements in an ionosphere, can be more then variations, caused by irregular movements. The adaptive methods of the spectral analysis based on use of wavelet-transformation are applied for correct account of influence of regular wind structure. Opportunity on phase measurements on spaced - carried array antenna to estimate of angular distribution of an scattered signal is other moment allowing essentially to improve reliability of results. At this configuration the array antenna it is possible to achieve of single-valued definition of angle of arrival no more than for 2 mode of signal in each frequency filter. At a large quantity of scattering irregularity the problem can be solved only statistically. In cases when the dominating mechanism of formation of a signal is incoherent scattering   on small-scale ionospheric inhomogeneity, the estimation of angular distribution of capacity of a signal can be found according to criterion of the maximal plausibility. Presence of angular distribution allows to reduce essentially uncertainty of an estimation of a corner of dispersion, and therefore, a spectrum of the scattering irregularity

---

sizes. In work examples of an estimation of a spectrum of irregularity are resulted by various methods of processing of a signalThe work was conducted under the support of grant RFBR 01-05-65251

INVESTIGATING TRAVELING IONOSPHERIC DISTURBANCES WITH THE DPS-4 IONOSONDE

Konstantin G. RATOVSKY, Andrey V. MEDVEDEV, Boris G. SHPYNEV, Dmitriy S. KUSHNAREV (Institute of Solar-Terrestrial Physics)

The DPS-4 digisonde, produced by the Center for Atmospheric Research, University of Massachusetts Lowell, USA, is among the most advanced and widely used ground-based ionospheric sounding facilities. The worldwide DPS network includes over 70 stations. DPS-4 ionosondes are used in two basic areas of ionospheric research. One involves the study of the behavior features of the electron density profile obtained from height-frequency characteristics. The other area encompasses the investigation of the ionospheric plasma drift velocity. Drift velocity calculations are based on measuring angles of arrival and the frequency Doppler shift; essentially, DPS-4 are used as a HF radar. The method for calculating the velocity assumes the presence of three echo signals as a minimum, i.e. an essentially inhomogeneous ionosphere. Thus the method provides better results for high-latitude stations when compared with mid-latitude stations where the inhomogeneous structure is much more poorly pronounced. On the other hand, even in the presence of a single echo signal, the possibility of measuring angles of arrival and the frequency Doppler shift allows for using DPS-4 in investigating traveling ionospheric disturbances. Measurements on several carrier frequencies make it possible not only to calculate the horizontal velocity of disturbances but also to investigate their height structure. In contrast to existing facilities for investigating traveling ionospheric disturbances, DPS offers improved spatial and temporal resolution and enables continuous measurements, i.e. monitoring. This paper presents the results derived from investigating traveling ionospheric disturbances with the Irkutsk DPS-4 ionosonde during January through June 2003, as well as the results of comparison with experimental data obtained with the Irkutsk incoherent scatter radar.

GAII.06/11P/D-005 Poster 1400-057

STRONG TURBULENCE STRUCTURES IN MODIFIED IONOSPHERE

Andrey Valentinovich KOCHETOV[1], Galina Ivanovna TERINA[2] ([1]Department of Physics and High Power Electronics of Institute of Applied Physics, RAS, [2]Department of Solar and Terrestrial Physics & Wave Phenomena of Radiophysical Research Institute)

The experimental and theoretical results of study of nonlinear dynamic structuresexciting in ionospheric plasma under action of powerful electromagnetic emission arepresented. The experimental results were obtained in the Nizhny Novgorod region at theheating facilities ˝Zimenki˝ and ˝Sura˝ by the method of sounding of artificiallydisturbed ionospheric plasma by probing radio pulses. Spatio-temporal evolution of amplitude and phase characteristics of caviton signal(CS) (G.I. Terina, J. Atm. Terr. Phys., 1995, v.57, p.273) and main signal (MS)of probing transmitter were considered. For theoretical interpretation of thecharacteristics of CS and MS the numerical solution of nonlinear Shroedingerequation) with driven extension (DNSE) in nonuniform plasma are presented for the linearinhomogeneous plasma layer and for one with prescribed densities depletions. The simulationenables us to study spatial structures of electromagnetic field and plasma density, theirtime and spectrum characteristics at formation and relaxation states. The comparison of the experimental results with the simulation ones shows their qualitativeagreement, namely: correspondence of the time phase evolution of the MS ofprobing transmitter to the calculated time dependencies of reflectedwave phase and correlation of the time phase evolution of CS to the calculated time phasedependencies of the wave field at plasma resonance point. Moreover, the simulation resultsallow to interpret qualitatively the following characteristics of CS: periodicgeneration of CS; the dependencies of CS period on heating power andheating time; the travel of CSmaximum height down the density gradient (A. V. Kochetov, V.A.Mironov, G.I. Terina, Advancesin Space Res., vol. 29, pp. 1369-1373, 2002).Observed evolution of the phase characteristics ofthe main signal and CS as welldemonstrates powerful radio wave penetration into overdense, in linear approach, plasma regionat formation state.The obtained results show the excitation of strong turbulence structures and allow us to interpret CScharacteristics, and so far inexplicable phenomena as ˝spikes˝ too (L. M. Erukhimov, et. al., Geomagnetism and Aeronomia, (in Russian), vol. 23, pp. 433-439, 1983). The work is supported in part by the Ministry of Higher Education of Russia (Grant No. E02-3.2-90)and the Russian Foundation for Basic Research (Grant No. 02-02-17277).

STATISTICAL CHARACTERISTICS OF VHF RADAR OBSERVATIONS OF LOW-LATITUDE E REGION FIELD-ALIGNED IRREGULARITIES OVER GADANKI

Amit Kumar PATRA[1], Sripathi S.[1], Sivakumar V.[1], Rao P.B.[2] ([1]National MST Radar Facility, [2]National Remote Sensing Agency, Hyderabad)

In this paper, we present the statistical characteristics of the low-latitude (6.30 north magnetic latitude) E region field aligned irregularities observed using the Gadanki MST radar. We present diurnal and seasonal characteristics of a variety of parameters (percentage of occurrence of signal, signal-to-noise ratio, mean Doppler velocity and spectral width). The echoes are observed both during day- and night-time, nighttime being more intense and larger in height extent than daytime. The thickness of the echoing region is minimum during noon and maximum during midnight. The echoes could be observed at altitudes as low as 87 km and as high as 160 km. The percentage of occurrence of signal is found to be as high as 95% during sunrise and 80% just before sunset. Further the E region echoes are stronger and occur more frequently during local summer, and weaker and occur less frequently in winter. We also present some characteristics of the sunset echoes, which we believe that they could be used for studies related to the onset of equatorial spread-F since some of the magnetic field lines of the E region over Gadanki connect to that of the F region over the equator. The mean values of the Doppler velocities above 102 km are about 10 m s-1 upward during daytime and 10 m s-1 downward during nighttime, representing the electrodynamical drift due to zonal electric field. The Doppler velocities below 102 km do not have any specific trend and they are driven mainly by meridional winds.

GAII.06/11P/D-007 Poster 1400-059

TO IMPROVE A REGIONAL IONOSPHERIC TEC MODEL OVER JAPAN ISLANDS

Jinsong PING[1], Akinori SAITO[2], Yusuke KONO[1], Koji MATSUMOTO[1], Kosuke HEKI[1], Nobuyuki KAWANO[1] ([1]Earth Rotation Division, National Astronomical Observatory, Japan, [2]Department of Geophysics, Graduate School of Science, Kyoto University, Japan)

The high density regional GPS (Global Positioning System) Earth Observation Network (GEONET) of Japan, with everage distance between nearby receivers as 25 km, is a

---

powerful facillity to monitor the ionospheric variation over Japan Islands. Based on the phases and codes observables of this network, the total electron content (TEC) distribution and variation with very high time and spatial resolutions can be obtained continuousely. Ping et al. (2002) expanded the obtained GEONET TEC by using the spherical harmonic function method through a full 60x60 degrees and orders for each 10 minutes. In this report, this regional ionospheric TEC model (RIM) is upgraded by means of both the spatial and time resulotions. A RIM model of coefficients through 150x150 degrees and orders for each 5 minutes has been carried out. However, the attempt to improvemore of the resolution for this RIM by using spherical harmonic function expanding method is not successful. Of this RIM, a daily map time series are arranged in an array to show the TEC evolution. The evolution history of medium and short scales traveling ionospheric disturbances (MSTIDs and SSTIDS), i.e. the polarward intense TEC enhancement near the geomagnetic equator and an isolated TID of medium or small scale with extremely high TEC density, have been found in each month during the period of which the data is analyzed. The isolated TID is appears in either day time or in night with period of several hours. Reasonable explanation about the source and mechanism of this kind of phenomenon is looking forward to being discovered. The RIM model discussed at here will benefit the application of other fields, like s/c radio tracking and orbiting.

GAII.06/11P/D-008 Poster **1400-060**

ANNUAL TEC VARIATION IN THE EQUATORIAL ANOMALY REGION DURING THE SOLAR MINIMUM: SEPTEMBER 1996 - AUGUST 1997

Chin-Chun WU[1], C.D. FRY[2], J.-Y. LIU[3], K. LIOU[4], C.-L. TSENG[5] ([1]CSPAR/The University of Alabama in Huntsville, [2]Exploration Physics, International, Inc., EXPI, 614 Nashua Street, \#222,Milford, NH 03055-4917, [3]Institute of Space Science, NationalCentral University, Chung-Li, Taiwan, ROC, [4]Johns Hopkins University, Apply Physic Laboratory,Laurel, MD 20723, USA, [5]Satellite Geoinformatic Research Center, NationalCheng Kung University, Tainan, Taiwan, ROC)

The ionospheric total electron content (TEC) in the equatorial anomaly regionis studied by analyzing dual-frequency signals of the Global Position System (GPS)acquired from a meridional chain of 9 observational sites clustered aroundTaiwan (21.9°-26.2°N, 118.4°-112.6°).This relatively dense GPS chain observation provides a powerful tool forstudying ionospheric ionospheric total electron content in the northern hemisphericequatorial anomaly region with an unprecedented spatial resolution. Specifically,we studied seasonal and geomagnetic effects on the equatorial ionospheric anomalyduring the solar minimum period between September 1996 and August 1997.It is found that the surveyed data indicated double peaks in the magnitude ofTEC, I_c, at the anomaly crest in the equinoxes, similar to the semi-annualvariation of geomagnetic activity. The values of I_c were found to maximize in April, 1997 and minimize in July, 1997. Statistical studiesindicated that the monthly values of I_c do not correlate with theplanetary magnetic *Kp* index (r=0.41) but correlate wellwith the geomagnetic activity *Dst* index (r=0.72), suggesting that variations ofTEC are mainly driven by a low-latitude forcing. The most likely time forIc to occur was 1400 local time (~30%) at 20°N geographiclatitude ~37% for the surveyed period..

GAII.06/11P/D-009 Poster **1400-061**

A STUDY OF EQUATORIAL SPREAD F DURING A SOLAR MAXIMUM PERIOD, 1999-2000

Chien-Chih LEE[1], J.Y. LIU[1], B.W. REINISCH[2], W.S. CHEN[1], F.D. CHU[1] ([1]Institute of Space Science, National Central University, [2]Center for Atmospheric Research, University of Massachusetts)

We examine the onset conditions of the equatorial spread F (ESF) using a digisonde and 5 GPS stations. One digisonde, located at Jicamarca (11.9°S, 76°W), gives the time, h'F (the lowest virtual height of the F-layer), and vertical drift velocity (dh'F/dt) of the ESF onset. The GPS stations along 75°W provide the total electron content (TEC), the ionization strength and asymmetry indices (Is and Ia) of the equatorial ionization anomaly (EIA), and the phase fluctuation. We intercompare the dh'F/dt, Is, and Ia, and find that the vertical drift velocity is the most important factor for the ESF onset. Furthermore, we find that ESF of ionogram is not fully coincident with the phase fluctuation of GPS at the equator, which could be owing to the magnitudes of h'F and dh'F/dt of the ESF onset.

GAII.06/11P/D-010 Poster **1400-062**

SIMULTANEOUS RADAR AND OPTICAL OBSERVATION OF E-REGION IRREGULARITIES AND F-REGION TRAVELING IONOSPHERIC DISTURBANCES

Fumiki ONOMA[1], Tadahiko OGAWA[1], Yuichi OTSUKA[1], Kazuo SHIOKAWA[1], Mamoru YAMAMOTO[2] ([1]Solar-Terrestrial Environment Laboratory, Nagoya University, [2]Radio Atmospheric Science Center, Kyoto University)

On the night of August 6, 2002, the powerful 46.5-MHz middle and upper atmosphere (MU) radar with 5 beam directions at Shigaraki, Japan, observed typical quasi-periodic (QP) echoes from field-aligned electron density irregularities in the ionospheric E-region. The QP echoes exhibited a wavy structure that propagated southwestward at 100 m/s with a wavelength of 30 km. During this QP event, a 630.0 nm all-sky CCD imager at the MU radar site detected traveling ionospheric disturbances (TID) at altitudes of around 250 km in the F-region. The TID also propagated southwestward at 80 m/s with relative fluctuation amplitudes of 30-50% and a wavelength of 300 km. This propagation direction is very similar to the direction of the QP echoes movement. Also, a 630.0 nm Fabry-Perot interferometer at the radar site detected neutral winds (U) of 106 m/s that generates an electric field of 4.5 mV/m through UxB, where B is the geomagnetic field. From these observed values and average F-region electric field of 1.0 mV/m that is derived from previous MU radar observations in summer under high solar activity conditions, we estimate polarization electric fields associated with TID are 1.2-2.0 mV/m toward the northeast. When these polarization fields are mapped down along B without attenuation, ExB plasma drift velocities of 28-47 m/s are induced in the E-region. In actual, drift velocities in the QP echoes observed with the MU radar was 42 m/s, which is very consistent with the values (28-47 m/s) estimated above. Moreover, the direction of the ExB drift estimated is almost identical to that of the plasma drift in the QP echoes observed with the MU radar. Thus, the electric fields associated with the F-region TID seem to be closely coupled to those that generate QP echoes in the E-region.

THE STRUCTURE OF THE TMA-INDUCED OPTICAL EMISSION OBSERVED IN THE SEEK-2 CAMPAIGN

Makiko ARAKAWA[1], Hiroshi FUKUNISHI[1], Yukihiro TAKAHASHI[1], Mitsuteru SATO[1], Takayuki ONO[1], Mamoru YAMAMOTO[2], Kazuo SHIOKAWA[3], Akinori SAITO[4], Masa-yuki YAMAMOTO[5], M.F. LARSEN[6], Ryuichi TAMURA ([1]Graduate School of Science, Tohoku University, [2]Radio Science Center for Space and Atmosphere, Kyoto University, [3]Solar-Terrestrial Environment Laboratory, Nagoya University, [4]Graduate School of Science, Kyoto University, [5]Communications Research Laboratory, [6]Clemson University)

The SEEK-2 (Sporadic-E Experiment over Kyushu) campaign was carried out to investigate the Sporadic-E generation mechanisms. Two rockets (S-310-31 and 32) were launched successively toward the east-southeast at a 15 minutes interval on August 3, 2002 from Uchinoura (31.25° N, 131.08° E), Kagoshima, Japan. The S-310-32 rocket released trimethyl aluminum (TMA) over the altitude range from about 80 km to the apex of 117 km. Neutral wind profile can be derived based on the triangulation of TMA optical emission from the ground. On this campaign, we confirmed occurrences of TMA-induced artificial optical emissions, which were different from TMA emissions. We operated an image-intensified CCD (II-CCD) camera which captures image at the standard video frame rate (30 frames/sec) near the launch site. An all-sky imager with OI 557.7-nm, OI 630.0-nm, OH emissions (720 - 910 nm) and background (572.5 nm) filters was operated at Tanegashima. A film camera with an exposure of 5 minutes captured the TMA trails and the artificial emissions from Tengu-plateau (33.5°N, 133.0°E), which is located about 400 km northward of the rocket orbit. The artificial emissions were confined within a region just under the rocket orbit, though TMA trails moved following background neutral atmosphere winds. The artificial emissions appeared in the altitude range from about 90 km to about 110 km, with layer structures separated about 10 km in altitude to each other. These layers have a thickness of about 3 km, and appeared continuously during the upleg and downleg releases. The artificial emissions extend from the kinks of the TMA trails, corresponding to the wind sheer of the neutral atmosphere and increase of electron densities. The artificial emission lasted more than 40 minutes. All filters of the all-sky imager confirmed the artificial emission, suggesting that the artificial emissions included continuum emission. We investigate the generation mechanism of these emissions by comparing the optical structure with the structures of electron densities, plasma waves and neutral winds measured by the same rocket. It is speculated the TMA-induced optical emissions are generated by some plasma processes in the sporadic-E layer.

RAPID-RUN IONOSONDE OBSERVATIONS OF SPORADIC-E DURING THE SEEK-2 CAMPAIGN

Takashi MARUYAMA[1], Hisao KATO[1], Maho NAKAMURA[1], Mamoru YAMAMOTO[2], Shoichiro FUKAO[2] ([1]Communications Research Laboratory, [2]RASC, Kyoto University)

A quasi-periodic striation pattern appearing in range-time-intensity (R-T-I) maps of radar backscattering from the sporadic-E has been extensively studied by using VHF radars, rockets, ionosondes, and satellite radio beacons, in this decade. Their generation mechanism, however, is not clearly resolved yet. Coordinated observations including two rockets were conducted in Kyusyu Island, Japan in August 2002 (SEEK-2) to study the generation mechanism of the striation pattern in R-T-I maps of the radar backscattering and related upper atmospheric disturbances. During the campaign, we ran the ionosonde in its rapid-run mode at Yamagawa that is close to the rocket launch site. Ionograms were obtained every minute and foEs, fbEs, h'Es, and foF2 were scaled. Rockets were launched when intense VHF radar signals were observed. An increase in foEs was observed in accord with the period of the intense radar backscattering. During this event, foEs and fbEs varied out of phase. At the onset of the radar backscattering, foEs increased and fbEs decreased both rapidly. Prior to the onset, foEs and fbEs varied, also out of phase, periodically with a period of 10 minutes. These findings strongly suggest that the spatial inhomogeneity of electron density in the sporadic-E layer and associated polarization electric fields play an important role in the generation of radar backscattering. Also periodic variations of sporadic-E parameters prior to the onset of radar backscattering suggest that there exists some kind of fluid instability such as K-H instability modulated by a wave activity.

HIGH RESOLUTION VHF RADAR OBSERVATIONS OF DAYTIME QP STRUCTURES IN LOWER E REGION OVER GADANKI

Sripathi SAMIREDDIPALLE[1], Amit Kumar PATRA[1], Sivakumar V.[1], Rao P. B.[2] ([1]National MST Radar Facility, Department of Space, [2]National Remote Sensing Agency, Hyderabad)

In this paper, we present high resolution observations of the daytime quasi-periodic (QP) structures of the lower E region irregularities made using the Gadanki VHF radar. The structures are found to display striations with negative altitude rates of ~ 10 m s-1, periods of 1 - 3 min and vertical wavelength of ~1 km. The Doppler velocities associated with these structures are found to be mostly in the range –20 - 10 m s-1. More importantly, these structures are found to be associated with a descending irregularity layer having descent rate of ~ 0.3 m s-1. The characteristics of these structures although resemble closely to that of nighttime low altitude structures observed earlier at Gadanki as well as at midlatitudes, the periodicities observed during daytime are found to be higher than that observed as few tens of seconds during nighttime. These observations are discussed in terms of their generation mechanism in the framework of the large scale Gradient drift instability and recently advanced theories on well known QP echoes based on atmospheric gravity waves and Kelvin Helmholtz instability. We believe that these structures are generated on the low altitude metallic ion layers formed at the node of the tidal wind field.

SOME CHARACTERISTICS OF THE VHF RADAR OBSERVATIONS OF THE LOWER E REGION IRREGULARITIES AS DIAGNOSTIC TOOL TO IDENTIFY THEIR GENERATION MECHANISM IN TERMS OF PLASMA INSTABILITIES OR NEUTRAL TURBULENCE

Amit Kumar PATRA[1], Sripathi S.[1], Rao P.B.[2] ([1]National MST Radar Facility, [2]National Remote Sensing Agency, Hyderabad)

VHF radar observations of the lower E region (<95 km) irregularities over Gadanki are presented to address the characteristics difference of these echoes with that of the normal E region. We present several unusual observations of the lower E region echoes displaying slowly descending layer structures of 2-3 km thickness, resembling their characteristics to the low altitude tidal ion layers observed over Arecibo. These structures have been found to descend to altitudes as low as 86 km. We also compare the characteristics of these echoes with that of the intermittent echoes observed at this altitude region and down below in the mesosphere. The characteristics of these echoes show remarkable degree of aspect sensitivity representing their field alignment as compared to that expected from neutral turbulence. In this paper, we emphasize on the source mechanism of these echoes and present evidence in support of plasma related process than neutral turbulence as the causative mechanism.

HEIGHT DEPENDENCE OF GRAVITY WAVE ACTIVITY IN THE F-REGION IONOSPHERE

Petra SAULI[1], Patrice ABRY[2], David ALTADILL[3], Josef BOSKA ([1]Institute of Atmospheric Physics ASCR, Czech Republic, [2]Laboratoire de Physique, ENS de Lyon, France, [3]Observatori de l'Ebre,

A

URL-CSIC, Spain)

The height dependence of gravity wave activity is studied in the electron concentration in the F-region ionosphere. The analysis is based on data measured at two stations, Ebro (Spain, 40.8N, 0.5E) and Pruhonice (Czech Republic, 49.9N, 14.5E), mainly on the data collected during the world campaign HIRAC 23 April – 29 April 2001 (low, moderate and high geomagnetic activity in a period of high solar activity). Time series consists of vertical ionospheric sounding measurement with 5 min repetition time. The analysis is made for 5 corresponding days at two stations. From these measurements, a set of 1D times series are extracted, consisting of the fluctuations of electron concentration at various fixed heights (ranging from 155km to the altitude of the maximum electron concentration). The time series are analyzed using Wavelet Transforms. They are used to detect wave-like structures and to characterize them (with respects to occurence times, phase and group velocity, etc). Preliminary studies give evidences of a change of the wave-like activity pattern at a height around 200 km. Below that altitude, a larger number (compared to above 200km) of wave-like structures are detected and they almost all have shorter periods. These findings are consistent for data measured on both stations. The characteristics measured for one wave-like structure detected on one station are compared to those obtained for the same structure on the other station.

LATITUDINAL VARIABILITY OF SPECTRA OF PLASMA IRREGULARITIES INDUCED BY TURBULENT MIXING IN THE LOWER IONOSPHERE

Yurij KYZYUROV (Department of Space Plasma Physics, Main Astronomical Observatory NASU)

Rocket-borne probes and ground-based radar systems are powerful tools for study of plasma in the lower ionosphere of the Earth. Radar observations and in-situ rocket measurements at various latitudes have shown the presence of plasma irregularities induced by turbulent mixing in the ionosphere below the turbopause level. An investigation of spectra of the irregularities is very important for better understanding complicated coupling processes between neutral and ionized atmosphere. In this report a possible latitudinal dependence of the spectra is analyzed by using a formula that was recently derived for the 1D spectrum of plasma fluctuations formed in turbulent flow of weakly-ionized gas. The analysis is carried out for 3 directions of the possible spectral measurements: (a) the vertical direction along the gradient in the ambient plasma density, (b) the horizontal direction perpendicular to both the gradient and the geomagnetic field, and (c) the horizontal direction perpendicular to the gradient but along the horizontal component of the magnetic field. The case (a) can be realized in rocket measurements, while (b) and (c) in radar experiments, say, under the proper direction of the mean neutral wind. Using the assumption that parameters of the ionosphere and the neutral air turbulence are unchanged, a comparison of the irregularity spectra is made for different angles between directions of the mean plasma-density gradient and the geomagnetic field. It is shown that the slope of the spectrum which can be measured by rocket probes along the vertical direction has to increase with an increase in latitude; in the case of radar experiments under the zonal drift of the irregularities, the shape of the spectrum is unchanged, but for the drift in the meridional direction, the spectral slope has to decrease with latitude. The changes in the spectra have to appear mainly under large wavenumbers, i.e. for the small-scale fluctuations that resulted from interaction of plasma embedded in turbulent flow of neutral gas with the geomagnetic field.

E-REGION DOPPLER SPECTRAL BANDS DETECTED USING HF DIGISONDE AND MF RADAR AT SOUTHERN HIGH LATITUDES

Ray MORRIS[1], D.P. MONSELESAN[1], D.A. HOLDSWORTH[2], D.J. MURPHY[1], P.L.DYSON[3]
([1]Australian Antarctic Division, [2]Atmospheric Radar Systems, [3]La Trobe University)

A HF digisonde and an MF radar were operated concurrently at the polar cusp station Davis (78.0˚E, 68.6˚S geographic, 74.6˚S magnetic), Antarctica during the austral summer of 2002-03. The digisonde transmitted in a swept-frequency mode from 1.2 MHz to 2.7 MHz while the MF radar transmitted at a single frequency at 1.98 MHz. The two independent instruments were programmed to record E-region backscatter from ionospheric irregularities. This paper presents preliminary results from this novel campaign to observe Bragg scatter in the E-region from a multi-instrument campaign. Preliminary results from spectral signal analyses show evidence of Doppler spectral splitting in the respective HF digisonde and MF radar processed data. The backscattered signals as observed from these different radar techniques appear to originate from the same E-region heights. Moreover there is a remarkable tendency for such spectral splitting to occur during intervals of ionosphere slant Es condition (SEC) with lacuna. Earlier independent MF radar observations from Davis and HF digisonde observations from Casey (66.3˚E, 110.5˚S geographic, 80.4˚S magnetic) augment and support these findings. The plausibility of these spectral splitting events being related to E-region ionosphere plasma instability processes will be discussed.

MERIDIONAL NEUTRAL WINDS DERIVED USING THE E REGION FIELD ALIGNED IRREGULARITIES (FAI) AS TRACERS OVER GADANKI AND A COMPARISON WITH MODEL AND HRDI DATA

Sripathi SAMIREDDIPALLE[1], Amit Kumar PATRA[1], Rao P. B.[2], Manas Ranjan PADHY[1]
([1]Department of Space, [2]National Remote Sensing Agency, Hyderabad)

We have derived the meridional neutral winds in the E region altitudes using the field aligned irregularities observed by the Gadanki VHF radar. It may be mentioned that wind information at this height region is limited and episodical and hence continuous measurements of winds at this height region are of significant value. The observations were made along the north bearing (130 off zenith) of the Gadanki radar beam that satisfies the perpendicularity condition with the earth's magnetic field lines at E region heights. Hence, the radar detects the secondary plasma irregularities present in the meridional plane transverse to the magnetic field. For the radar geometry used here, the irregularities especially in the collision dominated E region will be driven by both meridional neutral wind and the zonal electric field. Using the dispersion relation of the gradient drift instability and model values of the collision and gyro frequencies of the electrons and ions, we have estimated the zonal electric field and meridional neutral winds. While deriving meridional neutral winds, the contribution from the zonal electric filed has been taken into consideration. The estimated winds have been compared with the model and UARS-HRDI satellite data. We found that the model wind amplitudes are quite low as compared to that observed here whereas the HRDI winds are found to be comparable. The results show that the semidiurnal component is more dominant in comparison to that of the diurnal component. We also present the seasonal characteristics of these winds.

INHOMOGENEOUS STRUCTURE OF THE HIGH-LATITUDE IONOSPHERE AS OBSERVED AT EAST SIBERIA

Yury V. LIPKO, Gely Aleksandrovich ZHEREBTSOV (Lipko Yury)

The results of investigation of the inhomogeneous structure of high-latitude ionosphere are presented. The observation were carried out at Norilsk (geomagnetic latitude and longitude 64.2 N and 160.4 E, and L=5.3) in the 1970s and 1990s years. Small-scale irregularities (SSI) (with lifetime of several seconds and spatial scale less than 5-7 km), and medium-scale travelling ionospheric disturbances (MS TID) (with period of 10-50 min, and the horizontal size of tens and hundreds of kilometres) were investigation under different geophysical conditions. The following results were obtained: 1. The average patterns of motions in F- and E-layers of the ionosphere for various season of the year and for levels of geomagnetic activity were obtained. There are two-cells pattern of plasma drift for winter and one-cell pattern for summer. 2. The dependencies of SSI and MS TID parameters on geomagnetic activity was obtained. Auroral activity has a significant effect on the propagation velocity of irregularities and some other parameters. 3. The propagation directions and velocities of small- and medium-scale irregularities are different. Medium-scale TIDs travel predominantly in a southward direction with velocities of 40-100 m/s. The prevailing direction of small-scale irregularities is eastward and westward, and their velocities lie in the range of from 100 to 200 m/s.

OBSERVATIONS OF VENUS UPPER ATMOSPHERE AND IONOSPHERE BY JAPANESE VENUS ORBITER

Takumi ABE[1], Takeshi IMAMURA[1], Shinobu MACHIDA[2], Masato NAKAMURA[1], Takayuki ONO[3], Koh-ichiro OYAMA[1], Andrew W. YAU[4], Ichiro YOSHIKAWA[1], Kiyohumi YUMOTO[5] ([1]Institute of Space and Astronautical Science, [2]Department of Geophysics, Kyoto University, [3]Geophysical Institute, Tohoku University, [4]University of Calgary, Department of Physics and Astronomy, [5]Department of Earth and Planetary Sciences, Kyushu University)

We present a planned exploration of the Venus atmosphere and ionosphere carried out by the Japanese Venus orbiter (Planet-C), which will be launched in 2008 and arrived at Venus in 2009. Direct and/or indirect measurements of charged and neutral particles, plasma wave and magnetic field, as well as optical sounding (remote sensing) of the lower atmosphere, will be made in this mission. In this presentation, we concentrate on describing the principal scientific objectives related to the upper atmosphere and the ionosphere and discussing observation strategies for various phenomena occurring in these regions and the particle escape processes from Venus atmosphere. Despite extensive studies based on Pioneer Venus Orbiter observations, there still remain many unresolved issues of the plasma dynamics in the upper atmosphere and ionosphere on Venus: 1) global particle circulation, 2) plasma dynamics and characteristic structure in the nightside ionosphere (ion hole, patch, cloud, streamer etc.), 3) plasma transport processes in the ionosphere, and 4) mass and energy transfer mechanism through the ionopause. The observation of particle escape processes from Venus is one of the most important scientific objectives in this mission, given the important influence of these processes on the evolution of the Venus atmosphere and the critical lack of quantitative information on the total flux of the escaping particles. We are assessing the feasibility of installing several instruments on the spacecraft for the observation of these processes: 1) extreme ultraviolet imager, 2) nonthermal ion mass/spectrum analyzer and electron spectrum analyzer, 3) thermal plasma analyzer, 4) plasma wave analyzer and sounder, and 5) magnetometer. Considering that Planet-C will arrive at Venus during solar maximum period, a nominal operation period of 2-3 years will provide a significant data set of the Venus ionosphere, which is known to exhibit a remarkable dependence on the solar activity. We will discuss the current status of our feasibility study and the instruments and methodology necessary for understanding the key scientific issues.

GAII.07/11A/A12-002   0905

THE IONOSPHERE OF VENUS

Hiroyuki SHINAGAWA (Solar-Terrestrial Environment Laboratory, Nagoya University)

Venus has no intrinsic magnetic field, and the solar wind interacts directly with the ionosphere. Previous studies of Venus suggest that the ionospheric thermal pressure (Pi) and the solar wind dynamics pressure (Psw) are the most important parameters, which determine the nature of the solar wind-ionosphere interaction. When Pi is larger than Psw, the solar wind flow is deflected at high altitudes. The magnetic field pile-up region (the magnetic barrier) and the ionospheric plasma region are usually clearly separated by a sharp boundary, which is called the ionopause. When Psw is larger than Pi, the whole ionosphere is magnetized. Under such conditions, the ionopause tends to be thicker, and a magnetic field belt is formed in the lower ionosphere. Although the basic behavior of the Venus ionosphere could be reproduced by MHD models, recent theoretical studies suggest that kinetic processes also play an important role in the structure and dynamics of the ionosphere. The ionosphere of Venus is reviewed in light of previous observations as well as theoretical studies.

GAII.07/11A/A12-003   0925

NUMERICAL MODELING OF THE INTERACTION BETWEEN THE SOLAR WIND AND VENUS IONOSPHERE

Shinobu MACHIDA (Department of Geophysics, Kyoto University)

In this paper, the models of the interaction between the solar wind and the Venus ionosphere are reviewed. In particular, the electromagnetic hybrid model in which ions are treated as finite-size particles and electrons as a massless fluid is described. This model enables us to treat the kinetic effect of ions, especially the Finite Larmor Radius (FLR) effect,

which is significant because the Larmor radius of pick-up oxygen ions is comparable to the planetary radius. Immediately after the production of the pick-up ions, they are accelerated in the direction of the solar wind electric field. Hence, an asymmetric structure can be created depending on the direction of the solar wind electric field. Recently, a new 2-1/2 D electromagnetic hybrid code adopting the boundary fitted coordinates has been developed and this code was adopted to study the solar wind interaction with the Venus ionosphere [Terada et al., 2002]. This code allows us to treat the dynamics of the solar wind and Venus ionosphere self-consistently in available computer resources today by realizing the mesh size of ~10 km in the ionosphere and the mesh size of ~100km in the solar wind region keeping the total number of grid points to be small. They found a pronounced development of the Kelvin-Helmholtz (K-H) instability at the ionopause in the hemisphere to which the solar wind electric field directs, and a development of very long and small amplitude K-H waves in the opposite hemisphere. A notable detachment of the ionospheric oxygen cloud from the night side ionosphere was found to occur in the opposite hemisphere. They also found that a vortex generated by the K-H instability gives similar time variations in the velocity and magnetic field to the data obtained by Pioneer Venus Orbiter (PVO), which was formerly interpreted to be a flux rope. Also, there are challenging attempts to model the solar wind interaction with the Venus ionosphere employing 3D electromagnetic hybrid code. In a study performed by Shimazu [2001], the effect of two major processes, i.e., the charge exchange and the photo-ionization were examined. These two processes gave us opposite results in the thickness of the magnetosheath with respect to the solar wind electric field. It was found that the charge exchange is favorable to explain the observational result obtained by PVO, i.e., the thickness of the magnetosheath is enhanced in the hemisphere to which the solar wind electric field directs. Recent electromagnetic hybrid models including the kinetic effects such as the FLR effect and chemical effect give us a powerful tool to study elementary and fundamental processes operating in the solar wind and Venus ionosphere interaction.

GAII.07/11A/A12-004   0945
IMAGING OF INTERACTION REGION BETWEEN VENUSIAN IONOSPHERE AND SOLAR WIND

Atsushi YAMAZAKI[1], Ichiro YOSHIKAWA[2], Naoki TERADA[3], Miho KANAO[2], Takumi ABE[2], Masato NAKAMURA[2] ([1]Communications Research Laboratory, [2]Institute of Space and Astronautical Science, [3]Solar-Terrestrial Environment Laboratory)

Japanese Venus Climate Orbiter (the Planet-C spacecraft) will be launched in 2008, and will reach the orbit of Venus in 2009. We propose two eXtreme UltraViolet (XUV) imagers to take global 2-Dimensional snapshots of the Venusian ionosphere including the interaction region between the solar wind and the Venusian ionospheric plasmas. The imagers can detect the resonantly scattering emissions of oxygen ions (O II 83.4nm) and atoms (O I 130.3nm), and neutral helium (He I 58.4nm) and hydrogen (H Ly-a 121.6nm). We estimate the intensity of these emission lines and discuss the requirement for the specification of the imagers and the available temporal and spatial resolution. Scientific goals of the XUV imagers are to investigate mechanisms of momentum and mass transfer across the ionopause, of convection in the upper atmosphere and ionosphere, and of atmospheric and ionospheric escape. Especially we emphasize that sequential images of the O II emission illustrate temporal evolution of the vortex produced by the Kelvin-Helmholtz (K-H) instability at the Venusian ionopause. Though it is known that the vortex structure due to the K-H instability is also generated at the terrestrial magnetopause, oxygen ions is too tenuous to take 2-D images of the evolution. On the other hand at the Venusian ionopause oxygen ions have enough density to detect the resonance emission, i.e., the Venusian ionosphere plays a role as a space laboratory for plasma physics.

GAII.07/11A/A12-005   Invited   1035
ANALYSIS OF WAVE AND PARTICLE SIGNATURES OBSERVED IN PLASMA ESCAPE AT VENUS

Richard E. HARTLE[1], Joseph M. GREBOWSKY[1], Devrie S. INTRILIGATOR[2], Dana H. CRIDER[3] ([1]NASA-Goddard Space Flight Center, [2]Carmel Research Center, Santa Monica, CA, [3]Catholic University, Washington, DC)

Atmospheric gases escape from Venus as neutral and ionized atoms and molecules. Ion escape, considered here, occurs through ion pickup or collective plasma processes. The latter can arise from upward flow of nightside ionospheric plasma into the ionotail, day to night ionospheric flow into the ionotail, and scavenging of ionospheric plasma by ionosphere-magnetosheath instabilities at the ionopause. These plasma processes produce differing signatures in ion velocity and energy distributions and in ULF waves in the magnetic field. Using plasma ion spectra measured by the Pioneer Venus Orbiter (PVO) Orbiter Plasma Analyzer (OPA) and magnetic field fluctuations observed by the PVO Orbiter Magnetometer (OMAG) along with the expected particle and field signatures, various ion escape processes occurring along Pioneer Venus orbits are identified. In particular, OPA ion energy distributions are used in parallel with magnetic field power spectra and wave phase angles derived from OMAG measurements to study the characteristics of escaping ions. The principle ions observed escaping the influence of Venus are H+, He+ and O+. In the ion energy distributions of the OPA, pickup ions appear hot relative to the much cooler ions flowing away from Venus in the ionotail and in the plasma clouds detached from the ionopause. This energy contrast is particularly evident downstream when PVO crosses the ionotail boundary from the hot solar wind plasma to the much cooler plasma within the tail. Magnetic field signatures accompanying the escaping ions appear as peaks in the power spectra at the corresponding ion cyclotron frequencies. Also, coherent wave trains at the same frequencies are observed in the phase angle plots of magnetic field fluctuations about the mean field.

GAII.07/11A/A12-006   Invited   1105
CLUES FAVOURABLE TO THE DRAPING MAGNETIC FIELD MODEL ON THE VENUS HOLE

Yoshihiro KAKINAMI[1], Koh-ichiro OYAMA[2], Shigeto WATANABE[1] ([1]Division of Earth and Planetary Sciences, Graduate School of Science, Hokkaido University, [2]The Institute of Space and Astronautical Science)

Formation of the hole in Venus ionosphere is still controversial. We intensively studied the data observed with Pioneer Venus orbiter(orbit 1 - 570) in order to find the clues for the formation mechanism. Especially we use the information on electron temperature Te, which was so far rarely used for the discussion. Our major findings are; 1. The X component of the magnetic field prevails around the terminator, while the direction scatters more toward midnight (SZA > 120). 2. Three cases exist for Te of Venus hole: Case 1, Te decreases toward the midst of the hole and elevates in the midst of the hole, and two other cases are that Te in the hole is lower and higher than that of the ambient plasma. Case 1 can be theoretically reproduced if energy is injected into the hole along the magnetic field. The case requires that the ion temperature in the hole should be lower than that of the ambient, which suggests that the hole of low ion temperature rises from the lower ionosphere where ion

temperature is lower than at higher altitude. Two other cases can be explained by controlling the amount of energy deposited in the hole whose Te is equal to that of the ambient. The above two features on the hole are favorable to one of the mechanisms which were proposed in the past ″draping magnetic field″. However energy should come from dayside ionosphere.

GAII.07/11A/A12-007   Invited   1135
NATURAL SUPERROTATION OF A RAREFIED SLOWLY ROTATING PLANETARY ATMOSPHERE

Peter Alexeevich BESPALOV[1], Olga Nikolaevna SAVINA[2] ([1]Institute of Applied Physics, Russian Academy of Sciences, [2]Nizhny Novgorod State Technical University)

We consider the kinetics of a rarefied slowly rotating planetary atmosphere. The spatial distributions of the atmospheric-gas density and mean angular velocity were determined by analyzing the exact solution of the two-dimensional kinetic equation. We show that the angular velocity of the gas at some distance from the planet could be higher than that in the initial layer starting from which the atmosphere is rarefied. Our model calculations elucidate the superrotation mechanism under consideration. Experimental studies of atmospheric flows carried out for Venus, Earth, and Mars have established the possibility of superrotation of their atmospheres at large heights. This superrotation is characterized by the ratio (more than one) of the angular velocities of the atmosphere and the planet. Several possible superrotation mechanisms have been discussed in the literature. Several mechanisms responsible for atmospheric superrotation were proposed, but none of them was universal. Here,we consider the kinetics of a rarefied atmosphere replenished with particles injected from a spherical surface inside which collisions are significant. As we show below peculiarities of the motion of a rarefied gas in the gravitational field of a slowly rotating planet can give rise to superrotation. It follows from the laws of motion that sufficiently fast particles can rise high and even recede to infinity. Because of the axial rotation of the planet, the particles whose velocity have the same direction as the rotational velocity of the planet will have a higher (in magnitude) initial velocity. Primarily these particles can recede appreciably from the planet to become its ″satellites ″ due to weak collisions. Therefore,we have reason to expect that the mean angular velocity of the particles in the upper planetary atmosphere can exceed the angular velocity at its inner boundary. A quantitative analysis of this problem based on the exact solution of the kinetic equation. We have shown that one of the superrotation mechanisms for rarefied planetary atmospheres is the separation of particles: some of them fly away from the planet, while others become its satellites. Based on the proposed mechanism, we estimated the superrotation for the exospheres of Venus, Earth, and Mars. Our main results are as follows. (1) We found an exact solution of the boundary-value problem for the two-dimensional collisionless Boltzmann equation that includes particles with elliptical and hyperbolic orbits. (2) We obtained and analyzed the solution of the kinetic equation with weak elastic collisions. (3) We determined the spatial distributions of the atmospheric-gas density and mean angular velocity and established the possibility of exospheric superrotation. This study was supported by the Russian Foundation for Basic Research (project nos. 01-02-17796, and 00-15-966674).

THE MARTIAN THERMOSPHERE: A NEW PERSPECTIVE

Gerald M. KEATING[1], Michael E. THERIOT[1], Robert H. TOLSON[1], Stephen W. BOUGHER[2], Jeffrey M. FORBES[3], Francois FORGET[4] ([1]The George Washington Univ. at NASA Langley, Hampton, VA, USA, [2]Univ. of Michigan, Ann Arbor, MI, USA, [3]Univ. of Colorado, Boulder, CO, USA, [4]Univ. of Paris, Lab de Meteorologie Dynamique, Paris, France)

Recently thousands of vertical structures have been measured from pole to pole of the Martian thermosphere by means of accelerometers aboard Mars Global Surveyor and Mars Odyssey 2001. Only three in situ measurements of vertical structure had been obtained previously. Measurements are directly obtained of atmospheric density and from analysis of vertical structures, scale heights, temperatures, pressures and other characteristics are determined. Analysis of this data has revealed latitudinal/seasonal variations, diurnal variations, aphelion/perihelion variations, persistent planetary-scale waves, dust storm responses, winter polar warming, asymmetries between the Northern and Southern Hemispheres, and strong coupling between the lower and upper atmospheres. Analyses have also been performed of the global lateral and vertical temperature structure from the accelerometer data. The observations will be compared with general circulation models and previous measurements.

LONGITUDINAL DISTRIBUTIONS OF THERMOSPHERE AND IONOSPHERE AT LOW LATITUDE OF MARS : COMPARISON WITH ACCELEROMETER AND RADIO MEASUREMENTS

Syed Aftab HAIDER (Physical Research Laboratory, Ahmedabad)

We have developed global AYS approach to calculate longitudinal distributions of photoelectron flux, ion production rates and electron densities in the dayside Martian ionosphere at two wavelength ranges 1.9 nm and 9-102.57 nm produced by soft X-ray and EUV radiation respectively. These calculations are carried out at solar zenith angle 75 degree between latitudes 0 and 25°N in spring season with medium solar activity condition, appropriate for accelerometer and radio occultation measurements made by MGS in Phobos-2 aerobraking period. In these calculations, the neutral densities are derived from accelerometer data which were obtained by MGS at same latitude range during orbit # P0790-P0910 for one month period of December, 1998. The ionosphere produced by these two sources were compared with MGS radio occultation measurements made at high latitude in December, 1998 between solar zenith angle 78° and 81°. This measurement shows two peaks near altitudes 134 km and 110-112 km at most of the longitudes in the dayside ionosphere. These measured densities are in better agreement with AYS calculation using combined source of ionization (EUV + X-ray). However, lower peak is more visible in this calculation in comparison to MGS radio occultation measurements. In order to compare these calculations and measurements with other models, we have run MTGCM code which calculates neutral densities and ion/electron densities self consistently at three latitudes (2.5°N, 22.5°N and 67.5°N) and nine East longitudes (0, 45, 90, 135, 180, 225, 270, 315 and 360) for same observational period. It has been found that the neutral densities calculated at latitudes 2.5°N and 22.5°N are in reasonable agreement with accelerometer measurements. The peak value of low latitude ionosphere produced by MTGCM is larger by a factor of 1.5-2.0 as compared to that calculated by AYS approach. This difference may arise due to different technique used in both model calculations. AYS approach calculates photoionization impact rates using ionization cross sections and solar flux corresponding to solar moderate condition. MTGCM uses parameterization method to

A

calculate photoionization, photoelectron production rates and solar EUV/UV/X-ray fluxes at 81-day average f10.7 cm indices. These differences may, however produce larger uncertainty in production rates and solar fluxes used in MTGCM. It should be noted that same chemical reactions, neutral ion and electron temperatures have been used in both calculations.

CHARACTERISTICS OF THE MIGRATING DIURNAL TIDE IN THE MARTIAN ATMOSPHERE

Yoshiyuki O. TAKAHASHI, Hitoshi FUJIWARA, Hiroshi FUKUNISHI (Department of Geophysics, Tohoku University)

We have investigated the basic characteristics of the migrating diurnal tide in the Martian atmosphere using our Mars general circulation model (GCM) and linear response model (LRM). The Mars GCM used in this study is a spectral model. This model covers from the ground up to about 120 km altitude. In this Mars GCM, almost all physical processes appropriate for the Martian atmosphere are incorporated. This Mars GCM has successfully reproduced the general characteristics of the Martian atmospheric circulation. The LRM used in this study is based on the linearized primitive equation system. The governing equations are solved by the spectral technique. The model covers almost the same vertical domain as the GCM. The heating rates for wave generation and the distributions of the zonal mean zonal wind and temperature are obtained from the GCM. Using the Mars GCM, we have performed numerical simulations in a low dust condition (dust optical depth at 0.67 μm of 0.3). Furthermore, we have performed numerical experiments using the LRM to reveal the important processes characterizing the migrating diurnal tide. The GCM simulation shows that the vertical wavelength of the migrating diurnal tide in the low latitude region is about 45 km. This vertical wavelength is longer than the vertical wavelength of 25-35 km predicted from the classical tidal theory. This long vertical wavelength is caused by the effect of the zonal mean vorticity, in other words, latitudinal shear of the zonal mean zonal wind. It is suggested that the vertical wavelength of the migrating diurnal tide increases through the changes of the effects of the planetary rotation rate in the presence of the zonal mean vorticity. The amplitude of the migrating diurnal tide in the low latitude region is much smaller than that expected in an inviscid atmosphere. This small amplitude of the migrating diurnal tide is caused by the radiative process of the thin CO_2 atmosphere of Mars. On the other hand, the eddy diffusion process does not change the amplitude and phase of the migrating diurnal tide. This ineffective eddy diffusion process may be caused by the effective radiative damping and the long vertical wavelength of the migrating diurnal tide depending on the zonal mean vorticity. At solstices, the structures of the migrating diurnal tide are strongly asymmetric around the equator. It is suggested that the effect of zonal mean vorticity as well as the Doppler shift by the zonal mean zonal wind play an important role in determining the wave structure at solstices.

WAVE STRUCTURES IN THE MARTIAN TOPSIDE IONOSPHERE OBSERVED BY MARS GLOBAL SURVEYOR

Jing-Song Wang WANG[1], Erling NIELSEN[2] ([1]Department of Geophysics, Peking University, [2]Max-Planck-Institut fuer Aeronomie)

We analyzed the Martian ionospheric electron density altitude profilesobtained by Mars Global Surveyor radio occultation observations, and itis found that about 80% of the upper parts of these profiles displaysignificant wavelike structures with spatial scales of about some tenskilometers. These structures appear like wave activities superposed onbackground electron density distributions that principally decrease withaltitude exponentially. The relative density deviations in the wavelikestructures to the background are scattered but most limited in ±50%. Above ~145km, the wavelike structures are prominent and the backgroundelectron densities generally distribute according to a single scaleheight. Below ~145km altitude, the wavelike structures are much lessstriking and simple exponential distributions can not describe theprofiles any more. The altitude of ~145km, the beginning altitude oftransference from the photochemistry dominant region to the dynamicsdominant region, appears also the lower boundary of both the wavelikestructures and the exponential approximation to the ionospheric densitydistribution. Spectrum analysis is applied to those topside ionosphericprofiles and it is found that the wavelength of ~38km is prevailing.With a modeled Martian ionosphere including wave activities with aconstant wavelength of 38km but random phase at different solar zenithangle, the processes of radio occultation observation and the followedinversion of the radio signals are simulated and electron densityprofiles similar to MGS measurements are obtained. The same spectrumanalysis is applied to the artificial profiles and proves a reliablemethod to find out the prevailing wavelength. Those statistical featuresas well as the prevailing scale of the wavelike structure agree withthat of the wave activities predicted by Wang and Nielsen [2002, 2003]very well, and it is very likely that the wavelike structure discussedhere is the appearance of the predicted or similar waves. If so, the~145km altitude is also the end to which the effects of the externaldynamic disturbances out the Martian ionosphere can reach, and could bea physics lower boundary of the topside ionosphere.

MARS ATMOSPHERE AND ITS EFFECTS ON RADIO WAVE PROPAGATION

Christian M. HO, Miles K. SUE, Steve D. SLOBIN (Jet Propulsion Laboratory, California Institute of Technology, Pasadena, CA, USA)

Because the Mars atmosphere is significantly different from Earth's in its composition and structure, the effects of the Martian environment on radio wave propagation are also expected to be different. We have done some preliminary studies in understanding the effects. The Martian atmospheric gaseous attenuations have been calculated as a function of radio frequencies using the abundance information of H2O and O2. It is found that Martian gaseous absorption is at least three orders of magnitude lower than at Earth. Radio noise at Mars are mainly from its surface emissions. For a downward-looking antenna, the total noise temperature is about the same as the Earth's for all frequency bands of interest with ±15% deviations. For an upward looking antenna, the noise temperature is slightly below that of Earth. The sky noise temperature is the highest at UHF (about 55 K) and lowest at X- and Ka-band (about 5 K). It is also found that the Martian atmospheric radio refractivity is about two orders of magnitude smaller than that of Earth because of its lower atmospheric pressure. Mars ionospheric scintillation loss for UHF band is one tenth of Earth's, while the refractive index fluctuations in the Martian troposphere is only about 0.5% of that at Earth. The Martian clouds are similar to terrestrial high-level cirrus clouds. The total attenuation due to Martian clouds, fog and aerosols should be less than 0.3 dB at Ka-band. Dust storms in Mars can significantly affect a communication link. A large dust storm can cause a 3-dB loss at Ka-band (32 GHz) for a zenith path. Most large storms occur in the southern hemisphere during later spring and early summer.

THE PLASMA ENVIRONMENTS OF THE GALILEAN SATELLITES OF JUPITER

Arvydas J. KLIORE[1], Andrew F. NAGY[2] ([1]JPL, California Institute of Technology, [2]SPRL, University of Michigan)

The Galileo spacecraft has been orbiting Jupiter since 1995. During that time it has provided several opportunities for the study of the plasma environments of the icy Galilean satellites Europa, Ganymede, and Callisto by means of radio occultation of its S-band (13.5 cm. Wavelength) signal. There have been five occultations each by Europa, Ganymede, and Callisto, however, one of the Ganymede and one of the Callisto occultations occurred near superior conjunction, and did not provide useful data. Analysis of these data revealed small excursions in frequency (of the order of 0.01 Hz, or about 4 parts in 10^{12}), which indicated the presence of tenuous plasma above the surfaces of these bodies. When observed, the maximum electron densities range from about 5 to about 20×10^3 cm^{-3}. The apparent vertical structure of these plasma layers range from classical ionospheric profiles observed at Callisto on two occasions to multi-peaked structures observed at Europa. On several occasions no discernible plasma was observed. These observations could be explained by a process in which a tenuous neutral atmosphere (about 10^{10} cm^3 is created on the trailing hemisphere by sputtering from the icy surface by energetic particles of the Jovian magnetosphere. If the trailing hemisphere is also illuminated by the Sun, plasma is produced by photoionization and is observed by radio occultation. The configuration of this plasma is, however, determined by its interaction with the corotating Jovian magnetospheric plasma, which under certain geometries would lead to the observation of multipeaked structures.

NEW RESULTS ON ATMOSPHERIC AND SURFACE FEATURES ON TITAN

Athena COUSTENIS (LESIA, Observatoire de Paris-Meudon)

I will present new findings on Titan´s atmosphere and surface composition derived from recent observations using artificial satellites (such as ISO) and large telescopes (such as the CFHT or the VLT) both in spectroscopy and imaging (essentially with adaptive optics). Titan is becoming a more and more intriguing place as we manage to uncover further information about its lower atmosphere and its ground. While we await the Cassini/Huygens mission arrival in 2004, we put to use all available means both from the ground and from space so as to (a) investigate this wonderful planetary-scale laboratory for studying primitive-Earth conditions and (b) optimize the return of the Cassini/Huygens mission. Among our recent results, we have found evidence for seasonal and diurnal effects in Titan's atmosphere (asymmetry inversion and morning fog) and we have evidence for cloud (or more probably vortex) formation close to the South pole. We have also gathered new information on the spectral behavior of the surface constituents. References: Combes et al (1997), Icarus 129, 482; Coustenis et al. PLASMA CONVECTION IN THE Y-Z CROSS-SECTION OF THE MAGNETOTAIL

Kiyoshi MAEZAWA, Toshifumi MUKAI, Yoshifumi SAITO (Institute of Space and Astronautical Science)

Plasma convection pattern in the cross-section of the magnetotail is derived for the first time from the electron plasma dataset of the Geotail spacecraft.In this statistics, the measured ion velocities are first divided into two independent components, i.e. components parallel and perpendicular to the magnetic filed, respectively, and only the result for the perpendicular component is discussed. Since Geotail has an equatorial orbit, only the portion of the tail close to the plasma sheet has been covered by Geotail, but still the result provides sufficient information to identify some of the interesting characteristics of the plasma convection in the y-z plane. Some characteristics are consistent with the standard view of the convection in the magnetotail, but others are not readly compatible with the standard view. Important findings are as follows. (1) The plasma convection is directed from the lobe toward the plasma sheet near the midnight meridian plane as is consistent with the standard theory. (2) Near the flanks of the magnetotail, however, the convection direction is reversed, that is, directed from the plasma sheet to the lobe. This means that two convection vortices are formed within the y-z plane for each hemisphere, and some of the plasmas convecting from high latitudes are deflected towards flanks before they reach the neutral sheet and finally return to the high-latitude portion of the tail along the flank magnetopause. (3) The sense of rotation for these plasma vortices is not apparently correlated with the sign of the z component of IMF. That is, the plasma convection always has a component directed toward the plasma sheet near the midnight meridian even in the case of northward IMF. This probably means that the conversion process of closed field lines to open field lines is occurring at the dayside magnetopause even during periods of northward IMF. The reverse convection expected for the northward IMF seems to be spatially limited to the higher latitude portion of the tail not covered by GEOTAIL observations. (4) The effect of the y-component of the IMF is visible as an intensification of one of the two vortices, whose dawn-dusk asymmetry is controlled by IMF-By.The effect is smaller than expected, and barely visible at the distances of x=-15 to -25 Re.

ENERGETIC ELECTRON TRANSPORT IN THE EARTH'S MAGNETOTAIL: THE DAWN-DUSK ASYMMETRY

Shinsuke IMADA[1], Masahiro HOSHINO[1], Toshifumi MUKAI[2] ([1]Department of Earth and Planetary Science, University of Tokyo, [2]Institute of Space and Astronautical Science)

The particle acceleration and transport of energetic electrons are the essential and fundamental problems in space. To reveal the origin of energetic particles, several past

satellite observations contributed to understanding these problems. Both of the local structure such as magnetic reconnection and the global structure of the magnetotail which depend on the solar wind condition are important to understand the accelerating and transport mechanism of energetic electrons. We conduct a statistical and systematical study of the dawn-dusk plasma sheet/magnetosheath asymmetry using both the thermal/middle energy electrons of < 40 keV (LEP) and the energetic electrons of >38keV (EPIC) onboard the Geotail satellite. The dawn-dusk plasma sheet asymmetry can be confirmed for the energetic electrons of > 38 keV, while the asymmetry is not clearly found for the low energy electrons of < 10 keV. These results are consistent with the dawn-dusk plasma sheet asymmetry of energetic particles observed by the Interball [Sarafopoulos et al., 2001]. The similar energy dependence can be found for the magnetosheath plasma adjacent to the magnetopause. This result can be interpreted as the result of the leakage of plasma sheet electrons to magnetosheath. To confirm the above, we also studied the 60 magnetopause crossing events in detail. From the 60 magnetopause crossing events, we discuss from LLBL to magnetosheath energetic electrons. We find that the leakage process of energetic electrons from the plasma sheet to the magnetosheath is controlled by the local IMF Bz and magnetopause conditions, and energetic electrons flux intensity are decrease gradually through the magnetopause boundary layer which scale is defined by ion thermal. These results suggest that the energetic electrons effectively leak from plasma sheet to magnetosheath.

GAIII.05/07A/A06-003   0930

MAGNETOTAIL OBSERVATIONS DURING LONG INTERVALS OF SOUTHWARD IMF BZ: TRANSITION FROM LOADING-UNLOADING TO STEADY MAGNETOSPHERIC CONVECTION

E. TANSKANEN[1], J.A. SLAVIN[1], D.H. FAIRFIELD[1], D.G. SIBECK[1], T. MUKAI[2], T. NAGAI[3], A. IEDA[2] ([1]Nasa Goddard Space Flight Center, Greenbelt, USA, [2]Institute of Space and Astronautical Sciences, Japan, [3]Tokyo Institute of Technology, Earth and Planetary Sciences, Japan)

In this study we have examined the response of the Earth´s magnetotail to long intervals of southward interplanetary magnetic field (IMF $B_z < 0$). Southward IMF B_z is known to produce enhanced energy input into the magnetosphere. We used ACE interplanetary magnetic field (IMF) observations to identify prolonged (>2h, >3h, >4h, >5 hours) periods of southward IMF B_z during the last four Geotail seasons in the magnetotail (November through April, 1998 through 2002). Geotail plasma sheet observations obtained during these intervals are classified as ´steady magnetospheric convection´ or ´periodic loading-unloading´. Examples of both responses have been found and will be described. We will present statistical analyses of the frequency of the occurrence of both types of tail convection, estimate the relative contributions of each to the tail energy budget, and determine their relationship to the upstream solar wind and IMF conditions.

GAIII.05/07A/A06-004   0945

TAIL LOBE CONVECTION AS OBSERVED BY CLUSTER/EDI 2001-2002

Stefan MUEHLBACHLER[1], Hirotomo NODA[2], Rumi NAKAMURA[1], Wolfgang BAUMJOHANN[1], Götz PASCHMANN[3], Hans VAITH[3], Pamela PUHL-QUINN[4], Roy B. TORBERT[4], Jack M. QUINN[4], Helfried K. BIERNAT[1], Helmut O. RUCKER[1] ([1]Space Research Institute, Austrian Academy of Sciences, Schmiedlstr. 6, 8042 Graz, Austria, [2]National Astronomical Observatory of Japan, Tokyo, Japan, [3]Max-Planck Institute for Extraterrestrial Physics, Garching, Germany, [4]Institute of the Study of Earth, Oceans, and Space, University of New Hampshire, Durham, USA)

One of the major parameters influencing phenomena within the terrestrial magnetosphere is the orientation of the interplanetary magnetic field (IMF). This orientation is illustrated in the IMF clock angle. In this paper we study average tail lobe convection of the terrestrial magnetosphere as a function of the IMF clockangle and extend earlier work of the authors. For this we used drift velocity data from the years 2001 and 2002 measured in the near-Earth tail lobe by the Cluster Electron Drift Instrument. The data confirm the convection pattern toward the neutral sheet in the meridional (XZ) plane. As a result of the solarwind-induced electric field to the magnetotail lobe via daysidereconnection we find that the IMF B_y component controls the convection direction in the perpendicular to the Sun-Earth line (YZ). The convection velocity becomes smallest for positive IMF B_z and largest for negative IMF B_z.

GAIII.05/07A/A06-005   Invited   1000

FORMATIONS OF THE CUSP AND PLASMA SHEET AS A PART OF DYNAMO PROCESS DRIVING THE CONVECTION

Takashi TANAKA (Department of earth and planetary science, Kyushu University)

Based on the magnetosphere-ionosphere coupling scheme, convection as a compound system is considered including the generation of plasma population regimes in the magnetotail. In these considerations, primary elements that must be set to a self-consistent configuration are convection flows in the magnetosphere and the ionosphere, filed aligned current (FAC) systems, ionospheric currents, energy conversion processes, and plasma population. Then from the magnetohydrodynamic force balance controlling the convection, plasma population regimes such as the cusp and plasma sheet are shown to be indispensable to fulfill the self-consistency in the convection system. In the traditional Dungey model, the line-tying current which overlaps on the shoulder of the magnetosphere behind the cusp with the pure Chapman-Ferraro current drives the convection. This overlapping region must be the dynamo (J•E <0) for the region 1 current system. However, it results in a peculiar current configuration in which same current simultaneously branches to the dayside Chapman-Ferraro current and region 1 current at the frank magnetopause. Therefore, the confinement of earth's magnetic field conflicts with the generation of region 1 FAC, resulting in a statement that the generation of open field lines and following stretching is the primary cause of magnetotail formation. In the present model, however, the confinement of earth's magnetic field by the dynamic pressure is the primary cause of the magnetotail formation. With negative IMF Bz, the Chapman-Ferraro current is not directly connected with the region-1 FAC but connected with the neutral sheet current in the dayside merging region. As a consequence, tangential Maxwell stress on the magnetopause acts to increase plasma internal energy around the cusp. This configuration is also same to tail theta current system in which tangential Maxwell stress on the tail surface acts to increase plasma internal energy in the plasma sheet through the convection. The plasma internal energy accumulated in the cusp and plasma sheet further drives the region 1 and 2 FAC, respectively. Thus, mechanisms to drive the region 1 and region 2 current systems are the same two step process; the tangential Maxwell stress on the magnetopause pumps up plasma internal energy, then plasma internal energy drives the FACs.

GAIII.05/07A/A06-006   1025

DEDUCING THE LENGTH OF THE MAGNETOTAIL FROM GEOTAIL, POLAR, AND WIND OBSERVATIONS OF TAPERED TAIL LOW FREQUENCY BURSTS

Roger R. ANDERSON[1], Roger R. ANDERSON[2], Hiroshi MATSUMOTO[2], Kozo HASHIMOTO[2],

Hirotsugu KOJIMA[2], Michael L. KAISER[3], Jean-Louis BOUGERET[4], Jean-Louis STEINBERG[4] ([1]Department of Physics and Astronomy, The University of Iowa, Room 615 Van Allen Hall, Iowa City, IA 52242-1479, USA (roger-r-anderson@uiowa.edu), [2]Radio Science Center for Space and Atmosphere, Kyoto University, Gokanosho, Uji, Kyoto 611-0011, JAPAN (anderson, matsumot, kozo, or kojima@kurasc.kyoto-u.ac.jp), [3]NASA Goddard Space Flight Center, Laboratory for Extraterrestrial Physics, Code 695, Greenbelt, MD 20771, USA (kaiser@lepmlk.gsfc.nasa.gov), [4]LESIA, Observatoire de Paris-Meudon, F-91295 Meudon Cedex, FRANCE (Jean-Louis.Bougeret or Jean-Louis.Steinberg@obspm.fr))

Among the more interesting phenomena detected by the GEOTAIL and POLAR Plasma Wave Instruments (PWIs) and the WIND Radio Science Experiment (WAVES) are the auroral kilometric radiation (AKR) low frequency (LF) bursts. These electromagnetic emissions are the low frequency extension of AKR and are most frequently observed during the most geomagnetically disturbed times. In the solar wind the LF bursts are observed to extend in frequency down to the local electron plasma frequency (Fpe) with increasing time delay the lower the frequency. In the magnetosphere the LF bursts often display a tapered tail that has maximum time delay at a distinct frequency which we call Ftt. The LF bursts then show increasing time delay as Ftt is approached from frequencies above it and from frequencies below it. When one of the spacecraft is in the solar wind and another is in the magnetosphere during a LF burst observation, we see that Ftt almost always appears equal to the solar wind Fpe in the near past (some few hours). We speculate that AKR generated in the Earth´s magnetospheric auroral region at frequencies below the magnetosheath plasma frequency (2Fpe near the nose) is reflected and refracted down the tail since it cannot penetrate the magnetosheath directly. As it travels down the tail, AKR of a given frequency finally reaches a point where the tail magnetosheath plasma frequency is equal to it and it can propagate into the solar wind. Ftt is believed to be the AKR frequency which is equal to the local solar wind plasma frequency at the point down the tail where the magnetosheath frequency and local solar wind plasma frequency are equal and where waves of this frequency are broadly scattered. Upstream in situ measurements of the solar wind Fpe and the flow speed allow us to determine how far down the tail the local solar wind Fpe and Ftt are equal. The results so far have ranged from 200 Re to 2000 Re which is the same range found from other methods.

GAIII.05/07A/A06-007   1055

SUBSTORM ONSET BY PLASMA SHEET DIVERGENCE

Larry R. LYONS[1], Chih-Ping WANG[1], Tsugunobu NAGAI[2], John C. SAMSON[3] ([1]Department of Atmospheric Sciences, UCLA, [2]Department of Earth and Planetary Sciences, Tokyo Institute of Technology, [3]Dept. of Physics, University of Alberta)

Substorms have been an active research topic for over thirty years. However, there is as yet no general agreement on what causes the substorm expansion phase. To understanding the cause of the expansion phase, it is necessary to understand what cause the formation of the substorm current wedge. This can be shown to be equivalent to understanding what causes a reduction in equatorial plasma pressure within the current wedge and an azimuthal gradient in equatorial pressure. We first use Geotail spacecraft measurements obtained near the center of plasma sheet at r ~10 RE to show that a reduction in equatorial plasma pressure is indeed a general feature of substorms. We also show that, when viewed as a function of the adiabatic invariant parameter for the plasma sheet, there is actually a reduction in particle fluxes at all invariant energies despite the flux enhancements seen when energetic particle fluxes are viewed at fixed particle energy. This shows that the expansion phase is associated with a significant reduction in the flux tube content of plasma sheet particles, and that this reduction in flux tube content gives the reduction of equatorial plasma pressure that leads to the formation of the substorm current wedge. After discussing the Geotail observations, we apply the continuity equation for plasma sheet particles derived by Heinemann [J. Geophys. Res., 104, 28,397, 1999]. We show that this equation can account for the growth-phase enhancement in plasma pressure that occurs after an increase in the strength of magnetospheric convection. It is now known that that the majority of substorms are associated with reductions in the strength of large-scale convection that is imparted to the magnetosphere from the solar wind, and we apply the Heinemann continuity equation to show that diamagnetic drift should lead to a divergence of plasma sheet particles following a reduction in the strength of magnetospheric convection. We furthermore show that this divergence should lead to a reduction of flux tube content that is appropriate to account for current wedge formation and thus the initiation of the substorm expansion phase.

GAIII.05/07A/A06-008   1120

IMPLICATIONS OF THE DOUBLE OVAL FOR SUBSTORM DEVELOPMENT IN THE MAGNETOTAIL

Gordon ROSTOKER (Department of Physics , University of Alberta)

It is now clear that substorm activity develops in two separate regions of space. The onset occurs in the equatorward portion of the midnight sector auroral oval, mapping to the inner region of the plasma sheet. However, most of the dynamic variations in the later stages of the substorm occur at the poleward edge of the oval, mapping to regions considerably further out in the magnetotail. In this paper, I will summarize the evolution of a typical substorm as detected in the ionosphere. I will relate each of the ionospheric signatures to the regions of the magnetotail to which they must map, and in doing so identify changes in the tail plasma and fields which relate to the ionospheric observations. Particular attention will be paid to the relevance of bursty bulk flows to substorm features in the ionosphere.

GAIII.05/07A/A06-009   1135

CURENT SHEET FORMATION, SUBSTORM ONSET AND DIPOLARIZATION

C.Z. CHENG, S. ZAHARIA (Princeton Plasma Physics Laboratory, Princeton University)

At the end of the substorm growth phase, the plasma pressure profile steepens and a thin current sheet is formed in the near-Earth plasmasheet around the local midnight with a finite radial and azimuthal domain. In the current sheet the plasma beta becomes about 50 or larger and magnetic field curvature is enhanced. We find that the kinetic ballooning instability (KBI) can be excited with amplitude localized at the maximum plasma beta region. The KBI explains the low frequency(about 1 min period) instability observed by AMPTE/CCE with period on the order of 1 min is observed about 2-3 minutes before the substorm onset [Cheng and Lui, GRL, 1998]. Recent observations by Geotail at X = -10 R_E have also confirmed the low frequency instability before or during substorm expansion. The KBI is responsible for substorm onset because as it grows to a large amplitude with dB/B >01, it causes an enhanced westward ion drift during the explosive growth phase that lasts about 30 sec. The KBI then excites higher frequency instabilities, and the plasma and magnetic field become strongly turbulent. The plasma transport in both radial and azimuthal direction caused by the turbulence relaxes the steep plasma pressure profile during the expansion phase. As the plasma pressure profile relaxes, the magnetic field configuration dipolarizes and returns to the pre-substorm more dipole-like geometry. Theories of current sheet formation, KBI mechanism and dipolarization will be presented along with numerical solutions of 3D

A

magnetospheric structure.

THE RELATIONSHIP AMONG NEAR-TAIL MAGNETIC RECONNECTION, GEOSYNCHRONOUS SAWTOOTH INJECTIONS, PERIODIC MAGNETOSPHERIC SUBSTORMS, AND SOLAR WIND VARIATIONS

Chaosong HUANG (Haystack Observatory, Massachusetts Institute of Technology, Westford, MA 01886, USA)

Outstanding problems in magnetospheric substorms include what causes substorm onsets, whether substorms have some specific periodicity, and what determines the periodicity. We will present multiple space-based and ground based observations of solar wind, magnetospheric, and ionospheric parameters during two magnetic storms. Energetic plasma particle injections from the magnetotail to geosynchronous orbit are often periodic with periods of 2-3 hours during storms. We will show that there is a one-to-one correspondence among the near-tail reconnection onsets, particle injections at geosynchronous orbit, energetic neutral atom emissions in the inner magnetosphere, and auroral brightenings. The multiple measurements provide unambiguous evidence that the sawtooth injections at geosynchronous orbit represent true substorm onsets and that magnetospheric substorms can be indeed periodic. Solar wind variations may trigger the periodic substorms. However, the period of substorms is determined by the magnetosphere. We suggest that magnetospheric substorms have an intrinsic cycle time of 2-3 hours. If solar wind pressure oscillations with periods comparable to the substorm cycle time are imposed on the magnetosphere, some magnetospheric resonant state may be excited, and periodic substorms can be triggered. Otherwise, if the solar wind oscillates too fast, no enough energy is accumulated in the magnetotail for substorms to occur; if the period of solar wind pressure oscillations is too long, magnetospheric energy may be released through other processes including internally triggered substorms.

CLUSTER OBSERVATIONS OF MAGNETOPSHERIC SUBSTORM BEHAVIOR IN THE MID-TAIL REGIONS

Daniel N. BAKER[1], Robert L. MCPHERRON[2] ([1]Laboratory for Atmospheric and Space Physics, [2]IGPP/Univ. California Los Angeles)

The Cluster constellation of spacecraft has returned a wealth of new data on particle and field variations in the near- and mid-magnetotail region of Earth's magnetosphere. Using the Research with Adaptive Particle Imaging Detectors (RAPID) systems onboard the four Cluster vehicles, we have identified substorm-related energetic (E >20 keV) electron enhancement events during the period March 2001 through October 2001 in the geocentric radial range of 4 to 19 Earth radii. A similar seasonal interval has been examined for the Cluster tail passages of 2002. We have used concurrent data from other Cluster instruments as well as from the IMAGE, FAST, GPS, and geostationary orbit spacecraft in order to understand particle injection and transport phenomena throughout this key region of the magnetotail. Electron enhancements in the plasma sheet at intermediate radial distances have been studied in a global substorm context. We find evidence that Cluster was often very near the near-Earth substorm neutral line and that magnetic reconnection often is closely associated with the substorm auroral brightening of the expansive phase onset. Several examples of these relationships will be discussed.

A SELF-CONSISTENT TWO DIMENSIONAL CONFIGURATION FOR THE MAGNETOTAIL

Devashis BANERJEE, Gurbax Singh LAKHINA, Satyavir SINGH (Indian Institute of Geomagnetism)

A physically plausible two-dimensional (say x- and z-dependent) equilibrium configurations for magnetotail, ignoring variations in the cross-tail direction ($\partial Y \equiv 0$) is studied analytically. The asymptotic theories valid for tail configurations that vary only weakly in the antisolar direction. The magnetotail equilibria by using an asymptotic expansion parameter ε, defined as the ratio of the charateristic lengths in z and x directions (ε=LZ/LX), upto O(ε). In the present analysis, the effects of directed flow are being neglected and pressure function is assumed to remain isotropic throughout in the tail configuration. The cross-tail magnetic field along with poloidal fields have been incorporated for the first time in the formulation to obtain a more realistic equilibrium configurations. The formulation is self-consistent in the sense that the kinetic pressure forces are taken as the same order as the stresses exerted by the magnetic field for any volume element in the framework of Vlasov's theory. The asymptotic expansion solutions are valid only for the tail region where the conditions $\varepsilon \ll 1$, $|BZ| / |BX|_{max} \ll 1$, and $|BY| / |BX|_{max} \ll 1$. The analytical forms of the solutions are determined for all three magnetic field components, particle density function, pressure function, all three components of the drift velocities and the corresponding drifted Maxwellian distribution function satisfying the Maxwell-Vlasov equation. These solutions can reproduce the one dimensional Harris solutions in the limiting case.

3D FORCE-BALANCED MAGNETOSPHERIC STRUCTURES

Sorin G. ZAHARIA, C.Z. CHENG (Princeton University, Plasma Physics Laboratory)

For most times, the average plasma flow energy in the Earth's magnetosphere is much smaller than the plasma thermal energy, therefore the magnetosphereexhibits a ``quasi-equilibrium'' between the Lorentz force **J x B** and the plasma pressure force. Because the magnetic field configurations given by empirical models commonly in use in the magnetospheric physics community are not force-balanced states and because force-balanced states are crucial for many physical applications, it is necessary to find an alternate

---

way of obtaining magnetospheric configurations. Such a model is presented, in which 3D solutions are calculated for magnetospheric fields and currents in force balance with several pressure distributions observed bysatellites (e.g. Geotail). The fully 3D magnetospheric states are obtained by expressing the magnetic field in terms of Euler potentials and numerically solving the equation of force balance in a flux coordinate system. The calculation domain includes both closed and open magnetospheric field regions,and its boundaries are dependent on external conditions such as the solar winddynamic pressure and interplanetary magnetic field (IMF). The output of our model will be discussed for both quiet and active magnetospheric conditions. The emphasis of the discussion will be on the structure of the magnetotailand the plasma sheet in particular, where the plasma β is verylarge (typically $\beta > 100$) and therefore the pressure cruciallydetermines the magnetic field configuration. We will also discuss theappearance of thin cross-tail current sheets close to Earth ($|X| < 10$ R_E)during active magnetospheric times, whose existence has been observationally confirmed. By gradually changing the boundary conditions and pressure profiles,the model also allows one to obtain a series of ``snapshots´´ of the magnetosphere at different times, thus permitting for example the study of theslow temporal variations in the magnetotail during events such as the magnetospheric substorm onset.

MAGNETOTAIL ASSIMILATION MODEL

Simon WING, Patrick T. NEWELL (Applied Physics Laboratory, Johns Hopkins University)

Progress in space plasma physics requires coordinated analysis of multi-point observations and hence, many upcoming ionospheric and magnetospheric missions will consist of multispacecraft. With the launch dates of these missions only a few years away, there is an urgent need to develop a method that can assimilate the unprecedentedly large multi-point data sets in coherent and unified manners. We have recently developed a technique that integrates low-altitude ionospheric observations to create 2-D/3-D global images of the plasma sheet ion pressure, temperature, and density. This method relies on the plasma sheet plasma isotropy, which has a strong theoretical foundation as well as overwhelming observational supports. Previously developed algorithms are used to detect the plasma isotropy boundary and to detect and exclude acceleration events. The plasma properties obtained with this method compare favorably with previous in situ measurements in the magnetotail. The technique can be refined to include mid-altitude and high-altitude observations. Therefore, it can serve as a foundation for building a model that assimilates multi-point plasma observations from multi-spacecraft missions into globally coherent and unified images of the magnetotail, tailward of ~8-10 Re. The power this method for magnetotail investigations is illustrated in two examples: (1) the dynamics of the 2D equatorial plasma sheet under northward and southward IMF orientations and (2) the quiet time plasma sheet ion pressure contribution to the field-aligned currents.

ENHANCEMENT OF PLASMA SHEET DENSITIES DURING LOW-DENSITY SOLAR WIND INTERVALS

Masaki N. NISHINO[1], Toshio TERASAWA[1], Masahiro HOSHINO[1], Masaki FUJIMOTO[2], Toshifumi MUKAI[3], Yasumasa KASABA[3], Hirotsugu KOJIMA[4], Hiroshi MATSUMOTO[4] ([1]University of Tokyo, [2]Tokyo Institude of Technology, [3]Institute of Space and Astronautical Science, [4]RASC)

It has been known that density (Nps) andtemperature in the near-earth plasma sheet arecontrolled by density (Nsw) and velocity of the solar wind. Especially, during northward IMF (NIMF)intervals the near-earth plasma sheet is filled with a cold anddense plasma, for which Nps/Nsw becomes as large as 20%.It is noted that the this ratio, Nps/Nsw ~20%, was obtained under the nominal NIMF solar wind condition where the Nsw >~1/cc.It is of interest whether this percentageholds under the extremely low densitysolar wind condition, which has recentlyattracted massive attention (e.g., theMay 1999 event of ´solar wind disappearance´).We have made a search for low-Nsw and NIMF intervals during (or shortly after) which Geotail measured the plasma sheet status. What we have found is quite remarkable:The ratio Nps/Nsw could become as large as~1 during such intervals. We will discuss the physical implications of such large enhancementof Nps/Nsw for the understanding of theplasma transport process from the solar wind to the plasma sheet.

THE SPATIAL DISTRIBUTION AND TEMPORAL VARIATION OF THE TOTAL PRESSURE IN THE DISTANT MAGNETOTAIL

Ayako MATSUOKA (Institute of Space and Astronautical Science)

The total pressure in the magnetotail depends on the distance from the earth and also on the solar wind condition. In order to study the dynamics of the magnetosphere, it is important to know the spatial distribution and temporal variation of the pressure. We statistically analyzed the total pressure measured by GEOTAIL in the distance between 30 and 220 Re. We found that the pressure at X > -150 Re was mainly influenced by the dynamic pressure in the solar wind while that for X < -150 Re was often determined by the static pressure in the solar wind. Moreover, we found that, when the solar wind condition quickly changed or the magnetotail condition was disturbed, the measured pressure is sometimes considerably different from the predicted one from our statistics. We investigated an observation on 941002 in detail where static pressure variations in the distant magnetotail lobe were caused by the passage of a plasmoid. The traveling speed of the plasmoid is estimated to have been faster than the concurrent magnetosonic speed in the lobe. The magnetic field variation along the maximum variance direction was linearly related to the variation in the field strength, which suggests that a magneto-hydrodynamic compressional mode might have occurred. The propagation direction of the variation is determined from the background field direction and the maximum variance direction of the field. Shortly after the passage of the plasmoid, the relation between the field and velocity variations is consistent with the fast mode. Pressure variation in the fast mode was possibly generated in the trail of the plasmoid to restore equilibrium. ACKNOWLEDGMENTS: We are grateful to Drs. T. Mukai and T. Nagai for providing the LEP and MGF data from Geotail.

SLOW MHD WAVES AND DIAMAGNETIC PROCESSES IN THE MAGNETOTAIL PLASMA SHEET

Aoi NAKAMIZO[1], Takesi IIJIMA[2] ([1]Department of Earth and Planetary Sciences, Kyushu University, [2]Communications Research Laboratory)

We focused on the changes of three kinds of energy density (plasma kinetic energy density, plasma internal energy density and magnetic energy density) in the magnetotail plasma sheet, considering their primary importance, their relationship and their flux transport. Using the magnetic field and low-energy particle data measured by the MGF and LEP instruments on board the Geotail satellite, we investigated the disturbances occurred in the magnetotail

---

region with a geocentric distance of ~9 to 30 R_e. We divided the disturbances into the Pi2-range (with a period of ~40-150s) variations (hereafter magnetotail Pi2s) and the background disturbances on which the magnetotail Pi2s are superimposed. Confirmed characteristics were as follows: In magnetotail Pi2s, (1) magnetic pressure perturbation and thermal pressure perturbation vary exactly in out-of-phase. (2) The field-aligned energy fluxes due to the plasma pressure perturbation along the magnetic field and the magnetic tangential stress (i.e. the Poynting vector component along the magnetic field) are much larger than the energy fluxes due to the magnetic and plasma pressure perturbations perpendicular to the magnetic field. The substance of magnetotail Pi2 is the slow MHD wave. The Poynting vector component parallel to the magnetic field is often directed toward the ionosphere, indicating coexistence and/or the coupling of the slow and transverse Alfven wave. In background disturbances, <1>the internal energy density and the magnetic energy density are dominant in the energy balance (the contribution of the kinetic energy density is usually much weaker), and the time changes of them are always in out-of phase, in turn, the plasma thermal pressure and the magnetic pressure vary exactly in out-of-phase. <2> The intensity of the energy flux is greater in the direction parallel to the magnetic field than in the direction transverse to it. These tendencies are similar to the characteristics of the magnetotail Pi2s. The nature of background disturbances indicates slow MHD disturbances. The plasma fluid clearly exhibits the diamagnetic properties. We suggests the importance (and/or dominance) of diamagnetic currents in the current system of magnetotail in terms of the time changes of its configuration and magnitude.

FAST FLOWS AND COMPRESSIONAL WAVES IN THE MAGNETOTAIL

Martin VOLWERK[1], Rumi NAKAMURA[1], Wolfgang BAUMJOHANN[1], Andrei RUNOV[1], Zoltan VOROS[1], Tielong ZHANG[1], Karl-Heinz GLASSMEIER[2], Rudolf TREUMANN[3], Berndt KLECKER[3], Andre BALOGH[4], Henri REME[5] ([1]IWF/OEAW, Graz, Austria, [2]TU Braunschweig, Germany, [3]MPE, Garching, Germany, [4]Imperial College, London, UK, [5]CESR/CNRS, Toulouse, France)

Compressional waves are responsible for the main wave power in the Earth´s current sheet [Bauer et al., JGR 100, 9605, 1995]. We now study 2 years of Cluster magnetotail crossings and search for prolonged (12 minutes) intervals in which the spacecraft were in or near the neutral sheet. We relate the results from spectral analysis of the (FGM) magnetic field data with the flow velocities measured by the (CIS-CODIF) plasma instrument. For fast flows in the neutral sheet (>150 km/s) the power level of the turbulence in the frequency range 0.08 < f < 1 Hz. is greater than the noise level of the instrument. We will show that the spectral index for the compressional waves lies around 3, indicative of fully developed 2D turbulence. The finite extension of the current sheet in z determines the 2 dimensionality and it can be shown that its z-extent also determines the break in the powerspectrum at low frequencies. Using a proxy for the total power in this ″high-frequency″ turbulence we find that there is a linear relationship between flow velocity and power. We also integrate the total power in the Pi2 band, and relate that to the flow velocity. We find that pre-midnight sector of the magnetotail shows greater Pi2 power, albeit with a larger spread, than the post-midnight sector. The power in the turbulence and in the Pi2 are highly correlated.

CHARACTERISTICS OF ENERGY-DISPERSED ION SIGNATURES IN THE PLASMA SHEET OBSERVED BY GEOTAIL

Yoichi KAZAMA[1], Toshifumi MUKAI[2] ([1]Swedish Institute of Space Physics, [2]Institute of Space and Astronautical Science)

Based on the Geotail observations, we have found unexpectedly frequentoccurrence of the dispersed ions in the plasma sheet. We reportcharacteristics of energy dispersed ion signatures in the magnetotailregion by event study and statistical study. The dispersed signatureobserved in October 10, 1997 was studied in detail. It is found thatdispersed ions can be categorized into two types by their sourceregions, such as the magnetosphere and the ionosphere. The analysisshowed that magnetospheric ions were accelerated probably by fastflows in the plasma sheet at 20-30 Re down the tail. On the otherhand, the ionospheric protons were launched nearly at the same timeinto the same flux tube with the magnetospheric ions. To investigatethe dispersed ions statistically we selected 172 events from Geotaildata by visual inspection. The results from the statistical analysisindicate that the dispersed events occur with the dipolarizationsignatures, fast bulk flows, electron parallel pressure enhancement,and magnetic field disturbances. The dispersed ion events accompaniedwith ionospheric ions occupy approximately 40% of the selecteddispersed events, and hence are not of special cases in the near-Earthplasma sheet. To investigate the relation between the tail events andthe ionospheric ones, 18 events are selected by criteria in which theevents have clear dispersed signatures for both the ionospheric andthe magnetospheric ions. The results show that the magnetospheric ionscome mainly from a mid-tail region (~40-50Re downtail), but also fromthe distant tail (XGSM <140Re). The distance is rather unexpectedlyfar, and further study should be pursued. The results also indicatethat some disturbances in the tail might cause the ionospheric ionacceleration into the same flux tube.

ANALYSIS OF THE GEOTAIL CLOSE ENCOUNTER DATA WITH THE MAGNETIC NEUTRAL LINE UTILIZING THE GENERALIZED OHM'S LAW

Shinobu MACHIDA[1], Tsugunobu NAGAI[2], Masahiro HOSHINO[3], Masaki FUJIMOTO[2], Iku SHINOHARA[4], Yoshifumi SAITO[4], Toshifumi MUKAI[4] ([1]Department of Geophysics, Kyoto University, [2]Dept. Earth & Planetary Sci., Tokyo Inst. Tech., [3]Dept. Earth & Planetary Physics, Univ. Tokyo, [4]Inst. of Space & Astronautical Sci.)

 We have conducted an analysis of the Geotail data obtained at around 1750UT on December 10, 1996 with the use of the generalized Ohm's law. This is one of the best close encounter data of Geotail with the magnetic neutral line. By analyzing the time series of the y-component of E, VxB and JxB/qN contained in the generalized Ohm's law, we found that it is impossible to achieve a balance only with those three terms without invoking other terms that are related to the violation of frozen-in relation. Namely, the time series data of JxB/qN term has the largest amplitude and a spiky structure, while the VxB has the smallest amplitude and shows gradual time variation. This tendency becomes apparent when we take the Fourier spectrum of these data. The Fourier amplitude of the (JxB)y/qN does not attenuate in the high frequency domain and largely has a flat distribution although there are jerky structures. In contrast, the Fourier amplitude of (VxB)y rapidly decreases as a function of frequency. The Ey has a moderate structure. The amplitudes of these three curves roughly agree in the very low frequency domain, i.e., below 0.002 Hz. The result of the Fourier analysis suggests that the actual Ey, an approximated electric field -(VixB)y from ion flow, and -(VexB)y from electron flow roughly agree in the low frequency domain, but not in the high frequency domain. As a result, it is not possible to achieve a balance among E, VxB and JxB/N in the generalized Ohm's law without invoking other terms associated with the violation of frozen-in relation between the magnetic field and plasma. We also found a correlated time variation between the wave electric field and (JxB)y/qN term, suggesting a

---

significance of the anomalous resistivity in the PSBL region. In the vicinity of the magnetic neutral line, the frozen-in relation seems to approximately hold. However, this relation should be violated at the real center of the neutral line. The combined analysis of the Geotail data with the generalized Ohm's law gives us a comprehensive tool for detecting and understanding the nature of the magnetic neutral line.

ELECTRIC AND MAGNETIC FIELD FLUCTUATIONSIN THE NEAR-EARTH MAGNETOTAILASSOCIATED WITH DIPOLARIZATIONS:GEOTAIL OBSERVATIONS

Yukinaga MIYASHITA[1], Shinobu MACHIDA[2], Yohsuke KAMIDE[1], Toshifumi MUKAI[3], Yoshifumi SAITO[3], Hajime HAYAKAWA[3], Koichiro TSURUDA[3] ([1]Solar-Terrestrial Environment Laboratory, Nagoya University, [2]Department of Geophysics, Kyoto University, [3]The Institute of Space and Astronautical Science)

By using GEOTAIL data, we have studied electric and magnetic fieldfluctuations in the near-Earth magnetotail around X=-10 Re justbefore and after dipolarization onsets. We focused our examinationon a low-frequency range from 1 Hz to a few tens of Hz, includingthe lower-hybrid frequency. It was found that about 1-2 minutesbefore dipolarizations, electric field fluctuations from 1 Hz toabout 20 Hz were observed in some events, while no fluctuationswere observed in other events. There was a tendency for the plasmaβ to be larger in the latter events than in the former events.Then broadband electric field fluctuations in the range of 1-32 Hzand magnetic filed fluctuations below the lower-hybrid frequencywere observed in association with dipolarizations. The wavepropagation angle was nearly perpendicular to the ambient magneticfield. Furthermore, electrons and ions were heated in the eventsin which the electric field fluctuations were seen beforedipolarizations, while electrons were not very much heatedin the events without the prior electric field fluctuations.We will discuss the role and generation mechanism of thespre-dipolarization electric field fluctuations forunderstanding the substorm triggering mechanisms.

GAIII.05/07P/D-011   Poster   1400-109

STATISTICAL ANALYSIS OF THE RESPONSE OF THE SYNCHRONOUS MAGNETIC FIELD TO SUBSTORM EXPANSIONS

Tung-Shin HSU, Robert L. MCPHERRON (Institute of Geophysics and Planetary Physics, UCLA, USA)

It is generally accepted that the synchronous magnetic field becomes more tail-like during the growth phase and more dipole-like during the expansion phase of magnetospheric substorms. However, a close examination of high resolution data reveals that the various components of the field do not always respond at the same time, and that there are significant delays in the onset of effects at different local times. In this paper we examine a number of substorms from the ISTP era for which we have detailed information about the time history of activity. We utilize superposed epoch analysis to characterize the response of each component of the synchronous field as a function of the locations of the spacecraft from the center of the substorm current wedge. The center of the substorm current wedge is determined by the extensive ground observations and/or auroral images. We will attempt to interpret the observations in terms of various current systems thought to be present at substorm onset.

GAIII.05/07P/D-012   Poster   1400-110

FORMATION OF THE SUBSTORM CURRENT WEDGE INSIDE OF THE GEOSYNCHRONOUS ORBIT: A CASE STUDY OF THE MAY 27, 1997, STORM-TIME SUBSTORM

Tetsuya SHIRAISHI[1], Hideaki KAWANO[1], Kiyohumi YUMOTO[2], Akira MORIOKA[3] ([1]Department of Earth and Planetary Sciences, Kyushu University, Japan, [2]Space Environment Research Center, Kyushu University, Japan, [3]Planetary Plasma and Atmospheric Research Center, Tohoku University, Japan)

It is well known that the substorm current wedge is formed in the region of -6.6 >X >-15Re during the expansion phase of isolated substorms. However, it has not been well studied where the substorm current wedge is formed during the expansion phase of storm-time substorms. We study the formation of the substorm current wedge in a storm-time substorm which took place on May 27, 1997. In this event, many substorm onset signatures were observed at various regions (auroral ionosphere, high, mid and low-latitude ground geomagnetic stations and geosynchronous orbit). POLAR/UVI showed that auroral breakup occurred at latitudes lower than 60 MLat. and 2200-2230 MLT at 0501:57 UT. A clear positive bay and an isolated Pi2 pulsation were observed at a low-latitude station EUS (0.1 Mlat., 0230 MLT). A negative bay and an increase in the Z component (positive downward) were observed at a high-latitude CANOPUS station ISLL (64.7 Mlat., 2240 MLT), and this implies that the westward auroral electrojet developed at latitudes lower than ISLL. The above features suggest that the substorm current wedge was formed much closer to the Earth than usual isolated substorms. At mid-latitude stations, Y component (positive eastward) increased at the time of a positive bay at the ground stations to the west of BSL (40.8 Mlat., 2300 MLT) while it decreased at stations to the east of BSL. This feature suggests that the center of the newly formed substorm current wedge was located at 2300 MLT. The GOES 8 satellite which was located at 2400 MLT observed a clear dipolarization and an increase in the eastward component of the magnetic field. It is well known that a geosynchronous satellite which is located to the east of the center of a substorm current wedge often observes a decrease in the eastward component of the magnetic field because the substorm current wedge is often formed tailward of the geosynchronous orbit. However for our event, the GOES 8 satellite which was located to the east of the center of the substorm current wedge observed an increase in the eastward component of the magnetic field. Taking into consideration the above features, it is suggested that the substorm current wedge was formed inside of the geosynchronous orbit.

VALIDITY OF THE FLUID DESCRIPTION OF CRITICAL BETA AND ALFVEN TIME SCALE OF BALLOONING INSTABILITY ONSET IN THE NEAR-EARTH COLLISIONLESS HIGH-BETA PLASMA

Akira MIURA (Department of Earth and Planetary Science, University of Tokyo)

For a realistic highly stretched 2-D tail configuration, in which the pressure gradient force is balanced with the curved field line tension force at the equator, the growth rates of the ideal and nonideal MHD ballooning modes, in which the nonideal MHD means that the Hall and the electron pressure gradient terms are included in the Ohm's law, the ion bounce frequency, the ion magnetic drift frequency, and the ion cyclotron frequency are calculated numerically at the equator as a function of X from the near-Earth tail (X = -15 Re) to the mid-tail (X = -30 Re). Contrary to the well-known dipole field case, in which the bounce frequency decreases with increasing |X|, the ion bounce frequency increases with |X| for the 2-D tail

configuration. The growth rates of the ideal and nonideal ballooning modes, which are nearly equal, are given by the Alfven velocity divided by the field line curvature radius at the equator. The growth rates are larger than the ion bounce, ion magnetic drift frequencies and smaller than the ion cyclotron frequency in the near-Earth tail at X~ -15 Re for ions with a thermal velocity and with an average pitch angle at the equator. Also, the ion motion remains adiabatic and the magnetic moment is conserved in the near-Earth tail at X~ -15 Re. Therefore, it is a posteriori verified that the fluid or nonideal MHD description of the linear stability of the ballooning instability is valid and the critical beta and the Alfven time scale of the ballooning instability onset obtained by the fluid theory are validated in the near-Earth tail as close as 15 Re from the Earth. Despite the plasma being collisionless and high-beta in the near-Earth tail, the subtle collisionless kinetic effects due to the field line curvature in a high-beta collisionless plasma are not significant enough to invalidate the fluid description in the near-Earth tail, although they become more and more important as |X| increases. The Alfven time scale of e-folding growth of the nonideal MHD ballooning (drift ballooning) instability due to the Alfven wave trapped within a field line curvature radius in the equatorial region is usually less than a few tens of seconds in the near-Earth tail. It is faster than the ion bounce time and can explain the observed rapid time scale of a substorm onset.

GAIII.05/07P/D-014   Poster   1400-112

TAILWARD PERPENDICULAR FLOWS IN THE NEAR-EARTH PLASMA SHEET AROUND SUBSTORMS

Rui YAMAGUCHI[1], Hideaki KAWANO[1], Shinichi OHTANI[2], Kiyohumi YUMOTO[3], Kan LIOU[2], Ching MENG[2], Toshifumi MUKAI[4], Yoshifumi SAITO[4], Hajime HAYAKAWA[4], The CPMN Group[3] ([1]Dept. of Earth and Planetary Sci. Faculty of Sci. Kyushu Univ., [2]The Johns Hopkins University Applied Physics Laboratory, USA, [3]Space Environment Research Center, Kyushu University, Japan, [4]Institute of Space and Astronautical Science, Japan)

Tailward flows in the plasma sheet are sometimes observed even in thenear-Earth region (-15＜Xgsm [Re]＜-8), which have not been explained byconventional substorm models. In order to understand the cause andeffect of these flows in the framework of substorms, we haveinvestigated features of the perpendicular flows in the plasma sheetmeasured by GEOTAIL in terms of their occurrence positions, durations,relative timings to substorm onsets, motions, and structures. Thetiming of the auroral onset determined by Polar/UVI images has beenused. We have so far found (1) the tailward flows are observedubiquitously in the near-Earth plasma sheet and their average flowdirections are approximately along the Xgsm axis, (2) their occurrencerate significantly rises after substorm onsets, and (3) the tailwardflows are often preceded by earthward flows. The result (3) suggeststhat the tailward flows represent reflection of earthward flows orpassage of vortical flows. Regarding the possibility of reflection,we have statistically estimated the length of traveling path of theseflows, that is, the distance from GEOTAIL to the reflection point, asa function of the satellite position. As a result, the travel pathlength decreases as the observing position (i.e., at GEOTAIL)approaches the Earth, but thus estimated reflection point approachesthe Earth as the observing position approaches the Earth; this isunreasonable, suggesting that reflections do not occur at a fixedpoint in the near-Earth region. As for the possibility of vorticalflows, we have applied the minimum variance method to these flows.The result suggests that these flows may correspond to the vortices inthe plasma sheet for some events. We have estimated a scale and amotion of a vortex during a large substorm. The result shows that itis difficult to interpret this vortex to be a part of the wedgecurrent system.

CHARACTERISTICS OF THE GROUND MAGNETIC VARIATIONS AT LOW AND MIDDLE LATITUDE ASSOCIATED WITH THE SAWTOOTH EVENT ON APRIL 18, 2002

Kentarou KITAMURA[1], Hideaki KAWANO[2], Shin-ichi OHTANI[3], Akimasa YOSHIKAWA[2], Kiyohumi YUMOTO[2], The CPMN Group[1] ([1]Space Environment Research Center, Kyushu University, [2]Department of Earth and Planetary Sciences, Kyushu University, [3]The Johns Hopkins University Applied Physics Laboratory)

During recovery phase of a magnetic storm which occurred on 18 April, 2002, quasi periodic variations of the low-energy electron flux are observed by the LANL satellites at the geosynchronous orbit, which is named 'Sawtooth event' On the other hand, on the ground, magnetic bays and Pi2 pulsations appeared corresponding to the variations of the particle flux, and they are usually typical magnetic variations during substorms. However, any northward-turnings of the IMF-Bz corresponding to the sawtooth event were not observed by the ACE satellite. In this study, we have used the ground magnetic data from the middle and low latitude stations, which widely spread in the longitudinal direction, selected from the CPMN (Circum-Pan Pacific Magnetometer Network) stations, and compared the magnetic variations during the sawtooth event with that of the typical substorm (Lester et al., 1984). As a result, local time distribution of the polarization axis of the Pi 2 pulsations show a good agreement with that of typical substorm. However, the magnetic variations of the magnetic bay did not show a tendency typical to usual substorms. From the above, it is suggested that the current wedge was formed during this sawtooth event, and generated the Pi 2 pulsations on the ground; however, the other current system (ex. partial ring current) may have been superposed on the current wedge, and made unclear the DC-component (magnetic bay) of the substorm-associated magnetic variations on the ground.

CHARACTERISTICS OF IONOSPHERIC ECHOES WITH VERY NARROW SPECTRAL WIDTHOBSERVED BY THE SUPERDARN HF RADARS DURING GEOMAGNETICALLY ACTIVEPERIODS

Nozomu NISHITANI[1], Tadahiko OGAWA[1], Mark LESTER[2], Steve E. MILAN[2], Jim WILD[2], Stanley W.H. COWLEY[2], Natsuo SATO[3], Hisao YAMAGISHI[3], Akira Sessai YUKIMATU[3] ([1]STELAB, Nagoya University, [2]Dept. Phys. Astron., University of Leicester, [3]National Institute of Polar Research)

The spectral width of the ionospheric backscatter echoes obtained with the SuperDARN radars has been regarded as a useful tool for locating specific ionospheric regions such as the cusp. In this paper we report the presence of ionospheric echoes with high (> 450 m/s) Doppler velocity and very narrow (< 60 m/s) spectral width, observed by the CUTLASS and Syowa East and South SuperDARN radars. These echoes have the following characteristics. (1) They have a close correlation with geomagnetic activity such that as the Dst index decreases, the radars tend to observe ionospheric echoes with high Doppler velocity and very narrow spectral width more frequently. (2) Their existence does not depend on magnetic local time. (3) They are located preferably in the polar cap region, where anti-sunward convection prevails. (4) They sometimes exist over a large spatial extent, so they are more likely to be F-region rather than E-region echoes. The occurrence of these echoes during active periods is associated with the suppression of the electric field turbulence. We also show that the appearance of ionospheric echoes with very narrow spectral widths in the polar cap is associated with the highly tail-like configuration of the magnetotail, by using the geosynchronous satellites data and Cluster satellite data. This result is consistent with the statistical results and their interpretation by Golovchanskaya et al. [2002]. Detailed

---

discussion of the possible generation mechanisms of these echoes will be presented.

MAGNETOTAIL STRETCHING AS A DIAGNOSTIC TOOL FOR AURORAL SUBSTORM ENERGY DEPOSITION

Ching-I MENG, Kan LIOU, Patrick T. NEWELL (The Johns Hopkins University Applied Physics Laboratory)

Enhanced magnetotail field stretching is a key feature in the near-Earth magnetotail during enhanced couplings between the solar wind and the magnetosphere. Therefore, the degree of the field stretching is likely controlled by the amount of solar wind energy coupled into the magnetosphere, and it can be used as a proxy for the magnetospheric energy input to the ionosphere. Recent studies have shown, indeed, a good correlation between the magnetotail stretching index, b2i, and auroral power. For the purpose of space weather application this study focus on the relationship between the magnetotail stretching and auroral energy deposition during substorm periods. The data set consists of global auroral images acquired from Polar ultraviolet imager (UVI) and magnetic field data from GOES magnetometers. The strength of substorms in terms of auroral power is inferred from auroral luminosity in the long wavelength bands (160-180 nm) of molecular nitrogen Lyman-Birge-Hopfield (LBHl) auroral emissions observed from UVI, whereas the degree of magnetotail field stretch is estimated from the magnetic field elevation angles in the solar magnetic coordinates system. Universal time and seasonal effects are removed by subtracting empirical model field from the observed field. The result indicates that the relationship between the two quantities is nonlinear. We will present quantitative relationship between the two quantities and discuss the potential use of the result in substorm intensity forecasting.

AURORAL POLEWARD BOUNDARY INTENSIFICATIONS: THEIR TWO-DIMENSIONAL STRUCTURE AND THE ASSOCIATED DYNAMICS IN THE PLASMA SHEET

Eftyhia ZESTA[1], Larry R. LYONS[1], Eric DONOVAN[3], Harald U. FREY[2], Tsugunobu NAGAI[4] ([1]Department of Atmospheric Sciences, UCLA, [2]Space Sciences Laboratory, University of California, Berkeley, [3]Department of Physics, University of Calgary, [4]Department of Earth and Planetary Sciences, Tokyo Institute of Technology)

Auroral poleward boundary intensifications (PBIs) have an auroral signature in ground meridional scanning photometer (MSP) data that appears as an increase in intensity at or near the magnetic separatrix. This increase is often seen to extend equatorward through the ionospheric mapping of the plasma sheet. PBIs are associated with plasma sheet flow bursts and are thus important to plasma sheet dynamics. We previously found that equatorward extending PBIs are either north-south (NS) aligned structures or east-west (EW) arcs that mostly propagate equatorward. We further investigate the plasma sheet dynamic structures associated with these two types of PBIs by combining data from the CANOPUS MSPs, auroral images from the IMAGE spacecraft, and magnetic field and plasma data from the Geotail spacecraft. We study a period on January 3, 2001, when a series of PBIs were seen in the MSP data for 2.5 hrs. From simultaneous IMAGE and Geotail data we find that: (a) PBIs correlate well with plasma sheet fast flows observed within the local time sector of the PBIs. There can be several PBIs over the longitudinal range of fast flows in the tail, (b) multiple PBIs can occur over the whole width of the plasma sheet or in a more restricted local sector (i.e. only pre-midnight). When PBIs are seen only in a local sector fast flows are seen only in that local sector as well. Where no PBIs are seen no fast flows are seen, (c) most of the observed PBIs were EW arcs that initiated near the poleward boundary and then propagated equatorward. They often tilted and became mostly NS structures as they propagated equatorward and duskward, (d) there is a local time dependence on the type of PBI structure. Most PBIs seem to be narrow structures and primarily aligned with a line that goes through the 02 MLT and 17 MLT sectors. This results in PBIs that are NS structures in the postmidnight sector and EW arcs in the dusk sector. In the premidnight sector (22-00 MLT) PBIs start as EW arcs that then tilt and become primarily NS structures. These results suggest that the same plasma sheet dynamics produce EW and NS PBI structures.

TWO TYPES OF PSBL ION BEAMS OBSERVED BY GEOTAIL: THEIR RELATION TO LOW FREQUENCY ELECTROMAGNETIC WAVES AND COLD ION ENERGIZATION

Taku TAKADA[1], Kanako SEKI[1], Masafumi HIRAHARA[2], Toshio TERASAWA[3], Masahiro HOSHINO[3], Toshifumi MUKAI[4] ([1]STEL, Nagoya University, [2]Rikkyo University, [3]University of Tokyo, [4]Institute of Space and Astronautical Science)

The plasma sheet boundary layer (PSBL) in the Earth's magnetotail is a region where hot plasma in the plasma sheet borders on the cold lobe plasma. Plasma in PSBL often consists of counter streaming ion and/or electron beam components generated from the nightside reconnection site. Although this beam component is considered to be a main energy source of broadband waves in PSBL, the mechanism responsible for generation of low-frequency waves is not identified. On one hand, it is often seen that cold ions from the lobe are accelerated gradually up to the plasma sheet energies in PSBL [Hirahara et al., 1994]. There are many candidates of heating processes via the electrostatic [e.g., Dusenbery and Lyons, 1989] or electromagnetic waves [e.g., Gary and Winske, 1990]. However, relative contribution of electrostatic and electromagnetic instabilities to the acceleration and heating of these cold ions still remains to be understood. It is a purpose of this study to clarify the causal relation of the ion beams, waves and cold ion energization in PSBL. Using high-sampling (16 Hz) magnetic field (MGF) and 12-s low-energy particle (LEP) data of Geotail, here we investigate characteristics of low-frequency (10 mHz to 1 Hz) electromagnetic waves and their relation to changes in ion distribution functions in PSBL. Two types of the PSBL crossings are analyzed in detail: During the periods of enhanced auroral activities with southward IMF, a collimated freshly injected earthward beam is observed together with the large-amplitude electromagnetic waves having a peak around 25 mHz (~1/10 of the local ion cyclotron frequency). Cold ions are energized during the same period. Before the disturbed period, however, we observed counter-streaming thermalized beams with neither cold ion energization nor significant wave activities in the low frequency range. The themalized beams may be generated from the distant magnetotail and have undergone thermalization before reaching the Geotail position of X~-30 Re. These observations suggest that fresh beams from the near-Earth neutral line (NENL) play an important roll in the cold ion energization. References: Dusenbery, P. B., and L. R. Lyons, J. Geophys. Res., 94, 2484, 1989. Gary, S. P., and D. Winske, J. Geophys. Res., 95, 8085, 1990. Hirahara, M., et al., Geophys. Res. Lett., 21, 3003, 1994.

CLUSTER RAPID IES OBSERVATIONS OF HIGH-ENERGY ELECTRONS IN THE MAGNETOTAIL

Jackie A. DAVIES[1], Malcolm W. DUNLOP[1], Manuel GRANDE[1], ChrisH. PERRY[1], Martin K. CARTER[1], Pat W. DALY[2], Andre BALOGH[3] ([1]Rutherford Appleton Laboratory, [2]Max Planck Institute for Aeronomy, [3]Imperial College)

The RAPID instrument on each of the four Cluster spacecraft comprises both an imaging ion mass spectrometer (IIMS) and an imaging electron spectrometer (IES). The latter is capable of detecting electrons within the energy range of some 40 to 500 keV. When operated in burst mode, each IES instrument provides complete angular coverage every 4 seconds (spacecraft spin period). Such high energy electrons provide a useful diagnostic of the occurrence of acceleration processes during, for example, reconnection. Between July and October 2002, the orbit of Cluster was such that near apogee the spacecraft crossed through the night-side plasma sheet at large separation (5000 km), covering some 8 hrs of local time from the dawn to the dusk-side flank. For many of the crossings, the spacecraft were operating in burst mode. These RAPID IES burst mode observations have been examined, in conjunction with data from the fluxgate magnetometer (FGM), to identify and classify the regions of the magnetotail within and adjacent to the current sheet. The data have thus provided the multi-point information necessary to enable us to characterise the energetic electron signature under a variety of conditions, such as tail reconfiguration and substorm activity.

Z-MODE WAVE IN THE MAGNETOTAIL : GEOTAIL OBSERVATION

Hironobu TAKANO[1], Isamu NAGANO[1], Satoshi YAGITANI[1], Yasuhiro OKUDA[1], Kozo HASHIMOTO[2], Hiroshi MATSUMOTO[2] ([1]Graduate School of Natural Science and Technology, Kanazawa University, [2]Radio Science Center for Space and Atmosphere, Kyoto University)

Electromagnetic Z mode waves have been observed in the auroral regionand the Jupiter´s magnetosphere. The Z mode wave consists of two frequencycomponents having different polarization. The lower frequency component fromthe L-O mode cutoff frequency (f_{L-O}) to the electron plasma frequency (f_p) is the left-handed polarization. On the other hand, the higher frequency component extended to the upper hybrid resonance frequency (f_{UHR}) is the right-handed polarization. The Z mode wave can freely propagate by a linear mode conversion into an L-O mode through a radio window at the plasma frequency. The Z mode wave observed in the auroral zone is converted into the L-O mode wave on the auroral plasma cavity wall, which is radiated asthe Auroral Myriametric Radiation (AMR). The L-O mode wave converted fromthe Z mode wave observed in the Jupiter´s magnetosphere is emitted as JovianContinuum Radiation (JCR). Terrestrial Continuum Radiation (TCR) is alsogenerated by the linear mode conversion from the upper hybrid wave via theradio window at the geomagnetic equatorial plasmapause, and is emitted to theEarth´s magnetospheric cavity. The low frequency CR, which is called as LobeTrapped CR (LTCR), has been observed by GEOTAIL spacecraft in the distantmagnetotail. The LTCR would be generated at the plasma sheet boundary layer(PSBL) and the low latitude boundary layer (LLBL) by the same mechanism of CRemitted from the plasmapause and JCR. The Z mode observation in the PSBL andLLBL of the distant magnetotail would be an evidence of LTCR generation by thelinear mode conversion. However, Z mode wave has not been observed in suchregions. In the distant magnetotail, the narrow banded emission near the local electronplasma frequency is sometimes measured by the Wave Form Capture (WFC), which issubsystem of the Plasma Wave Instrument (PWI) onboard GEOTAIL. Although themagnetic field component of this emission cannot be observed because of thelack of sensitivity of magnetic search coils, we consider this emission is theelectromagnetic wave mode by analyzing the spectral structure with WFC data.By using the wave form data of electric field components, the spectral andpolarization analysis determine the propagation mode of this emission. We willshow the detailed spectral structure and polarization of this emission, anddiscuss whether this emission is the Z mode wave related to the LTCRgeneration or not.

KELVIN-HELMHOLTZ TYPE MODES DRIVEN BY OXYGEN IONS IN PLASMA SHEET REGION

A.P. KAKAD, S.V. SINGH, G.S. LAKHINA (Indian Institute of Geomagnetism, Colaba, Mumbai, 400 005, India)

The Kelvin-Helmholtz type modes can be excited by the streaming ofionospheric oxygen ions in the plasma sheet region. In threecomponent plasma consisting of electrons, protons and oxygenions, the linear dispersion relation is derived with velocityshear in each component. The dispersion relation is studiednumerically for the case of oxygen ion beam passing throughstationary electron-ion plasma. The effects of oxygen ion beamspeed, velocity shear and oxygen ion temperature on the growthrate of the Kelvin-Helmholtz mode are investigated. The resultsare applied to understand the low frequency turbulence observedin the plasma sheet region during substorm processes.

THREE-COMPONENT PSBL ION BEAMS OBSERVED IN THE DISTANT MAGNETOTAIL

Yoshifumi SAITO[1], Toshifumi MUKAI[1], Toshio TERASAWA[2], Shinobu MACHIDA[3] ([1]Institute of Space and Astronautical Science, [2]University of Tokyo, [3]Kyoto University)

The most conspicuous feature of the Plasma Sheet Boundary Layer (PSBL) in the Earth´s magnetotail is the existence of high-energy ion beams. These ion beams have been observed by several satellites in the near-tail region of $X_{GSE} > -25Re$. In spite of the previous observational and theoretical works, the source and acceleration mechanism of the PSBL

ion beams is still unclear. The insufficiency of the ion observation in the source region of the PSBL ion beams is one of the major reasons. The purpose of this paper is to identify the source of the PSBL ion beams by analyzing the data obtained by the GEOTAIL satellite in the distant magnetotail $X_{GSE} < -40Re$. Detailed structure of the Plasma Sheet Boundary Layer (PSBL) in the upstream region of slow-mode shocks in the distant magnetotail is investigated using low energy particle data. The existence of the slow-shock plasma sheet-lobe boundaries bounding the magnetic reconnection region in the Earth´s magnetotail has already been proved by the GEOTAIL observations. When the plasma sheet-lobe boundary is a slow-mode shock, magnetic field is connected between the upstream lobe region and the downstream plasma sheet region. Three-component ions: cold ions and two-component PSBL beam ions were observed in the PSBL. One of the two-component PSBL beam ions was observed in the outer region of the PSBL. Its distribution function looked like ˝kidney bean˝ shape. The energy of this component was higher than the energy of the other component while the temperature was much lower. The number flux of this component was comparable with the number flux of the cold ions observed simultaneously. The other beam ion component was observed throughout the PSBL. It had characteristics that its low energy cut off gradually decreased as the satellite approached the plasma sheet. The number flux of this component was much higher than the number flux of the cold ions. The source of the former component may be the current sheet accelerated lobe cold ions. Since current sheet acceleration is most effective around the X-type neutral line where Z_{GSE}-component of the magnetic field is weak, this component is observed mainly in the outer region of the PSBL whose magnetic field is connected to the region near to the X-type neutral line. The source of the latter component may be the ions leaked from the hot plasma sheet towards the lobe region along the magnetic field that is connected between the lobe region and the plasma sheet region. Our statistical study has also revealed that three-component PSBL ions were observed with 34% of the slow-shock plasma sheet-lobe boundaries identified in the distant magnetotail.

GEOTAIL AND CLUSTER OBSERVATIONS OF FLUX ROPESIN THE MAGNETOTAIL FROM X ~ -15 TO -200 RE

James A. SLAVIN, Eija TANSKANEN (NASA GSFC)

In the distant magnetotail flux ropes with diameters of 10 to 30 Re were frequently observed by Geotail and ISEE 3 often in association with magnetospheric substorms. We refer to these flux ropes as being of the ˝plasmoid-type˝ due to their being embedded in high-speed flow downthe tail. More recently Geotail and Cluster observations have been used to study the occurrence of flux ropes in the near-tail. Earthward of X ~ -25 Re most of the flux ropes are immersed within earthward directed bursty bulk flows. They are referred to as being ˝BBF-type˝ flux ropes.These near-tail flux ropes have diameters that are just ~ 1 to 2 Re or one order of magnitude smaller than what is seen in the distant magnetotail.We will compare and contrast the observations and models of magnetic flux ropes in the near and distant tail. The formation of small diameterflux ropes in the near-tail will be discussed in terms of the ˝filamentation˝ of the thinned cross-tail current layer while several competing modelswill be presented for the formation of large plasmoid type flux ropes in the distant tail. Finally, the implications of the Geotail and Cluster flux rope measurements for tail stability and dynamics will be discussed.

CLUSTER MULTI-POINT OBSERVATIONS OF FAST FLOWS IN THE PLASMA SHEET

Rumi NAKAMURA[1], Wolfgang BAUMJOHANN[1], Andrei RUNOV[1], Martin VOLWERK[1], Zoltan VOEROES[1], Tielong L. ZHANG[1], Berndt KLECKER[2], Andre BALOGH[3], Henri REME[4], Lynn KISTLER[5], Christopher MOUIKIS[5] ([1]IWF/OEAW, [2]MPE, [3]Imperial College, [4]CESR, [5]UNH)

Fast flows in the plasma sheet are considered to play an essential role in the energy conversion process in the magnetotail. Cluster spacecraft, which traversed the plasma sheet from the north to south at an apogee around 19 RE, observed fast flows at different location of the plasma sheet and for various conditions of the magnetosphere. Using multipoint measurements, we examine the spatial structure of the fast flows in the vicinity of a thin current sheet, in a thick plasma sheet configuration, associated with expansion of the plasma sheet, and thinning of the current sheet. We discuss on possible mechanisms responsible for these variety of flux transport process and how these fast flows interact with the ambient field and plasma.

CLUSTER OBSERVATIONS OF THE DYNAMICS OF THE TAIL CURRENT DURING SUBSTORMS

Robert L. MCPHERRON[1], Daniel N. BAKER[2], Scott THOMPSON[1], Margaret G. KIVELSON[1], Khrishan KHURANA[1], Andre BALOGH[3], Henri REME[4] ([1]Institute of Geophysics and Planetary Physics, University of California Los Angeles, Los Angeles, CA 90095-1567, USA, [2]Laboratory for Atmospheric and Space Physics, University of Colorado, Boulder, CO, [3]Space and Atmospheric Physics Group, The Blackett Laboratory, Imperial College, Prince Consort Road, LONDON SW7 2BW, UK, [4]CESR BP4346, 9 avenue du Colonel Roche, 31028 TOULOUSE Cedex 04, France)

We have carried out a detailed examination of the behavior of the tail current during several substorms that occurred during Cluster tail passes on August 15 and 27, 2001. We contrast this behavior to that seen during a quiet pass without a substorm expansion on September 22, 2001. We use minimum variance analysis to transform the magnetic field observations to a more convenient coordinate system and then use a Harris current sheet model to remotely sense the properties of the tail current. On August 15 Cluster was Earthward of the x-line at all times and we find that the current sheet systematically thins during substorm growth phase and expands during the expansion phase. On August 27 Cluster was initially tailward of the x-line. Several minutes before the ground onset a flux rope passed Cluster reversing the flow and field in the manner expected for a tailward moving x-line. On September 22 a growth phase was in progress during the passage and the sheet was extremely thin and changing with time. In all three cases it is necessary to assume that the location of the center of the current sheet and its thickness are varying with time to obtain agreement between the total measured current and the lobe field strength. We interpret these observations in terms of the near-earth neutral line model which argues that the tail effects are consequences of magnetic reconnection caused by current sheet thinning.

GAIII.05/08A/A06-005   0940

CURRENT CARRIERS OF THE CROSS-TAIL CURRENT: GEOTAIL OBSERVATIONS

Toshifumi MUKAI[1], Yoshihiro ASANO, Yoshifumi SAITO ([1]Institute of Space and Astronautical Science, [2]Kwasan Observatory, Kyoto University)

The cross-tail current is a basic element to sustain the magnetotail, and the identification of its current carriers is important to study the structure and dynamics of the current sheet,

A

especially physical processes in the evolution of a thin current sheet during magnetospheric substorms. In the adiabatic case, the current perpendicular to the magnetic field can be expressed as a sum of two terms: One is the pressure gradient term, and the other is due to the pressure anisotropy term divided by the local radius of the magnetic field. The first term is dominant in a normal thick current sheet, but several researchers have also argued for the significance of the second term in a thin current sheet. It has generally been presumed that ions are the dominant carriers in either case, since their temperature is much higher than the electron temperature in the plasma sheet. In principle, the current carriers can be identified by the distribution functions of ion and electrons and their velocity moments. However, the estimation of the electron current has been considered to be notoriously unreliable, because of various spurious effects in low-energy electron data as well as because the ratio of the electron bulk velocity to thermal velocity is usually very small (order of 1%). We have challenged this hard work with special cares to remove the spurious effects, and in some cases, succeeded in estimating the current density from the velocity difference between ions and electrons. As the result, the validity of the above general view is confirmed, but we have found that thin current sheets in which electrons are the dominant carriers evolve in the mid-tail region in the course of substorms. It is also noteworthy that the electron dominated current sheets appear not in the neutral sheet but in the off-neutral region, and the thickness is of order of the ion inertial length. In this situation, ions are unmagnetized while electrons are magnetized, and the electric field directing to the neutral sheet makes electrons drifting dawnward.

GAIII.05/08A/A06-006 Invited 0955

CURRENT SHEET STRUCTURE AND DYNAMICS IN MAGNETOTAIL

M. HOSHINO[1], T. MUKAI[2] ([1]Department of Earth and Planetary Science, University of Tokyo, [2]ISAS)

The magnetotail plasma sheet is one of the key elements for understanding the dynamic phenomena in the earth's magnetosphere. The current sheet is usually of the order of a few Re with a single peak current sheet, but a thin current sheet with the thickness of the order of ion inertia length is also known to exist before and during active phase. The structure of the thin current sheet is very important to understand the onset of substorms which is probably linked to various plasma instabilities such as magnetic reconnection, ballooning instability and so on. The energy dissipation rate is believed to be crucially controlled by the current sheet structure as well. Recent high-quality and multi-point observation data on the current sheet structure by Geotail and Cluster satellites revealed that a thin and double current sheet structure often exists in the magnetotail. Namely, the electric current density has two maxima away from the neutral sheet, and are embedded in a thick plasma sheet. This stratified structure seems to be very important not only on local plasma instabilities at the current sheet but also on the global dynamics in the magnetotail. We review a wide variety of the current sheet structures and dynamics observed in the magnetotail, and we argue the plasma heating and acceleration focusing on plasma kinetic effects in the relation to the stratified current sheet in the magnetotail.

GAIII.05/08A/A06-007 1040

ACCELERATION AND HEATING OFIONOSPHERIC IONS IN THE MAGNETOTAIL

Jean-Andre SAUVAUD[1], H. REME[1], P. LOUARN[1], G. FRUIT[1], L. KISTLER[2], G.K. PARKS[3], M. ANDRE[4], A. BALOGH[5], M. DUNLOP[6], N. CORNILLEAU[7] ([1]CESR/CNRS, Toulouse, France, [2]UNH, Durham, USA, [3]SSL, Berkeley, USA, [4]SISP, Uppsala, Sweden, [5]Imperial College, London, UK, [6]RAL, Oxfordshire, UK, [7]CETP, Velizy, France)

We present a study of the dynamics of the terrestrial ions in the mid-plasma sheet (10-19 RE). The high time resolution measurements of H+, He+, O+ ions made onboard Cluster allow to show that these ions are massively injected into the tail during substorms and dispersed by time of flight effects. A single oxygen injection being able to account for over 80% of the oxygen population of the mid-tail plasma sheet. Ionospheric protons can at times have a sufficient energy to be directly measured inside the lobes. However, this population is generally very cold, quite often not fully measurable by a charged spacecraft, except when the ions acquire a large drift motion. We show that this is indeed the case during frequent disturbances of the plasma sheet boundary layers. In accordance with previous works, this boundary is found to be unstable, affected by perturbations associated with large pressure gradients and fast flows.The use of the four Cluster spacecraft allow a unique determination of the geometry of the perturbations. We show that these disturbances lead to the generation of shear Alfven waves propagating earthward inside the lobes. The wave electric field modulate there the energy of the near mono-energetic O+ ions flowing from the Earth and dispersed by convection and also reveal the presence of the cold proton lobe population of ionospheric origin. Finally using the four cluster satellites, we show how cold ionospheric oxygen ions gain parallel velocity inside the PSBL where they are heated by low frequency waves.

GAIII.05/08A/A06-008 1055

PARTICLE SIMULATION OF PLASMA RESPONSE TO INDUCTION ELECTRIC FIELD IN THE MAGNETOSPHERE

Yoshiharu OMURA[1], Masataka MATSUNAGA[1], Takayuki UMEDA[1], Walter J. HEIKKILA[2], Hiroshi MATSUMOTO[1] ([1]RASC, Kyoto University, [2]Center for Space Sciences, University of Texas at Dallas)

We study response of thermal plasmas to an induction electric field via particle simulations. We assume a small segment of the magnetic field line in the magnetotail where a large scale of induction electric field appears due meandering of the current sheet. We first performed one-dimensional electrostatic particle simulations with a constant external electric field applied to the Maxwellian thermal plasma with isotropic electrons and ions. The electric field is assumed to be due to the magnetic induction which takes place with a much longer time scale compared to that of the microscopic plasma wave instabilities to be studied in the present simulations. Therefore, we assume the external electric field is constant in time for simplicity. In the presence of the external electric field, thermal electrons are accelerated to form an electron beam drifting against the thermal ions. We observed onset of the Buneman instability after the electron acceleration. In spite of the strong diffusion of electrons due to the Buneman instability, we found formation of an electron beam running away from the acceleration region. We also performed two-dimensional electromagnetic simulations with external electric field applied to a localized area in the simulation model. Electrons are accelerated along the magnetic field, and they are diffused by the Buneman due to nonlinear trapping inside the acceleration region, while the untrapped electrons escaping from the acceleration region induce the bump-on-tail instability which results in the electrostatic solitary waves as observed in the plasma sheet boundary layer.We discuss possible connection of these nonlinear processes with specific plasma waves observed in the magnetosphere.

GAIII.05/08A/A06-009 1110

CLUSTER OBSERVATIONS OF ELECTRON POPULATIONS DURING MAGNETOTAIL RECONNECTION: 3-D STRUCTURE AND DYNAMICS

Christopher J. OWEN[1], Andrew N. FAZAKERLEY[1], Jason P. DEWHURST[1], Yulia BOGDANOVA[1], Malcolm W. DUNLOP[2], James A. SLAVIN[3], Jean-Michel BOSQUED[4], Andre BALOGH[5], Henri REME[4] ([1]Mullard Space Science Laboratory, University College London, [2]Rutherford Appleton Laboratory, UK, [3]NASA/Goddard Space Flight Center, USA, [4]CNES/CESR, France, [5]Imperial College, London, UK.)

We report on multi-point observations made by the 4 Cluster spacecraft during the first two magnetotail seasons (autumn 2001 and autumn 2002). Although we present data from a number of instruments for contextual purposes, we concentrate primarily on observations by the PEACE Electron spectrometers on each spacecraft. In particular, we survey the 3-dimensional structure of the electron populations in the vicinity of a number of plasma sheet flow reversal signatures that have previously been reported by Cluster researchers as possible encounters with active reconnection X-lines. We test the form of the electron distributions for consistency with the predictions of models of this region, in which a system of Hall electron currents flows within the ion diffusion region and causes characteristic magnetic field perturbations in the surrounding medium. We also compare these results with observations made further from active X-lines, for example as the spacecraft sample the separatrix layers during the passage of a plasmoid/flux-rope. In this way, we qualitatively assess the variation of the electron populations with distance from the X-line.

GAIII.05/08A/A06-010 Invited 1125

QUICK RECONNECTION TRIGGERING AND CROSS-SCALE COUPLING IN THE MAGNEOTOTAIL CURRENT SHEET

Iku SHINOHARA[1], Masaki FUJIMOTO[2] ([1]Institute of Space and Astronautical Science, [2]Tokyo Institute of Technology)

Understanding cross-scale coupling between MHD and dissipation scales in collisionless plasmas is challenging. Magnetic reconnection is an impressive example of the cross-scale coupling. While there is observational evidence that the magnetotail current sheet thickness becomes as thin as comparable to the relevant ion inertia length, whether it thins further down to electron scale to initiate reconnection is an open question. Carrying out a large scale 3D full particle simulation, we have recently found that quick triggering of magnetic reconnection is possible even in an ion-scale current sheet. If one thinks of the two-dimensional tearing mode as the triggering agent of magnetic reconnection in a current sheet of the Harris-type, the current sheet has to thin down to the electron scale for the instability to grow quickly. When the third dimension in the current-wise direction is taken into account, we have found that reconnection can be triggered very quickly. For the quick triggering, the lower-hybrid drift waves excited at the edges of the current sheet is indispensable. This wave excitation brings about formation of a thin current layer sustained by accelerated electrons. The inductive electric field, which is generated through change of the current profile, can efficiently accelerate meandering electrons around the magnetic neutral sheet. As a result, electric current in the thin layer is mostly carried by non-adiabatic electrons. Thus, the electron acceleration is playing a crucial role in making the quick triggering available. The result shows that the cross-scale coupling process is essential to enable the quick triggering of magnetic reconnection in an ion-scale current sheet. In the presentation, we will briefly introduce a Japanese future project of the magnetospheric explorer, namely the SCOPE project, in the context of understanding the cross-scale coupling in space plasma.

GAIII.05/08A/A06-011 Invited 1150

THE NATURE OF BURSTY BULK FLOWS AND THEIR INFLUENCE ON MAGNETOTAIL STRUCTURE AND DYNAMICS: A KEY SCIENCE TOPIC FOR THE MAGNETOSPHERIC CONSTELLATION MISSION

Harlan E. SPENCE[1], Thomas E. MOORE[2], Larry KEPKO[1], Charles GOODRICH[1] ([1]Center for Space Physics, Boston University, [2]NASA Goddard Space Flight Center)

Recently, 3D simulations of the magnetosphere have been shown to exhibit a behavior that appears to be a global realization of the MHD plasma bubble phenomenon discussed first by Chen and Wolf. Bubble formation and dynamics appears to be a candidate mechanism for the production of bursty bulk flows, a term that is derived purely from observations of lone spacecraft in the magnetotail. We explore the evidence which links the simulated phenomenon to such observations and then use the simulation results to quantify their predicted important contributions to magnetotail structure and dynamics. Ultimately, reaching closure between theory and observation for such a three-dimensionally structured, dynamic phenomenon will require constellation-class observations having extent and resolution in space and time commensurate with global simulations, i.e. ~1-2 RE and ~10 sec. We treat the phenomenon of MHD plasma bubbles as representative of the general class of important magnetospheric dynamical structures that can practically be studied only by a distributed constellation of spacecraft, in order to obtain vector field ˝streamline˝ movies of the magnetotail plasma flow, magnetic field, and energetic particle fluxes. Relevant capabilities of the NASA Magnetospheric Constellation Mission (MCM) needed to resolve these outstanding key science questions are summarized.

INHERENTLY THREE DIMENSIONAL MAGNETIC RECONNECTION: A MECHANISM FOR BURSTY BULK FLOWS?

Michael Anthony SHAY[1], James F. DRAKE[1], Marc SWISDAK[1], William DORLAND[1], Barrett ROGERS[2] ([1]University of Maryland, [2]Dartmouth College)

We examine the development of mesoscale structure during 3-D magnetic reconnection which initiates from random perturbations. Reconnection develops as multiple, finite length (on the order of 1 - 4 Earth Radii) x-linesegments corresponding to strong variation in the cross tail direction. Forrelatively wide initial current sheets (several ion inertial lengths), thesefinite length x-lines remain spatially isolated and drive reconnection whichis strongly reminiscent of bursty bulk flows (BBFs) in the magnetotail. In narrower initial current layers the x-line segments merge together to a state in which large scale magnetic energy release takes place. Thus, the degreeof compression of the magnetotail may ultimately determine if energy is released in local bursts or globally as a substorm.

A NUMERICAL SIMULATION OF A GEOMAGNETIC SUDDEN COMMENCEMENT

Shigeru FUJITA[1], Takashi TANAKA[2], Takashi KIKUCHI[3] ([1]Meteorological College, [2]kyushu University, Graduate School of Sciences, [3]Communications Research Laboratory)

A MHD simulation technique is utilized in order to investigate dynamic behavior of the magnetosphere-ionosphere coupled system corresponding to the solar wind disturbances. In this talk, we present a numerical simulation of a SC, including a negative SC revealed from a global 3D MHD simulation of the magnetosphere-ionosphere coupled system. A SC is divided into three phases in the point of view of the magnetosphere-ionosphere coupling. The preliminary impulse, the first signal just appearing on the onset of a SC, is explained with a MHD wave propagation in the non-uniform magnetosphere. The MHD wave is originally the compressional mode, which is converted to the Alfven mode with a FAC in a region of steep gradient of plasma density. Thus, we confirm the previous Tamao-Araki model of a PI. In this phase, the ionosphere does not play a role in the magnetospheric disturbance. Following the PI phase, the compressional signal in the magnetosphere is still propagating in the magnetosphere. Behind the wavefront of the compressional wave in the magnetosphere, plasmas are decelerated and excess kinetic energy is converted into electric current energy. This phase is called as the first stage of a Main Impulse. The ionosphere begins to control the magnetospheric plasma dynamics, but its behavior is complex and transient. In the last phase, the ionospheric convection and the magnetospheric convection are corresponding to each other. The magnetosphere-ionosphere current system is quite similar to the steady region 1 current system. However, the current generation mechanism is not related to the magnetic reconnection in the magnetopause, but compressional of the magnetopause in the nightside cusp region. A negative SC is regarded as a mirror image of a positive SC after Takeuchi and Araki [2001] from morphological study of observed data. Our simulation results support this conclusion. However, the first compression of the magnetopause in the positive SC and the first expansion of the magnetopause in the negative SC seem to yield different current generating mechanisms. We will discuss this in the talk.

MORPHOLOGY OF THE RING CURRENT DERIVED FROM IN-SITU MAGNETIC FIELD OBSERVATIONS

Guan LE[1], C.T. RUSSELL[2], K. TAKAHASHI[3] ([1]NASA/GSFC, Greenbelt, MD, USA, [2]IGPP, University of California, Los Angeles, CA, USA, [3]Johns Hopkins University, Applied Physics Laboratory, Laurel, MD, USA)

We use the magnetic field data in the inner magnetosphere observed by Polar, ISEE, and AMPTE/CCE spacecraft to study the morphology of the ring current distribution. The combined data set from 5-year Polar mission, 10-year ISEE mission, and 5-year AMPTE/CCE mission provides extensive coverage of the equatorial inner magnetosphere in L-values, local times, and the Dst index for quantitative study of the ring current. Using intercalibrated magnetic field data from the three spacecraft, we are able to construct the magnetic field maps and the corresponding currrent density maps for different range of Dst*, the corrected Dst index by the solar wind dynamic pressure which represents the true ring current strength. In the results, both an eastward inner ring current at ~ 3 RE and a westward outer ring current at ~ 4-7 RE are evident for all ranges of Dst*. There is a local time asymmetry for the westward outer ring current for all levels of magnetospheric disturbances. The peak of the westward ring current is around the local midnight during the quiet time. The local time asymmetry intensifies and the current peak shifts towards pre-midnight sector as the ring current strengths. During moderate magnetic storms (-100 nT $<$ Dst* $<$ -80 nT) the peak of the westward ring current occurs at ~ 2000 local time.

INFLUENCE OF SUBSTORMS AND STORMS IN THE SAR ARC DYNAMICS. STATISTICAL ANALYSIS

Igor B. IEVENKO, Valery N. ALEXEYEV (Institute of Cosmophysical Research and Aeronomy, SD RAS)

Population growth and urban development, with the consequent requirementof improved supplies and development of new potential water resources,have increased the need of an accurate knowledge of hydrological phenomenaat basin scale, such as runoff, erosion-sedimentation and mass movements,in order to assess the possible consequences of their future evolution onhuman activities. However, the prediction of these evolutionary trends isoften difficult due to the lack of data concerning hydrological parameters.This problem can be mainly connected to the difficulties in the measurementof such data. In particular, mass transfer rates are generally measured atfew chosen points along the main channels of the watershed. This approachusually leads to unsatisfactory results since sediment transfer is mainlycontrolled by scale invariant pulse processes which are spatially andtemporally scattered everywhere within the watershed. Local pointmeasurements unavoidably involve the loss of information on spatialvariability generating averaged or lumped values. In this contextthe extraction of such information could benefit from the use of a remotesensing technique, characterized by large scale and low cost. SpaceborneSAR interferometry in the last few years has been successfully applied toreconstruct the topography of the observed scene and to measure with amillimeter accuracy changes on the earth surface induced by differentgeophysical phenomena. The aim of the present work is to investigatethe possible contribution of the interferometric technique in the retrievalof hydrologically-related geomorphic parameters. In particular the attentionhas been focused on the possibility to obtain two different types of data:i) continuously updatable DEMs of basins with a suitable vertical accuracyand ii) quantitative spatially distributed estimates of sediment transferamong hillslopes and between hillslopes and channels. These information canbe extremely valuable for the calibration of hydrological models as wellasfor a better understanding of the spatial and temporal distribution of thelandscape sculpting processes in a wide range of scales within the basin.The method has been applied by using SAR data acquired by the ERS satelliteson different test-sites located in the Italian Alps and Apennines.

WHAT IS HILDCAAS?

Kazuya YAGO, Yohsuke KAMIDE (Solar-Terrestrial Environment Laboratory, Nagoya University)

Data of magnetic disturbances at high latitudes and those at low latitudes are coupled for periods of HILDCAAs (High-Intensity Long-Duration Continuous AE Activity) during the recovery phase of geomagnetic storms. During HILDCAAs, highly fluctuate interplanetary magnetic field are seen, and Dst values do not fully recover to the pre-storm level for several days. This study addresses the question of what causes HILDCAAs and what are their effects on low-latitude magnetic disturbances.

A COMPARISON BETWEEN TAIL AND LOW ALTITUDE OBSERVATIONS DURING A LONG PERIOD OF ENHANCED GEOMAGNETIC ACTIVITY

Rune STADSNES[1], Knut SVENES[2], Kjell AARSNES[1], Finn SOERAAS[1], Kjellmar OKSAVIK[1], Marita SOERBOE[1], Marit Irene SANDANGER[1], Kjartan OLAFSSON[1] ([1]University of Bergen, Norway, [2]Nowegian Defence Research Establishment)

A geomagnetically disturbed period commenced with a storm sudden commencement at about 19 UT on August 18 2002. The Dst went down to – 30nT and stayed depressed at this level until 16 UT on August 20. At this time a prolonged period of southward IMF-Bz started, lasting for 23 hours. During this period Cluster was located in the magnetotail. The magnetotail data provided by Cluster and the low altitude data provided by the NOAA satellites constitute an excellent combination to study the correspondence between particle boundaries close to and distant from the Earth. The period with increased southward IMF-Bz caused the Dst to reach down to –96 nT. The whole period under consideration exhibits an enhanced AE-index almost continuously above 500 nT.The relation between the solar wind energy input to the magnetosphere (the Akasofu epsilon-parameter), the particles observed in the tail, and the particle energy dumped into the upper atmosphere is investigated. By comparing particle boundaries in the tail and in the ionosphere constraints on magnetic field line models are obtained.

DOMINANCE OF TOROIDAL OSCILLATIONS IN DAWN/DUSK SECTORS- A PLAUSIBLE EXPLANATION IN TERMS OF VARIATIONS IN SOLAR WIND DYNAMIC PRESSURE

Ashwini Kumar SINHA (Indian Institute of Geomagnetism, Colaba, Mumbai 400 005.)

The changes in the solar wind dynamic pressure produce the oscillations in surface currents at the magnetopause boundary in order to establish equilibrium. These currents cause compressional variations in the magnetic field within the magnetosphere. The response of transverse field line oscillations to such variations in the magnetic field has been computed in dipole field geometry in reflecting ionospheric conditions. The analysis clearly shows the dominant characteristics of fundamental toroidal modes in the dawn and the dusk sectors as revealed by the statistical studies of pulsations observed by the satellite AMPTE/CCE [*Anderson et al.,* 1990]. It is traditionally believed that such oscillations are mainly driven by Kelvin-Helmholtz (K-H) instability. Our analysis shows that the dominance of fundamental toroidal modes in the dawn and dusk sectors can also be explained in terms of response to impressed pressure impulses without invoking K-H instability. The analysis also shows that poloidal modes do not exhibit any longitudinal structures. These results are consistent with the observations [*Anderson et al.,* 1990]. **References:** Andersan, B. J., M. J. Engebretson, S.P. Rounds, L. J. Zanetti, and T. A. Potemra, A statistical study of Pc3-5 pulsations observed by the AMPTE/CCE magnetic fields experiment 1. Occurrence distributions, *J. A TEST OF THE MAGNETOSPHERIC SOURCE OF TRAVELLING CONVECTION VORTICES

Mai Mai LAM, Alan S. RODGER (Physical Sciences Division, British Antarctic Survey)

Travelling convection vortices (TCVs) are a powerful tool for probing the nature of the coupling between the solar wind, the magnetosphere, and the ionosphere. Existing theoretical models of their generation do not properly represent the coupling between the magnetosphere and the ionosphere. We use conjugate ground magnetometer data from the Greenland magnetometer chain and Antarctica to test the nature of the magnetospheric source of 18 TCV events associated with changes in the magnetopause dynamic pressure. This is achieved by statistically comparing two groups of TCV events, one containing events for which the conjugate ionospheres are of similar conductivity, the other containing events for which the conductivity of the conjugate ionospheres differs by an order of magnitude. We find that the TCV intensity has a similar magnitude in both hemispheres regardless of any difference in conductivity between the two hemispheres. We propose that this is evidence in favour of the magnetospheric source of TCVs being a constant current source.

ENERGETIC ION INJECTION AND FORMATION OF THE STORM-TIME RING CURRENT

L. XIE[1], Z.Y. PU[1], X.Z. ZHOU[1], S.Y. FU[1], Q.G. ZONG[2], T.A. FRITZ[2], Z.X. LIU[3] ([1]Department of Geophysics, Peking University, [2]CSP, Boston University, [3]CSSAR, Chinese Academy of Science)

In this paper we made an extensive study of storm-time ring current formation through 3-D test particle trajectory calculations (TPTCs). We focus our attention on injection of the energetic Oxygen ions whose abundance and energy density in the inner magnetosphere are extraordinarily high near the Dst minimum of the main phase of great storms. Two sources of Oxygen ions are considered: The Oxygen ion population of a few tens keV originally situated in the near-Earth magnetotail ($L \leq 8$) or in the mid-magnetotail ($L\sim15$), and the thermal population ($\leq 10keV$) up-flowing from the Earth's ionosphere. Different convection electric field models, such as the uniform electric field, the Volland electric field model (Volland, 1978) and the Heppner-Maynard-Rich model (Heppner, Maynard, and Rich, 1990) are applied to incorporate, respectively, with the co-rotation electric field. The TPTC runs show that the intense magnetospheric convection electric field can effectively energize (within 2 to 3 hours) Oxygen ions which are initially located either in the near-Earth tail or in the mid-tail as they drift into the inner magnetosphere. Meanwhile, the thermal Oxygen ions can be considerably energized by the co-rotation electric field once they come closer to the Earth along a closed orbit. In addition to the convection and co-rotation electric fields, a semi-quantitative and time-independent shielding electric field model is included in a few studies. The calculated results demonstrate that the shielding electric field plays an important role in the formation of the symmetric ring current.

STUDY OF THE DST-AL CORRELATION DURING MAGNETIC STORMS

Fiori-Anastasia I. METALLINOU[1], Ioannis A. DAGLIS[2], Yohsuke KAMIDE[3] ([1]Aristotle University of Thessaloniki, Department of Physics, Section of Astrophysics, Astronomy and Mechanics, GR-541 24 Thessaloniki, Greece, [2]National Observatory of Athens, Institute for Space Applications, GR-152 36 Penteli, Greece, [3]Nagoya University, Solar-Terrestrial Environment Laboratory, 442 Toyokawa, Japan)

A dispute on the role of substorms in storm development has emerged during the last few years; the community has not yet reached a definite conclusion. Our study assesses the storm-substorm relationship through an investigation of the geomagnetic indices SYM-H and AL for a number of magnetic storms. The data were provided by the World Data Center for Geomagnetism, Kyoto, and by STELab, Nagoya University. We have selected a group of magnetic storms with SYM-H values in the range between -50nT and -350nT. We have calculated the integrals of SYM-H and AL indices over the storm duration, aiming to get a proxy of the total intensity of the two phenomena (storm/substorm). The integrals of the two geomagnetic indices exhibit a linear correlation. The linear correlation method yields a correlation index of $r=0.867$ for the SYM-H / AL pairs for the selected storm periods. We have also calculated the integrals of the SYM-H and AL squares, to represent magnetic field energy for the two associated processes. In this case the correlation index reaches a value of $r=0.907$. Our results imply a strong coupling between storm and substorm energy dissipation.

Yukimatu[9] and the inner magnetosphere section, Society of Geomagnetism, Earth, Planetary, and Space Sciences ([1]Solar-Terrestrial Environment Laboratory, Nagoya University, [2]Faculty of Science, Tohoku University, [3]Communications Research Laboratory, [4]Faculty of Science, Kyoto University, [5]Faculty of Engineering, Kanazawa University, [6]Faculty of Science, Rikkyo University, [7]Institute of Space and Astronautical Science (ISAS), [8]Faculty of Science, Kyushu University, [9]National Institute of Polar Research (NIPR))

The Earth´s inner magnetosphere (the radial distance from the Earth less than 10 Re) has been a ˝missing˝ region from scientific investigation, particularly for the plasma dynamics. This is because there have been few satellites that made simultaneous measurements of the plasma distribution function, composition, and magnetic and electric fields in the inner magnetosphere near the equatorial plane. The inner magnetosphere contains several interesting regions from the viewpoint of the plasma dynamics, i.e., the inner plasma sheet, ring current, radiation belts, and plasmasphere. In the radiation belts, the electrons have the highest energy in the Earth´s magnetosphere. Various unresolved processes of particle energization have been proposed to explain generation of relativistic electrons in these regions. In order to examine each candidate mechanism, continuous energy coverage of electrons as well as observations around the magnetic equatorial plane is essential. Investigation of these energization processes in the inner magnetosphere will also provide important clues for understanding of plasma acceleration mechanisms in the dipolar magnetic field of other planets and stars. Identification of dominant acceleration mechanisms of radiation belt electrons is also important for the space weather. In this talk, we review current status and unsolved problems related to the plasma dynamics of the inner magnetosphere in order to address scientific objectives and strategy of a possible future satellite mission, which investigates the dynamics of the inner magnetosphere. The subjects will be covered are: 1) substorm dynamics and energetics, 2) radiation belt dynamics, 3) ring current dynamics, 4) ULF waves, 5) plasma waves inside and outside the plasmasphere, and 6) mass transport including heavy ions.

MULTI-POINT MEASUREMENTS OF PLASMA DRIFTS AND DENSITIES NEAR THE PLASMAPAUSE

Harri E. LAAKSO, A. MASSON, P. ESCOUBET, R. GRARD, F. PITOUT (ESA/ESTEC/Code SCI-SH, Noordwijk, The Netherlands)

Erosion and recovery of the plasmasphere are important issues that are inherently related to the global dynamics and structure of the magnetosphere. The plasmapause is a highly dynamic region where the density decreases a few orders of magnitude over a relatively short distance and the plasma drift is switched from corotation into convection. Sometimes the changes occur suddenly, sometimes slowly, but under some conditions, the transitions are quite oscillatory. This paper presents a variety of plasmapause crossings by the four Cluster satellites. We utilize the measurements from the electric fieldexperiments that measure both the plasma drift and total plasma density variations along the satellites´ trajectories across the plasmapause. Suchmeasurements show that the flow separatrix and density decline do not necessarily occur simultaneously. We show cases of a modulating plasmapause either via wave activity (of a few minute periods) or radial motion of the plasmapause. Occasionally outside the plasmapause, large-scale density enhancements are observed that are likely related to plasma tails.

GAIII.06/07P/D-012 Poster 1400-132

GLOBAL 3D ELECTROMAGNETIC PARTICLE SIMULATION FOR SATELLITE OBSERVED SASH EVENT

Xiaoyang YAN, Dongsheng CAI, Nishikawa K. -I, Bertrand LEMBEGE (University of Tsukuba)

We made our efforts to parallelize the global 3D HPF Electromagnetic particle model (EMPM) for several years and have also reported our meaningful simulation results that revealed the essential physics involved in interaction of the solar wind with the Earth´s magnetosphere using this EMPM in our PC cluster and supercomputer. Sash phenomena was observed and reported in some satellite observation. And some MHD simulations for it was accomplished. We investigate it with this HPF EMPM and recently new simulation for it was run in the new VPP5000 supercomputer. In the new simulations were performed on the new VPP5000 supercomputer of Tsukuba University, we used larger domain size, 305×205×205, smaller grid size Δ, 0.5RE (the radium of the Earth), more total particle number, 200,000,000 (about 8 pairs per cell). And other parameters used in this simulation are, solar wind speed is 0.5c, the mass ratio of ion to electron is 16, the position of the Earth is at x=100, y=100, z=100, electron thermal velocity is v_the=0.01, electron plasma frequency is about 0.01, the electron Debye length is about λ_De=1.0Δ. The position of magnetopause is at about x=20 Δ=10RE. At first, we run this code up to 1000 time steps

without IMF, and get the called quasi-stationary status; After the quasi-stationary status was established, we applied a northward IMF (Bz=0.4), then run it for 800 time steps, at this time, the IMF arrives at about x=-50RE, and then we change the IMF from northward to dawnward (IMF By=0.4). The results revealed that the groove structure at the day-side magnetopause, that causes particle entry into inner magnetosphere and the cross structure or S-structure at near magneto-tail are formed. Moreover, in contrast with MHD simulations, kinetic characteristic of this event is also analyzed self-consistently with this simulation. The new simulation provides new and more detailed insights for the observed sash event.

GAIII.06/07P/D-013 Poster 1400-133

STORMTIME MAGNETOSPHERIC ELECTRIC FIELD MODELING USING ION DRIFT MEASUREMENTS IN THE IONOSPHERE

Phillip Charles ANDERSON (Space Science Applications Laboratory, The Aerospace Corporation, Los Angeles, CA)

Knowledge of the magnetospheric convection electric field pattern is essential to any study of the inner magnetosphere. While a number of empirical and theoretical electric field models have been developed in the past, none of them contains a good description of the stormtime magnetospheric electric fields, in particular the electric fields that penetrate to low L-values as a result of the breakdown of the shielding near the inner edge of the ring current. The potential drop equatorward/earthward of the auroral oval/electron plasma sheet can exceed 60 kV, a substantial fraction of the total potential drop across the polar cap/magnetosphere. The Defense Meteorological Satellite Program (DMSP) spacecraft has been providing ion drift measurements in the ionosphere since 1988 as well as precipitating auroral particle measurements since 1982 and geomagnetic field measurements since 1994. At times, these measurements have been provided simultaneously by 5 separate spacecraft. We are in the process of developing an empirical, stormtime magnetospheric electric field model using the data from the DMSP spacecraft. We report the initial results of the development, focusing on the penetration electric fields associated with geomagnetic storms.

GAIII.06/07P/D-014 Poster 1400-134

CAN THE SURFACE-IONOSPHERE WAVEGUIDE TRANSMIT CONVECTION CHANGES TO LOW LATITUDES?

Robert J. STRANGEWAY (IGPP, University of California, Los Angeles)

The frozen-in electron condition, which applies for the upper E- and F-region ionosphere, leads to the equivalence between mechanical and electromagnetic loads. As a consequence, the work done in moving the ionosphere against the neutral atmosphere equals the Poynting flux dissipated in the ionosphere. This implies that in general any motion of the ionosphere is driven by the magnetosphere, unless there is an excess of Poynting flux into the ionosphere. In that case, the excess Poynting flux is available to make the ionosphere appear to be a driver of magnetospheric convection. In order to assess how and if Poynting flux, and by implication changes in convection, can be transmitted via the ionosphere we have investigated wave propagation across the ionosphere with a Green´s function analysis and through the ionosphere into the surface-ionosphere waveguide. The Green´s function analysis shows that signals will tend to propagate across the ambient field at higher altitudes, with diffusion dominating at lower altitudes, although this analysis ignores the altitude dependence of the collision frequencies and Alfven velocity. The analysis of vertical propagation demonstrates that the ionosphere tends to absorb most of the wave Poynting flux, implying that the surface-ionosphere waveguide is an inefficient means for transferring wave energy. An important aspect of the analysis is that the surface ionosphere waveguide is not simply a free space cavity, but electron collisions are still important down to about 40 km altitude. Thus the absorption is not restricted to the E- and F-regions only, but extends down into the atmosphere. Furthermore, in order that the surface-ionosphere waveguide by a means for transmitting convection information, the incident wave energy must overcome the Joule dissipation at both the entry and exit sites, further arguing against the waveguide as a means for driving magnetospheric convection.

GAIII.06/07P/D-015 Poster 1400-135

TSUBASA(MDS-1) OBSERVATIONS OF HIGH-ENERGY CHARGED PARTICLES IN THE MAGNETOSPHERE

Kiyokazu KOGA, Haruhisa MATSUMOTO, Hideki KOSHIISHI, Hitoshi MATSUOKA, Masao NAKAMURA, Tateo GOKA (Office of R&D, NASDA)

In-situ observations are required to investigate fully fluctuations in the radiation belt. Tsubasa (MDS-1) measures the magnetic field and high-energy charged particle fluxes (electron, proton, alpha-particle) in the equatorial plane from 500 to 36000 km, so that, particle flux, pitch angle distribution, phase space density and radial distribution can be measured. Information from these measurements is very useful for revealing the cause of the radiation belt fluctuations, particularly those of high-energy electrons and protons. TSUBASA was successfully launched by the H-IIA launch vehicle from the Tanegashima Space Center on February 4, 2002. It was then injected into a geostational transfer orbit (GTO), with a spin rate of 5 rpm for attitude stabilization. We report magnetic field observations, particle flux and pitch angle distributions during magnetic storms, and examine these results in the light of relevant radiation belt fluctuation theory.

GAIII.06/07P/D-016 Poster 1400-136

SC TRIGGERED PLASMA WAVE AND FIELD PHENOMENA OBSERVED BY THE AKEBONO SATELLITE IN THE PLASMASPHERE

Atsuki SHINBORI[1], Takayuki ONO[1], Masahide IIZIMA[1], Atsushi KUMAMOTO[1], Hiroshi OYA[2] ([1]Geophysical Institute, Gradual School of Tohoku University, [2]Fukui University of Technology)

Since sudden commencements (SCs) are very clear isolated global signature, they have been recognized as important phenomena in understanding the response of the earth's magnetosphere, plasmasphere and ionosphere associated with a passage of solar wind discontinuity of density and velocity. In order to study on the propagation feature of SC disturbances in the plasmasphere, DC electric and magnetic field phenomena and the generation of plasma waves associated with SCs, plasma wave and field phenomena were analyzed in the relationship to the SCs based on the Akebono satellite observations which have been carried out more than 13 years since March 1989. For the present data analysis, plasma wave data of PWS (20 kHz-5.1 MHz), VLF (3.16 Hz-17.8k Hz) and ELF (0 Hz-80 Hz) were used. Within a period from January 1989 to December 2002, 2803 events of SCs have been identified in SYM-H data as a rapid increase with more than 5 nT per ten minutes, and 263 events were covered by the simultaneous observation records of the Akebono satellite. For accurate determination of the SC onset time, we referred the geomagnetic variation data with the time resolution of 1 sec obtained at Kakioka Magnetic Observatory. Within the simultaneous Akebono observation data of 101 SC events in the low latitude region, we found that plasma waves are enhanced with one-to-one correspondence to SCs in the

plasmasphere. The SC related plasma wave phenomena show clear spectral modulation and increase of the center frequency of whistler mode, LHR waves, and electromagnetic ion cyclotron waves. On the other hand, the response of DC electric field perturbations associated with SCs also shows peak amplitude of 1-30 mV/m followed by dumping oscillation of Pc3-4 ULF waves with a period from 40 seconds to 60 seconds in all geomagnetic local times. The ULF waves have continued for about 3 to 6 minutes after the SC onset with a damping. The initial variations of the electric field perturbations at the onset of SC's in space are directed westward. About 1-2 minutes later, the dawn-to-dusk convection electric field is also enhanced with the amplitude of 0.5-1.5 mV/m in the plasmasphere. The Poynting vector is directed earthward with the amplitude of 0.000041-0.00015 W/m^2. This analysis indicates that a compressional wave propagates inside the plasmasphere with refraction. Difference between onset times of SC and plasma wave enhancement showed propagation characters of SC triggered disturbances from dayside to nightside regions. The distribution of the delay time of the plasma wave disturbances suggested that the propagation route of SC disturbance inside the plasmasphere locates near the geomagnetic equator region with a speed of about 350 km/sec.

KILOMETRIC RADIATION ASSOCIATED WITH PLASMASPHERIC DISTURBANCES

Manabu SATO[1], Takayuki ONO[1], Masahide IIZIMA[1], Hiroshi OYA[2], Atsushi KUMAMOTO[1] ([1]Department of Geophysics, Graduate School of Science, Tohoku University, [2]Department of Space Communications, Faculty of Engineering, Fukui University of Technology)

Due to the unique orbital character of the Akebono satellite, it became possible to obtain detail characters of plasma and plasma waves inside the plasmasphere. For example, within an early period of data analysis phase of the plasma wave and sounder experiment (PWS) on board Akebono satellite, the "Donkey Ear" phenomenon (Oya, 1997) was discovered as a significant density depletion region inside plasmasphere near the equatorial region. On the other hand, plasma wave observation inside the density depletion region revealed radiation of electromagnetic waves within a frequency range of several hundreds kHz that seems to be trapped inside the density depletion region. Interesting fact is that the propagation mode of the majority of the kilometric radiations tends to show the right-handed polarized waves (R-X mode). The electromagnetic wave is named as kilometric radiation since the wavelength is the order of kilometric scale length. There are 578 events of the kilometric radiation found in the observation results of the Akebono satellite during the period from 1989 to 1999. It shows clear that association of "Donkey Ear" phenomena with 41.3% of kilometric radiation events. The observation region is concentrated within ± 50 degree geomagnetic range, and it appears in an altitude range more than 4,000km. The occurrence probability of the kilometric radiation showed clear relation with the variation of the solar activity and significant concentration near the geomagnetic equator. This nature suggested that the source region of kilometric radiation is located near the geomagnetic equatorial region. Kp and Dst dependences were also investigated; it became clear that the kilometric radiation occurred in a condition of large geomagnetic disturbances. 64% of radiation events showed relation to geomagnetic storms, with the magnitude more than 50nT in Dst. A correlation analysis of occurrence probability to the phase of magnetic storms showed that there is occurrence peak near the start time of the recovery phase of geomagnetic storms. The kilometric radiation is expected to spread outside of plasmasphere through a window where plasma density is low comparing with the radiation frequency. The kilometric continuum observed by GEOTAIL satellite (Hashimoto et al., 1999) may be a part of the kilometric radiations propagating outside plasmasphere through the window. The present results may support the model proposed by Green et al. (2002) that the origin of kilometric continuum is located in the bite-out structure of plasmasphere by using the data observed by IMAGE satellite.

SOLAR WIND - PLASMASPHERE - IONOSPHERE COUPLING DURING GEOMAGNETIC STORMS

Galina A. KOTOVA[1], V. BEZRUKIKH[1], M. VERIGIN[1], L. LEZHEN[1], J. SMILAUER[2], J. LEMAIRE[3] ([1]Space Research Institute of Russian Academy of Sciences, [2]Institute of Atmosphere Physics, Czech Academy of Sciences, Prague, [3]Institute d'Aeronomie Spatiale de Belgique, Brussels, Belgium)

The ALPHA 3 thermal plasma measurements obtained on INTERBALL 1 and 2, andsubsatellite MAGION 5 in the plasmasphere of the Earth are analyzed in conjunctionwith simultaneous solar wind data and ground-based ionospheric measurements during geomagnetic storms. Previously it was found, theoretically unpredicted increasing of cold ion density in the dusk and dawn outer plasmasphere with increasing solar wind ram pressure probably connected to the overall magnetospheric compression. Enhancements in solar wind pressure frequently initiate the development of geomagnetic storm in the whole magnetosphere. In the present talk detailed case study of some strong magnetic storms occurred in 1999 and 2000 is performed. Dynamics of the plasmapause and thermal plasma parameters during geomagnetic storms is interpreted taking into account the overall coupling in solar wind –plasmasphere–ionosphere system.

MEASUREMENTS OF THE SAPCE RADIATION ENVIRONMENT WITH SDOM

Haruhisa MATSUMOTO, Hideki KOSHIISHI, Tateo GOKA (National Space Development Agency of JAPAN)

TSUBASA satellite was launched on February 2002. TSUBASA is placed in a geostationary transfer orbit having roughly a perigee of 500 km, an apogee of 36,000km, a 28.5 inclination, and a 645 minute period. The Standard Dose Monitor (SDOM) onboard TSUBASA has carried out measurements of energetic electrons, protons, and alpha particles. We report the dynamic feature of the radiation belt environment, and the change of ptich angle distribution of the radiation belt particles by the geomagnetic storm.

MOLECULAR ION OBSERVED BY AKEBONO SATELLITE NEAR THE INNER MAGNETOSPHERE

Manabu YAMADA[1], Shigeto WATANABE[1], Takumi ABE[2], Yoshizumi MIYOSHI[4], Eiichi SAGAWA[3], A.W. YAU[5] ([1]Division of Earth and Planetary Science, Graduate School of Science, Hokkaido University, Sapporo, Japan., [2]The Institute of Space and Astronautical Sciences, Sagamihara, Japan., [3]Communications Research Laboratory, Koganei, Japan., [4]Planetary Plasma and Atmospheric Research Center, Tohoku University, Sendai, Japan., [5]University of Calgary, Calgary, Canada.)

The importance of the ionosphere as a source of magnetospheric plasmahas been confirmed by recent studies. The existence of heavy ion in themagnetosphere, such as O+

coming from the ionosphere, means that we haveto investigate in detail the processes of ion heating, ion acceleration,ion outflow, ion dynamics in the magnetosphere and the wave-particleinteractions. The suprathermal ion mass spectrometer (SMS) on Akebonosatellite has observed the polar topside ionospheric ions of 1-64 m/qwith low energy (0-25keV) over the long period more than one solarcycle. SMS data is, therefore, useful for the statistical analysis ofthermal ion heating and outflow phenomena, and provide us importantinformation on the dynamics of molecular ions such as N2+ and NO+ inaddition to O+ in the inner magnetosphere.In this paper, we discuss in detail about the molecular ion outflowevents and show the molecular ion flux and the occurrence frequency inthe inner magnetosphere.

DEPARTURES FROM COROTATION IN THE INNERMAGNETOSPHERE

Bill R. SANDEL, William T. FORRESTER, Robert A. KING (Lunar and Planetary Laboratory, University of Arizona)

Using maps of the distribution of singly-ionized helium in the plasmasphere made by the IMAGE Extreme Ultraviolet Imager, we investigate departures from corotation in the inner magnetosphere. We deduce the angular velocity of the plasma by tracking discrete,long-lived features within the plasmasphere. On the basis of first-order theory, we would expect the cold plasma that we observe (energy <1 eV) to be locked by the Lorentz force to Earth´s magnetic field and to corotate with it. In contrast, our analysis shows that the plasma in the range $2<L<4$ most frequently rotates at a rate that is roughly85-90% of the corotation rate. A particular feature may move at a constant or variable rate during its lifetime. It may move at the corotation rate for a time, and then begin to lag. Our analysis is based on features that persisted for times in the range 15-60 hours. We find a range of angular velocities (averaged over the lifetime of the features) that is 77% to 93% of the corotation velocity. Structures having large radial extent frequently maintain their shapes over the period of observation. In these cases, measurable shearing by an L-dependent corotation lag must therefore be absent. We investigate the implications of these measurements for our understanding of electric fields and plasma motions in the inner magnetosphere.

IMAGE EUV OBSERVATIONS OF PLASMASPHERIC EROSION: INDICATIONS OF PLASMASPHERE/RING-CURRENT/IONOSPHERE COUPLING

Jerry GOLDSTEIN[1], Bill R. SANDEL[2], Pontus CSON BRANDT[3], Stanislav Y. SAZYKIN[4] ([1]Space Science Division, Southwest Research Institute, [2]Lunar and Planetary Lab, University of Arizona, [3]Applied Physics Lab, Johns Hopkins University, [4]Department of Physics and Astronomy, Rice University)

The IMAGE extreme ultraviolet (EUV) imager obtains global images of the He+ plasmasphere as seen in 30.4 nm light. EUV directly observes the effects of plasmaspheric erosion by capturing the motion of the plasmapause. Several erosion events have been identified in which the nightside plasmapause moves inward, while at the same time the dayside fills up with (presumably sunward-moving) plasma. This global transport of plasmaspheric material from the nightside to the dayside is generally accepted to be connected in some way to enhanced convection electric fields that arise during periods of increased geomagnetic activity following southward turnings of the interplanetary magnetic field (IMF). However, the precise chain of events between a southward IMF turning and the onset of plasmaspheric erosion has not been established. EUV data consistently indicate a time delay of about 30 minutes between a southward IMF turning at the magnetopause, and the onset of plasmaspheric erosion. One simple explanation for this 30-minute delay is that the global convection field requires some time after a southward IMF turning to reach a new configuration with well-established flows, and thus the inner magnetosphere would not experience the effects of enhanced convection until that new global configuration is established. There are strong indications that this simple picture is incomplete and that coupling (between the inner magnetosphere and other regions of the magnetosphere) plays a significant role. Partial ring currents at the inner edge of the plasmasheet participate in the erosion process (to an unknown extent) by providing a dynamically-changing shielding layer and/or by coupling to the ionosphere to produce regions of intense azimuthal flows known as sub-auroral polarization streams (SAPS). This raises the possibility that the 30-minute delay may be explained as an interval of buildup of ring current pressure. We shall present a picture of this plasmaspheric erosion process from an observational and theoretical/simulational perspective.

ULF RESONANCE, EUV REMOTE SENSING, AND IN SITU PLASMASPHERIC OBSERVATIONS

Mark B. MOLDWIN, D. BERUBE, J. WEYGAND (Earth and Space Sciences, UCLA)

The location of the plasmapause and the density structure of the plasmasphere can be determined from ground-based ULF resonance techniques, in situ plasma wave receivers and particle detectors, and the EUV imager on the IMAGE spacecraft. We take advantage of the opportunity to make simultaneous observations from these variety of techniques in order to understand the global behavior of the plasmasphere in response to storms.

IMAGE OBSERVATIONS OF PLASMASPHERE/RING CURRENT INTERACTIONS

Dennis L. GALLAGHER[1], Mark L. ADRIAN[2], Joseph D. PEREZ[3], Bill R. SANDEL[4] ([1]NASA Marshall Space Flight Center, [2]University of Alabama in Huntsville, [3]Auburn University, [4]University of Arizona)

Evidence has been found in IMAGE observations that overlap of the plasmasphere and the ring current may lead to enhanced loss of plasma into the ionosphere. It has long been anticipated that this mixing of plasma leads to coupling and resulting consequences on both

populations. Wave generation, pitch angle scattering, and heating are some of the consequences that are anticipated. IMAGE plasmasphere, ring current, and auroral observations will be presented and used to explore these interactions and their effects.

FORMATION OF MAIN PHASE RING CURRENT AND RECOVERY PHASE RING CURRENT

Yusuke EBIHARA[1], Masaki EJIRI[1], Hans NILSSON[2], Ingrid SANDAHL[2], Manuel GRANDE[3], Joseph F. FENNELL[4], James L. ROEDER[4] ([1]National Institute of Polar Research, Japan, [2]Swedish Institute of Space Physics, Sweden, [3]Rutherford Appleton Laboratory, UK, [4]The Aerospace Corporation, USA)

Data from the Polar/MICS instrument (1-200 keV) and results of a single particle simulation are used to investigate the formation of the proton ring current during both the storm main and recovery phases. We performed a numerical simulation that tracks bounce-averaged trajectories of particles under various magnetic field models (the dipole and Tsyganenko 1989 and 1996 models), electric potential models (the Volland-Stern type and Weimer 2000 models) and induction electric field models. Three different transport processes were tested to account for the formation of *the main phase ring current*; the convection electric field, the substorm-associated induction electric field and the radial diffusion. Data from Polar/MICS shows that during a storm main phase a dramatic enhancement of the proton differential flux is seen on the night side. No significant enhancement is, in most cases, found on the dayside when Dst decreases monotonically. This may exclude some physical hypotheses that are simulated to produce a rather symmetric ring current, that is, the substorm and the diffusion processes are probably a minor contributor to the ring current formation when the local time asymmetry of the enhancement appears during the main phase. The simulation under a time-dependent convection electric field model gives a fairly reasonable result in comparison with the Polar/MICS data. *The recovery phase ring current* is not simply understood to the result of decay of the ring current. According to the Polar/MICS data, high-energy population of the ring current ($>$100 keV), which is minor during the main phase, appears in the heart of the ring current (L=3-5) when the recovery phase starts. A simple convection electric field model does not account for this kind of development. The substorm and diffusion processes are also unlikely because they are thought to be more effective during the main phase than during the recovery phase. We discuss the possibility that an azimuthal electric field induced by the storm-associated increase in the ambient magnetic field of the ring current is important to produce the development of the high-energy portion of the ring current during the recovery phase.

ANALYSIS OF RING CURRENT CONTROL OF ELECTRIC FIELDS IN THE INNER MAGNETOSPHERE DURING THE APRIL 2002 MAGNETIC STORMS

Michael W. LIEMOHN[1], Janet U. KOZYRA[1], Aaron J. RIDLEY[1], Jichun ZHANG[1], Gang LU[2], Darren L. DE ZEEUW[1], Daniel M. OBER[3], Phil C. ANDERSON[4], Cynthia CATTELL[5], Jerry GOLDSTEIN[6], Pontus C:SON BRANDT[7], M. F. Thomsen, A. J. Mannucci ([1]SPRL, University of Michigan, [2]National Center for Atmospheric Research, [3]Mission Research Corporation, [4]The Aerospace Corporation, [5]Department of Physics, University of Minnesota, [6]Department of Physics and Astronomy, Rice University, [7]Applied Physics Laboratory, Johns Hopkins University, [8]Los Alamos National Laboratory, [9]Jet Propulsion Laboratory)

Modeling results of the inner magnetosphere during the April 17-22, 2002, magnetic storms are presented, showing the importance of a self-consistent calculation between the electric field and the hot ion fluxes. In particular, the control of the subauroral electric fields by the ring current will be discussed, along with their impact on the ionospheric and magnetospheric plasma. Using a kinetic plasma transport code that highly resolves the velocity space distribution, results from several simulations with different input and boundary conditions are examined. Output from a global MHD code is also presented for context. These results are analyzed in combination with observations of the inner magnetospheric and subauroral plasma populations and electric fields. Thus the global spatial and temporal evolution during the event is determined from several methods and all of these are compared together. This comparison yields information about the accuracy of the assumptions built in to the various models (e.g., formulations, conductances, boundary conditions, magnetic field descriptions) as well as the ability of the various data sets to accurately reveal the development of the event. These findings are discussed in detail. The aeronomic consequences of the stormtime electric fields, including storm-enhanced densities in the ionosphere from the subauroral region to the polar cap, are also discussed.

MAGNETIC FIELDS AND PLASMAS IN ACTIVE SUBSTORMS AND STORMS

Thomas E. MOORE[1], J.F. FENNELL[3], M.-C. FOK[1], M.B. MOLDWIN[2], J.A. SLAVIN[1], R.J. STRANGEWAY[2] ([1]Laboratory for Extraterrestrial Physics, NASA's Goddard Space Flight Center, [2]IGPP, University of California in Los Angeles, [3]The Aerospace Corporation)

In this paper, we review recent advances and the current state of knowledge of the inner magnetosphere, defined as the region within which the ionosphere is the dominant source of plasma, including the bulk of the ring current and at least the inner plasma sheet. To limit scope, we focus on the magnetic field and plasma description of this region, rather than on the electric field and current description, taking the latter to be complementary but to some degree redundant, and in any case, less readily observed. We consider the significant recent contributions of remote sensing and imaging to our knowledge of the inner magnetosphere, as well as the recent development of a Comprehensive Ring Current Model (CRCM) and radiation belt forecasting tools. These have given us the first system description to account for interactions with the ionosphere and thermosphere, including the enhancement of ionospheric outflows into the high latitude regions. Next, we consider recent developments in the acceleration of charged particles to form the dynamic ring current and radiation belt environment, including mechanisms involving interplanetary shocks, ULF pulsations, and compressive impulses originating in the plasma sheet. Finally, we summarize by presenting a case that future progress in inner magnetospheric weather forecasting will require more and better coordinated observations of magnetic fields and plasmas in active substorms and storms, to better define the environment within which such dynamical effects arise and develop.

THE RING CURRENT AND INNER MAGNETOSPHERE DURING STEADY MAGNETOSPHERIC CONVECTION EVENTS

Calvin Robert CLAUER[1], M.W. LIEMOHN[1], D.L. DEZEEUW[1], J.U. KOZYRA[1], J. GOLDSTEIN[2] ([1]Center for Space Environment Modeling, Univ. of Michigan, [2]Southwest Research Institute)

The behavior of the inner magnetosphere in response to an increase or decrease of the

---

convection electric field is examined during periods of so-called Steady Magnetospheric Convection events. These events are distinctive in their lack of substorm signatures during intervals of enhanced convection driven by large, quasi-steady southward IMF. The temporal and spatial development of the ring current is measured using LT-UT maps of the low latitude ground magnetic disturbance measured by a chain of about 20 magnetic observatories. Temporal and spatial variations of the plasmasphere are measured using images obtained from the Extreme Ultra Violet Imager (EUV) instrument on the IMAGE satellite. Results from the Michigan inner magnetosphere models are consistent with the observations in many ways. We discuss the physical interpretation of the combined analysis of the model and observational results.

GAIII.06/08A/A02-009   **1215**

EVOLUTION OF RING CURRENT ENERGY DENSITY DURING GEOMAGNETIC STORMS

Natalia Yu. GANUSHKINA[1], Yusuke EBIHARA[2], Tuija I. PULKKINEN[1], Masaki EJIRI[2], Ted A. FRITZ[3] ([1]Department of Geophysical Research, Finnish Meteorological Institute, [2]National Institute of Polar Research, Tokyo, Japan, [3]Department of Astronomy, Boston University, Boston, MA, USA)

Changes in the ring current energy density during storm periodsare studied. Ring current energy densities and total ringcurrent energies are obtained using particle data from PolarCAMMICE/MICS instrument during several storms during year1997-1998. Four different energy ranges for particles areconsidered: total (1-200 keV), low (1-20 keV), medium (20-80 keV)and high (80-200 keV). Evolution of contributions fromparticles with different energy ranges to the total energydensity of the ring current during different storm phases isfollowed. To model this evolution we trace protons with arbitrarypitch angles numerically in the drift approximation. Tracing isperformed in stationary (T96, Volland-Stern) and time-dependentmagnetic and electric field models. Time-dependent electric fieldis given by Gaussian electric field pulse with azimuthal fieldcomponent propagating inward with constant velocity of 100 km/s.We model particle inward motion and energization by a series ofelectric field pulses representing substorm activations duringstorm events. We demonstrate that such fluctuating fields caneffectively energize the plasma sheet particles and transportthem inward to closed drift shells. Analysing the modelcontributions from particles with different energy ranges to themodel total energy density of the ring current during differentstorm phases and comparing with observations we show that theformation of the ring current is a combination of large-scaleconvection and pulsed inward shift and consequent energization ofthe ring current particles.

CRITICAL TEST OF THE DST INDEX AS A MEASURE FO THE STORM INTENSITY

Shin-ichi OHTANI, Pontus C:SON BRANDT, Donald G. MITCHELL (The Johns Hopkins University Applied Physics Laboratory)

The Dst (or Sym-H) index has been ideally regarded as a measure of the ring current intensity, and the development and decay of the magnetospheric storm have been conventionally addressed in terms of the change of this index. However, caution needs to be exercised since the tail current makes a significant contribution to Dst. In the present study we examine the storm event of August 12, 2000 and compare variations of the ENA flux measured by the IMAGE/HENA instrument with the associated variations of the Dst index. The result indicates that substorm-associated changes of the tail current and the ring current have the opposite effects on Dst, and the former overcompensates the latter. We statistically test this result by cross-examining the near-Earth tail magnetic field and Dst for storm-time substorms. Possibility of estimating the ring current intensity from Dst is also discussed.

GAIII.06/08P/A02-002   Invited   **1425**

COUPLING BETWEEN THE INNER MAGNETOSPHERE AND THE IONOSPHERE DURING MAGNETIC STORMS AND SUBSTORMS

Anthony T.Y. LUI (Applied Physics Laboratory)

The inner magnetosphere is an important geospace region for magnetic storms since it contains the storm-time ring current responsible for the worldwide magnetic depression in magnetic storms. A relatively new tool in investigating the dynamics of the ring current is the energetic neutral atom (ENA) emissions. In this study, we present evidence of coupling between the inner magnetosphere and the ionosphere during magnetic storms as well as substorms through ENA observations from Geotail. It is found that ENA oxygen emissions are temporarily enhanced during substorms in a magnetic storm interval, consistent with earlier reports of transient ionospheric oxygen ion outflow in association with substorm activity. The spectral evolution of ENA oxygen during the main phase of a magnetic storm is also used to examine the temporal coupling of the ionosphere to the inner magnetosphere during the development of the storm-time ring current.

GAIII.06/08P/A02-003   Invited   **1450**

THE GLOBAL SCALE OF SAWTOOTH INJECTIONS AND IMPLICATIONS FOR MAGNETOSPHERIC AND IONOSPHERIC COUPLING

Geoffrey D. REEVES, Michelle F. THOMSEN, Joe E. BOROVSKY, Michael G. HENDERSON, Ruth M. SKOUG (Space and Atmospheric Sciences Group)

Sawtooth injections were first identified as an intriguing signature in the LANL geosynchronous energetic particle fluxes showing sharp increases in particle fluxes followed by gradual decreases which repeat roughly every 2-3 hours. The variations are similar to the standard dropout and injection of energetic particles seen in isolated substorms. However, unlike isolated substorms, after each injection a new dropout begins immediately, over a broad range of energies, producing the characteristic sawtooth profile. Space magnetometer data show that the dropouts and injections are produced by exceptionally strong stretching and dipolarization of the magnetic field and confirm that the stretching begins immediately after the preceding injection without an intervening recovery phase. However, ENA observations show that these events are true injections of fresh particles and not an adiabatic re-arrangement in response to the field changes. Auroral observations likewise show clear auroral onsets with each sawtooth injection, but those onsets can be embedded in ongoing auroral activity rather than distinct episodes separated by quiet intervals. It is not surprising that sawtooth activity is a subset of geomagnetic storm activity (intervals of large negative Dst). The quasi-periodicity and clear separation of each onset are not, however, characteristic of most geomagnetic storms. Additionally, each individual sawtooth is associated with an increase in the SYM-H component. One of the most intriguing

characteristics is that sawtooth signatures are seen at all local times, not just the near-midnight sector. By analyzing multi-satellite data we are able to determine the scale of these injection events. Data from up to 7 simultaneously-operating geosynchronous satellites show that the injections there frequently cover more than 12 hours of local time. They are more prominent in the dusk sector than in the dawn sector and frequently, perhaps even typically, extend well past the dusk terminator toward local noon. We will discuss the spatial extent of the sawtooth injections, the possible signatures of propagation, and the implications for global coupling to the ionosphere and other magnetospheric regions.

GAIII.06/08P/A02-004   1515

DYNAMICS OF FIELD ALIGNED CURRENTS ASSOCIATED WITH GLOBAL QUASI-PERIODIC GEOSYNCHRONOUS PARTICLE INJECTION EVENTS

Brian J. ANDERSON[1], M. THOMSEN[2], R. SKOUG[2] ([1]Space Department, The Johns Hopkins University Applied Physics Laboratory, [2]Los Alamos National Laboratory, Space and Atmospheric Sciences, Los Alamos, New Mexico, USA)

Quasi-periodic particle injection events, also called 'ssawtooth events, have been reported in geosynchronous orbit particle observations. They are characterized by a recurring sequence of dropout and nearly dispersionless recovery or injection of 50 to 400 keV ions at multiple satellites with repetition intervals ranging from one to several hours. The events typically occur during geomagnetic storm-times and give the appearance of substorm injections except that they are dispersionless on a scale that often exceeds 12 hours in longitude. To help characterize the magnetospheric electrodynamics associated with these events we examine observations from engineering magnetometers of the Iridium satellite system. These data provide global scale, 2-hour local time resolution, estimates of the high latitude Birkeland currents with a time and latitude resolution of approximately 2-latitude-hours. For this study we use 30 minute windows which provide 4 degree latitude resolution to examine the dynamics of nightside field aligned currents (FACs) associated with sawtooth injections. The nightside FACs display a systematic sequence with each dropout-injection event. The period of minimum flux is associated with a FAC pattern consistent with the classical Iijima-Potemra statistical pattern in which the morningside upward region 2 current is contiguous with the duskside upward region 1 current. Particle injection is associated with disruption of this pattern in the region of the Harang discontinuity in which a downward FAC appears at latitudes of the most equatorward (region 2) upward current. This change is consistent with the appearance of a pair of field aligned currents, downward post-midnight and upward pre-midnight, consistent with a substorm wedge current system.

GAIII.06/08P/A02-005   1530

MODELING THE INNER PLASMA SHEET PROTONS AND MAGNETIC FIELD UNDER ENHANCED CONVECTION

Chih-Ping WANG[1], Larry R. LYONS[1], Margaret W. CHEN[2], Richard A. WOLF[3], Frank R. TOFFOLETTO ([1]Department of Atmospheric Sciences, UCLA, [2]Space Science Applications Laboratory, The Aerospace Corporation, [3]Department of Physics and Astronomy, Rice University)

To understand the evolution of the inner plasma sheet from quiet to disturbed conditions, we incorporate a modified version of the Magnetospheric Specification Model with a modified version of the Tsyganenko 96 magnetic field model to simulate the protons and magnetic field under an increasing convection electric field with two-dimensional force balance maintained along the midnight meridian. The local-time dependent model boundary proton sources are a mixture of hot plasma from the mantle and cooler plasma from the low latitude boundary layer. We previously used this model to simulate the inner plasma sheet under weak convection corresponding to a cross polar-cap potential drop (DFPC) equal to 26 kV and obtained two-dimensional quiet time equilibrium for proton and magnetic field that agrees well with observations. We start our simulation for enhanced convection with this quiet time equilibrium and increase DFPC steadily from 26 kV to 146 kV in 5 hours while keeping the boundary particle sources time independent. Simulations are also run separately to steady states by keeping DFPC constant after it is increased to 98 and 146 kV. The magnitudes of proton pressure, number density, and temperature and their increase from quiet to moderate activity (DFPC = 98 kV) are consistent with most observations. Our simulation at high activity (DFPC = 146 kV) underestimates the observed pressure and temperature. This disagreement indicates possible dependence of the boundary particle sources on activity and possible effects of solar wind dynamic pressure enhancements that have not yet been included in our simulation. The equatorial distributions of the simulated equatorial pressures, density, and temperatures and their change with activity agree qualitatively with the DMSP observations. The simulated proton flow speed at the equatorial plane increases with enhancing convection while the overall flow direction does not change significantly, a result of enhancement in both the earthward electric drift and azimuthal diamagnetic drift. The equatorial magnetic field strength decreases more in the near-Earth plasma sheet than at larger radial distances as DFPC increases, resulting in an increasing flat radial profile with enhancing convection. The feedbacks from diamagnetic drift and magnetic fields to increasing convection are found to restrain the pressure increase. Based on the good agreement between our results and observations at moderate activity, our magnetic field indicates the plasma and magnetic field in the plasma sheet can be in a state far from possible force balance inconsistency during periods of moderately enhanced convection. A scale analysis of our results shows that the frozen-in condition E = --v'LB is not valid in the inner plasma sheet for moderate activity.

GAIII.06/08P/A02-006   1545

MAGNETOSPHERIC CONVECTION IN MHD SIMULATIONS AND THE INFLATION OF THE INNER MAGNETOSPHERE DURING STRONG, STEADY SOLAR WIND DRIVING

Ramon E. LOPEZ[1], Michael J. WILTBERGER[2] ([1]Department of Physics, University of Texas at El Paso, [2]NCAR/HAO)

The coupling between the inner and outer magnetosphere during periods of strong steady driving by the solar wind is a basic problem in magnetospheric physics. A fundamental issue that arises is how steady, adiabatic magnetospheric convection can occur when the consequence would appear to be either physically unrealistic plasma pressures in the inner magnetosphere, or the development of deep Bz minima that would lead to substorms, and hence unsteady convection. Our studies using the Lyon-Fedder-Mobarry global MHD simulation indicates that part of the solution is that the inner magnetosphere is inflated during such steady (or quasi-steady) convection periods so that the resulting compression of plasma as it convects into the inner magnetosphere is limited. We will present the results of those studies, along with a comparison to observations in order to validate the results of the simulations.

GAIII.06/08P/A02-007   Invited   1615

THE EARTH'S RADIATION BELTS: SOLAR WIND, MAGNETOTAIL AND ATMOSPHERIC CONNECTIONS

Daniel N. BAKER (Laboratory for Atmospheric and Space Physics)

The time of solar (sunspot) maximum is characterized by frequent solar transient events and coronal mass ejections (CMEs). These aperiodic disturbances can cause very powerful geomagnetic storms (if the solar outputs strike the Earth). On the other hand, during the approach to sunspot minimum, the solar corona is characterized by large coronal holes that are the source of powerful high-speed solar wind streams. Such streams also produce geomagnetic storms (which often are recurrent with a 27-day period). CME-driven storms, and even more so, high-speed stream-driven storms, produce powerful enhancements of relativistic electrons in the Earth's outer radiation belt. We present analysis of multiple long-term data sets including those from SAMPEX, POLAR, GOES, and other radiation belt-monitoring missions. We discuss the highly dynamic variability of the radiation belts and we show how this variability relates to solar wind inputs and plasma sheet source populations. We also consider the precipitation loss of radiation belt electrons and the subsequent effects in the Earth's upper and middle atmosphere.

GAIII.06/08P/A02-008   1640

RELATIVISTIC ELECTRON INCREASE AND LOSS DEPENDING ON OTHER PARTICLE POPULATION, GEOMAGNETIC ACTIVITY AND MAGNETOSPHERIC CONVECTION

Takahiro OBARA[1], Yoshizumi MIYOSHI[2], Akira MORIOKA[2] ([1]CRL, [2]PPARC, Tohoku University)

Geomagnetic storm is the most dramatic interval in which particle energization takes place greatly in the inner magnetosphere. With the start of the geomagnetic storm relativistic electrons in the outer radiation belt disappears. During the recovery phase of the geomagnetic storm the outer radiation belt is filled with plenty of relativistic electrons, which sometimes exceed pre-storm level. We have investigated outer radiation belt by means of Akebono satellite over 14 years and following results were obtained. 1) Loss of relativistic electrons during the main phase of the geomagnetic storm was due to the enhancement of the magnetospheric convection as well as the precipitation into the atmosphere. 2) Location of the outer belt was coinciding with plasma pause location and both locations had a strong dependence on the magnetic activity. 3) Sufficient supply of intermediate-energy electrons from the plasma sheet was made during and after storm main phase, and these electrons were accelerated up to the relativistic energy range during the storm recovery phase. 4) Increase in the intensity of outer belt electrons strongly depends on the magnetic activity during the storm recovery phase. Possible candidates for the acceleration would be chorus emissions. 5) In the super storm, a new belt was created in so-called slot region, which sometimes persisted more than months. Only the betatron effect accelerated electrons and no additional acceleration was observed with the lack of plasma wave activities in the vicinity of the new belt region.

GAIII.06/08P/A02-009   1655

VARIATIONS OF ENERGETIC ELECTRON FLUXES AND MAGNETIC FIELD IN THE OUTER RADIATION BELT DURING MAGNETIC STORMS

Masao NAKAMURA, Hitoshi MATSUOKA, Hideki KOSHIISHI, Kiyokazu KOGA, Haruhisa MATSUMOTO, Tateo GOKA (Space Environment Measurement Engineering Group, Office of R&D, National Space Development Agency of Japan)

We have investigated energetic electron flux variations (> 0.4 MeV) and the magnetic field in the outer radiation belt obtained from the Standard DOse Monitor (SDOM) and the MAgnetoMeter (MAM) of the Space Environment Data Acquisition equipment (SEDA) onboard Tsubasa (Mission Demonstration Test Satellite (MDS)-1) launched on February 4, 2002. Since Tsubasa operates in geostationary transfer orbit (GTO), it has provided a rare opportunity for directly observing near-equatorial radiation belt plasma particles and the magnetic field during magnetic storms. Energetic electrons in the outer radiation belt are important contributors to the total radiation dose deposited on lightly-shielded electronics on board spacecraft in high-altitude orbits, and are known to display drastic flux variability associated with magnetic storms and high-speed solar wind streams. Sharp drops and subsequent slower recoveries that occur in the energetic electron flux in the outer radiation belt during magnetic storms are linked respectively to typical variations of the magnetic field. These observations could shed light on possible mechanisms for the depletion and subsequent recovery and/or build-up of energetic electrons in the outer radiation belt.

GAIII.06/08P/A02-010   1710

MAGNETIC FIELD VARIATIONS AT GEOSYNCHRONOUS ORBIT AND THEIR RELATIONS TO THE RELATIVISTIC ELECTRON DYNAMICS

Tsutomu NAGATSUMA, Takahiro OBARA (Applied Research and Standards Division, Communications Research Laboratory)

We have examined the characteristics of magnetic field variations at geosynchronous orbit (GEO) and its relations to the relativistic electron dynamics using magnetic field and particle data from GOES satellites located at different geomagnetic latitudes, and solar wind data from Wind and ACE satellites. The results of our data analysis suggest that the magnetic field variations at GEO strongly depend on the dynamic pressure of solar wind and pressure corrected Dst index (Dst*). Dst* dependence shows some difference between the cases of IMF Bz positive and negative. The Dst* dependences of magnetic field variations derived from two different magnetic latitudes suggest that these magnetic field variations can be explained by the existence of equivalent westward current beyond the GEO. This means that magnetic field structure during storm time is highly stretched. Enhancement of the dynamic pressure also stretches magnetic field structure in the tail region. The flux of relativistic electrons at GEO drops off under the highly stretched magnetic field configuration. The timing of this drop off sometimes differ between the two GOES satellites. This difference indicates that the flux drop off start from the distant L-shells. The signature of the rapid drop off is often seen in the dusk sector. These suggest that the non-adiabatic loss mechanism is significant for the relativistic electron dynamics at GEO.

VARIATION OF RADIATION BELT ELECTRONS AND O+ IONS OBSERVED BY FAST AT LOW LATITUDES DURING MAGNETIC STORMS

K. SEKI[1], R.C. ELPHIC[2], M.F. THOMSEN[2], G.D. REEVES[2], J.P. MCFADDEN[3], J.W. BONNELL[3], E.J. LUND[4], M. HIRAHARA[5] ([1]Solar-Terrestrial Environment Laboratory, Nagoya University, Honohara 3-13, Toyokawa, Aichi 442-8507, JAPAN, [2]Los Alamos National Laboratory, NIS-1, MS466, Los Alamos, NM 87545, USA, [3]Space Science Laboratory, UC Berkeley, Berkeley, CA 94720-7450, USA, [4]Space Science Center, University of New Hampshire, Durham, NH 03824, USA,

[5]Department of Physics, Rikkyo University, Toshima, Tokyo 171-8501, JAPAN)

Previous observations have shown that the O+ ion population becomes an important contributor to the ring current during large magnetic storms. Its importance in terms of energy density increases with increasing geomagnetic activity. On the other hand, the processes responsible for this dramatic composition change of the ring current are still under debate. Enhanced polar outflows during geomagnetically active periods are considered to be responsible for the composition change. However, the link between the outflows and high-energy ring current is not clear due to the lack of low-energy ion observations in the inner magnetosphere inside GEO (R~6.6 Re). Penetration of radiation-belt electrons into instruments makes direct observations of low-energy ions difficult in the inner magnetosphere. A correction method to remove this background is also one of key elements needed for inner magnetospheric missions in the future. The Electrostatic Analyzer (ESA) onboard the FAST satellite had been operated in the mid-latitude regions above ~45 degrees for the past 4 years and observed ions below 30 keV. Radiation belt contamination is quite uniform in energy. Utilizing this feature, we developed an automated method to subtract the radiation contamination from ESA data and estimated the background counts and ion moments during several magnetic storms. Comparison between the estimated background and energetic particle data at GEO orbits indicates that electrons with energies of 0.5-1.5MeV are the main contributor to the background. The background count variation during a magnetic storm from April 11, 2001 indicates that the outer radiation belt electron fluxes decreased dramatically during the storm main phase and recovered from the inner L shells (ILAT~53-55 degrees) during the rapid recovery phase. Finally, the peak flux of the penetrating population moved to higher latitudes, near to its pre-storm position. The data after the background correction enable us to monitor behavior of low-energy ($<$30 keV) ions as a function of ILAT in a particular MLT range. For example, O+ ions appeared in the inner magnetosphere at the beginning of the April 11, 2001 storm and became the major ion component in the inner magnetosphere during the storm. Preceding the development of the O+ ring current, large numbers of O+ ions comprising multiple energy bands below 12 keV were observed at low latitudes (50-60 degrees). The ionospheric O+ are transported to the inner magnetosphere during the storm, and the observation suggests that it contributes, at least partially, to the O+ ring current during the large storm. On the basis of these observations, the supply mechanisms of O+ ions to the storm-time ring current will be discussed.

DYNAMICS OF LOWER-ENERGY (30-250 KEV) PROTONS IN THE INNER MAGNETOSPHERE

Akira MORIOKA[1], Yoshizumi MIYOSHI[1], Yo-ichi MATSUMOTO[1], Hiroaki MISAWA[1], Fuminori TSUCHIYA[1], Takahiro OBARA[2], Tsutomu NAGATSUMA[2] ([1]Planetary Plasma and Atmospheric Research Center, Tohoku University, [2]Communications Research Laboratory)

Dynamics of lower-energy protons in the energy range from 30 to 250 keV was studied using data from NOAA satellites. During the main phase of magnetic storms, the spiky enhancement of proton flux in the energy range from 30 - 80 keV was always detected deep in the inner zone almost simultaneously with increase in the outer magnetosphere, and its lower boundary was less than L = 2 during large storms. The flux enhancement usually reached up to 100 folds at around L=2 and 1000 folds at around L=3.5. The time profile of the proton flux variation was quite similar to that of Dst. These observations suggest that ring current protons are injected not only in the outer region but also into the bottom region of the radiation belt. After the main phase, the spiky enhancement disappeared and an "inner-belt like" proton structure remained in the region around L=2. The structure was more clearly seen in the energy range from 80- 250 keV and seemed to be diffusing from the main proton belt to lower L shells during the recovery phase in the L-t diagram. The location of the 'inner-belt like structure was slightly different from that of the electron inner belt; proton peak was located near L=2.2 - 2.5, and the electron peak was near L=2.0 - 2.4. This newly observed proton belt might necessitate the modification of the proton dynamics in the lower L regions.

COMPLEXITY AND FSOC IN SPACE PLASMAS

Tom T.S. CHANG (Center for Space Research, Massachusetts Institute of Technology)

Bak et al. suggested in 1987 that nonequilibrium stochastic systems have a general tendency to organize themselves into complex states similar (but not identical) to the static critical states in equilibrium phase transitions. They dubbed such phenomena as self-organized criticality (SOC). Since then the topics of complexity and SOC have become hot topics in nearly every field of science. The first definitive observation that provided convincing evidence indicating certain turbulent space plasma processes are in states of complexity and SOC was the discovery of the apparent power-law probability distribution of solar flare intensities. Recent statistical studies of complexity in space plasmas came from the AE index, UVI auroral imagery, and in-situ measurements in the solar wind and the Earth´s magnetotail. In this review, we describe the physics and a companion theory of dynamical complexity and forced and/or self-organized criticality (FSOC) for space plasma systems far from equilibrium. We demonstrate that the sporadic and localized interactions of magnetic coherent structures are the origin of complexity and FSOC. Such interactions generate the anomalous transport, diffusion, acceleration, and evolution of the macroscopic states of the overall dynamical system. Several illustrative examples related to the magnetospheric system are considered. These include: the dynamical multi- and cross-scale interactions of the macro- and kinetic coherent structures in a sheared magnetic field, the Alfvenic flux tubes and coexisting propagating and non-propagating fluctuations in the auroral turbulence region, the onset of fluctuation-induced nonlinear instabilities that can lead to magnetic reconfigurations, and the resonant energization of charged particles by non-propagating fluctuations.

GAIII.07/09A/A14-002   0930

ANALYSIS OF GEOMAGNETIC STORMS USING FRACTAL THEORY

Chandrasekhar ENAMUNDRAM[1], Mohan N. L.[2] ([1]Indian Institute of Geomagnetism, Dr. Nanabhoy Moos Road, Colaba, Mumbai - 400 005, India., [2]Centre of Exploration Geophysics, Osmania University, Hyderabad - 500 007, India.)

Geomagnetic storms exhibit a deterministic chaotic phenomenon. Fractal theory isa unique tool for better understanding of such chaotic phenomena in a broaderperspective. In an attempt to characterize and scale the different phases ofgeomagnetic storms, both the sudden and gradual commencement storms havingwell-defined space-time characteristics have been selected for the present analysis. The selected data sets, corresponding to the solar active year, 2001,have been procured from Indian magnetic observatories. The Mellin-Fourier transform (MFT) technique is employed to formulate a mathematical model for chaotic nature of geomagnetic storms and determine the Fractal scales for different phases of geomagnetic storms. The MFT technique facilitates to determine unified values of scale parameters corresponding to different phases of geomagnetic storms. Further, to estimate global scale value corresponding to each of the well-defined phases of geomagnetic storms, the Lyapunov exponents are also computed. The results of this analysis will be discussed in the present paper.

GAIII.07/09A/A14-003   0950

SELF-ORGANIZED CRITICALITY IN EARTH'S MAGNETOTAIL DYNAMICS AND ITS IMPLICATIONS FOR SUBSTORM ONSET

Vadim M. URITSKY[1], Alex J. KLIMAS[2], Dimitris VASSILIADIS[3], Daniel M. BAKER[4] ([1]St. Petersburg State University, St. Petersburg, Russia, [2]NASA / Goddard Space Flight Center, [3]USRA / Goddard Space Flight Center, [4]LASP, University of Colorado, Boulder)

A recent analysis due to Uritsky et al. [JGR, 2002] of auroral emission bright spots in POLAR UVI images has revealed a remarkable set of scale-free power-law avalanche distributions for several of the spots´ physical characteristics. The most straightforward and, at present, sole explanation for these distributions is that localized reconnection in the plasma sheet leads to a self-organized critical avalanching system that is scale-free over a broad range of scales. This analysis will be reviewed and a more recent study of the spreading dynamics of the auroral bright spots will be discussed. It will be shown that the spreading dynamics provides further evidence of self-organized criticality (SOC) in the plasma sheet. Based on these results plus an additional ongoing analysis of the UVI data, a new scenario for substorm onset will be proposed.

GAIII.07/09A/A14-004   1030

THE STATE TRANSISION MODEL OF THE SUBSTORM ONSET

Takashi TANAKA (Department of earth and planetary science, Kyushu University)

The onset mechanism of substorm is investigated from a resistive magnetohydrodynamic (MHD) simulation under the assumption that the magnetotail becomes more diffusive as it goes further downtail. The calculation started from a stationary solution under a northward interplanetary magnetic field (IMF) condition with non-zero IMF By. After a southward turning of the IMF, the simulation results show the progress of plasma sheet thinning in the magnetosphere, together with increases in the size of the auroral oval and in the magnitude of the field-aligned current (FAC) in the polar ionosphere. This thinning is promoted by the drain of closed flux from the plasma sheet occurring under the enhanced convection. In this stage, the reclosure process in the plasma sheet which determines the flux piling up from the midtail to the near-earth plasma sheet is not so effective, since it is still controlled by the remnant of northward IMF. The substorm onset occurs as an abrupt change of pressure distribution in the near-earth plasma sheet and an intrusion of convection flow into the inner magnetosphere. After the onset, the simulation results reproduce both the dipolarization in the near-earth tail and the near-earth neutral line (NENL) at the midtail, together with plasma injection into the inner magnetosphere and an enhancement of the nightside FAC. Dipolarization is hastened by a northward re-turning of the IMF indicating that it is triggered off through the breakdown of dynamic stress balance in the near-tail plasma sheet established under the convection-controlling tail thinning. It is concluded that the direct cause of the onset is the dipolarization, which is not a mere pile up of the flux ejected from the NENL but the state (phase-space) transition of the convection system from a thinned state to a dipolarized state associated with a self-organizing criticality.

SELF-ORGANIZED TURBULENCE, FRACTIONAL KINETIC PROCESSES, AND POWER-LAW FLUCTUATION SPECTRA IN THE EARTH'S STRETCHED MAGNETOTAIL

Alexander V. MILOVANOV, Lev M. ZELENYI (Department of Space Plasma Physics, Space Research Institute)

The focus of the present study is on the structuralstability properties of the Earth´s stretched andthinned magnetotail, meaning vanishing component ofthe normal field and unmagnetized particles (ions) inthe current sheet plane. Such conditions (that are thecase in the distant tail, as well as near-Earth tailat the substorm growth phase) offer a fertile playground for kinetic instabilities driving turbulent dynamics ofparticles and fields. The multiscale interaction ofnonlinear relaxation processes and self-organizationmechanisms operating in the turbulent media customarilyresults in a transition to a nonequilibrium (quasi)stationarystate (NESS) dominated by long-range correlations in space and time. We argue that the inherent dynamics of the NESS is manifested in the low frequency power law fluctuation spectrum 1/f. At higher frequencies, the spectrum has a steeper shape with exponent -7/3 and reflects the structural characteristics of the magnetotail turbulence.A self-consistent kinetic description of turbulentplasma and fields at the NESS is proposed. Our modelis based on a nonlinear fractional kinetic equationwhich helps include the marginal correlation (memory) effects on the microscopic particle dynamics in the magnetotail plasma sheet. We find that the particle energy distribution function contains a power law nonthermal tail with the slope ranging between -6 and -7. The formation of the tail is justified from thermodynamical arguments involving the issue of generalized entropy in the Tsallis sense. The results obtained are in close agreement with the spacecraft observations on the Earth´s magnetotail.

GAIII.07/09A/A14-006   1130

GLOBAL AND MULTI-SCALE DYNAMICS OF THE MAGNETOSPHERE

A. Surjalal SHARMA, Alexander Y. UKHORSKIY, Mikhail I. SITNOV (University of Maryland)

The magnetosphere is a large scale natural system driven by by the turbulent solar wind, and exhibits both global and multi-scale characteristics. The global features arise mainly from the nonlinear nature of the plasma and the electrodynamic coupling between its

different parts. On the other hand, its open and driven nature is the source of many multiscale features. The magnetospheric substorms, which can be charactrized as nonequilibrium transitions, exhibit both global and multi-scale behavior. The global nature of substorms is evident in many observations as well as simulations and has been quantified from time series data using nonlinear dynamical techniques in terms of low dimensional behavior. However, there are significant deviations from the low-dimensional picture and these multi-scale characteristics are evident in the power law nature of many variables. These two aspects of the magnetospheric dynamics can be unified in the framework of nonequilibrium phase transitions. The global dynamics, obtained by an averaging of the dynamical trajectories, is amenable to a mean field description and is represented by a first order phase transition. The multi-scale substorm activity resembles second-order phase transitions and is characterized by a critical exponent. This description of the nonequilibrium transitions in the magnetosphere provides a new approach in the study of global and multi-scale processes, and yields a basis for developing improved forecasting tools. The global features are predicted dynamically using a mean field approach and the multi-scale features, which lead to deviations from the dynamical predictions, are characterized by conditional probabilities computed using the solar wind input and the corresponding magnetospheric response.

GAIII.07/09A/A14-007   1150
A MINIMAL SUBSTORM MODEL THAT EXPLAINS THE OBSERVED STATISTICAL DISTRIBUTION OF TIMES BETWEEN SUBSTORMS

Mervyn Paul FREEMAN (British Antarctic Survey, Cambridge, U.K.)

We propose a minimal model for the evolution of the global dynamical state of the magnetotail during the substorm, involving only three simple rules. Rather than concentrate on the physical nature of the substorm instability, we consider the instability in a more general sense. The substorm is modelled as an integrate-and-fire process in which integrated solar wind power input during the substorm growth phase is eventually released in whole or in part by a firing mechanism at substorm onset. We propose that this nonlinear property is because the magnetosphere is prevented from moving to the lowest energy state appropriate to the prevailing solar wind boundary condition by some configurational constraint involving the magnetic field. When this configurational constraint is overcome, a substorm occurs and the magnetosphere moves towards the minimum energy state appropriate for that time. When driven by a real solar wind power input, the minimal substorm model produces a probability distribution of times between substorm onsets that compares favourably with the distribution of 1001 inter-substorm intervals found by Borovsky et al. from observation. We discuss these results in terms of the distributions of first-passage times from the general class of integrate-and-fire processes, and propose possible further tests of the model.

GAIII.07/09A/A14-008   1210
MAGNETOSPHERIC DYNAMICS DRIVEN BY SOLAR WIND PRESSURE PULSE: SPATIO-TEMPORAL STRUCTURE FROM THE AVERAGE MUTUAL INFORMATION

A. Surjalal SHARMA[1], J. EDWARDS[1], M.I. SITNOV[1], Y. KAMIDE[2], B.T. TSURUTANI[3] ([1]University of Maryland, [2]Solar Terrestrial Environment Laboratory, [3]Jet Propulsion Laboratory)

The magnetosphere exhibit complex behavior during substorms and such behavior have been widely studied using the well-known auroral electrojet indices. However, these indices suffer from the limitations due to the loss of information associated their definitions. The time scales of magnetospheric dynamics are studied using the high resolution time series data of the AL index and of the magnetic field data from the high-latitude magnetometers. Considering the inherent nonlinearity of the magnetosphere it is important to use measures that are appropriate for nonlinear sytsems. The average mutual information (AMI) of a nonlinear dynamical system yields the coherence or memory time before dynamical information is lost and are computed from the time series data. Considering the differences in the magnetospheric dynamics during quiet and active periods, the AMI for these two periods are computed from the AL and the magnetic field measurements at 11 magnetometer stations. For active periods the coherence time for AL is less than 10 min and for the individual stations it ranges from 10 min to 30 min, thus showing considerable loss of information when AL is used instead of the magnetometer data. Studies of the magnetospheric response to sudden changes in the solar wind dynamic pressure show dominant features of the spatio-temporal structure not captured by linear functions.

GAIII.07/09P/A14-001   1400
DOUBLE LAYERS AND THEIR ROLES IN MAGNETOSPHERIC PLASMA TURBULENCE

Nagendra SINGH (University of Alabama in Huntsville)

Double layers provide a universal mechanism for supporting electric fields parallel to the ambient magnetic field in collisionless plasmas. Depending on the application and the plasma processes, the double layers could be strong or weak. Strong double layers produce energetic electrons and ions, like in the auroral plasmas. The electron and ion beams accelerated by the strong double layers generate a host of plasma instabilities. Nonlinear plasma structures resulting from such instabilities are now commonly measured by satellites; electron and ion phase-space holes are prime examples of such structures. In turn, these spatially localized laminar plasma structures radiate plasma waves. These waves are eventually absorbed by the thermal (low energy) plasmas, affecting the dissipation of the energy supporting the double layer. The generation of VLF saucers in the auroral plasma is an example of this chain of processes. Weak double layers are consequences of plasma instabilities (Buneman and ion acoustic) driven by currents in the plasma. The instabilities in their nonlinear stage generate density cavities, and the charging of the cavities gives rise to the weak double layers. When parallel currents in the plasma encounter naturally occurring plasma depletions or cavities, the charging leads to a spontaneous double layer formation and acceleration of charged particles, providing a mechanism for dissipating the electromagnetic energy associated with the current. This mechanism may be operative in dissipating narrow Alfven wave structures, which carry a significant level of current.

NONLINEAR ELECTRON ACOUSTIC WAVES WITH NON-THERMAL DISTRIBUTION OF ELECTRONS

Satyavir SINGH, Gurbax S. LAKHINA (Indian Institute of Geomagnetism)

Nonlinear propagation of electron-acoustic waves is studied in an unmagnetized, three-component plasma consisting of non-thermally distributed electrons, fluid cold electrons and ions. The analysis employs Sagdeev pseudo-potential techniques and is valid for any

arbitrary amplitude of the wave. The soliton amplitude and width are numerically obtained and are compared with the spiky structures observed by several spacecrafts in the Earth´s magnetosphere.

ELECTRON HOLES AND DOUBLE LAYER-LIKE STRUCTURES OBSERVED ALONG THE CLUSTER ORBIT: CHARACTERISTICS AND INFLUENCE OF THE MAGNETIC FIELD ON THEIR AMPLITUDES

Jolene S. PICKETT, Li-Jen CHEN, Scott W. KAHLER (Dept. of Physics and Astronomy, The University of Iowa)

We present examples of isolated electrostatic structures observed by the four Cluster Wideband (WBD) Plasma Wave Receivers at various locations in the Cluster orbit. These locations include the magnetosphere at 5-8 Re along magnetic field lines that map to the auroral zone, the magnetosheath just downstream of the bow shock at 15-19 Re, the plasma sheet boundary layer at 17-19 Re and other boundaries crossed by Cluster. These electrostatic structures appear in the WBD waveform data in two primary forms: 1) as bipolar pulses with durations on the order of tens up to hundreds of microseconds and amplitudes of hundredths up to a few mV/m, and are interpreted as electron holes, 2) as continuous waveforms consisting of bipolar pulses immediately followed by a half-sinusoid in the direction of the initial pulse, interpreted as double layer-like structures. We provide the typical characteristics of these structures in the various regions in which they are encountered, i.e., amplitude and time duration, and the results of a cross correlation study, the purpose of which was to identify electron holes that have propagated from one spacecraft to another. Finally, we compare the observed characteristics of the electron holes to the theory of BGK electron solitary waves (electron holes) and the influence of the local magnetic field on their amplitudes.

GAIII.07/09P/A14-004   1510
PARTICLE SIMULATIONS OF ELECTROMAGNETIC EMISSIONS FROM ELECTROSTATIC SOLITARY WAVES

Takayuki UMEDA, Yoshiharu OMURA, Hiroshi MATSUMOTO (Radio Science Center for Space and Atmosphere, Kyoto University)

We present particle simulations of electrostatic solitary waves (ESW)observed by the GEOTAIL spacecraft and recent spacecraft in the Earth´s magnetosphere. Recent particle simulations have demonstrated that ESW are Bernstein-Greene-Kruskal (BGK) electron holes formed through nonlinear evolution of electron beam instabilities. Since an electron hole is coherent electrostatic potential structure, electron beam instabilities were conventionally studied by electrostatic particle simulations. However, the FAST spacecraft observed electromagnetic field signatures associated with ESW. To study interaction between coherent electrostatic potential and electromagnetic waves, we extend the previous electrostatic particle simulations to electromagnetic particle simulations. In a two-dimensional simulation, we found that multi-dimensional electron holes are accompanied by magnetic field components. On the other hand, one-dimensional electron holes do not have any electromagnetic signatures. Two-dimensional electron holes have perpendicular electrostatic fields E_y. Electrons lead to $E_y \times B_0$ drift in the z direction, and the current density J_z is enhanced at perpendicular edges of two-dimensional electron holes. Magnetic fields B_x and B_y are enhanced around the current Jz. However, the current structure excited by the $E_y \times B_0$ drift of electrons is not closed in the two-dimensional simulation. In the real space plasma, we expect that the current structure may form a loop along the perpendicular edge of a multi-dimensional electron hole. Such a closed current structure will be studied by a three-dimensional simulation. We also study electromagnetic emissions from such moving current loops.

GAIII.07/09P/A14-005   1530
GENERATION OF ELECTRON HOLES BY MAGNETICTURBULENCE ON AURORAL FIELD LINES

Gurbax S. LAKHINA[1], Bruce T. TSURUTANI[2], Jolene S. PICKETT[3] ([1]Indian Institute of Geomagnetism, Mumbai, India, [2]Jet Propulsion Laboratory, California Institute of Technology, Pasadena, California, USA, [3]Department of Physics and Astronomy, University of Iowa, Iowa City, IA, USA)

Electric bipolar pulses (electron holes) have been observed on auroral zone field lines at various altitudes ranging from close to the ionosphere, to magnetopause low-latitude boundary layer (LLBL) and cusp on the dayside, and to plasma sheet boundary layer on the nightside. High-resolution wave magnetic component data from Polar spacecraft show ˝magnetic noise bursts˝, Alfvén waves,and large amplitude (~ ±14 nT peak-to-peak) obliquely propagating proton cyclotron waves. On the other hand, high-resolution dataof the electric field components indicate three types of intense electric signals, namely, solitary structures (with bipolar, monopolar and offset bipolar pulses), lower hybrid waves, and narrow-band waves near electron plasma frequency (most likely the upper hybrid resonance waves due to their perpendicular polarization). It is proposed that obliquely propagating nonlinear Alfvén and proton cyclotron waves could accelerate electrons parallel to the magnetic field. These field aligned electron beams could act as free energy source for several electron beam instabilities leading to the formation of electron holes.

GAIII.07/09P/A14-006   1610
CLUSTER OBSERVATIONS OF DYNAMIC PHENOMENA NEAR THE BOW SHOCK AND IN THE MAGNETOSHEATH

Andre BALOGH, Timothy HORBURY, Elizabeth LUCEK (Imperial College London)

The complexity of many magnetospheric phenomena at small scales is highlighted by the four-point observations made by the Cluster mission. In many cases, the observed phenomena are dominated by (ion and/or electron) dynamics at scales comparable or even smaller than the typical range of spacecraft separations between 100 km and 5000 km. This is the case at the bow shock and in the magnetosheath. In this paper, we present typical examples of the dynamic behaviour of the quasi-parallel bow shock and observations of Hot Flow Anomalies associated with the interaction of the quasi-perpendicular bow shock with discontinuities in the solar wind. In addition, we review the Cluster observations that have led to the determination of the anisotropic structure of mirror-mode waves in the

A

magnetosheath. We conclude by an overview of how the Cluster observations are capable of constraining the dynamic scale of phenomena and also the limitations due to the finite range (too small or too large) of the observations.

GAIII.07/09P/A14-007 1640
ELECTRON HEATING PROCESSES AT QUASI-PERPENDICULAR SHOCKS

Tooru SUGIYAMA[1], Masaki FUJIMOTO[2], Yoshiharu OMURA[1], Hiroshi MATSUMOTO[1] ([1]Radio Science Center for Space and Atmosphere, Univ. of Kyoto, [2]Earth and Planetary Sciences, Tokyo Institute of Technology)

The role of micro-instabilities in dissipation process in collosionlessquasi-perpendicular shocks is investigated by a full-particle numerical code. It is well-known that an anomalous dissipation is necessary in the super-critical Mach number shock. The reflected ions are mainly considered to produce the dissipation. Recently, the contribution of electrons is also well discussed and many waves are listed-up for the candidate of the dissipation process: ion acoustic waves, upper hybrid waves, whistler waves, and so on. In the present study, we discuss the variation of the wave types depends on both the shock parameters (shock Mach number, upstream plasma beta) and time. We have taken a low mass ratio between ion and electron. This assumption allows us to see a strong interaction between ions and electrons even though the shock Mach number is not so large (<15). Here, the reflected ions again act as an important role. The instability between the incoming ions and the reflected ions excites electrostatic waves in the ramp region. When the amplitude of the electrostatic wave is large, the incoming electrons are also reflected. This is the case that the Mach number is large, because the growth rate of the instability is large. The reflected electrons are also accelerated by the upstream motional electric field as reflected ions are accelerated. We can see another kinetic effect for electron heating process at collisionless shocks which is different from resonance interaction between particles and waves.

GAIII.07/09P/A14-008 1700
ORIGIN OF PHASE COHERENCE AMONG MHD WAVES IN THE SOLAR WIND

Tohru HADA[1], Daiki KOGA[1], Eiko YAMAMOTO[2] ([1]E.S.S.T., Kyushu University, Fukuoka, Japan, [2]N.A.S.D.A., Ibaraki, Japan)

Large amplitude MHD waves are ubiquitous in the solar wind. Nonlinear interactions between the MHD waves are likely to produce finite correlation among the wave phases. For discussions of various transport processes of energetic particles, it is fundamentally important to determine whether the wave phases are randomly distributed (as assumed in quasi-linear theories) or they have a finite coherence. By comparing structure functions of original data and its phase-shuffled surrogates, we analyzed Geotail magnetic field data to evaluate the phase coherence among the MHD waves in the earth´s foreshock region. We show that the correlation of wave phases does exist, indicating that the nonlinear interactions between the waves is in progress. Furthermore, by applying a wavelet filtering technique, we find that, although the turbulence consists of waves with a wide range of plasma rest frame frequencies, only the wave modes whose frequencies were lower than the ion gyrofrequency are responsible for generating the phase coherence.

GAIII.07/09P/A14-009 1720
CAUSAL THERMODYNAMICS OF MAGNETOFLUIDS

Tadas K. NAKAMURA (Center for Arts and Sciences, Fukui Prefectural University)

Large scale phenomena in the magnetosphere are often successfullyformulated with the MHD theory with phenomenological dissipationterms. However, this kind of dissipation terms are known to beinconsistent theoretically. For example, the heat conductioncalculated with the second-order spatial derivative would result ainfinite propagation speed. A controversy has arisen since 1970s on the dissipation terms of fluiddynamics in connection with the relativity. Straight-forwardgeneralization of the Navier-Stokes theory would result a pathologicalunrealistic instability, in addition to the infinite propagation speedmentioned above. There have been proposed so called ˝CasualThermodynamics˝ to overcome these difficulties, however, there areseveral different theories in Casual Thermodynamics, and the finalsolution is still yet to come. The present paper propose a systematic way to handle the dissipationmechanisms based on the definition of relativistic thermodynamicalquantities by van-Kampen (Phys. Rev. 1968). Using four-vector inversetemperature, we can regard the heat conduction and viscosity ascomponents of a same tensor. Electromagnetic dissipation can betreated in the same way. Possible applications to the magnetosphericphysics will be briefly discussed in the presentation.

GAIII.07/09P/A14-010 1740
FULLY NONLINEAR ANALYSIS OF AURORAL SOLITARY WAVES IN THE PRESENCE OF MAGNETIC FIELD

Suktisama GHOSH, Gurbax S. LAKHINA (Plasma Group, Indian Institute of Geomagnetism)

Over the past two decades, several spacecraft observations have revealed solitary wavestructures in different regions of magnetospheres. Besides low altitude rarefactive ionsolitary waves, subsequent satellite observations have also reported fast moving electronsolitary waves with positive potentials at higher altitudes of the auroral region. Thoughthere were extensive analytical and numerical investigations, little attention has beengiven so far to explain their width-amplitude characteristics. Recent FAST and POLARobservations have showed that for both ion and electron solitary waves, the width tends to increase with increasing amplitude. A small amplitude theory thus remains inadequatefor the process while a complete theory of large amplitude solitary waves is still lacking. It is proposed that the observed increase in the width with increasing amplitude is essentially an intrinsic characteristics of large amplitude rarefactive ion (electron) acoustic solitary waves which differs qualitatively from its small amplitude limits. In the present work, a fully nonlinear approach is adopted for a two electron (ion) temperature magnetized plasma. The overall width-amplitude profiles for rarefactive ion (electron)acoustic solitary wave solutions in the presence of ion (electron) beams are investigatedfor different parameter ranges. The characteristics of the complete width-amplitudeprofile of a rarefactive ion acoustic solitary wave appears to be very much consistentover all the parameter ranges including unmagnetized as well as magnetized plasmas. Asimilar analysis is also applied for an electron acoustic solitary wave. The outcome of theanalytical investigations is compared with recent space observations.

WHAT IS THE ROLE OF NON-LINEAR PROCESSES AND COMPLEX SYSTEM DYNAMICS IN DETERMINING MAGNETOSPHERIC BEHAVIOR?

PARTICLE DYNAMICS IN FULL PARTICLE SIMULATION OF SLOW WAVES

DongSheng CAI[1], Bertrand LEMBEGE[2] ([1]University of Tsukuba, [2]CETP/UVSQ)

Magnetohydrodynamic theory predicts that the slow shock pairs should be generated by magnetic reconnection in the Earth magnetotail. One question is focussed on conditions/mechanisms responsible for the survival time of such waves. For this purpose, kinetic and nonlinear effects of the slow waves dynamics are analyzed with the help of a1-2/2-dimensional electromagnetic full particle code (1-D in x-space and3-D in velocity space)with periodic boundary conditions. At the initial time of the simulation, the particles are loaded with sinusoidal density perturbation (30% of its background value) in x-space with consistent sinusoidal magnetic field in z; these pertubations are provided by results issued from MHD equations. Magnetic field and density profiles have opposite phase as a slow wave nature. In the present report, trajectories of preselected self-consistent electrons (in contrast with the test particle approach) have been analyzed in order to determine the slow shock reflection condition. The particle is accelerated in Vpara direction in the Tsteepening,PIC and saturated after Tsteepening,PIC. The particle Vperp1 and Vperp2 is oscillated in ion gyroperiod. The particle gains the energy Ekpara and Ekperp after Tsteepening,PIC.

GAIII.07/10P/D-002 Poster 1400-106
NONLINEAR EVOLUTION OF MIRROR-MODE INSTABILITY

B.-J. WANG, L.-N. HAU (Institute of Space Science, National Central University)

Linear theory has shown that the mirror instability criterion derived from the double-polytropic MHD model with $\gamma\perp$ =2 and $\gamma_{\parallel}$ =0.5 is the same as the one from the kinetic theory (Hau and Sonnerup, GRL, 20, 1763, 1993). In this study we investigate the nonlinear evolution of mirror instability that is solved numerically based on the nonlinear double-polytropic MHD and Hall MHD equations. The results show that an initial sinusoidal mirror wave will evolve into soliton-like structure with increased density and decreased magnetic field. The effect of Hall current may lead to dispersive multiple solitons with thickness of a few ion inertial lengths.

NONLINEAR EVOLUTION OF WAVE PARICLE INTERACTION BY A PARTICLE-IN-CELL NUMERICAL CODE

Manashi Na ROY, G.S. LAKHINA (Indian Institute of Geomagnetism)

A plasma system comprising electrons, protons and oxygen ions is investigated by a particle-in-cell code. The initial configuration is nine protons, four oxygen ions and equal number of electrons per cell. The simulation box is two dimensional with velocities of all the particles having three components. A magnetic field is applied along one direction. The mass ratio of oxygen to proton is assumed to be 400. Periodic boundary condition is applied. The initial distribution of the particles is assumed to be beam plasma for the oxygen ions and a part of the protons. The electron distribution is assumed to be maxwellian with a finite temperature. This system is allowed to develop in time with different parameters like the ratio of the ion temteratures to the electron temperatures etc. The field configuration shows the development of the waves similar to the beam plasma instabilities. The distribution functions of the particles show considerable departure from their initial configurations. The nature of these waves will be discussed as function of various initial plasma parameters. As these waves grow with time we investigate the nature of the evolution of both the wave charaistics as well as the plasma distribution. The possibility of generation of any localised structures will be explored.The results will be applied to observations at the auroral and the plasmasheet regions of the magnetosphere.

SIMULATION STUDY ON GENERATION MECHANISM OF ELECTRON/ION HOLES INSPACE PLASMAS

Keisuke NINOMIYA, Yoshiharu OMURA, Hiroshi MATSUMOTO (RASC, Kyoto University)

In recent spacecraft observations, it has been found that a variety ofcoherent potential structures exist along magnetic field lines of various regions of the magnetosphere. We assume that some of coherentpotential structures are electron holes and ion holes corresponding topositive solitary potentials and negative solitary potentials, respectively.We performed one-dimensional electrostatic particle simulations of the Buneman instability, which occurs when beams of electrons and ions have a relative drift velocity. We used the real ion/electron mass ratio and performed simulations with boundaries are periodic boundaries and open boundaries.We varied thermal velocities of electrons and ions, and found that nonlinear evolutionare mainly classified into two potential structures.One is an electron hole, other one is an ion hole. It is also found that electron holes andion holes coexist and interfere with each other under some conditions.In the present study we first calculated linear growth rates andphase velocities in order to study dependence of the instabilityon the thermal velocities of ions and electrons in detail. The difference of nonlinear evolutions depends not only on the thermal velocities of beams but also on the maximum growth rate and the phase velocity of the waves at the initial stage. Especially, the phase velocity is an important parameter which determinescharacteristics of interaction between the waves, electrons and ions.It affects the final states of nonlinear evolutions significantly.The electron holes are generated through coalescence of waves generated at the initial state. This mechanism is the same as foundin a two-stream electron instability or bump-on-tail instability. On the other hand, the generation mechanism of ion holes is differentfrom that of electron holes.At first, a double layer potential is formed at some localposition in the system. A negative potential becomes graduallybigger at the boundary of the layer. Finally, the potential grows totrap ions, resulting in an ion hole in the velocity phase space of ions.The ion hole is unstable and disappears after a time. New double layer potential is generated at other local position after the disappearance, then an ion hole appears again.The process repeats in the simulation system.While the negative potential

exists, some electrons are reflected by thepotential and excite a two-stream instability with non-reflected electron.We will present detail analyses of electron and ion dynamics related to the generation of double layers and ion holes.

EVALUATION OF PHASE COHERENCE AMONG MHD WAVES

Daiki KOGA, Tohru HADA (E.S.S.T., Kyushu University, Fukuoka, Japan)

Large amplitude MHD waves are commonly found in the solar wind, inparticular, in the earth´s foreshock. The waves within this regionexhibit various peculiar waveforms, suggesting that nonlinearinteraction between the waves is in progress (e.g., SLAMs, shocklets,etc). When we Fourier analyze such data, usually more emphasis isplaced on the power spectrum than the phase distribution of wave modes,although the latter contains important information on nonlinearcoupling between the eigenmodes (e.g., synchronization of phases). Wehave recently developed a method to quantitatively evaluate the phasecoherence of a given time series data, by comparing structure functionsof original data and its phase-shuffled surrogates. In thispresentation we discuss critically some fundamental properties of thismethod, and show how one should determine such basic parameters usedin the method as the data length for getting the optimum results.Furthermore, we discuss some extensions of the method, including theanalysis of 2-dimensional data obtained by simulations.

AURORAS DYNAMICS AS STRANGE ATTRACTOR MANIFESTATION

Victoria G. VASILYEVA (Institute of Cosmophysical Research and Aeronomy)

Large scale visual data and rather localized aurora video registrations demonstrate multi-scale, sporadic and localized structure. It allows to estimate statistical parameters of power law distributions for global disturbance scales, witch were proposed in our ensemble interpretation of Kp-indeces (JUGG, 1999). It is shown that for increased auroral injections we are to differ the differential (spectral) duration witch became shorter and integral one increasing versus of activity growth. There were resume this temporal parameter duality is set by non-linearity of disturbance nature caused by non-divisional unity of global injection power and just local lifetime acceleration of non-homogeneity. The statistical modulus defines the integral scales (durations) distributions. Ensemble applications respond to its universality at all in complex systems drawings according to Prigojin´s presentation (2002). It independently brought to lowdimentional modeling and now is consonant with SOC- model. We can conclude that an ensemble application is fruitful from physical and instrumental point of views. Since the resonance conditions by means statistical modulus and an elementary (some ideal˝) substorm have been founded as matter intermidiate state between two virtual states (ensembles), the auroral oval dynamics may be considered like strange attractor manifestation. The investigation is presented in accordance with percolation conceptual approach (L.Zelenyi, A.Milovanov,2000), T. Chang´s proposals and foundations (1992,1999), representations of N.Watkins, S.Chapman, M.Freeman(2000). For part of global activities it looks like we can to unify equilibrium phase transition and topological one. It is possible with ˝dynamic factor-spectrum of fractals˝, if the fractal initiator is related to the driver, basic cycle of the dissipative system and defines the generalized function. Then underlying statistical consideration at all may satisfy dynamic symmetry approach.

NONLINEAR BUNEMAN INSTABILITY UNDER THE PERPENDICULAR MAGNETIC FIELD

Keisuke MERA, Masahiro HOSHINO (Department of Earth and Planetary Science, University of Tokyo)

The electron phase space hole excited by Buneman instability (BI) is essentially important for the heating and acceleration of electrons, in a perpendicular shock region. The dynamics of the electron phase space hole under perpendicular magnetic field, however, is not fully understood yet. To understand the relationship between the electron phase space hole and the perpendicular magnetic field, we studied the saturation mechanism of BI under a finite perpendicular magnetic field. We used the 1-dimentional full particle simulation code, with the condition of periodic boundary. In our simulation, cold ions drift in background cold electrons, in the state of uniform magnetic field perpendicular to the ion beam. In case of the null magnetic field, it is well known that the saturation level of electric field energy of BI is the order of 1/3 power of the mass ratio (electron mass per ion mass) of the initial electron drift energy. In case of introducing a weak magnetic field perpendicular to the ion beam, it is believed that the BI breaks down. But, we found that, up to the electron gyro frequency equal to the electron plasma frequency, the growth rate and the saturation level of the BI are almost the same as the electrostatic case. This result is really important to study the heating and acceleration of electrons in the perpendicular shock region.

ON THE CONTRIBUTION OF IONOSPHERIC IONS TO THE EARTH'S MAGNETOSPHERE: INSIGHT FROM GEOTAIL OBSERVATIONS

Kanako SEKI[1], Masafumi HIRAHARA[2], Masahiro HOSHINO[3], Toshio TERASAWA[3], Toshifumi MUKAI[4], Richard C. ELPHIC[5] ([1]Solar-Terrestrial Environment Laboratory, Nagoya University, Honohara 3-13, Aichi 442-8507, JAPAN, [2]Department of Physics, Rikkyo University, Toshima, Tokyo 171-8501, JAPAN, [3]Department of Earth and Planetary Science, University of Tokyo, Tokyo 113-0033, JAPAN, [4]Institute of Space and Astronautical Science, Sagamihara, Kanagawa 229-8510, JAPAN, [5]Los Alamos National Laboratory, NIS-1, MS466, Los Alamos, NM 87545, USA)

It is well known that a large flux of terrestrial ions is flowing out from the polar ionosphere. While these ionospheric ions are considered to contribute to the magnetospheric plasma, their energization and transport mechanisms, i.e., how and where they contribute to the magnetospheric plasma, are far from fully understood. A statistical study, which compares O+ fluxes at low and high altitudes during a solar minimum period, shows that there is a large gap between average fluxes of polar ionospheric O+ outflows (~43×10^24 ions/s) and O+ observed in the magnetosphere (~5×10^24 ions/s). There are three possibilities to explain this discrepancy: One possibility is that there exists a significant return flux from the magnetosphere back into the low latitude ionosphere, because more than 90 % of observed O+ outflows had energies less than 1 keV and many of them will be trapped in the near-Earth magnetosphere within the distant neutral line. The second candidate is the escape of cold O+ ions at energies below 50 eV either to the magnetosheath or through the plasma sheet, which are difficult to observe in the magnetosphere without spacecraft (s/c) potential control. The third possibility is the charge exchange loss of ring current ions that become dominated by O+ during large magnetic storms. In this study, we focus on examining the validity of the second candidate on the basis of GEOTAIL observations. A spacecraft in sunlight usually undergoes positive charging due to photoelectron emission from its sunlit surfaces, and this charging prevents positive ions with energies below the s/c potential from reaching detectors. However, there are several occasions we can detect cold ions without the s/c potential control. For example, under existence of the large-amplitude oscillations such as Pc5 and/or enhanced convection velocity, or during time intervals when the spacecraft enters the shadow of the Earth, we can examine whether the cold ions exist in the plasma sheet or not. On the basis of GEOTAIL observations of these cases, we will discuss on the fate of ionospheric ions in the magnetosphere.

THE STRUCTURE OF THE PLASMA SHEET UNDER NORTHWARD IMF

Masaki FUJIMOTO (Department of Earth and Planetary Sciences, TITech)

The structure of the plasma sheet under northward IMF is studied by the data from Geotail. It is now well known that the plasma sheet becomes cold and dense (CD) during extended northward IMF. We show that such CD ions appear mostly more than 10 Re off to the flanks from the tail axis.The dawnside CD ions are found to have higher temperatures with some of them reaching the upper limit of 2 keV used to identify CD ions in this study. These ˝high temperature˝ CD ions are detected at smaller geocentric distances and are connected to hot and dense (HD) ions located in the further inner region. A survey shows that the HD ions under nominal solar wind dynamic pressure is a northward IMF phenomenon. These results altogether suggest that HD ions are the inner-extension of the CD ions in the dawn-flanks, while such a partner to the duskside CD ions cannot be found. This structure of the plasma sheet implies significant asymmetry in transport and heating in the magnetotail under northward IMF when the convection electric field is not dominating.

FIELD-ALIGNED ACCELERATION OF O+ IONS BY THE PONDEROMOTIVE FORCE. CASE STUDY: APRIL 12, 2001

Sachiko JOKO, Hans NILSSON, Rickard LUNDIN, Ingrid SANDAHL (Swedish Institute of Space Physics)

We have investigated the cause of field-aligned acceleration of O+ ion in the case of April 12, 2001, 07:30 - 09:30 UT. Before around 08:30 UT acceleration due to a diverging magnetic field could explain most of the trend of increase of O+ ion bulk velocity parallel to the magnetic field ($v_{//}$). On the other hand, to explain much more increase of $v_{//}$ after around 08:30 UT than that expected by only acceleration due to a diverging magnetic field, the ponderomotive force was estimated. The ponderomotive force in this case was considered to act on O+ ions under the action of Alfvén waves as well as under the action of electromagnetic cyclotron (EMIC) waves. As to the increase of $v_{//}$ after around 08:30 UT, the ponderomotive force calculated from spin-averaged (4 seconds) electric field data could explain the large scale trend of increase of $v_{//}$ if the oscillation frequency of electric field (f) is less than or approximate to 0.1 Hz which was independently estimated from power spectra using high-resolution electric field data (0.04 second-interval). On the other hand, the bursty increase of $v_{//}$ in fine scale structure can be explained by an amplitude of electric field in high-resolution.

AURORAL ION OUTFLOWS AND CIRCULATION THROUGH THE MAGNETOSPHERE

James P. McFADDEN (SSL, University of California, Berkeley)

Magnetic storms and substorms are characterized by a large increase in the ion outflow from both the cusp and midnight polar cap boundary. Low energy ions from the cusp form the bulk of lobe plasma and become a primary seed population to the plasma sheet. These lobe ions are subsequently energized through interactions at the plasmasheet boundary layer and the neutral sheet. The cusp activity also increases the density of the low altitude plasma on polar cap flux tubes. When this low altitude polar wind plasma moves to the nightside auroral zone, it is energized forming a more energetic ionospheric component injected into the plasmasheet. Both the cusp and nightside outflows occur on recently reconnected flux tubes that have associated strong Alfvenic turbulence and intense counter streaming electrons. Both the cold cusp and hotter nightside ionospheric outflow contribute significant plasma to the plasma sheet. During a storm main phase, these ions are subsequently injected into the inner magnetosphere near midnight, with the inner edge of the plasmasheet shifting Earthward to as close as L=2.5. These ions subsequently drift through the inner magnetosphere and are observed at local times that depend upon ion energy and phase of the storm. An asymmetry in the inner magnetospheric drift is observed with low energy ions preferentially observed on the dawn side and energetic ions observed at dusk. Low latitude oxygen densities of 100-1000/cc and temperatures of several hundred eV are not uncommon in the inner magnetosphere during storms. These ions subsequently convect to the dayside magnetopause where they can dominate the magnetospheric density and may affect the physics of reconnection. During magnetic storms, oxygen accelerated at the magnetopause can be observed as a distinct peak in the cusp velocity dispersed ion signatures.

SPATIAL AND TEMPORAL TEXTURE OF BURSTY BULK FLOWS AND THEIR ROLE IN PLASMASHEET TRANSPORT

Harlan E. SPENCE, Larry KEPKO, Shannon MCCURDY (Center for Space Physics, Boston University)

Localized high-speed flows ($>$ 400 km/s), called bursty bulk flows (BBFs), occur frequently in the inner central plasma sheet of Earth´s magnetotail. BBFs are observed to occur semi-periodically with a characteristic period of approximately 10 minutes. A large collection of BBF events from 1996 are identified using Geotail magnetic field and plasma data, at times when the spacecraft was located between 10 and 25 Earth radii in the anti-sunward

direction. An ensemble BBF time series is constructed using a super-posed epoch analysis of the magnetic field and bulk plasma properties of the individual events. Epoch time is defined by the initial sharp increase in sunward velocity during a BBF, rather than at the time of the peak flow. The super-posed analysis interval spans one hour pre-epoch time to two hours post-epoch time. Fourier analysis of the post-epoch BBF interval reveals strong periodicities in plasma velocity, temperature, and magnetic field. Results of the analyses characterizing these periodicities, as well as representative case studies of BBF events, will be detailed. Additional properties of BBFs, including their association with magnetic field turbulencewill be explored. The significance of these properties to net plasma sheet transport will be examined.

TRANSPORT AND ACCELERATION OF IONS DURING STORM-TIME SUBSTORMS

Ioannis A. DAGLIS[1], Fiori-Anastasia METALLINOU[2], Dominique DELCOURT[3], John H. SEIRADAKIS[2] ([1]Institute for Space Applications, National Observatory of Athens, [2]Department of Physics, University of Thessaloniki, [3]Centre d'ét ude des Environnements Terrestre et Planét aires)

In this paper we intend to study life-history of particles in the magnetosphere in order to assess the role of substorm ion acceleration in storm-time ring current growth. Particle orbit tracing is performed in time-dependent electromagnetic fields to study the effects of substorm reconfigurations. The model can give insight on energy transfer processes, particle acceleration, and non-adiabatic effects of particle orbits. Mass-dependence effects on particle trajectories and energisation are also investigated. Particular emphasis is given on the impulsive transport and energisation of ionosphere-originating ions during substorms and on their subsequent injection into the ring current. The response of these ionospheric populations to the large electric fields induced by magnetic field line relaxation from tail-like to dipole-like configuration is of critical importance to storm evolution.

GAIII.08/10A/A16-007   1040

FATE OF THE PLASMA SHEET IONS

Yusuke EBIHARA[1], Masaki EJIRI[1], Ingrid SANDAHL[2], Lars ELIASSON[2], Hans NILSSON[2], Manuel GRANDE[3], Joseph F. FENNELL[4], James L. ROEDER[4], Lynn M. KISTLER[5] ([1]National Institute of Polar Research, Japan, [2]Swedish Institute of Space Physics, Sweden, [3]Rutherford Appleton Laboratory, UK, [4]The Aerospace Corporation, USA, [5]University of New Hampshire, USA)

We investigate the possible fate of the plasma sheet ions with energy ranging between hundreds eV and tens keV by using results of a particle simulation and data from Polar/MICS, Equator-S/ESIC and NOAA/MEPED. The plasma sheet ions, previously trapped by a geomagnetic field line, undergo sunward drift motion, and flow into the region where the earth's dipolar magnetic field governs their drift motion. Some of them drift into the deep inner magnetosphere, and contribute to the ring current buildup. Some of them experience pitch angle scattering and fall into the atmosphere. Some of them experience charge exchange with neutral atoms, and become free from the magnetic field. We performed a particle simulation that tracks ion drift trajectories under various magnetic field models (pure dipole or Tsyganenko 89) and various convection electric field models (Volland-Stern or Weimer 2000). The simulation is designed to conserve the phase space density except for loss terms. The following topics are particularly focused on in terms of impact of the changes in the phase space density of the plasma sheet ions on the inner magnetosphere. (1) "Imaging" of meso-scale structure (~1Re) of the ions. This "imaging" technique utilizes structured energy dispersion of sub-keV ions (wedge-like dispersion) seen in the dayside magnetosphere, and enables us to "image" remotely the spatial distribution of the ions in the inner magnetosphere and the near-earth plasma sheet. (2) Importance of the phase space density of the plasma sheet ions as a driver of the storm-time ring current buildup. (3) Estimation of number of plasma sheet ions reaching different regions; the ionosphere, the dayside magnetopause, and somewhere with energetic neutral atoms. This estimation will clue us on the large-scale circulation of the ions in the magnetosphere.

STORM-TIME NITROGEN IONOSPHERIC ION INJECTION INTO THE MAGNETOSPHERE

Andrew W. YAU[1], Takumi ABE[2] ([1]Dept of Physics and Astronomy, University of Calgary, [2]Institute of Space and Astronautical Science)

Composition studies of ionospheric ion injection to the magnetosphere often focus on the two most dominant components, H+ and O+, and neglect the N+ component, because of the latter's proximity to O+ in the mass spectrum and the inability or difficulty of most ion mass spectrometers to resolve the two species; also, N+ is often regarded as a minor ion species and assumed to have negligible influence on magnetospheric dynamics. We present ion composition observations of storm-time low-energy (<50 eV) ionospheric ion injections from the Akebono suprathermal mass spectrometer (SMS), which has a mass resolution of 0.07 and a sharp (exponential) mass line shape and is capable of resolving N+ from O+ over a wide range of N+/O+ ratio. These observations were acquired during a number of magnetic storms in different phases of the solar cycle. They reveal the substantial enhancement of N+ ions during large magnetic storms, when the N+/O+ ratio sometimes reach or exceed unity. We discuss the origin of the enhancement and its possible influence on ring current decay, in terms of prolonged thermospheric heating and non-resonant charge exchange of N+ with atomic hydrogen, respectively.

GAIII.08/10A/A16-009   1115

SOLAR WIND DRIVING OF RING CURRENT RECOVERY: DAYSIDE OUTFLOWS AND PLASMA SHEET DROP OUTS

Janet U. KOZYRA[1], Michael W. LIEMOHN[1], Michelle F. THOMSEN[2], Joseph E. BOROVSKY[2], Thomas H. ZURBUCHEN[1], Ruth SKOUG[2] ([1]Space Physics Research Lab, University of Michigan, [2]Los Alamos National Laboratory)

As a reservoir of ring current particles, the plasma sheet is a key participant in magnetic storm dynamics. In general, the plasma sheet density is higher during active than quiet times; the ring current begins to decay when convection decreases due to northward turning of the IMF B_z. For a number of magnetic storms, a drop in plasma sheet densities has been observed to trigger a recovery of the ring current/partial ring current (seen in Dst*) even though the Earth was engulfed in a region of southward IMF from the passage of an intense interplanetary magnetic cloud. During the cloud passage, magnetospheric convection remained strong; the ring current decay, to first order, was a consequence of moving low-density plasma into the inner magnetosphere along open drift paths to replace high density plasma exiting these same open drift paths at the dayside magnetopause. In this presentation, LANL observations are examined to identify cases of plasma sheet density decreases during times of enhanced magnetospheric convection associated with magnetic storms. ACE observations are used to characterize the solar wind drivers. The impact on

ring current decay is determined using sym H and asym H indices along with ring current model results. Collected events will be examined individually and through superposed epoch analysis techniques to investigate: (1) the role of plasma sheet dynamics in triggering ring current recovery and (2) magnetospheric and solar wind drivers linked to the depletions in plasma sheet density in the ring current source region.

GAIII.08/10A/A16-010   1135

LOGNORMAL FORM OF THE RING CURRENT ENERGY CONTENT

Michael W. LIEMOHN, Janet U. KOZYRA (SPRL, University of Michigan)

It is shown that the stormtime ring current energy content, from kinetic simulations, has a lognormal distribution. This type of functional form naturally arises from the superposition of many processes with a common initiation event but with differing growth and decay timescales. For the ring current, such a situation occurs from the disparate timescales of energization and decay for the hot ions at various energies, pitch angles, and spatial locations. The summation of this plethora of small currents results in a single current system (the ring current, both partial and symmetric) that has a loss time scale that decreases and then increases during every storm. The consequence is that the stormtime Dst index, which also has a lognormal shape, can be (and in fact usually is) dominated by this single current system.

THE LIFE HISTORY OF A 'KILLER': THE ORIGIN AND FATE OF RELATIVISTIC ELECTRONS

Geoffrey D. REEVES (Space and Atmospheric Sciences Group)

Relativistic electrons in the Earth's radiation belts have sometimes been called ″killer electrons″ in the popular press because of their sometimes severe impact on spacecraft systems and satellite instruments. While relativistic electrons (E >.5 MeV) have been studied for decades , many questions about their origins, dynamics, and fate remain unanswered. New observations have added new uncertainties and new challenges. Among the questions to be addressed are: Where do the radiation belt electrons come from? The plasma sheet is a obvious source but there appears to be a sufficient population of electrons of the right energy only at certain times and the question of where energetic plasmasheet electrons come from remains an unanswered logical extension. How are untrapped plasmasheet electrons transported and to and trapped in the inner magnetosphere? We will examine the role of storms and substorms in this process. How are particles accelerated to energies of 10 MeV or more? What are the relative role of diffusive and stochastic processes and what are the evidence for and against each? When are electrons lost? How? And How Many? We will track the life history of this highly energetic population of magnetospheric electrons and highlight areas where recent investigations have shed light on these questions, where significant gaps in our understanding remain, and how future missions can ultimately solve these problems.

GAIII.08/10A/A16-012   1210

OUTER PLASMASPHERIC CIRCULATION

Mark B. MOLDWIN[1], D. BERUBE[1], M. THOMSEN[2], B. SANDEL[3] ([1]Earth and Space Sciences, UCLA, [2]Los Alamos National Laboratory, [3]University of Arizona)

The behavior of the outer plasmasphere and plasmapause will be reviewed. Recent observations that have advanced our understanding of the outer plasmasphere, particularly those during extreme quiet and extreme active conditions will be highlighted. Studies that utilize combinations of ground based, in situ, and IMAGE EUV remote sensing data have shown the extreme variability of the structure of the outer plasmasphere, but emphasize the overall flow of plasmaspheric plasma to the dayside magnetopause.

ANALYSIS OF THE ENERGETIC PARTICLES DATA FROM DETECTORS ONBOARD 'ZY-1' SOLAR SYNCHRONOUS SATELLITE

Zou XIAO, Hong ZOU (Department of Geophysics, Pekin University)

Based on the knowledge and related theory of the earth's radiation belt, the data of energetic particles observed by detectors onboard 'ZY-1' satellite at a solar synchronous orbit during the past 4 years are summarizedand analyzed. Energetic electrons and protons at this orbit are only appeared at polar and SAA regions. On average, fluxes on the southern polar region arelarger that at the northern polar region. Their latitudinal distributions are along the geomagnetic latitudes instead of geographic ones. At nearly the same longitudes of SAA, there is a clear gap of occurrence of flux events on the northern polar region. Proton events

in general only occur in South Atlantic Anomaly region while electron events appear at both SAA and polar regions. Electron flux of 0.5-2Mev in polar regions is dominant over that of electrons of higher than 2Mev, while at SAA, fluxes from the two channels are about the same.The particle radiation is very sensitive to solar proton events and always has a positive response, but the amplitudes of enhancements and detailed features at polar regions and SAA are dependent on the individual solar proton event.It is proved that the observational results are in agreement with the theoretical description of the radiation belt structures. Although at high latitudes the energetic particles are mainly located in three regions with a wide geographical latitudinal coverage, at each longitude the latitudinal coverage is much narrower and particles are along the geomagnetic latitude of about ±60° (except at SAA). Analysis showed that in SAA, usually both electrons and protons are observed, which should come from inner radiation belt; in Polar regions only energetic electrons are observed under quiet condition, which belongs to the outer radiation belt. The distribution of outer radiation electrons is asymmetrical for northern and southern polar regions, also for longitudes. This asymmetry can be explained with the reflecting altitudes of the mirror points of charged particles at the same L shell. So, the measured variations of the energetic particles and their response to solar disturbances at this orbit are actually a manifestation of the morphological features of the earth's radiation belts.

EFFICIENCY OF THE MAIN MECHANISMS OF THE MAGNETOSPHERIC RING CURRENT DECAY

Lilia Z. SIZOVA (Institute of terrestrial magnetism, ionosphere and radio wave propagation, 142190 Troitsk, Russia)

The principal magnetospheric ring current dissipation mechanisms are used for estimation of its characteristic lifetime. The characteristic lifetime is calculated in connection with the ion composition of the ring current. The values of the characteristic lifetime of ring current decay obtained from experiments and theory are compared. It is shown that during main and recovery phase of magnetic storm the different mechanisms can play main role in dissipation of the ring current. The characteristic lifetime of the ring current decay was calculated from Dst-variations during 80 magnetic storms. Dst-variations were corrected for the solar wind dynamic pressure and DR- variations were calculated from the equation:DR = 2/3Dst-DCFd-DCFq. For determination of the ring current characteristic lifetime we used the ring current energy balance equation using 3-8 h intervals of Bz IMF $>$ 0, i.e.the additional energy input to the ring current could be neglected. The results show that lifetime of the ring current differs essentially during the main and recovery phases of magnetic storms. Lifetime of the ring current particles determined by Coulomb scattering and lifetimes of the ring current particles determined by the charge-exchange processes for different ions: H+, He+, He++, O+ were also examined on the basis of the experimental cross-sections and the numerical models of the hydrogen geocorona. The theoretical characteristic lifetimes for these dissipation mechanisms were compared with the observed ones. The available ion composition data for L-shells make possible to assume that the rise of the ring current characteristic lifetime in the recovery phase of magnetic storms is accounted for the ion composition variations. These can attribute to the changing value (and hence position) of the ring current and /or to rising of energetic proton fraction on low L-shells.The short lifetime of the ring currents during main phase of magnetic storms possible to explain by the instability mechanisms.

STUDY OF INTENSE GEOMAGNETIC STORMS

Geeta V. JADHAV, Shobhana ALEX, G.S. LAKHINA (Indian Institute of Geomagnetism)

Availability of satellite measurements of various parameters involved in the development of geomagnetic storms provides a good platform for the better understanding of geomagnetic storms. The present study analyses intense geomagnetic storms (Dst $>$100 nT) with the aid of satellite and ground databases. The study intends to confirm the earlier results such as crucial role of southward IMF in triggering the storm main phase as well as controlling the magnitude of the storm. The effect of the impingement of the solar energetic particles (SEP) on the earth's magnetosphere leading to the development of major geomagnetic storms is studied. We also examine the time profile of the energy injection into the ring current. An attempt is made to identify the multi peak signature in the energy injection rate during main phase of the storm. The relationship between the intensity and the duration of the main phase is also examined. We discuss these results in terms of the existing concepts of geomagnetic storms.

RELATIOSHIPS BETWEEN MAGNETOSPHERIC DISTURBANCES AND SOLAR ACTIVITIES OBSERVED FROM APRIL 30 TO MAY 5, 1998

Haruka ADACHI[1], Tohru SAKURAI[1], Katsuhide MARUBASHI[2] ([1]Department of Aeronautics and Astronautics, Tokai University, [2]Communication Research Laboratory)

Three magnetic disturbances occurred successively during 6 days from April 30 to May 5, 1998, in which the Dst index grew greatly to the minimum value of about -200 nT. These strong magnetospheric disturbances were brought by attacks of three successively shocked solar winds observed during this period. In this paper we examined the storm and substorm signatures, and their related magnetic disturbances including ULF wave activities observed on the ground and in the magnetosphere by the Geotail satellite and the Geosynchronous satellite, Goes 8 and 9. The storm activities appeared in the development of the Dst index. The first SSC was observed at 0930 UT on 30 April, which was not so strong. However, clear Psc ULF waves were observed on the ground from high to low latitude ground stations, and simultaneously very interesting excitation of Pc 5 ULF waves was observed by Geotail in the morning side outer magnetosphere. The second SSC was observed at 2200 UT on 1 May, which brought the first clear negative excursion of the Dst index to -100 nT. This magnetic disturbance was caused by the second high speed solar stream in excess of about 600 km/s. Magnetic disturbances observed on the ground were very severe with strong substorm activities. ULF waves observed on the ground were also enhanced. The third SSC

was observed at 0330 UT on 4 May, which appeared with a very steep decrease of the Dst without any clear initial phase, but with strong substorm activities with large amplitude Pc 3 and 5 ULF waves. The speed of the third shocked solar stream was in excess of 800 km/s, highest among the three solar streams. The travel time was estimated as being very short only with about 45 hours. We also examined the relationship of the magnetic structure between the magnetic cloud observed on 2 May and the CME on 29 April, and found that the orientation of the flux rope was good agreement with the orientation of the filament disappearance. Magnetospheric disturbances associated with these interplanetary disturbances are discussed in more detail.

HOW TO USE MODERN SPACE SCIENCE MODELSAT THE COMMUNITY COORDINATED MODELING CENTER

Masha M. KUZNETSOVA, Lutz RASTAETTER, Michael HESSE, Kristi KELLER, Ayris FALASCA, John DORELLI (Community Coordinated Modeling Center, NASA/GSFC)

The Community Coordinated Modeling Center (CCMC) is offering runson request of space weather models residing at CCMC to a broadspace science community. Runs on request support an open modelpolicy by providing community access to state-of-the-art researchmodels. They also facilitate model testing by a large number ofresearches. Runs on request can be used for education purposes aswell as for comprehensive scientific research. We have developeduser friendly Web interfaces for on-line run submission andvisualization of the simulation results. At the present time, runson request are available for two global MHD magnetosphere models(BATSRUS and UCLA-GGCM), two ionosphere/thermosphere models (SAMI2and Coupled Thermosphere Ionosphere Plasmasphere model) and oneinner magnetosphere model (Fok ring current model). We willpresent examples of successful research through the www. We willdemonstrate the run on request submission mechanism. We willillustrate the features of the www interface for visualization,discuss the post-processing options, as well as tools, whichfacilitate comparisons between simulation results and satellite andground-based observations.

OBSERVING GLOBAL PROCESSES IN THE SUN-EARTH SYSTEM WITH SOLAR TERRESTRIAL RELATIONS OBSERVATORY (STEREO) AND THE INTERNATIONAL HELIOPHYSICAL YEAR

Joseph Michael DAVILA, Nat GOPALSWAMY (NASA Goddard Space Flight Center)

The solar magnetic field is constantly generated beneath the surface of the Sun by the solar dynamo. To balance this flux generation, there is constant dissipation of magnetic flux at and above the solar surface. The largest phenomenon associated with this dissipation is the Coronal Mass Ejection (CME).The Solar and Heliospheric Observatory (SOHO) has provided remarkable views of the corona and CMEs, and served to highlight how these large interplanetary disturbances can have terrestrial consequences.STEREO is the next logical step to study the physics of CME origin, propagation,and terrestrial effects. Two spacecraft with identical instrument complements will be launched on a single launch vehicle in November 2007. One spacecraft will drift ahead and the second behind the Earth at a separation rate of 22 degrees per year. Observation from these two vantage points will for the first time allow the observation of the three-dimensional structure of CMEs and the coronal structures where they originate. An international research program, the International Heliophysical Year (IHY) will provide a framework for interpreting STEREO data in the context of global processes in the Sun-Earth system. In 1957 a program of international research, inspired by the International Polar Years of 1882-83 and 1932-33, was organized as the International Geophysical Year (IGY) to study global phenomena of the Earth and geospace. The IGY involved about 60,000 scientists from 66 nations, working at thousands of stations, from pole to pole to obtain simultaneous, global observations on Earth and in space. There had never been anything like it before.   The fiftieth anniversary of the International Geophysical Year will occur in 2007. We propose to organize an international program of scientific collaboration for this time period called the International Heliophysical Year (IHY). Like it predecessors, the IHY will focus on fundamental global questions of Earth science. The STEREO mission will be a major contributor to IHY research objectives.

PROPAGATION AND CHARACTERISTICS OF EJECTA AT 1 AU USING HALO CME EXPANSION SPEEDS AND INTERPLANETARY OBSERVATIONS

Alisson DAL LAGO[1], Walter GONZALEZ[1], Rainer SCHWENN[2], AliciaLuiza CLUA DE GONZALEZ[1], Luis Eduardo Antunes VIEIRA[1], Ezequiel ECHER[1], Fernando Luis GUARNIERI[1], Laura BALMACEDA[1], Nelson Jorge SCHUCH[3] ([1]Instituto Nacional de Pesquisas Espaciais, Brazil, [2]Max-Planck-Institut fuer Aeronomie, Germany, [3]Centro Regional Sul de Pesquisas Espaciais, Brazil)

The Large Angle and Spectroscopic Coronagraph (LASCO) has observed 38 halo coronal mass ejections that were correlated with interplanetary ejecta at 1AU during the period from January 1997 to April 2001. We have measured the lateral expansion speed of these CMEs using LASCO C3 images, and we used them as an indication of the sun-earth line initial speed. Interplanetary ejecta speed observations made by the Advance Composition Explorer (ACE) have given us the interplanetary counterparts of these CMEs, allowing us to construct models to predict their characteristics and their travel time to 1 AU. During this same period, 5 out of the 8 most intense geomagnetic storms (Dst$<$-200nT) were caused by this kind of interplanetary ejecta.

CME-ASSOCIATED MAGNETIC CLOUD STRUCTURES IN ASCENDING PHASE OF SOLAR CYCLE 23

Takashi WATANABE[1], Haruka ADACHI[2], Katsuhide MARUBASHI[3], Yuko NAMIKI[1] ([1]Department of Environmental Sciences, Ibaraki University, [2]Department of Aeronautics and Astronautics, Tokai

University, [3]Communications Research Laboratory)

CME images taken by SOHO/LASCO coronagraphs show that CMEs were tend to be formed along the magnetic neutral line on the source surface in the solar corona. This leads to a suggestion that the axial orientation of an interplanetary magnetic cloud (IMC) will be coincide with the local inclination of the magnetic neutral line near the sub-Earth point (e. g. Mulligan et al., GRL, 28, 891, 2001). According to an analysis of CME-associated IMC events observed in the ascending phase of the present solar activity cycle (1997-2000), general increase of the inclination of the IMC axis is seen following the increase of a meandering tendency of the source-surface magnetic neutral line(from Wilcox Solar Observatory). At the same time, we found a number of IMCs which did not follow the general law mentioned above. To establish the CME-IMC connection, it is necessary to find solar sources of relevant CMEs. To do this, we examine coronal images taken by EIT/SOHO and SXT/Yohko to find characteristic coronal phenomena, e.g. X-ray dimming (Sterling and Hudson, Astrophys. Lett., 491, L55, 1998), transient coronal holes (Watanabe et al., in Proc. 3rd SOHO Workshop, ESA SP-373, 269, 1994) and other signatures indicating the formation of CMEs. A provisional analysis showed that a large-scale change in EIT coronal images took place near the solar disc center, beneath the neutral line, we found a reasonable angular coincidence between the neutral line and the IMC axis. Detailed analysis is in progress.

TRACING THE SOLAR PARTICLE CHAIN IN APRIL 2002

Daniel N. BAKER[1], Richard A. MEWALDT[2], Glenn MASON[3], Shri KANEKAL[3], Janet U. KOZYRA[4], David S. EVANS[5], Scott M. BAILEY[6], M.J. REINER[7] ([1]Laboratory for Atmospheric and Space Physics, [2]California Institute of Technology, [3]University of Maryland, [4]University of Michigan, [5]National Oceanic and Atmospheric Administration, [6]University of Alaska Fairbanks, [7]Goddard Space Flight Center)

Soon after the RHESSI spacecraft observed an X-class solar flare early on 21 April 2002 a coronal mass ejection (CME) moving at ~2500 km/sec was observed by SOHO to emerge from near the west limb of the Sun. Almost simultaneously, Type-II and Type-III radio emission was observed by the Wind spacecraft, indicating the onset of particle acceleration near the Sun. The active region on the Sun responsible for this event was magnetically well-connected to the Earth, leading to a prompt enhancement at 1 A.U. of solar particles ($E > 10$ MeV) as seen by the ACE and SAMPEX spacecraft. Strong shock-related particle acceleration continued to occur as the CME propagated outward from the sun. The solar particle enhancement lasted from 21 April to 26 April (as seen by the NOAA/POES spacecraft) and included enhancement not only of solar protons and heavier nuclei extending to hundreds of MeV/nucleon but also solar electrons. The energetic particles produced near the sun, at this and preceding interplanetary shock waves, and deep within the Earth´s radiation belts were all observed using TIMED and SNOE to produce substantial effects on the chemistry of the Earth´s middle and upper atmosphere. We examine the impacts of this set of events on atmospheric heating and cooling rates and on ozone densities in the mesosphere. Using the remarkable constellation of available spacecraft, we are able to follow the particle chain from the Sun´s surface all the way to the deep layers of Earth´s atmosphere with unprecedented completeness.

SOURCES AND ACCELERATION OF PARTICLES AT SHOCKS FROM THE SUN TO THE EARTH

Eberhard MOEBIUS, Harald KUCHAREK (Department of Physics and Space Science Center, University of New Hampshire)

Shocks at solar wind stream interaction regions, coronal mass ejections and magnetospheric obstacles have long been known for their intimate link with particle acceleration. Much enhanced capabilities to determine mass and charge composition on ACE and SOHO and to obtain detailed distributions with commensurate time resolution on Cluster have enabled us to track down sources and injection mechanisms for the resulting energetic particles and to take a closer look at the processes. It has become apparent that both solar wind and interstellar pickup ions are substantial sources for particle acceleration in CIRs and at CME driven shocks. The relative contribution of these ions in the energetic particle populations does not only reflect their abundance variations with location in the heliosphere, but also their injection efficiency into acceleration. Most recently a more detailed look into shock structure and particle acceleration processes has become possible at the bow shock with Cluster. The emergence of the accelerated ion population out of the low energy population in the ramp of quasi-perpendicular bow shocks has become visible. Because simulations have shown that also in the case of quasi-parallel shocks the shock forming waves produce quasi-perpendicular conditions locally, where then particles are accelerated, the observations at the simpler quasi-perpendicular shocks provide us with more general information.

ACCELERATED PLASMA FLOWS IN THE CUSP BOUNDARY LAYER: A CLUSTER-FAST-POLAR-SUPERDARN CONJUNCTION STUDY

Charles J FARRUGIA[1], E. LUND[1], P.E. SANDHOLT[2], E. MOEBIUS[1], S.W.H. COWLEY[3], J. WILD[3], A. BALOGH[4], M. DUNLOP[5], C. MOUKIS[1], L. KISTLER[1], H. REME[6] ([1]Space Science Center, University of New Hampshire, USA, [2]Physics Department, University of Oslo, Oslo, Norway, [3]Ionospheric Physics Group, University of Leicester, Leicester, UK, [4]Imperial College of Science and Technology, University of London, UK, [5]Rutherford Appleton Laboratory, Chilton, Didcot, UK, [6]Centre d'Etude Spatiale des Rayonnements,Toulouse, France)

Observations during a multiple magnetic conjunction CLUSTER-FAST-Polar-SuperDARN are examined. CLUSTER was on an outbound pass through the exterior cusp. The IMF pointed south-west throughout. A solar wind dynamic pressure release shifted CLUSTER into the cusp boundary layer at the poleward edge of the cusp. There it observed 5 flow bursts and magnetic perturbations which are Alfvenic in nature. We interpret these flow events as being due to a sequence of reconnected flux tubes passing over CLUSTER (i.e., flux transfer events, FTEs). This interpretation is further supported by the following: (i) The observation at FAST of a staircase cusp ion signature on magnetic field lines nominally connected to CLUSTER; (ii) The observation by the SuperDARN radars of a sequence of pulsed poleward enhancements of ionospheric flows (PIFS) which are (a) in one-to-one correspondence with the flow bursts at CLUSTER and which (b) are well known from previous work to be an ionospheric signature of FTEs; (iii) Observations of the ion flow bursts at Polar, situated in the magnetosphere further downstream of CLUSTER, whose directional characteristics are consistent with the interpretation proposed above. The work extends previous studies of magnetospheric signatures of FTEs and associated energy and momentum transfer by showing flow bursts due with reconnection at sub-cusp latitudes but which are seen behind the cusp.

GAIII.09/11A/A11-007   Invited   **1140**

FLUX TRANSFER EVENTS OBSERVED BY DUAL SATELLITES: ISEE-1 AND ISEE-2

Hideaki KAWANO (Department of Earth and Planetary Sciences, Kyushu University, Japan)

Flux transfer events (FTEs) are transient events observed nearthe dayside magnetopause, characterized by bipolar perturbationin the magnetic field component normal to the magnetopause.They are generally thought to be generated by transient daysidereconnection, which transports solar wind energy into themagnetosphere. We have analyzed magnetic field data from dualsatellites ISEE-1 and ISEE-2 (usually separated from each otherby several hundred kilometers), in an attempt to directly detectthe motion of FTEs. From ten years´ data of ISEE, we haveidentified about thousand cases in which the two satellitesobserved the same FTE. Then, from the positions and observationtimes of each FTE at the two satellites, we have estimated thedirection of motion of the FTE. Preliminary results suggestthat the FTEs tend to move tailward, mainly in the east-westdirection, away from the subsolar point; this is inconsistentwith an east-west elongated structure caused by a transientreconnection at the (east-west elongated) equatorialreconnection line, but consistent with a flux-tube structurewhich has a small cross-section in the GSM XY plane.

ENERGY TRANSFER FROM THE SOLAR WIND INTO THE IONOSPHERE INSIMULATIONS OF THE EARTH MAGNETOSPHERE-IONOSPHERE SYSTEM

Lutz RASTAETTER[1], Maria M. KUZNETSOVA[1], Michael HESSE[1], Aaron RIDLEY[2], Tamas I. GOMBOSI[2], Joachim RAEDER[3] ([1]Community-Coordinated Modeling Center, [2]CSEM, University of Michigan, [3]IGPP, University of California Los Angeles)

Due to their different design, global magnetospheric models can generate different results for the same solar wind input conditions. However, the average of a quantity obtained from concurrentsimulations provides an estimate of the level of geomagnetic activity and the differences between the model results may serve as an estimated error level. The ultimate goal, of course, is to obtain modeled results that are close to actual observations and minimize the differences between the different model results by the use of better input data,improved algorithms or increased spatial resolution. Physics-based magnetospheric models may eventually be run in an ensemble to obtain forecasts like in terrestrial weather forecasting. As a first step toward the goals outlined, we use simulation results obtained with the global magnetospheric models BATSRUS (UM) and UCLA-GGCM.As an example, we can determine the energy and mass transferred into the inner magnetosphere and the ionosphere and compare those transfers with the varying solar wind condition to get transfer rates and reaction time constants. Modeled results will be compared by in-situ measurements or remote-sensing observations for selected events.

MULTIPLE SPACECRAFT MEASUREMENTS OF ENERGETIC IONS DURING A HIGH SOLARWIND PRESSURE EVENT

Jiasheng CHEN, Theodore A. FRITZ (Center for Space Physics, Boston University)

On June 28, 1999, the WIND spacecraft (near L1) observed a suddenincrease (by more than one order of magnitude) of the solar windpressure at about 4:45 UT and an upstream ion event at 5:23-5:45 UT,the INTERBALL-1 spacecraft located upstream of the bow shock(X=22.4Re, Y=-15.7Re, Z=6.25Re in GSE) measured an upstream ionevent from 5:16 UT to 6:00 UT, while the POLAR satellite at 7 hoursmagnetic local time detected an energetic particle event in thehigh-altitude region associated with turbulent diamagnetic cavitiesfrom 5:12 UT to 6:30 UT. Energetic oxygen ions of both ionosphericorigin and solar wind origin were observed by the POLAR during thisevent period. The energetic ions and the associated turbulentmagnetic field are very similar to what found in the high-altitudedayside cusp region. The interplanetary magnetic field (IMF) wasdominant by its tailward component; the IMF By was almost duskward,while the IMF Bz was almost southward at 5:00-6:00 UT. For aduskward IMF component, a cusp diamagnetic cavity found at 7 hourslocal time is unexpected by current MHD models. The relationbetween the cusp and the upstream energetic ions and the relationof these energetic ions with the interplanetary conditions willbe discussed.

OBSERVATIONS OF DISCRETE, GLOBALMAGNETOSPHERIC OSCILLATIONS DIRECTLY-DRIVEN BY SOLAR WIND DENSITY VARIATIONS

Larry KEPKO, Harlan E. SPENCE (Center for Space Physics, Boston University)

In this paper we present six events in which both the timeseriesand the spectral content of solar wind number density fluctuations andmagnetospheric magnetic field observations were highly correlated for intervalsranging from a few to twelve hours. The fluctuations were periodic andoccurred at discrete frequencies which often matched the f=1.3, 1.9, 2.6, and3.4 mHz oscillations that have been attributed to global magnetospheric MHDcavity and/or waveguide modes. We also observed significant power in thesub-mHz region, with frequencies as low as f=0.1 mHz. We show that these fluctuations were first observed in the solar wind, far upstream from the earth, and argue that the convected density perturbations slowly alter the size of the magnetospheric cavity leading to the appearance of multiple, discrete magnetospheric oscillations. We argue that for these events the discrete frequencies were an inherent property of the solar wind, and were not related to a possible cavity or waveguide mode of the magnetosphere. We then show that the solar wind density fluctuations, when converted into length-scales, organize into scalesizes of L=23, 30, 45, and 80-100 RE. Finally, we speculate on and show some evidence for a possible solar source for these particularly geoeffective solar wind structures, thereby suggesting a meansby which plasma energy may flow from the Sun, be transported through the heliosphere, and ultimately, couple into and energize the magnetosphere.

GAIII.09/11P/A11-003   Invited   **1440**

COUPLING OF ENERGY FROM THE SOLAR WIND INTO THE OUTER ZONE RADIATION BELTS THROUGH ULF VARIATIONS

Scot R. ELKINGTON[1], Michael J. WILTBERGER[2], Anthony A. CHAN[3], Yue FEI[3], Daniel N. BAKER[1], Mary K. HUDSON[2] ([1]Laboratory for Atmospheric and Space Physics, University of Colorado, [2]Department of Physics and Astronomy, Dartmouth College, [3]Department of Space Physics

and Astronomy, Rice University)

The outer zone radiation belts are comprised primarily of energetic ($>$200 keV)electrons geomagnetically trapped in orbits encircling the Earth. The bulk ofthe radiation lies at radial distances between 3-7 Earth radii, a region ofparticular significance due to the large number of spacecraft operating atthese altitudes, and global society´s increasing reliance on space-basedtechnologies for communications, navigation, weather prediction, and a varietyof other economic and geopolitical purposes. As spacecraft operating in thisregion have sometimes been found susceptible to ˝anomalies˝ related to changesin the local radiation environment, understanding the transmission of energyfrom the solar wind into the magnetosphere and radiation belts is ofparticular practical importance. Waves in the ULF spectrum, with periods of afew to tens of minutes, have been shown to be an effective means oftransporting and energizing particles within the radiation belts. Recent workhas also shown that variation in the solar wind often occurs on ULF timescales, suggesting a means by which energy could be effectively transmittedfrom the solar wind into the inner magnetosphere, and directly affect theglobal radiation environment. In this work we use 3D, globalmagnetohydrodynamic (MHD) simulations of the magnetosphere, driven by upstreamsolar wind observations, to examine the ULF mode and power structure in theinner magnetosphere. Radial and local time dependence of ULF wave power isexamined, and implications for radiation belt acceleration and transport arediscussed.

GAIII.09/11P/A11-004   1510
SOLAR WIND DRIVING OF THE MAGNETOSPHERE: RING CURRENT AND MHD RESULTS

Niescja E. TURNER[1], Ramon E. LOPEZ[1], Michael J. WILTBERGER[2], Elizabeth J. MITCHELL[1] ([1]Department of Physics, Univ. of Texas at El Paso, [2]Dartmouth College)

We use MHD simulations and ring current data to investigate themagnetospheric response to different types of solar wind energy input.The MHD simulations show that the dissipation of energy in the magnetosphere-ionosphere system is very sensitive to solar wind density variations during time of strong driving, with large density pulses during southward Bz exhibiting significantly greater geoeffectiveness than strong Bz without such pulses. This suggests that solar wind kinetic energy flux may play a significantrole during southward Bz. We compare this behavior with the behavior ofring current ions (using particle measurements and Dst) in order todetermine whether the ring current shows this same response to different types of solar wind energy coupling. Initial results suggest that the ringcurrent does indeed respond this way, and we present results showing the overall magnetospheric effect of these different solar wind drivers. Thiswork is a part of the Center for Integrated Space weather Modeling (CISM) initiative.

GAIII.09/11P/A11-005   1600
INTERPLANETARY SHOCKS AS A POSSIBLE TRIGGER OF SUBSTORM ONSETS: A STATISTICAL STUDY WITH POLAR ULTRAVIOLET IMAGER IMAGES

Kan LIOU[1], Patrick T. NEWELL[1], Chin-Chun WU[2], Ronald P. LEPPING[3], Ching-I MENG[1] ([1]The Johns Hopkins University Applied Physics Laboratory, [2]CSPAR, Univeristy of Alabama, Huntsville, AL 35899, [3]Laboratory for Extraterrestrial Physics, NASA/GSFC, Greenbelt, MD 20771)

One of the outstanding issues in magnetospheric physics is the trigger mechanism(s) of the substorm expansion phase onset. There is a large body of evidence indicating that an impingement of the high solar wind dynamic pressure may lead to the expansion phase onset of substorms. When high solar wind ram pressure impinges upon the magnetosphere, it compresses the lobe magnetic fields and enhances the cross-tail currents. Reconnection or current disruption may occur and ultimately lead to substorm onsets. Note that the forming of a negative magnetic bay has been the main proxy for a substorm used in previous studies, and we now know that some magnetic bays are not substorms but convection bays associated with the enhancement of convection. Therefore, it is reasonable to cast doubt on the compression trigger mechanism. In this study we use the classical substorm onset, the ˝auroral breakup,˝ as the most reliable substorm onset indicator. These are identified with global auroral images from the Polar ultraviolet imager (UVI), to investigate this issue. We examine 43 interplanetary shock events that occurred between 1996 and 1999 with simultaneous UVI auroral images and the auroral electrojet indices. It is found, indeed, that ~50% of the shocks produce magnetic bays (AL $<$ -100 nT). While most of the shocks enhance auroral luminosities, less than only ~10% of events show auroral breakups preceded by SSCs. These results strongly indicate that interplanetary shocks can produce negative magnetic bays but not auroral breakups.

GAIII.09/11P/A11-006   1620
ON THE PREDICTION OF MAGNETIC STORMS

Mervyn P. FREEMAN[1], Richard B. HORNE[1], Matthew DAWS[2], Paul S. WILSON[3] ([1]British Antarctic Survey, [2]University of Leeds, [3]Imperial College London)

Magnetic storms are globally coherent non-secular variations of the geomagnetic field that have been identified as a natural environmental hazard with adverse effects on radio communications, satellite operations, electrical power distribution, etc. Thus it is desirable to forecast the occurrence of magnetic storms to mitigate their impact. To this end, we have analysed the probability density function (PDF) of magnetic storm duration, non-storm duration, and waiting time between storm onsets, for two objective definitions of a magnetic storm based on historical precedent. In the first definition, a magnetic storm is defined as a classic extreme event - the interval for which a relevant geomagnetic measure (the Dst index) is above a given threshold, c. The PDF of storm duration, non-storm duration, and waiting time between storm onsets are all found to be truncated power laws, independent of threshold. Thus, under this definition, magnetic storms have no characteristic duration or recurrence time between 1h and 100h. In the second definition, we show evidence that the extreme events of the first definition are part of a longer coherent structure in the time series such that a magnetic storm can alternatively be defined as the interval for which the Dst index is above a given threshold b and the maximum Dst is above a second, higher threshold c. Over a region of the two-threshold parameter space {b, c}, the PDF of waiting times between storm onsets in 3-year samples is found to be a random stationary (Poisson) process with a Poisson statistic that varies with the solar cycle, and the PDF of storm durations is peaked at 20 - 30h. The analysis raises an interesting general question as to the occurrence properties of abstract extrema (e.g., gale force winds) compared to those of physical extreme events (e.g., hurricanes?). Moreover, an interesting similarity between the occurrence pattern of repeatable magnetic storms and of solar flares is noted.

GAIII.09/11P/A11-007   Invited   1640
EARTH IN THE THREE DIMENSIONAL SOLAR WIND FLOW

Ken'ichi FUJIKI[1], Masayoshi KOJIMA[1], Munetoshi TOKUMARU[1], Tomoaki OHMI[1], Masahiro YAMASHITA[1], Masaya HIRANO[1], Bernard V. JACKSON[2], Paul P. HICK[2] ([1]Solar-Terrestrial

Environment Laboratory, Nagoya University, Japan, [2]Center for Astrophysics and Space Science, UCSD, USA)

Ground-based remote-sensing using interplanetary scintillation (IPS) is a unique tool for the study of the global structure of the solar wind. This technique measures solar wind at locations that are difficult or impossible to access with in situ measurements. Recently we introduced a computer-assisted tomography (CAT) program to reproduce solar wind features and this has greatly improved the reliability of our IPS studies. We applied the CAT analysis to the IPS data obtained at heliospheric distances 0.1-0.9 AU over one solar cycle (1985-2002) and analyzed the variation of the solar wind structure during this period. We discuss several solar wind features found in these analyses. The solar wind consists of two velocity components (i.e. the solar wind is bimodal) not only around solar minimum but also in the rising and declining phases. The fast solar wind velocity is asymmetric between northern and southern hemispheres. Around solar maximum the solar wind structure evolved asymmetrically in both hemispheres, similar to the evolution of magnetic elements of the old/new polarity in the photosphere. Interplanetary disturbances are the other target of IPS observations, and their dynamics have been studied by using model-fitting analysis and a sophisticated time-dependent tomography method. We will report several results from these studies. We have started trial real-time solar wind forecasting using the IPS CAT analysis on a daily basis. The preliminary results of this trial will also be shown in this talk.

WAVELET ANALYSIS OF INTERPLANETARY MAGNETIC FIELD AND AE INDEX FLUCTUATIONS DURING HILDCAA EVENTS

Fernando Luis GUARNIERI[1], Walter Demetrio GONZALEZ[1], Bruce TSURUTANI[2], Ezequiel ECHER[1], Alisson DAL LAGO[1], Luis Eduardo VIEIRA[1], Alicia Luiza CLUA DE GONZALEZ[1], Nelson Jorge SCHUCH[3] ([1]Instituto Nacional de Pesquisas Espaciais/DGE, [2]Jet Propulsion Laboratory - JPL/NASA, [3]Centro Regional Sul de Pesquisas Espaciais/INPE)

HILDCAA events (High Intensity, Long Duration, Continuous Auroral Activity) were firstly discovered by Tsurutani and Gonzalez, in 1987. These events are characterized by an intense activity in auroral region, measured by AE index, despite the absence of a strong geomagnetic storm. The interplanetary magnetic field during these events presents Alfvenic fluctuations. The events must follow some criteria to be considered a HILDCAA: they must reach, at least, 1000nT in the AE peak, they can not drop below 200 nT in AE index by a period greater than 2 hours, have a minimal duration of 2 days and occur outside the main phase of a geomagnetic storm.For HILDCAAs identification, it was used high resolution (1 minute) ACE satellite data and AE index. The data were plotted simultaneously, and the results were analyzed in order to identify the event occurrences. It was analyzed the 13 strongest events occurred during year 1998.Wavelet analysis was applied in the AE index and interplanetary magnetic field Bz during periods of HILDCAA occurrences. The results show that only large periods were observed along the whole AE series, while short periods occur only in some periods of each event.

USING ULF WAVES AS DIAGNOSTIC PROBES OF THE MAGNETOSPHERIC DENSITY

Fred W. MENK[1], Mark A. CLILVERD[2], Bill R. SANDEL[3], Don L. CARPENTER[4], Ian R. MANN[5] ([1]School of Mathematical and Physical Sciences, University of Newcastle, [2]British Antarctic Survey, High Cross, Cambridge, CB3 0ET, U.K., [3]Lunar and Planetary Laboratory, University of Arizona, Tucson, AZ 85721, USA, [4]Space, Telecommunications and Radioscience Laboratory, Stanford University, Stanford, CA, [5]Department of Physics, University of York, Heslington, York, YO10 5DD, U.K.)

Ultra-low frequency (ULF; f~1-100 mHz) plasma waves distribute energy of solar wind origin throughout the Earth´s magnetosphere and down to the ground, where they are recorded as pulsations of the geomagnetic field. The waves propagate through the magnetosphere in the fast magnetosonic mode and may couple to shear transverse mode field line eigenoscillations. The frequency of these field line resonances (FLRs) is determined by the field geometry and the plasma mass density near the equatorial plane. The FLRs occur during the local daytime and can often be observed for several hours. Ground-based measurements of the resonant frequency can therefore provide information on the plasma mass density near the field line apex in the dayside magnetosphere. An array of latitudinally-separated ground magnetometers allows the plasma density profile to be monitored throughout the magnetosphere. This may be compared with ground-based VLF electron density measurements, and satellite-borne particle and imager observations. The average properties of the magnetospheric plasma are well established. However, case studies demonstrate that the magnetosphere exhibits density features that have only been partially described and which are far from understood. Regions of particular interest are in the vicinity of the plasmapause, where complex structures and temporal variations are frequently observed, and the outer plasmasphere, where small-scale density perturbations may occur. These regions may be examined by ULF FLR techniques on a time scale of 30-60 min and a spatial resolution in the range 0.15-0.4 RE. We describe case studies of the magnetospheric plasma using FLRs, and compare the observed mass densities with spacecraft data and models. In particular, we present illustrative examples of the density profile for the following cases: (1). Quiet conditions, when only a vestigial plasmapause is present; (2). Several days after a moderate magnetic disturbance; (3) Disturbed conditions; and (4). Cases when there are sudden changes in solar wind pressure. (5). A magnetic storm cycle. In addition to observing the erosion and refilling of the plasmasphere, we can detect small localized depletions and enhancements, and monitor the effect of heavy ion contributions. We also outline experiments that can provide multi-instrument studies of the same flux tube. These use (a) closely-spaced ground magnetometers to record the field line resonance frequency and hence provide mass density information, (b) co-located VLF receivers that simultaneously monitor the electron density, (c) RPI and EUV data from the IMAGE spacecraft, providing in situ electron and helium density information, and (d) mathematical modelling of the constituent densities and temperatures for this flux tube. These measurements provide the first intercalibration of different ground-based and in situ techniques and lend new insight on plasma dynamics within the plasmasphere.

PLASMASPHERIC MASS COMPOSITION DYNAMICS: IMAGE AND GROUND BASED RESULTS

David BERUBE[1], Mark B. MOLDWIN[2], James L. GREEN[3], Shing F. FUNG[3] ([1]Department of Earth and Space Sciences, University of California, Los Angeles, [2]Institute of Geophysics and Planetary Physics, University of California, Los Angeles, [3]NASA Goddard Space Flight Center, Geenbelt MD)

The dynamics of plasma composition in the inner magnetosphere is not fully understood. It is known that the concentration of heavy ions from the ionosphere increases during times of enhanced geomagnetic activity, with the highest concentrations occurring during severe storms. The equatorial plasma mass density of the inner magnetosphere can be inferred using pairs of ground based magnetometers by measuring field line eigenfrequencies and invoking a model of the plasma distribution along the field line. The Radio Plasma Imager(RPI) on the IMAGE spacecraft takes routine measurements of the electron number density in the plasmasphere and plasmatrough. Knowledge of the plasma mass density and electron number density allows us to track the average mass of particles in these regions as a function of geomagnetic activity, local time, and L shell. Using pairs of ground magnetometers from the MEASURE array and overflights of the IMAGE spacecraft from 2000 and 2001, we have constructed a database of average particle mass for field lines between L=1.75 and L=3.12 as functions of local time and magnetospheric conditions. Assuming the magnetospheric plasma consists only of hydrogen, helium, and oxygen, we are able to constrain the plasma composition.

GAIII.10/10P/A01-003   1440

CO-ORDINATED IMAGE SATELLITE AND GROUND-MAGNETOMETER OBSERVATIONS OF AN ANOMAOLUS CROSS-PHASE REVERSAL AT L = 3.2: THE SIGNATURE OF A STEEP PLASMAPAUSE?

Zoe C. DENT[1], Ian R. MANN[2], F.W. MENK[3], J. GOLDSTEIN[4], L.G. OZEKE[2] ([1]University of York, Heslington, York, YO10 5DD, UK, [2]University of Alberta, Edmonton, Canada, T6G 2J1, [3]University of Newcastle, Newcastle, NSW, Australia 2308, [4]Rice University, Houston, TX 77005-1892, USA)

The cross-phase technique was applied to magnetometer data from a meridional chain of ground-based magnetometers from the SAMNET, IMAGE and BGS chains in the northern European sector. Between 0800 and 1200 UT (UT = MLT) on the 14th May 2001 a region of anomalous cross-phase reversal was observed by two sets of station pairs (ESK-LER and GML-LER) whose mid-points are located at L = 3.16 and L = 3.33. On a conjugate pass by the IMAGE satellite the Radio Plasma Imager (RPI) instrument measured a sharp plasmapause signature close to this L-shell; a decrease of electron density by a factor of 8 being observed between L = 3.0 and L = 3.25 from 0840-0846 UT near the equatorial plane and within 90 minutes of LT of the reverse cross-phase signature observed on the ground. We believe that this event represents the first observation of a cross-phase reversal co-located with an in-situ measurement of a sharp plasmapause. Previous studies have looked for a reverse cross-phase plasmapause signature, however, such signatures are not routinely observed. Using a simple dipolar field model, we show that the density profile across the plasmapause must decay faster than L[-8] in order for a turning point in Alfvén frequency to be developed across L-shells. The IMAGE RPI data shows that this criteria is satisfied for the satellite pass conjugate to the ground-based reverse phase signature on this day. As the cross-phase reversal only exists in the European sector magnetometer data between 0800 and 1200 UT, this suggests that local- time structure is present in the radial density profiles on this day. Moreover if plasmapause density profiles shallower than L[-8] are more typical, then this may explain in part why observations of plasmapausal cross-phase reversals have remained so elusive.

GAIII.10/10P/A01-004   1500

STORM TIME PLASMA MASS DENSITY ESTIMATED USING ULF WAVES OBSERVED BY CRRES

Kazue TAKAHASHI[1], Richard E. DENTON[2], Roger R. ANDERSON[3], W. Jeffrey HUGHES[4] ([1]The Johns Hopkins University Applied Physics Laboratory, [2]Dartmouth College, [3]University of Iowa, [4]Boston University)

The frequency of standing Alfven waves has been used to estimate the plasma mass density based on the fact that the Alfven velocity depends on the density. This technique by itself provides no information on ion composition, but with additional information on the electron number density one can find the total contribution of heavy ions to the mass density. The capability to monitor the behavior of heavy ions is important in understanding the formation of the ring current. In this paper we estimate storm time ion mass density using ULF waves detected by the CRRES spacecraft. A 40-day period in August-September, 1991 is chosen for analysis because the spacecraft was located in the postnoon sector and routinely detected toroidal mode standing Alfven waves. Dynamic spectra of the B and E fields are generated for each CRRES orbit for identification of the fundamental frequency of the toroidal waves. A numerical method similar to that of Denton et al. [J. Geophys. Res., page 29,915, 2001] is used to relate the frequency to the mass density at the position of the satellite. We define a mass factor by dividing the mass density (in units of proton mass per cc) by the electron number density determined from the CRRES plasma wave data. The mass factor is greater than 1.0 as expected and varies significantly with Dst. A positive correlation is found between the mass factor and the magnitude of Dst. By contrast, the electron number density is not correlated with Dst. This result implies that intensification of the ring current does not occur from the increase of the number of particles and that a large fraction of the storm-time ring current is carried by heavy ions.

TRAVEL-TIME MAGNETOSEISMOLOGY: A NEW DIAGNOSTIC TOOL FOR SPACE WEATHER STUDIES

Peter J. CHI, Christopher T. RUSSELL (Institute of Geophysics and Planetary Physics, UCLA)

In the last few years, the studies on the propagation of sudden impulses and that of impulsive ULF waves have led to a new remote sensing method that is similar to what seismologists use to probe the interior structure of the Earth. This method, dubbed ``travel-time magnetoseismology´´, is to utilize the measurements of the signal arrival time at different locations, either on the ground or in space, to infer the plasma density that controls the propagation speeds of MHD waves. Not only does travel-time magnetoseismology provide a useful diagnostic tool of the state of the magnetosphere, it also closely ties with the physics of MHD waves propagation in the inhomogeneous magnetosphere. In this paper we present a comprehensive overview of the subject and discuss the directions of future development. We find that Tamao´s theory of preliminary impulse arrival provides a good and easy-to-use forward model in travel-time magnetoseismology. The time of wave energy propagation can be approximated by the sum of the travel time of fast-mode propagation from the source to the field line of concern and that of the subsequent Alfven-mode propagation to the point of

observation, both strongly dependent on the plasma density distribution in the magnetosphere. The characteristics of Tamao´s travel time have been confirmed by recent MHD simulations, as well as by observations of various impulsive perturbations of magnetic fields, such as the preliminary impulse of sudden commencements, magnetic impulse events (MIEs), and the beginning phase of Pi 2 waves. In particular, the capability of inferring the nightside plasma density from the arrival time of Pi 2 enables the travel-time method to be complementary to the the field line resonance method that is mainly effective for the dayside magnetosphere. We also developed a nonlinear optimization algorithm for inverting the parameters in plasma density distribution, and the results based on test data show that the procedure well determines the location of the plasmapause and the density in the plasmasphere. Also provided by the inversion is the source location of the signal, a valuable piece of information for understanding the generation mechanisms of these impulsive events. In the end, we will assess how the inclusion of spacecraft data enhances the accuracy of plasma density estimation, as well as the expanding capabilities of travel-time magnetoseismology in the future as ground magnetometer networks and multi-satellite missions proliferate.

PLASMA DENSITY DIAGNOSIS BASED ON FIELD LINE RESONANCES IN 3D MAGNETOSPHERE

C.Z. CHENG, S. ZAHARIA (Princeton Plasma Physics Laboratory, Princeton University)

Field line resonance (FLR) has been considered as a diagnostic tool for determining the density distribution in the magnetosphere. Most FLR theories are based on the cold plasma model which is limited in applicability to the low plasma beta region of the inner magnetosphere. In the plasma sheet and magnetotail, plasma beta canbe significantly larger than unity and we have developed a new MHD FLR theory for the magnetosphere by allowing arbitrary isotropic pressure distribution in the equatorial plane as well as cold plasma density distribution. A new contribution due to the longitudinal pressure gradient and geodesic magnetic field curvature is found in the shearAlfven FLR equation. This new term together with the coupling between shear Alfven waves and slow magnetosonic waves due to high plasma beta causes the shear Alfven FLR frequency to be reduced to the 1 - 4 mHz range observed at auroral latitudes. Numerical solutions of the FLR frequencies are presented for 3D magnetospheric field in force balance with plasma pressure as well as model magnetic fields such as Tsyganenko´s models. The results can be employed to compare with FLR observations to obtain the distribution of cold and warm plasma densities and magnetic field in the closed field line region of the magnetosphere.

GAIII.10/10P/A01-007   1600

MAGNETOSPHERE-IONOSPHERE-ATMOSPHERE-EARTH ELECTROMAGNETICALLY COUPLED MODEL FOR SPACE- WEATHER STUDY

Akimasa YOSHIKAWA[1], Kiyohumi YUMOTO[1], Masahiro ITONAGA[2] ([1]Department of Earth and Planetary Sciences, Kyushu University, [2]Space Environment Research Center, Kyushu University, [3]Faculty of Education, Yamaguchi University)

To clarify the aspects of space weather in the earth environments, it would be indispensable to understand the self-consistent picture of magnetosphere-ionosphere coupling in the context of global and transient. To achieve this, we construct a comprehensive model for ionosphere-atmosphere-Earth electromagnetically coupled system which enable to describe the formation process of global ionospheric current caused by field-aligned current (FAC) closure via the ionospheric conducting and atmospheric displacement currents. In this model, the ionospheric slab (conductor) is separated by Earth's ground plane by atmospheric region forms a capacitor. Outgoing current flows in the ionospheric slab and return current flows on the ground plane, which forms an inductor. Thus, ionospheric slab act as if it has a capacitor in parallel to ground inductor in series. Electric field between ionospheric slab and ground plane stores energy in dielectric atmospheric region. Charge present in ionospheric slab and induced in ground plane creates a shunt self-capacitance. Magnetic field around current in ionospheric slab stores energy in magnetic field. The magnetic field links the loop formed by the conductor and ground plane and creates series self-inductance. Using this model, the roles of the FAC closure via the currents in the ionosphere-atmosphere-Earth electromagnetically coupled system especially in the ULF range are clarified. The FACs lose their stored electromagnetic energy in the ionosphere through Joule dissipation; this process is caused by the closure of the FAC via the ionospheric divergent Pedersen current carried by ions. On the other hand, the FAC closure via the divergent Hall current carried by electrons gives a growing energy of rotational Hall current, causing it to radiate Poynting fluxes that lead to the growth of a poloidal-type magnetic field in the magnetosphere and atmosphere. Furthermore, the FAC closure via the atmospheric displacement current provides Poynting fluxes for generation of non-local ionospheric current system. In this study, we will show the detail of physics of the redistribution process of FAC's momentum and energy into current in the ionosphere-atmosphere loading region.

GAIII.10/10P/A01-008   1620

PROBING PLASMASPHERIC RESONANCES WITH TWO INDEPENDENT ULF TECHNIQUES

Fred W. MENK[1], Mark CLILVERD[2], Keith YEARBY[3], Gennadi MILINEVSKI[4], Neil Thomson[5], Mike ROSE[6] ([1]University of Newcastle, [2]British Antarctic Survey, [3]University of Sheffield, [4]Ukrainian Antarctic Center, [5]Unioversity of Otago, [6]British Antarctic Survey)

Previously it has been shown that by using arrays of ground-based magnetometers it is possible to determine the resonant frequency of ULF waves in the inner magnetosphere using the paired response of the magnetometers to pulsations i.e. the cross-phase. It is also well known that the motion of plasmaspheric field aligned ducts can be observed by analysing the Doppler shift of ducted man-made whistler-mode signals. Both of these measurements tend to be single point, or at least single longitude. The pulsations are essentially a daytime probe, while the whistler-mode signals are more often observed during nighttime. At dawn they should be complementary. Previously, using a VLF Doppler system several field-aligned plasmaspheric ducts have been observed to oscillate at close to the fundamental oscillation frequency for L=2.5 field lines. However no ground-based magnetometer data could be compared with these results as the nearby system was unable to resolve the <1 nT pulsation amplitudes that were presumably occurring at the time. During Doppler pulsations the field line has an anti-node of motion in the equatorial plane and the Doppler shift is responding almost entirely to the radial component of the duct motion, and good correlations are expected with the H-component of the geomagnetic field measurements. Here we analyse Doppler shift pulsations from the USA 24.0 kHz VLF transmitter received with an aerial located in the Antarctic Peninsula. Data were collected at L=2.5 during 2001 in the morning hours 08-12 UT (04-08 LT) when Pc3 field-line resonance was likely to occur. Magnetic pulsation information from an array of co-located magnetometers is compared to the Doppler pulsation data, and detailed resonance conditions inferred. We concentrate on several well-defined pulsation events using cross-phase analysis to conclusively identify resonance frequencies and associated harmonics,

comparing these with the pulsation frequencies observed in the VLF Doppler shift records.

GAIII.10/10P/A01-009   1640

THE ROLE OF WAVES IN RADIATION BELT MODELING AND SPACE WEATHER STUDIES

Danny SUMMERS (Department of Math and Stats,Memorial University of Newfoundland)

A full understanding of radiation belt physics is a prerequisite to successful modeling of the geospace environment and to accurate space weather forecasting. In addition to ULF wave driven cross-L diffusion,complete models of radiation belt electron transport should include wave-particle interaction effects,i.e.,energy diffusion and pitch-angle diffusion. Electrons can be accelerated by stochastic gyroresonant interactions with VLF chorus,while electron precipitation losses can result from pitch-angle scattering by VLF and EMIC waves. In this paper we present a CRRES survey of VLF wave data in the outer zone during 26 geomagnetically-disturbed periods,and discuss the significance of these observations with respect to local stochastic electron acceleration. We further present a comprehensive analysis of EMIC wave observations from CRRES,and discuss the implications of the results for electron precipitation by strong diffusion scattering. The importance of incorporating the effects of wave-particle interactions in radiation belt modeling and space weather investigations is emphasized.

GAIII.10/10P/A01-010   1700

STOCHASTIC TECHNIQUES FOR GLOBAL PLASMASPHERIC PROFILE ESTIMATION USING VLF WAVES

Yoshitaka GOTO[1], Yoshiya KASAHARA[2], Toru SATO[1] ([1]Department of Communications and Computer Engineering, Kyoto University, [2]Department of Information and Systems Engineering, Kanazawa Universtiy)

The global electron density distribution in the earth´s magnetosphere is one of the most important information for space weather studies. For such global distribution, however, there are limitations in a direct observation from a single satellite. Recently, several remote sensing techniques are proposed to obtain such global structures. In such techniques, global electron density distributions are generally represented by a parametric or nonparametric model and parameters in the model are evaluated by goodness-of-fit to observations. We have developed a determination technique of global electron density profiles in the earth´s plasmasphere using VLF waves observed by a scientific satellite. Since the characteristics of VLF waves propagating in the plasmasphere reflect electron density distributions along their propagation paths, parameters in a global plasmaspheric model can be determined from continuous observation of the waves along a satellite trajectory. In the present study, we use wave properties of Omega signals and nonducted whistlers for the reconstruction of electron density profile in the plasmasphere. The time delay and wave normal directions of the Omega signals can be determined from the observed wave data. On the other hand, these properties can also be calculated by ray tracing under an appropriate electron density model. In the same way, the spectrograms of the nonducted whistlers are also calculated by ray tracing. By comparing the wave properties obtained observationally and theoretically, the parameters in the density model are determined. The realization of the algorithm requires an appropriate model to represent global plasmaspheric density profile. A desirable model should satisfy the following two conditions; (i) the model is represented by a function which has as small number of parameters as possible, and (ii) any plasmaspheric profile can be reproduced by choosing a set of appropriate parameters in the model. We introduce a new analytical model which consists of a stochastic differential model and a parametric model. By applying the semi-parametric model, the number of model parameters are drastically reduced but the flexibility of the model is considerably improved. The parameters of the model are evaluated by the goodness-of-fit between observed wave properties and theoretically calculated ones. In order to take the various possibilities of the wave properties at an observation point into account, we introduce an evaluation technique in which the wave properties are represented by stochastic variables with their own probability distributions. The evaluation index is derived from the stochastic variables. From the sensitivity analysis of the evaluation index for the estimation error of densities, we confirmed that the index is valid to reconstruct the global plasmaspheric density profiles. The Akebono satellite have already observed for 13 years in the inner magnetosphere, and the data are accumulated in a database. It is expected that the long term variation and average features of the global electron density profiles for one solar cycle are revealed by the developed method.

GAIII.10/10P/A01-011   1720

THE AVERAGE ELF/VLF WAVE POWER RECEIVED ON THE GROUND IN ANTARCTICA, AND ITS DIURNAL, SEASONAL AND SOLAR-CYCLE VARIATIONS

A.J. SMITH (British Antarctic Survey, Madingley Road, Cambridge CB3 0ET, UK)

Space-weather events such as large magnetic storms are associated with changes in ground-observed ELF-VLF radio waves. For a fixed receiver, the causes may be a combination of a source effect and source-receiver propagation effects. For a magnetospheric source, the latter will generally comprise magnetospheric, transionospheric and subionospheric segments. In order to interpret such changes in the context of models, and conversely to use the data for diagnostics, we need to know the average wave power levels and their variations on different time scales, diurnal, annual etc. These will then serve as a reference against which to assess the sporadic space-weather related effects. Although several empirical models of ELF/VLF noise levels have been constructed in the past for VLF radio engineering applications, they have generally been poor in the polar regions, where space weather effects maximise, because of lack of data. Here we report the results of a systematic study of the VLF/VLF waves observed at Halley station, Antarctica (76S 27W, L=4.3). We use a complete solar cycle (1992-2002) of nearly continuous (>95%) data from the VELOX instrument which comprise 1s resolution measurements of ELF/VLF wave power, arrival azimuth, polarisation and peak-mean-minimum ratios, in eight frequency bands from 500 Hz to 10 kHz, though for the present purpose we have used only the wave power data. The original data are 1s time resolution, but the wave intensities are highly variable on this time scale, so we have worked initially with one-hour averages. At each of the eight frequencies we have found the average wave power and the amplitude and phase of the 1-day, 1-year and solar cycle components. Three different regimes are exemplified by the 1 kHz, 3 kHz and 9 kHz channels. At the lowest frequency the transionospheric propagation absorption is low while the subionospheric absorption is moderate. The receiver has a effective large field of view. The dominant signals are ducted whistler mode waves such as chorus, originating from a large volume of the magnetosphere; the dawn chorus peak and the equinoctial maxima can be identified and quantified. At 3 kHz, the transionospheric absorption is moderate while the subionospheric absorption is high. The receiver has a small effective field of view, and activity is dominated by whistler mode signals propagating close to the Halley field line. At the highest frequency, no transionospheric absorption is high while the subionospheric absorption is low. magnetospheric signals are observed (except auroral hiss), and radio atmospherics from tropical thunderstorms dominate. The latter still have space weather diagnostic applications as their propagation is

affected by downcoming particle precipitation from the magnetosphere.

GAIII.10/10P/A01-012   1740

NEAR-EARTH SPACE DIAGNOSTICS BY MF WAVES (ALTERNATIVE OF LF WAVES)

Donat V. BLAGOVESHCHENSKY[1], Olga MALTSEVA[2] ([1]St. Petersburg University of Aerospace Instrumentation, [2]Institute for Physics, University of Rostov-on-Don)

Instead of diagnostics of the solar wind-magnetosphere-ionosphere system by LF waves, we would like to propose the diagnostics of plasma structures of the mentioned system by hectometric waves (middle frequencies, MF) in the range 1-3 MHz. Novelty consists in experimental revealing the magnetospheric propagation of MF waves (along the plasmapause) and computer modeling the conditions of propagation in the magnetosphere. Present research is devoted to three problems as follows: a) discovery of the geophysical conditions under which magnetospheric channeling the MF waves from the Earth's surface is possible; b) working out the method to determine the location of the main ionospheric trough and the plasmapause during disturbed periods, which could be the basis to introduce an effective geophysical index describing a value of disturbance; c) elaboration of the diagnostics method to estimate an electron concentration in the magnetoshere by analysis of experimental data of sounding the magnetosphere with frequencies 1-3 MHz and by carrying out the modeling the MF waves propagation with the help of the ray tracing method. I. The insufficiently known phenomenon of MF-wave propagation from the Earth's surface through the ionosphere and magnetosphere (guiding) to conjugate hemisphere and back to the transmitter has been investigated. According to the observations at St. Petersburg's station (L = 3.2) the echo signals are characterized by a low level of absorption and there is practically no dispersion or Doppler shift. The guiding effect is caused by the electromagnetic wave propagation into the magnetosphere near the main ionospheric trough and the plasmapause. The effect of MF-wave guiding allows to model the conditions of the transionospheric propagation in order to obtain observational delays of waves and to study the influence of plasma parameters on the group time of propagation $t_{gr} = \tau$. II. Computer modeling fulfilled on the basis of ray tracing showed that guiding was possible only from area of the main ionospheric trough. The preliminary results are as follows. 1) The particular trough may be a duct for MF waves (f = 1.8 MHz) by means of which waves may be captured, guided and reflected back to a transmitter location with an observational delay τ = 0.29 s. 2) Magnetospheric ducting is connected with: (a) low f_oF2 (f ± 0.3 MHz),and (b) a low-altitude gradient of N_e along a magnetic field line. 3) Relations between the locations of the transmitter-receiver, trough and plasmapause were found to guide MF waves. The proximity of L_m, L_r and L_{pp} locations should take place. Thus, the effect of MF guiding is most useful for the diagnostics of the plasmapause, poleward edge of the trough and the diffuse precipitation boundary through different space weather conditions.

ULF WAVES AT VERY HIGH LATITUDES

Viacheslav A. PILIPENKO[1], Nadezda V. YAGOVA[1], Olga M. CHUGUNOVA[1], Mark J. ENGEBRETSON[2], Louis J. LANZEROTTI[3], Alan RODGER[4] ([1]Institute of the Physics of the Earth, [2]Augsburg College, Minneapolis, MN, [3]AT&T Bell laboratories, NJ, [4]British Antarctic Survey, Cambridge, UK)

The paucity of ULF studies at very high geomagnetic latitudes was partly due to a dominating view that the polar cap is a relatively quiet area and thus ULF variations in this region are merely a combination of residual cusp and auroral activity. Here we present two new classes of ULF pulsations specific for the polar cap that have been analyzed using the data of magnetometer array in Antarctica and still have no established physical understanding.The first class comprises the polar geomagnetic variations in the period range 4-20 min, that have been designated as the cap associated Pi-3 pulsations. Statistical 2D patterns of spectral power and coherence show an occurrence of intense, but low spatial coherent, variations near the cusp projection and in the night side auroral region. At the same time, low amplitude Pi-3 pulsations are very coherent throughout the polar cap and are decoupled from the auroral and cusp ULF activity. The primary sources of long-period polar pulsations are probably related to the magnetosheath turbulence or tail lobe oscillations.Though an occurrence of narrow-band Pc3-4 waves (periods about few tens sec) in the polar cap was not expected by the ULF community, the search using the data from the trans-Antarctic profile of magnetometers unexpectedly revealed two regions of the high Pc3-4 activity. The first region corresponds to the near-noon cusp, and the second one in the polar cap corresponds to the morning flank of the magnetotail lobe. These groups of Pc3-4 emissions have different characteristics, and, probably, are related to different mechanisms. Statistics of ULF features at polar latitudes and correlative relationships with the solar wind and IMF parameters confirms the occurrence of two sources of Pc3-4 activity. Besides traditional channels of propagation of upstream turbulence to the ground (via the equatorial magnetosphere and the cusp), additional path - via the lobe/mantle, in the region with open field lines, is possible. The occurrence of narrow-band Pc3-4 waves in the polar cap provides a challenge to the ULF physics, because so far no resonant conversion/filtering mechanism on the open field lines has been identified.

GAIII.10/11A/A01-002   0845

CONJUGATE PHASE STUDIES OF ULF WAVES IN THE PC5 BAND NEAR THE CUSP

Yonghua LIU[1], Brian James FRASER[2], Ruiyuan LIU[1], Pasha PONOMERANKO[2] ([1]Department of Upper Atmospheric Science, Polar Research Institute of China, [2]Department of Physics, University of Newcastle, NSW, Australia)

Conjugation of geomagnetic field lines at magnetic high latitude is variable, depending on solar wind and interplanetary magnetic field conditions. In this paper the geomagnetic conjugate point of a location on closed field lines near the cusp has been determined dynamically by examining the conjugate phase relation of ultra low frequency (ULF) waves in the Pc5 band using magnetometer data from high latitude ground stations at Longyearben (LYR), Hornsund (HOR) and Hopen Island (HOP) in the northern hemisphere and Davis (DAV), Zhongshan (ZHS) and Mawson (MAW) in the southern hemisphere. Cross spectral and coherency analysis methods are used to select conjugate Pc5 events and derive phase relations. The results show that near the cusp the geomagnetic field lines resonate mainly in the odd mode with the D component out of phase and the H component in phase, when observed at the two ends of the field line. Assuming this phase characteristic, the conjugate of LYR is typically located in the DAV/ZHS-region, and mainly east of Davis by about 10° CGM longitude. In a reverse mapping analysis the conjugates of ZHS and DAV are located in the LYR region, mainly west of LYR by 10. These results are qualitatively consistent with corresponding locations derived from the Tsyganenko 1996 (T96) model. The relationship of the longitude movement of the conjugate of LYR with respect to the variation of IMF By is quantitatively consistent with the T96 model. However, the expected position of the

conjugate site of LYR (DAV/ZHS) derived from Pc5 phase for $B_z = 0$ is moved westward (eastward) by about 10°CGM in longitude or ~300 km from that predicted by the T96 model.

CONJUGATE STUDIES OF ULF WAVES DURING MAGNETICALLY ACTIVEPERIODS: FIRST RESULTS FROM SAMBA

Athanasios BOUDOURIDIS[1], Eftyhia ZESTA[1], Dave BERUBE[2], Mark MOLDWIN[2], Ricardo MONREAL MAC-MAHON[3], Marina STEPANOVA[4] ([1]Department of Atmospheric Sciences, University of California, Los Angeles, [2]Department of Earth and Space Sciences, University of California, Los Angeles, [3]Universidad de Magallanes, Chile, [4]Universidad de Santiago de Chile, Chile)

We present initial results of ULF wave power during active periods fromthe newly installed South American Meridional B-field Array (SAMBA).SAMBA is a new low-latitude meridional chain of magnetometers installedalong the coast of Chile and in Antarctica. It is also partly conjugateto the MEASURE (Magnetometers along the Eastern Atlantic Seaboard forUndergraduate Research and Education program) magnetometer chain alongthe eastern coast of the United States. The combination of these twochains presents a unique opportunity for conducting conjugate studies ofULF waves at low latitudes (L<3). We present our initial results forPc3-4 and Pc 5 waves. We select periods of active magnetic conditions(Dst<-30) during the last eight months of 2002 when the first SAMBAstations became operational. We investigate the occurrence, power,phase, polarity and latitudinal dependence (within our latitude range)as well as the conjugacy of these waves during geomagnetically activeperiods. Initial results indicate that although there is generally goodconjugacy in the occurrence of the Pc3-5 pulsations the power can be distributed differently with respect to frequency in the two hemispheres. We also investigate the conjugacy of field line resonances (FLRs) byusing conjugate pairs of stations in the two hemispheres.

SOME CHARACTERISTICS OF EQUATORIAL PC3,4 PULSATIONS AND THEIR SOLAR CYCLE DEPENDENCE

Madhusudhan RAO, Svs Sarma Satyanarayana SREEPATI (MAGNETOTELLURICS DEPARTMENT, NATIONAL GEOPHYSICAL RESEARCH INSTITUTE,)

Based on the analysis of a long series of data set (1970-'89) spanning nearly two solar cycles (part of solar cycle No.20, solar cycle No.21 & part of cycle No.22) from two observatories, Choutuppal (Gm. Lat.: 70 28'N) and Etaiyapuram (Gm.Lat.:0. 60S), India, equatorial characteristics of Pc3,4 pulsations and their long term stability are examined. Pc3,4 pulsations together constitute nearly 75% of the total pulsation activity observed in the equatorial region of India. While Pc3's exhibit a highly stable double-peak pattern with peaks around 06 and 13hrs. LT in their diurnal occurrence, Pc4 activity is characterized by a sharp and dominant peak around 07hrs. LT for the entire period from 1970-'89. The Pc3,4 pulsation activity does not show any well-defined pattern in its seasonal occurrence pattern over the period of study. The solar cycle variation pattern of Pc3,4 activity is characterized by enhancements during years falling in the declining/minimum phase of the sunspot cycle unlike the longer period Pc activity (Pc5) which is known to closely follow the sunspot cycle. Pc3,4 pulsation examples from Etaiyapuram, the station located on the Dip equator, show good correlation pulsations with concurrent ISEE satellite data. The results are discussed in relation to the existing theories on their generation through upstream waves in the bow-shock region and their radial propagation towards equatorial latitudes.Key words: Pc3,4 pulsations, Dip equator, solar cycle, upstream waves.

THE LOCAL TIME DEPENDENCE OF PI2 DOMINANT FREQUENCY OBTAINED BY SIMULTANEOUS OBSERVATION AT 5 LOW-LATITUDE STATIONS

DeSheng HAN[1], Toshihiko IYEMORI[2], Yufen GAO[3], Masahito NOSE[2], Yasuharu SANOO[4], Fuxi YANG[5], Wansheng LI[6] ([1]Department of Geophysics, Kyoto University, [2]Data Analysis Center for Geomagnetism and Space Magnetism, Graduate School of Science, Kyoto University, Kyoto,Japan, [3]Institute of Geophysics, CSB, Beijing, China, [4]Department of Information Management, School of Business Administration, Asahi University, Gifu, Japan, [5]Urumqi Basic Seismic Station,Urumqi,Xinjiang Uygur Autonomous Region,China, [6]Yinchuan Geomagnetic Observatory,Yinchuan, Ninxia Hui Autonomous Region,China)

1-second digital data from 5 stations located at low-latitude for the period from October 2001 to October 2002 was used to confirm the local time dependence of the dominant frequency of Pi2 pulsations at low-latitude. By analyzing 183 Pi2 pulsation events simultaneously recorded at the 5 stations, we acquired some statistical results about the frequency properties of Pi2 pulsations at low-latitude. The dominant frequency of H component of the Pi2 pulsation is lower on the dust side than that on the dawn side. The dominant frequency has a peak value at the postnight. According to these results, we infer that the surface wave mode is also a plausible mechanism for generation Pi2 pulsations at low latitude. For the events, which have a common frequency at the 5 stations, the phase difference between any two stations shows that the Pi2 pulsations have no phase difference along longitude. We also found that the frequency of different part of Pi2 pulsation, i.e., the dominant frequency for the initial part and rear part of pulsation, is different.

MAGNETOSPHERE-IONOSPHERE CURRENT SYSTEM RESPONSIBLE FOR THE GROUND MAGNETIC PERTURBATIONS DURING THE GEOMAGNETIC SUDDEN COMMENCEMENT

Takashi KIKUCHI (Communications Research Laboratory)

Araki (Planet. Space Sci., 25, 373, 1977) demonstrated that the preliminary reverse impulse (PRI) of the geomagnetic sudden commencement (SC) occurred simultaneously at the afternoon high latitude and at the dayside dip equator, suggesting that the polar electric field was transmitted to low latitudes almost instantaneously. Instantaneous transmission to low latitudes on the nightside was identified with simultaneous onset of the high latitude PRI and the HF Doppler frequency deviations at low latitude (Kikuchi, J. Geophys. Res., 91, 3101, 1986). To explain the instantaneous transmission of the polar electric field, Kikuchi et al., (Nature, 273, 650, 1978), Kikuchi and Araki (J. Atmosph. Terrest. Phys., 41, 927, 1979) proposed the TM0 mode waves in the Earth-ionosphere waveguide. Kikuchi et al., (J. Geophys. Res., 106, 15,555, 2001) further suggested significant Biot-Savart's effects of the field-aligned currents on the ground magnetic perturbations at the dayside mid latitudes. Most of the ground magnetic perturbations during the SC are a result of the magnetic effects of the magnetosphere-ionosphere current system composed of the magnetopause current, polarization current, field-aligned current and ionospheric Hall and Pedersen currents (Araki, Geophysical Monograph 81, 183, 1994; Kikuchi et al., 2001). On the other hand, the PRI at

mid and low latitudes could be attributed to the Alfv'n waves converted from the three-dimensional compressional waves launched at the subsolar point on the magnetopause, resulting in the earlier occurrence of the maximum amplitude of the PRI at lower latitude (Tamao, Rep. Ionos. Space Res. Japan, 18, 16, 1964; Chi et al., J. Geophys. Res., 106, 18857, 2001). In this paper we examine the times of the onset of and of the maximum amplitude of the PRI recorded at two separate equatorial stations, showing that the onset is simultaneous but the maximum amplitude occurs earlier at higher latitude. The simultaneous onset does not match the scenario including the three-dimensional propagation of the compressional waves, but match the TM0 mode waves in the Earth-ionosphere waveguide. The latitudinal dependence of the time attained by the maximum amplitude is explained as caused by relative contribution of the components of the magnetosphere-ionosphere current system. To apply the TM0 mode to the transmission of the polar electric field under the nighttime ionosphere, we evaluate the attenuation of the TM0 mode using the three-layer model of Kikuchi and Araki (1979). The finite conductivity of the nighttime ionosphere causes an attenuation of 12 percent for the distance of 10,000 km, which is much less than the geometrical attenuation due to the finite size of the polar electric field. Consequently, the TM0 mode in the Earth-ionosphere waveguide plays a major role in the instantaneous transmission of the ionospheric electric field and current to low latitudes both on the dayside and nightside.

HOW MUCH ENERGY IS CONVERTED INTO ALFVEN WAVES FROM COMPRESSIONAL DISTURBANCE?

Dong-Hun LEE[1], Kihong KIM[2] ([1]Department of Astronomy and Space Science, Kyung Hee University, [2]Department of Molecular Science and Technology, Ajou University)

When sudden perturbations in the solar wind or the magnetotail disturbthe magnetosphere, this impact is expected to launch compressionalwave power. Owing to the inhomogeneity of plasma density and magnetic fields,it is well known that part of compressional energy is converted into transverse Alfven waves. We quantitatively investigate how much energy is possibly mode converted in variousboundaries such as at the magnetopause and the magnetotail. By adopting the invariant imbedding method, we calculate the absorption, reflection and transmission coefficients of compressional waves in an exact manner when the compressional waves propagate across the boundarieswhich include both cold and hot plasma regions.

SLOW MHD WAVES AS THE PRIMARY CAUSE OF MAGNETOSPHERE-IONOSPHERE DISTURBANCES

Takesi IIJIMA[1], Manabu SHINOHARA[1], Aoi NAKAMIZO[2] ([1]Communications Research Laboratory, [2]Kyushu University)

By using the low-energy plasma and magnetic field data acquired with the Geotail Satellite, we investigated the MHD characteristics of disturbances that were observed widely in the magnetosphere. This is an extension of the preceding study by Nakamizo and Iijima (2002), in which they found that the substance of magnetotail Pi2s is the slow MHD wave. We have determined the dynamical and thermodynamical properties of the disturbances whose components correspond to three groups of the time scale, 40-150 s, 150-600 s, and 600-1200 s. Principal characteristics determined here include the following: (1) For all the three frequency ranges, the disturbances exhibit almost same properties; (2) Plasma thermal pressure and magnetic pressure changes are exactly in antiphase; (3) Energy flux (i.e. the work done by the plasma and Maxwell stress) shows much larger intensity parallel to the magnetic field than that perpendicular to the field; (4) Overall stress balance is primarily determined by ∇p force and $J \times B$ force; (5) Nature of the disturbances is the slow MHD waves (disturbances). We conclude that the primary cause (source) of disturbances occurring in the magnetosphere-ionosphere system is ascribable to the generation of slow MHD waves (disturbances), and also the generation of field-aligned currents (transverse Alfven waves) coupled with the former. Energy and momentum changes associated with the slow MHD disturbances are transmitted to the ionosphere via field-aligned currents and contribute to cause the plasma flow, ionospheric currents and the energy dissipation in the collisional ionosphere.

SURFACE WAVE MODEL OF THE MAGNETOSPHERIC RESONANCES

Petko I. NENOVSKI[1], Umberto VILLANTE[2], Patrizia FRANCIA[2], Massimo VELLANTE[2], Alexander BOCHEV[3] ([1]Geophysical Institute, 1113 Sofia, Bulgaria, [2]Physics Department, University of L'Aquila, L'Aquila, Italy, [3]Central laboratory for Solar-Terrestrial Influences, Sofia, Bulgaria)

The magnetospheric cavity resonances in the Pc5 range exhibit specific amplitude, phase and polarization characteristics observed both in the magnetosphere and on the ground. They have been explained in the frame of recent cavity mode theories. On the other hand, although the mode frequencies are stable, close relationship exists between the solar wind parameters and the magnetospheric resonance occurrence and their intensity and dynamics. A lot of wave properties as different polarization in the magnetosphere (linear) and on the ground (elliptical), polarization plane orientation in the magnetosphere (roughly at 45 degree to the Sun-Earth direction) and occupation from low- to high latitudes remains unexplained. These evidences require more general examination of the magnetospheric resonance properties taking into account free boundary conditions being ignored in previous cavity theories. We suggest .a treatment of the problem in the framework of the theory of MHD surface waves. To simplify our problem we use slab geometry and homogeneous plasma environment. Additionally we take into account various plasma density distributions in the plasmasphere and simple reflection properties at the infinitely thin sheet ionosphere. We obtain dispersion equation of MHD surface modes that yields discrete set of frequencies close to those recorded from well-known ULF magnetic field experiments. We derive also complicated polarization properties of the MHD surface modes depending on phase changes occurring at the ionosphere heights. The theoretical results are used for comparison with data from both ground observatories (low- and high latitude) and satellite magnetic field measurements (Interball and POLAR).

MAGNETOSPHERE-IONOSPHERE COUPLING BY ALFVÉN WAVES AT MID- AND LOW-LATITUDES

Robert L. LYSAK (School of Physics and Astronomy, University of Minnesota)

Most previous theories describing the interaction of Alfvén waves with the ionosphere have concentrated on the auroral region at high latitude where the magnetic field lines enter the ionosphere nearly vertically. However, a number of wave phenomena indicate that wave propagation between high latitudes and lower latitudes may be important. Pc1 oscillations

can travel for over a thousand kilometers across magnetic field lines in the ionosphere, and the variation of dipole tilt over such distances can be significant. Ionospheric propagation of ULF waves is likely also to play a role in the propagation of signals during storm sudden commencements (SC's) in which signals can rapidly propagate around the Earth on time scales too fast for propagation through the magnetosphere. In addition, the relationship between low- and high-latitude Pi2 pulsations remains an open question. These wave propagation effects must be taken into account when using wave observations as diagnostics of magnetospheric processes.First results from a model of Alfvén wave propagation in the magnetosphere-ionosphere system that takes into account the dipolar structure of the field lines at lower latitudes will be presented in an attempt to address these wave propagation problems.

FLUCTUATION ANALYSIS OF THE IONOSPHERIC AND GEOMAGNETIC PLASMAS, USING VLF SIGNALS

Tomoya SAKAI[1], Shin SHIMAKURA[2], Kenji OHTA[3] ([1]Institute of Media and Information Technology, Chiba University, Japan, [2]Science and Technology, Chiba University, Japan, [3]Faculty of Engineering, Chubu University, Japan)

Artificial VLF signals observed at the geomagnetic conjugate point of the transmission station is analysed experimentally and theoretically in order to monitor the ionospheric and magnetospheric plasma dynamics.Since the VLF waves are considered to propagate along magnetospheric ducts in whistler mode and penetrate the ionosphere under specific conditions in mid-latitude, information about the plasma dynamics and structures along the propagation paths between transmitter and receiver can be extracted from the artificial VLF signals received on the ground. In this paper, the VLF signals which have been transmitted from Khabarovsk and received at Ceduna (L=1.8) are analysed by correlations among the received signal power, propagation delay time, location and scale of the ionospheric exit region, wave polarisation, and the fluctuation of the geomagnetic field.The influence of the geomagnetic pulsations Pc 3-5 is briefly discussed. The ionospheric exit region and wave polarisation are estimated by the ground-based direction finding techniques.The wave distribution function (WDF) method and the multiple signal classification (MUSIC) method are applied to the received signals.As the result, the exit region is found within the distance of about 200km from the observation site.The polarisation of the non-whistler mode due to the sub-ionospheric propagation is appeared quasi-periodically. In order to clarify the penetration mechanism in the ionosphere and the Earth-ionosphere waveguide effect, numerical calculations of the wave field on the ground induced by the VLF wave radiated from the magnetospheric ducts are also performed by the full-wave analysis.The received signal attenuation and estimation error of the direction finding results are evaluated by the full-wave calculations for a detailed discussion.

MAGNETOSPHERIC VLF HISS OBSERVATIONS BY ALOW-ALTITUDE POLAR ORBITER FOR SPACE WEATHER STUDIES

Tadanori ONDOH (Space Earth Environment Laboratory)

Latitudinal variations of magnetospheric VLF hiss observed in the topside ionosphere represent integrated spectra of whistler-mode VLF hisses propagating along geomagnetic field lines from wide sources in the magnetospher. Substorm changes of magnetospheric VLF hiss regions are analyzed by using 6 frequency narrow band VLF electric field (50Hz-30kHz) data received from ISIS-2 at Syowa station, Antarctica. In a geomagnetic quiet or weak disturbed period, a broad-band polar hiss normally appears at geomagnetic invariant latitudes from the middle of auroral zone to about 80° and a narrow-band mid-latitude hiss around 5 kHz occurs at invariant latitudes from about 50° to 65°. The polar hiss is interpreted as whistler-mode Cerenkov emissions generated from inverted-V electrons precipitating from the plasmasheet, and the mid-latitude hiss is whistler-mode waves generated by the electron cyclotron instability around the equatorial plasmapause. In a substorm period, the polar hiss region shifts to lower latitudes or to inner L-shells and joins the mid-latitude hiss region as the substorm develops. This implies that the polar magnetosphere or high latitude horns of inner plasmasheet, where the polar hiss is generated, comes closer to the plasmapause together with L-shells of inverted-V precipitating electrons as the substorm develops. So, observations of magnetospheric VLF hiss by low-altitude polar orbiters are useful means for space weather studies.

GAIII.10/11A/A01-013 — 1130
THE TEMPORAL EVOLUTION OF SUBSTORM ENHANCED WHISTLER-MODE WAVES; THE RELATIONSHIP BETWEEN SPACE BASED OBSERVATIONS, GROUND BASED OBSERVATIONS AND ENERGETIC ELECTRONS

Gary A. ABEL[1], Andy J. SMITH[1], Nigel P. MEREDITH[2], Roger R. ANDERSON[3] ([1]Physical Sciences Division, British Antarctic Survey, [2]Mullard Space Science Laboratory, University College London, [3]Department of Physics and Astronomy, University of Iowa)

One of the defining characteristics of substorm onset is the injection of energetic electrons. The observed evolution of the energy spectra of these injected electrons has been well documented and is understood in terms of energy dispersed gradient-curvature drifts. A less defining, but often observed, characteristic is the enhancement of equatorial whistler mode wave amplitudes. Whilst studies have categorised the occurrence of these waves in terms of location and geomagnetic activity levels, to our knowledge no attempt has been made to document and explain the evolution of the whistler frequency spectrum as has been done with injected electrons. In this paper we address this problem by examining 22 case studies of CRRES observations of substorm enhanced whistler mode waves. These observations were made close to the geomagnetic equator and between 02:00 and 06:00 MLT. The frequency of the enhanced whistler waves is seen to vary strongly with magnetic field strength and for this reason we re-plot the data in terms of the equivalent parallel resonant energy of an electron in first-order cyclotron resonance with a wave of a given frequency. We can interpret our findings in terms of the injected electron population and resonant ellipses in velocity space. Furthermore, we relate the findings of our study to observations of ducted waves seen on the ground as Substorm Chorus Events (SCEs) and conclude that the frequency dispersion seen in SCEs is dominated by electric field effects.

GAIII.10/11A/A01-014 — 1145
ELECTROSTATIC ELECTRON CYCLOTRON HARMONIC WAVES OBSERVED IN THE EQUATORIAL REGION OF THE PLASMASPHERE

Takayuki ONO[1], Hiroshi OYA[2] ([1]Graduate School of Science, Tohoku University, [2]Fukui Univeristy of Technology)

Within dynamic spectra of 12 years observation of the plasma waves and sounder experiment (PWS) on board Akebono satellite, electrostatic electron cyclotron harmonic

(ESCH) waves are frequently observed in the equatorial region (M-LAT<30 deg.) of the plasmasphere within an altitude range from 5000km to the apogee of the satellite (about 10,000km). The equatorial-plasmasphere ESCH waves (named as EP-ESCH waves) which appear above the UHR frequency at lowest harmonic number branch of the maximum frequency of the electrostatic electron cyclotron waves (Warren and Hagg, 1968), are commonly observable even in the quiet state of the plasmasphere. The EP-ESCH waves are observable in all the local time sectors, however, the occurrence probability showed clear enhancement in the early morning sector of 01-03 MLT. Sometimes the EP-ESCH waves are associated with other branch of the ESCH waves below the UHR frequency revealing a property of nonlinear wave particle interaction with the odd half harmonics branch of ESCH waves coupled by the cyclotron wave-particle interaction of the order of n = 1. Based on the analysis of the dispersion relation of ESCH waves, supra-thermal plasma with the energy of several tens eV with high temperature anisotropy is likely to generate the EP-ESCH waves in the plasmasphere. The similar type wave-particle interaction has been already identified in the topside sounder ionograms (Oya, 1971) and many plasma wave observations in the magnetosphere (Oya, 1972, Shawhan, 1979, Kurth et al., 1979). It is interesting that intense wave-particle interactions are stimulated in the plasmasphere which has been recognized as a moderate region of clod plasma only associated with radiation belt particles of very high energy. The occurrence character of the ESCH waves showed that there is a constant activation or a constant flow-in of free energy to generate the strong plasma instability of ESCH waves near the midnight sector of the plasmasphere. Existence of ESCH waves as well as the nonlinear wave particle interaction revealed more active and turbulent nature of the plasmaspheric plasma than it has been believed.

PC1 BURSTS IN THE POLAR CAP AS AN INDICATOR OF THE DAYTIME RECONNECTION

Vladimir V. SAFARGALEEV, Anna V. SEREBRYANSKAYA, Elena V. PCHELKINA (Polar Geophysical Institute, Apatity, 184200, Russia)

The data of induction magnetometer installed at Barentsburg observatory in Spitsbergen archipelago are analyzed in combination with the data of two other magnetometers located in Scandinavian and Kola Peninsulas. We considered the intervals of very large negative IMF Bz when the cusp is assumed to be shifted at large distance south of its statistical position and Spitsbergen turns out in the polar cup. Altogether, eight intervals were considered. In all cases the DMSP data indicated that Barentsburg observatory was in the polar cap, whereas the location of two others might be associated with either cusp or llbl or bps projections. The magnetic pulsations of Pc1 frequency range were observed around the local noon and in the polar cap only. They had a form of several short-living bursts and lasted for 15 minutes. In the cases when the CUTLASS data were available, the interval of Pc1 activity coincided well with the appearance and decay of fast ionospheric convection flow channel. We think that these pulsations are originated from the magnetosheath (namely, from the plasma depletion layer) where the plasma is anisotropic and undergoes the IC-instability. Due to impulsive reconnection, the unstable plasma turns out on the magnetic field lines connected with the Earth's ionosphere and IC-waves may be seen from the ground as the bursts of Pc1.

THE PLASMAPAUSE DETECTION BY MULTIPLE GROUND MAGNETIC FIELD OBSERVATIONS AT DIFFERENT LOCAL TIMES

Shuji ABE[1], Kiyohumi YUMOTO[2], Hideaki KAWANO[3], Akimasa YOSHIKAWA[3], Yuki OBANA[1], Stepan I. SOLOVYEV[4], Dmitry G. BAISHEV[4], John V. OLSON[5], E.W. WORTHINGTON[6] ([1]Graduate School of Science, Kyushu University, Japan, [2]Space Environment Research Center, Kyushu University, Japan, [3]Faculty of Science, Kyushu University, Japan, [4]IKFIA, Russian Academy of Science, [5]Geophysical Institute, University of Alaska, Fairbanks, [6]College Observatory U. S. Geological Survey)

One of the useful techniques for identifying the eigenfrequency of ULF waves is the dual-station H-component amplitude-ratio method. In this method, dynamic spectral pattern observed within the plasmapause boundary layer is opposite to that observed inside and outside the plasmasphere. The pattern inside and outside the plasmasphere is that naturally expected for the Alfvén speed decreasing with increasing L-value, which is expected for the geomagnetic field strength decreasing with increasing L and the plasma density whose L dependence is not strong; such an Alfvén speed profile leads to the resonant frequency decreasing with increasing L, consistent with the observation inside and outside the plasmasphere. Our explanation for the pattern observed within the plasmapause boundary layer is as follows: In the plasmapause boundary layer, the plasma density drastically decreases, and thus the Alfvén speed increases, with increasing L. Thus, the resonant frequency there increases with increasing L; this L dependence is opposite to that outside the boundary layer, and is consistent with the pattern observed at the plasmapause. Thus, we can detect the plasmapause from the ground by using this method. In this study, we use this method and analyze two data sets whose local times differ. One station pair consists of Tixie (geomagnetic latitude = 65.65, geomagnetic latitude = 196.90, L = 5.98; it belongs to the Circum-pan Pacific Magnetometer Network) and Chokurdakh (64.66, 212.14; CPMN), and the other pair consists of Poker Flat (65.60, 260.90; it belongs to the Geophysical Institute Magnetometer Array) and College (64.80, 264.11, CPMN). Analysis results and discussion on the plasmapause detection will be presented.

ON THE FIELD-LINE RESONANCE POLARIZATION

Petko I. NENOVSKI[1], Massimo VELLANTE[2] ([1]Geophysical Institute, 1113 Sofia, Bulgaria, [2]Physics Department, University of L'Aquila, L'Aquila, Italy)

Ionospheric effects on the field-line resonances (FLR) polarization are examined. We have taken into account the source (compressional) part of the field-line resonance magnetic field and studied its transmission through the ionosphere. Our examination of the FLR polarization reveals strong ellipticity effect (that is sometimes close to circular polarization). It

is found that there is an asymmetry in the ellipticity effect, i.e. the both maxima of ellipticity are of different magnitude and placed away from the FLR amplitude peak at distance ranging 1-3 times its semi-width. These FLR polarization features are dependent on frequency, horizontal scale and ionospheric conditions. The theoretical results are compared to experimental evidences.

GAIII.10/11A/D-004   Poster   0830-078

ULF SIGNATURE OF FIELD-ALIGNED CURRENTS IN THE DUSK MAGNETOSPHERE BY INTERBALL-AU AND POLAR

Alexander Z. BOCHEV[1], Petko I. NENOVSKI[2] ([1]Central Laboratory for Solar-Terrestrial Influences, Sofia, Bulgaria, [2]Geophysical Institute, Sofia, Bulgaria)

The POLAR and INTERBALL-AU spacecraft magnetic field experiments allow investigation of the time-spatial variation of large-scale field-aligned current (FAC) structures (Regions 1 and 2) at mid- and high-altitudes. The study includes two intervals over north high latitudes in the dusk magnetosphere: (1) 10 January 09-11 UT (consecutive transits) and (2) 11 January 03-06 UT (nearly conjugate situation at ~ 04:30 UT). FAC Regions 1 and 2 and concomitant ULF wave events that belong in the Pc5 range are simultaneously observed on both spacecraft. On January 11 a ULF wave period of ~5 minutes is identified. Within the FAC regions the ULF wave polarization goes from linear to elliptical. A polarization plane rotation at ~90 degree is clearly detected at the POLAR satellite heights. It occurs at the moment of transition from linear to elliptical polarization and coincides to the Region 2-Region 1 transition. One possible explanation of these ULF wave properties is changes in the plasma distribution and ionospheric conditions existing between upward and downward FAC regions.

GAIII.10/11A/D-005   Poster   0830-079

SEVERAL FACTORS OF PC 3-5 AMPLITUDES OBTAINED BY THE COORDINATED CPMN STATIONS

Yuki OBANA[1], Akimasa YOSHIKAWA[1], Ray J. MORRIS[2], Brian J. FRASER[3], Stepan I. SOLOVYEV[4], Kiyohumi YUMOTO[5] ([1]Earth and Planetary Sci. Kyushu University, Japan, [2]Australian Antarctic Division, Australia, [3]University of Newcastle, Australia, [4]Inst. of Cosmophysical Research and Aeronomies, Russia, [5]Space Environment Research Center, Kyushu University, Japan)

In order to understand several factors, which affect Pc 3-5 magnetic amplitudes, Pc 3-5 magnetic pulsations at the coordinated Circum-pan Pacific Magnetometer Network (CPMN) stations were analyzed. Amplitudes of magnetic pulsations observed on the ground can be expressed by $B = A\ F(MLT)\ f(LT)\ \sigma$ where A is amplitude of source wave, F(MLT) indicates magnetic local time dependence of amplitude in the magnetosphere , f(LT) is a function of ionospheric conductivities at local time of a station, and σ is an amplification factor for each stations (Chi et al, 1996). The geomagnetic data used here are from the CPMN stations at Chokurdakh (CHD; M.lat.=64.67 deg.,M.lon.=212.12 deg., L=5.46), Kotzebue (KOT; 64.52, 249.72, 5.40), and Macquarie Isl. (MCQ; -64.50, 247.84, 5.40) during the equinox seasons of 1994 and 1995. In the equinox, northern and southern hemispheres asymmetry of ionospheric conductivities can be neglected, thus, power ratio between KOT and MCQ can be considered to include a component of the local time difference factor: f(LT+dLT)/f(LT). By using the inversion method, contaminated information of F(MLT) and f(LT) can be derived from daily variation of power difference between CHD-KOT and CHD-MCQ. While, pure f(LT) component can be extracted from daily variation of power difference between KOT-MCQ, because they are geomagnetic conjugate points each other. From the analysis, the following results are obtained. The F(MLT) of H component of Pc 4 showed different diurnal variation by months and years. The f(LT) of H component of Pc 4 has the maximum around 6 and 18 LT, and minimum around 12 LT. The σ of Pc 4 normalized by σ at MCQ are 1.71±0.02 at KOT and 1.53±0.01 at CHD in the H component, and are 3.10±0.24 at KOT and 1.94±0.03 at CHD in the D component. The minimum of f(LT) around local noon implies that the H component of Pc 4 is shielded by high conductivity ionosphere around noon. The very stable values of σ are remarkable, because this result indicates a possibility that σ is a good index of geological effects on magnetic pulsations.

FIELD-LINE RESONANCES TRIGGERED BY SSC ONSETS

Harri E. LAAKSO[1], A. MASSON[1], K.-H. GLASSMEIER[2], M.J. ENGEBRETSON[3] ([1]ESA/ESTEC/Code SCI-SH, Noordwijk, The Netherlands, [2]Institut fur Geophysik und Meteorologie, Braunschweig, Germany, [3]Department of Physics, Augsburg College, Minneapolis, MN)

One of typical consequences of storm sudden commencements (SSC) in themagnetosphere is the occurrence of large-amplitude wave activities, such aslow-frequency field line resonances (FLR). They are triggered by compressionalwaves generated at the magnetopause by fast moving solar wind disturbances.During its lifetime, since February 1996, the Polar satellite has collectedobservations during a few hundred SSC´s, and in many cases the satellite wasappropriately located on dipolar field lines where the field-line resonancescan occur, and so we can study statistically the occurrence rate and waveproperties of FLR´s during SSC´s. More recently, the four Cluster satelliteshave collected valuable multi-point observations of the FLR´s, and in one SSCevent, occurred at 14:11 UT on August 30, 2001, the quartet was in the innermagnetosphere (at L = 4.3-5.5) at the moment of the onset. The SSC onset wasimmediately followed by strong field line resonances, persisting for an hour.During the time, Cluster 3 moved towards the perigee near L = 4, whereas theother three moved to higher L shells up to L = 7. This study will presentdetails of the electric and magnetic field oscillations and the Poynting vectorduring the event. We particularly compare wave characteristics at four points aswell as their L shell dependence.

MONITORING OF THE PLASMA DENSITY IN THE EARTH'S PLASMASPHERE DURING MAGNETIC STORMS BY USING MULTIPLE GROUND OBSERVATIONS (L~1.3)

Satoko TAKASAKI[1], Hideaki KAWANO[1], Yoshimasa TANAKA[2], Akimasa YOSHIKAWA[1], Masahiro SETO[3], Masahide IIZIMA[4], Kiyohumi YUMOTO[5] ([1]Department of Earth and Planetary Sciences, Kyushu University, Japan, [2]Venture Business Laboratory, Kyushu University, Japan, [3]Tohoku Institute of Technology, Japan, [4]Graduate School of Science, Tohoku University, Japan, [5]Space Environment Research Center, Kyushu University, Japan)

The field line resonance (FLR below) in the Earth´s magnetosphere is caused by hydromagnetic waves. In ground-based observations of FLR phenomena, it is known that the amplitude of the H-component perturbation reaches a maximum at the resonant point, and that its phase jumps by 180 degrees across the resonant point. The cross-phase method and the amplitude-ratio method are useful for identifying these properties and determining the resonant frequency. The field line eigenfrequency is dependent upon the plasma density and the magnetic field intensity in the region of space threaded by the field line, and the length of the field line. When we observe the eigenfrequency of the field line and assume models for the latitude profiles of the magnetic field and the plasma density (with the equatorial density as a free parameter), we can estimate the plasma mass density. Therefore, FLR is useful for monitoring temporal and spatial variations in the plasmaspheric density. In ground-based observations, we can identify FLR phenomena and measure the fundamental field line eigenfrequency by applying the cross-phase method and the amplitude-ratio method. We have installed three magnetmeters at L ~ 1.3, and observed geomagnetic pulsations in the Pc3 range. Each adjacent stations are separated in latitude by 50 ~ 100 km. We have analyzed the magnetic field data from these stations by using the two methods, the amplitude-ratio method and the cross-phase method. As a result, we have identified FLR events and measured their frequencies; these data provide the plasma density at L ~ 1.3 varying with time. By using these data, we will discuss the temporary variation of the plasma density at L ~ 1.3 during magnetic storms. In addition, we note that the observed FLR frequency decreased with decreasing latitude: We interpret this feature to be the result of heavy ion (for example oxygen ions from the ionosphere) mass loading at low latitudes, which decreased the magnetic field line eigenfrequency there. It is possible that the plasma is mainly composed of heavy ions at L ~ 1.3. It deserves to be studied if the activity of this mass loading effect seen in the ground data, depend on the storm activity.

DEDUCING PROPERTIES OF THE MAGNETOSPHERE USING HIGH LATITUDE PC 3-4 PULSATIONS

Fred W. MENK, Timothy A. HOWARD (School of Mathematical and Physical Sciences, University of Newcastle)

It is now generally accepted that Pc 3-4 (10-50 mHz)pulsations recorded on the ground at low latitudes are the result of standing shear Alfven mode field line resonances. At higher latitudes the resonance frequency moves into the Pc 5 (1-10 mHz) range. Although broadband activity extends into the Pc 3-4 part of the spectrum, narrowband signals are also recorded by ground magnetometers. The generation and propagation mechanism for these bandlimited pulsations is not clear. Using two months of IMAGE magnetometer data we have examined the amplitude, cross-phase and coherence of narrowband Pc3-4 pulsations as a function of latitude and longitude, and have determined the propagation velocity and coherence length of each event. Antarctic magnetometer have data provided information on conjugate point phase and polarization of these events. The pulsations may have a number of generation mechanisms. One of these involves propagation of fast mode waves Earthward, coupling to travelling waves along field lines. Ground phase information then may provide information on the Alfven velocity and hence magnetospheric density distribution. We illustrate this for specific events.

THE DEPENDENCE OF SPATIAL STRUCTURES OF PC 3 PULSATIONS ON THE SOLAR WIND PARAMETERS AND GEOMAGNETIC INDICES

Yoshimasa TANAKA[1], Kiyohumi YUMOTO[2], The CPMN Group[2] ([1]Venture Business Laboratory, Kyushu University, Japan, [2]Space Environment Research Center, Kyushu University, Japan)

We statistically studied two-dimensional spatial structures of the amplitude and phase of Pc 3 pulsations observed at the CPMN stations (L=1.0-5.5) on the ground. The obtained amplitude and phase structures indicated two characteristic components; one is strongly dependent on the magnetic latitude and the other is coherent over a wide range of latitude. It was concluded that the former is associated with the toroidal mode oscillations excited by the field line resonance (FLR) and the latter is likely to be global compressional mode oscillations. By mapping the obtained amplitude and phase structures onto the equatorial plane of the magnetosphere, we could see a twin-vortex structure of the magnetic perturbations in the magnetosphere. The centers of the vortices are located at 0600-800 LT and 1300-1400 LT around the plasmapause. It was interpreted that the vortex structure may be generated by the mode conversion from compressional waves, which propagate from the prenoon outer magnetosphere toward the Earth, to Alfvén waves around the plasmapause. In the present paper, we further investigate the dependence of the spatial structures of Pc 3 pulsations on the solar wind parameters and geomagnetic indices. Using the magnetic field data obtained from the CPMN stations during the period from March to September, 1994, the amplitude ratio, phase difference, coherence of Pc 3 pulsations are calculated by the fast Fourier transform (FFT) method. In the calculation, we use the H component of the sub-equatorial station, Guam (GUA, L=1.01), as a reference. The local time is divided into the 30-min intervals and each interval is categorized by the solar wind parameters and geomagnetic indices. The main results are summarized as follows. 1) Although the direction of the interplanetary magnetic field (IMF) is well correlated with the occurrence frequency, its effect on the phase structure of Pc 3 pulsations is small. 2) The phase structure is also independent of the IMF intensity. 3) The phase structure shows a weak dependence on the Kp and Dst indices. The FLR component statistically seen at L=2.1, 2.8 on the quiet geomagnetic condition is masked on the disturbed condition. It is supposed that the solar wind parameters and geomagnetic indices reflect conditions of the wave source and the magnetosphere, for example, the IMF direction and Kp index should be associated with the spatial distribution of upstream waves, which is one of major sources of Pc 3 pulsations, and the plasmapause position, respectively. Therefore, our results imply that the phase structure of Pc 3 pulsations is little affected by the source condition and is principally controlled by the magnetospheric condition.

PROPAGATION OF ULF WAVES THROUGH THE IONOSPHERE IN THE PRESENCE OF OBLIQUE MAGNETIC FIELDS

Colin WATERS, Murray SCIFFER, Fred MENK (Department of Physics, University of Newcastle and CRC for Satellite Systems)

Solutions for ultra low frequency (ULF; 1-100 mHz) wave fields that interact with the earth´s ionosphere in the presence of oblique background magnetic fields are presented. The inductive shielding effect (ISE) reduces the wave amplitude on the ground and arises from the generation of an ˝inductive˝ rotational current in the ionosphere. The inductive response of the ionosphere is described by Faraday´s Law and the ISE depends on the horizontal scale size of the ULF disturbance, its frequency and the conductivities. Previous descriptions of the ISE were developed within the context of a vertical background magnetic field which limits the application to high latitudes. In this presentation we have reformulated the description of the ISE in the ionosphere for oblique background magnetic fields so that the effect of an inductive ionosphere and the associated shielding of ULF waves for mid to low latitudes may be examined. It is found that the dip angle of the background magnetic field significantly affects the ground signature of ULF waves. Implications for inferring ULF wave properties in the magnetosphere from ground-based magnetometer measurements of ULF waves will be discussed.

FREQUENCY ESTIMATION OF IMPULSIVE PC3 MAGNETIC PULSATIONS ON THE BASIS OF MODIFIED MEM

Yoshihiro HIGUCHI (Department of Electronics and Information Engineering)

A modified method for estimating prediction error filter coefficients for a maximum entropy spectral analysis is presented. An averaged forward and backward prediction error power weighted by a window function is minimized and Levinson recursion is employed. Frequency shift for a truncated real sinusoid with additive noise can be reduced using a Blackman window function in computation of coefficient γmm in the m-th order prediction error filter. Spectra computed from a short truncated real sinusoid and compared with the Burg spectra show frequency resolution improvement and robustness of spectral peak locations. Modified maximum entropy spectral analysis is applied to make an accurate frequency estimation of impulsive Pc 3 magnetic pulsations observed at Yonezawa during morning hours. It is shown that the modified maximum entropy method using a Blackman window function can clearly resolve three components of spectral peak location at 30mHz, 55mHz and 85mHz.

DYNAMIC SPECTRA AND WAVELET STRUCRURE OF ULF WAVES IN THE MADNETIC STORM OF JULY 15, 2000

Olga Vasilievna KOZYREVA[1], Natalia Georgievna KLEIMENOVA[1], Jean-Jacques SCHOTT[2] ([1]Institute of the Earth Physics, 10.Bolshaya Gruzinskaya, Moscow, 123995, Russia, [2]Ecole et Observatoire des Sciences de la Terre, Strasbourg, France)

We studied the strong magnetic storm on July 15, 2000, caused by magnetic cloud (Bastille Day Event). The 1-3 mHz ULF waves, observed on the ground in the global scale, have been analysed by using 1-min sampling INTERMAGNET data. The analysis showed that strong IMF and ion density variations at the front edge of the magnetic cloud triggered the magnetic substorm and geomagnetic Pi3 range pulsations at the polar latitudes near the footprint of the open/closed field lines border. The dynamic spectra and wavelet structure of the polar Pi3 pulsation and IMF fluctuations showed a certain similarity. We suppose that ground pulsations, observed at polar latitudes, can be result of the direct penetration and nonlinear transformation of the interplanetary hydromagnetic waves into the polar cap. Another possibility can be attributed to the wave generation at ionosphere altitudes by the oscillations of the substorm electron precipitation, related to field aligned currents.

PI2 MAGNETIC PULSATION AT LOW LATITUDES

Yu-fen GAO, Gui-ming LE (Institute of Geophysics, China Seismological Bureau)

Data of Pi2 magnetic pulsations obtained from SMALL (Sino-Magnetometer Array at Low Latitudes) are analyzed with wavelet. The spacial and temporal characteristics at low latitudes are presented. The results of typical events show that the maximal amplitudes are correlated with longitudes and the arrived time of maximal amplitude are correlated with latitudes. At the same time interplanetary parameters will be shown.

DETERMINATION OF ONSET TIMES OF LOW-LATITUDE PI2 MAGNETIC PULSATIONS

Keiko FUKUYAMA[1], Tomoyuki HIGUCHI[3], Teiji UOZUMI[2], Hideaki KAWANO[1], Kiyohumi YUMOTO[2] ([1]Department of Earth and Planetary Sciences, Kyushu University, Japan, [2]Space Environment Research Center, Kyushu University, Japan, [3]The Institute of Statistical Mathematics, Japan, [4]the CPMN Observation Group)

Pi2 magnetic pulsations are observed globally and theiroccurrences are almost simultaneous with substorm onsets;therefore Pi2 has been known as a good indicator of onset ofsubstorm. However, its trigger process, propagation mechanismand relationship with substorm have not been well understood.In addition, it is very difficult to objectively determine theonset times of Pi2 magnetic pulsations; a visual inspectionfor determining the Pi2 onset times could make its estimatebiased. Therefore, it is necessary to establish an accurateand objective determination method. We have constructed andexamined two procedures for an onset time determination of low-latitude Pi2 magnetic pulsations. The first method is based on such assumption that Pi2 is described by stochastically perturbed quasi-periodic oscillations. We applied the time-seriesanalysis method developed for such data [Higuchi et al., 2002]. The second procedure that we developed relies on the definition in the literature [Saito,1961] that Pi2 starts with dH/dt >0 in the middle or low latitude. We examined the differenced sequences of the H-component and identified a positive variation seen in them. Then, we have compared these results, and found that the results of the first method have time lag with 3~50 seconds behind those of the second one. This suggests that Pi2 has a non-periodic fluctuation at its initial stage and we have to determine the Pi2 taking account of this non-periodic fluctuation.

RELATIONSHIPS BETWEEN NEAR-EARTH TAIL SUBSTORM SIGNATURES AND GROUND PI 2S ONSETS

Tohru SAKURAI, Yutaka TONEGAWA (Department of Aeronautics and Astronautics, School of Engineering, Tokai University)

Relationships between onsets of substorm signatures, such as dipole-like magnetic field changes, fast plasma flows and plasma injections observed in the near-Earth magnetotail in the midnight region and those of ground substorm/ Pi 2's are studied. Present study is only a case study, in which a substorm event, consisting of successive two occurrences of plasma flows in the magnetotail is studied. The results are as follows, i.e., the first earthward plasma flow was observed with a high speed in excess of 570 km/s at L = 10 in the midnight magnetotail, which brought only an onset of Pi 2 oscillations on the ground only near the sub-auroral latitudes. While, the second plasma flow, which was observed 12 minutes later than the observation of the first plasma flow, brought at first an onset of negative bay at high latitude ground stations and successive development of substorm activity. However, the onset of the negative bay began about two minutes before the observation of the second plasma flow in the magnetotail at L = 10, and the onset of low latitude Pi 2 and/or a simultaneous occurrence of positive bay began three minutes later than the onset of the negative bay. From these results where the substorm should be triggered in the magnetotail, earthward or tailward compared with the observation point, i.e., the satellite location at L = 10, and onsets of substorm and/or Pi 2 on the ground from high to low latitudes are discussed in relation to the plasma flow in the magnetotail.

CORRELATIONS BETWEEN HIGH- AND LOW-LATITUDE PI 2'S AS A FUNCTION OF LONGITUDINAL DISTANCE RELATIVE TO THE AURORAL BREAKUP REGION

Teiji UOZUMI[1], Kiyohumi YUMOTO[1], Hideaki KAWANO[2], Akimasa YOSHIKAWA[2], S. OHTANI[3], S.I. SOLOVYEV[4], E.F. VERSHININ[5], K. LIOU[3], C.-I. MENG[3] ([1]Space Environment Research Center, Kyushu University, [2]Department of Earth and Planetary Science, Kyushu University, [3]Applied Physics Laboratory, The Johns Hopkins University, [4]Institute of Cosmophysical Reserch & Aeronomy, [5]Institute of Cosmophysical Reserch & Radiowaves Propagation)

In order to investigate the generation and propagation mechanisms of Pi 2's in the magnetosphere, we made a comparative study between magnetometer data observed at high- and low-latitude CPMN stations and the ultraviolet image (UVI) data of aurora obtained by the Polar satellite. Correlation coefficients among H component of low-latitude Pi 2 and H, D component of high-latitude Pi 2 were calculated. Where, in this paper, we assumed and used high- and low-latitude Pi 2s as the manifestation of fast and Alfvén mode wave propagating in the magnetosphere, respectively. Results were classified by the relative position between each high-latitude station and the auroral breakup region. We then studied the dependence of the correlation coefficient of Pi 2s on the position relative to the auroral breakup region. In this paper we have found the following results. When high-latitude stations were separated longitudinally from auroral break up region larger than 1 hour, the average correlation coefficient between H component of low-latitude Pi 2 and H, D component of high-latitude Pi 2 became 0.86 and 0.87, respectively. On the other hand, when high-latitude stations were located in the same longitudinal span of auroral break up region, those coefficients decrease 0.69 and 0.63 respectively. We have found a tendency that, as the distance between a high-latitude station and the auroral break up region become larger, correlation coefficient between the H component of the low-latitude Pi 2 and the H (or D) component of the high-latitude Pi 2 increases. This means that the coupling between fast and Alfvén mode wave were observed clearly as away from auroral breakup region. This observational result suggested that high-latitude Pi 2´s, which occur at a distance from auroral breakup region, are generated via mode conversion from fast to the Alfvén mode. That is, fast mode waves are first generated at the Pi 2 source region, propagate from there in a three dimensional manner, and then excite shear Alfvén mode waves via mode conversion. It suggests that generation of fast mode wave in the magnetosphere at the onset of substorm is the essential process for global Pi 2 occurrence.

LONGITUDINAL STRUCTURE OF LOW-LATITUDE PI2 PULSATIONS

Masahito NOSE[1], K. LIOU[2], P.R. SUTCLIFFE[3] ([1]Data Analysis Center for Geomagnetism and Space Magnetism, Kyoto University, [2]Applied Physics Laboratory, Johns Hopkins University, [3]Hermanus Magnetic Observatory)

Recent studies have shown that when Pi2 pulsations were observed on the ground during nighttime, satellites that were inside the plasmasphere observed almost identical oscillations in the compressional and radial components of the magnetic field. Magnetic field oscillations in the plasma trough were less correlated with the ground Pi2 pulsations. This indicates that the plasmaspheric cavity mode resonance is a plausible mechanism for nighttime Pi2 pulsations. The plasmaspheric cavity mode is a wave mode in which fast mode waves emitted at a substorm onset bounce back and forth between two reflecting boundaries (the ionosphere and the plasmapause) and are radially trapped in the plasmasphere. This is likely to occur near the midnight meridian where substorms are thought to initiate, because the wave normal becomes nearly perpendicular to the reflecting boundaries there. On the contrary, waves may not be trapped for a long time on the flanks where the waves make oblique incident on the boundaries, resulting in no appearance of Pi2 pulsations. However, the longitudinal structure of the cavity mode resonance is yet to be investigated. In the present study we examined how characteristics of low-latitude Pi2 pulsations depend on longitude (magnetic local time), using ground data and auroral images from the Polar ultraviolet imager (UVI). The data period used in the study is from December 1996 through March 1997. The Polar/UVI images were used to identify the onset time and location of substorms as well as to infer auroral power enhancement. More than 500 events of auroral breakups with auroral power enhancement of >2.0 gigawatts are identified. Then we investigated variations of geomagnetic field in the Pi2 frequency band, using data from Kakioka (L=1.27, 208.5° geomagnetic longitude) and Hermanus (L=1.45, 82.2° geomagnetic longitude). We will present statistical results and discuss the longitudinal structure of the cavity mode wave.

ARE PI 2 MAGNETIC PULSATIONS A GOOD INDICATOR OF SUBSTORM ONSETS ?

Kiyohumi YUMOTO[1], Teiji UOZUMI[1], Rui YAMAGUCHI[2], Hideaki KAWANO[2], Kan LIOU[3], Ching -I MENG[3] ([1]Space Environment Research Center, Kyushu University, Fukuoka, Japan, [2]Department of Earth and Planetary Sciences, Kyushu university, Fukuoka, Japan, [3]The Johns Hopkins University applied Physics Laboratory, Laurel, USA)

Pi 2 magnetic pulsations recorded on the induction magnetogram appears at the beginning part of positive H-component bays on the ordinary magnetogram at mid- and low latitudes, starts with dH/dt > 0, and its onset had been believed to show one-to-one correspondence to individual bays. However, Yumoto et al.(2001) recently found non-perfect one-to-one correspondence between the auroral expansions identified by the Polar satellite and the Pi 2 pulsations, due to the wave characteristics of Pi 2s into low latitudes. In order to understand the role of Pi 2 magnetic pulsations in the substorm process, we re-examine one-to-one correspondence of low-latitude Pi 2s to magnetic bays observed at the CPMN stations, and auroral brightenings identified by the Polar ultraviolet images. At least 5 % of 119 multiple-onset Pi 2 events at the CPMN stations in the midnight sector of 2230-2330 LT, are found to occur without magnetic bays (and/or with bays of amplitude smaller than 0.4 nT at Guam) during magnetic quiet times of Kp~1. The Pi 2s without/with magnetic bays tend to occur À`10-40 s later than the start of N2 LBH-band auroral sudden brightenings. One-to-one correspondence of Pi 2s occurrence to auroral sudden brightenings (precipitations) is much better than that to magnetic substorm onsets (expansions). Pi 2s must be excited just as a manifestation of the coupling (intensification and/or formation of FAC) between the near-Earth magnetotail and the polar ionosphere. Pi 2s are still a good indicator of substorm onsets, but they should be used with care.

A NUMERICAL SIMULATION OF PI 2 PULSATIONS IN MIDDLE- AND LOW-LATITUDES

Shigeru FUJITA[1], Masahiro ITONAGA[2] ([1]Meteorological College, [2]Yamaguchi University, Faculty of Education)

The Pi2 pulsation shows a cavity-mode behavior in the middle- and low-latitudes. The present paper deals with the transient behavior of MHD perturbations in the inner

magnetosphere induced by an impulsive localized eastward current (source current) as a model of Pi2 pulsations. The magnetospheric model consists of a dipole magnetic field, plasmasphere, ionosphere with Pedersen conductivity, and a free outer boundary. The source current is an impulsive magnetospheric current at the onset of the substorm current wedge, and is distributed around the equatorial plane of L = 10 with 2 hour longitudinal extent around midnight. The numerical results allow us to track variation in the expected Pi2 pulsation signals in both local time and L. The poloidal mode wave exhibits plasmasphere virtual resonance (PVR), resulting in large amplitudes around midnight, weakening towards dayside. The toroidal mode wave is excited as a field-line resonance immediately after the wave front of the poloidal mode wave crosses regions where the radial gradient of Va is steep. The toroidal mode wave has largest amplitude at the local time of the east/west edge of the source current. The duration of this wave is about 5 min. In the middle plasmasphere where the radial gradient of the Va is smaller, the poloidal mode wave tends to predominate over the toroidal mode wave. These numerical results are consistent with satellite observations, in so far as the day-night asymmetry of Pi2 pulsations and observation of transient toroidal waves. In addition to this simulation, we perform another simulation by using a plasmasphere model that is non-uniform in longitudinal direction. Power spectra of a plasmaspheric virtual resonance are calculated. It is shown that the spectra depend on longitude. Therefore, a cavity resonance mode can have local time depending spectra when the plasmasphere is non-uniform in a longitudinal direction. This fact concludes that the local time dependent peak frequencies of the mid- and low-latitude Pi2 pulsations discussed by Kosaka et al. [2002] are also explained by the cavity resonance model. We also discuss that the surface eigenmode can be a possible generation mechanism for Pi2 pulsations localized in a longitudinal direction.

GAIII.10/11A/D-020 Poster 0830-094

PROPAGATION STRUCTURE OF PI2 PULSATIONS DURING SMALL BAYS

Yuko SEKI[1], Rui YAMAGUCHI[1], Teiji UOZUMI[2], Hideaki KAWANO[1], Akimasa YOSHIKAWA[1], Shin-Ichi OHTANI[3], Masahiro ITONAGA[4], Kiyohumi YUMOTO[2], the CPMN Group[1] ([1]Department of Earth Planetary Sciences, Kyushu University, Japan, [2]Space Environment Research Center, Kyushu University, Japan, [3]Applied Physics Laboratory, University of Maryland, U.S.A., [4]Faculty of Education, Yamaguchi University, Japan)

Pi2 magnetic pulsations are known to be excited at the substorm onset.However, Pi2s are observed even when magnetic bays do not develop well. Inthis paper we aim to study the effects of the ionospheric conductivities onthe ground Pi2 amplitudes, but auroral particle precipitations stronglymodifies the ionospheric conductivies in a time-dependent manner, which isdifficult to describe by simple equations. Thus, using data from Circum-panPacific Magnetometer Network´s (CPMN) stations along 210-deg magneticmeridian, we have statistically studied Pi2´s associated with ˝small bays˝,which are defined here as magnetic bays at a low-latitude station in Guamwhose H-component did not increase more than 1 nT in 10 minutes after onsets. We have studied the latitude dependence of the Pi2 amplitudes during northernsummer and winter, and found the following features: (1) When averaged forall seasons, the H-component amplitude is almost constant at low- to mid- ($<$ 50 deg) latitudes, exponentially increases with latitude at mid- to high-(50 ~ 65 deg) latitudes, and is generally large at higher ($>$ 65 deg)latitudes (where the latitude dependence is unclear). On the other hand, theD-component amplitude exponentially increases with increasing latitude. (2) The H-component amplitude is larger in the summer hemisphere than in thewinter hemisphere at low- to mid-latitudes, while the D-component amplitudedoes not show a clear season dependence. (3) A case study shows that thedominant frequency of a Pi2 was constant at low- to mid- ($<$ 50 deg)latitudes, suggesting the plasmaspheric cavity-mode wave. The above results,and comparisons of them with a model of the ionospheric conductivity andsimulation results of the cavity-mode wave, suggest that the H-componentperturbation of Pi2s in the nightside low- to mid-latitudes is caused by anenhanced Pedersen conductivity in the nightside F-layer and the east-west component of the electric field perturbations of the plasmaspherriccavity mode.

GAIII.10/11A/D-021 Poster 0830-095

A STATISTICS STUDY OF MAGNETOSPHERIC RESPONSE TIMES DURING QUASI-PERIODIC SOLAR WIND VARIATIONS

Kei KAMIKAWA[1], Kiyohumi YUMOTO[2], Kentarou KITAMURA[2], the CPMN Group[2] ([1]Department of Earth and Planetary Sciences, Kyushu University, [2]Space Environment Research Center, Kyushu University)

In May 1996, two types of DP 2 magnetic variations were observed at the Circum-pan Pacific Magnetometer Network (CPMN) stations. One correlates with quasi-periodic variations of the IMF-Bz component, and the other correlates with changes of the solar wind Dynamic Pressure (SW Pd). The ionospheric equivalent current patterns are obtained by using the ground magnetometer data from the CPMN and WDC stations. The ionospheric equivalent current patterns show almost the same in the both cases of DP 2, that is, at high latitudes, clockwise and counter-clockwise current vortices appear in the morning and afternoon sector, respectively. Furthermore, we examined cross-correlation of the ground magnetic variations with the IMF and plasma changes at the WIND satellite, in order to determine time delays of the variations between the satellite and ground (magnetospheric response time). It is found that DP 2 caused by the IMF-Bz was about 15 minutes, and that by SW Pd was about 4 minutes. The magnetospheric response times must be an important clue to understand the global response of the magnetosphere for the quasi-periodic solar wind variations. In the present study, we statistically analyze magnetosphric response times of 61 DP 2 events during the period of April, 1999 ÅEMarch, 2000. The following results are obtained. (1) DP 2s observed at the ground stations can be categorized into three types: one is correlated only with the IMF-Bz[Type A: 7 events], the second is correlated both Z-component of the IMF and solar wind velocity [Type B: 45 events], and the third is correlated with SW Pd[Type C: 6 events]. (2) The Magnetospheric response times are 25 (+/-) 6 minutes for Type A, 19 (+/-) 2 minutes for Type B, and 11 (+/-) 7 minutes for Type C.

Fabien DARROUZET[1], Walther N. SPJELDVIK[2], Joseph LEMAIRE[1], Georg GUSTAFSSON[3], Pierrette M.E. DÉCRÉAU[4] ([1]Belgian Institute for Space Aeronomy (IASB-BIRA), [2]Department of Physics, Weber State University, [3]Swedish Institute of Space Physics (IRFU), [4]Laboratoire de Physique et Chimie de l'Environnement (LPCE/CNRS))

The long-term objective of the SEVEM project (Statistical ELF and VLF Environment Models) is, by examining and analyzing satellite electromagnetic magnetospheric data, to build statistical maps of the VLF, ELF and plasma wave distribution in the magnetosphere, and to develop empirical and statistical models of the 3-dimensional distribution of wave parameters such as amplitude, polarization and frequency. We present here the SEVEM Web site (http://www.magnet.oma.be/sevem/), which contains a comprehensive catalogue/table of all the missions/satellites in the terrestrial magnetosphere which are, or have been, equipped with radio antennae and/or fluxgate magnetometers. The site contains a comprehensive description of each satellite, presenting, for example, country of origin, contact numbers, orbital parameters, description of experiments, bibliographical references concerning the experiments and preliminary results, location where the databases are archived, format of the data, hyperlinks to relevant web sites, etc...The statistical maps and models of ELF and VLF wave distribution are useful to evaluate the average, maximum and minimum electromagnetic noise levels at different frequency ranges (useful when designing antenna for future space missions). We report here the development of a data-based model of the electromagnetic power spectral densities in the VLF band (8-50 kHz) as surveyed onboard the Swedish Viking spacecraft in the high-latitude region in the northern hemisphere. The data have been sorted into bins in spatial location and wave frequency for different geomagnetic conditions defined by the Kp index. A preliminary statistical model is presented showing the mean electric power spectral density versus magnetic local time and versus invariant latitude at fixed height intervals and for fixed frequency bands within the VLF range. An empirical model fitting these averages with simple analytical functions is also proposed. We have also used wave measurements onboard the four Cluster spacecraft to complete the frequency and spatial coverage of this statistical study. Progress along these lines is reported.

GAIII.10/11A/D-023 Poster 0830-097

COSMIC RADIO NOISE ABSORPTION AND VLF BURSTS CAUSED BY THE SOLAR WIND SHOCK

Aleftina OSEPIAN[1], Sheila Catherine KIRKWOOD[2] ([1]Polar Geophysical Institute, Murmansk, Russia, [2]Swedish Institute of Space Physics, Kiruna, Sweden)

Variations of cosmic radio noise absorption (SCA) and bursts of VLF-emission at sub-auroral and auroral latitudes at the time of sudden commencements (SC) of geomagnetic storms are studied. About 300 SC and SI events in absorption and 140 records of VLF-emissions are considered. It is found that the response of cosmic radio noise absorption and VLF-emission records to the passage of an interplanetary shock depends on the level of the planetary activity before the onset of the SC event and the amplitude ΔB of the geomagnetic field perturbation at a given L-shell in the equatorial magnetosphere. For SC events observed against a quiet background, effects of the SC in absorption and VLF bursts can be seen only if the jump ΔB of geomagnetic field caused by the solar wind shock exceeds a critical value ΔBc. The magnitude ΔBc depends on both latitude and time of SCA and VLF observations It is shown that the existence of a threshold value ΔBc at a given L-shell can be explained by the existence of a threshold value Γc for the growth rate Γ of the whistler-mode waves which limits self-exciting waves and spontaneous generation of the cyclotron instability. Sharp and strong (ΔB $>$ ΔBc) compression of the geomagnetic field increase the anisotropy index and the number of resonant electrons due to the effect of betatron acceleration and as a result leads to the growth of the wave increment to values Γ $>$ Γc and to electron precipitation. With increase of the level of geomagnetic activity before the onset of the SC event, the magnitude of ΔBc decreases. SC events observed against an active background (Kp $>$ 3) are accompanied by bursts in the absorption and VLF-emission for any jump ΔB of geomagnetic field.

GAIII.10/11A/D-024 Poster 0830-098

GENERATION MECHANISM OF THE FUNDAMENTAL AND THE SECOND HARMONIC TERRESTRIAL HECTOMETRIC RADIATION

Masahide IIZIMA[1], Hiroshi OYA[2], Akira HOSOTANI[1], Atsushi KUMAMOTO[1], Takayuki ONO[1] ([1]Department of Astronomy & Geophysics, Tohoku Univ., [2]Department of Space Communication & Science, Fukui Univ. of Tech.)

In the spectra of terrestrial hectometric radiation (THR) observed by PWS onboard the Akebono satellite, intense discrete components have been frequently observed in two frequency bands, from 1.3MHz to 2.1 MHz (1.7MHz band) and from 2.6MHz to 4.2MHz (3.4MHz band) forming a harmonic relation in the frequency. Polarization measurements of such discrete THR have shown that the fundamental band emission shows the nature of the L-O mode wave and the second harmonics emission reveals the nature of the R-X mode wave. The same polarization characteristics have been found for the case of auroral kilometric radiation (AKR) (Oya, 1990), i.e., the fundamental and the second harmonic AKR are generated in the form of the L-O mode wave and R-X mode wave, respectively. This result suggests that there is a common polarization feature in the harmonic generation of the planetary radio emission. The polarization feature of the fundamental and the second harmonic THR and AKR can be understood by the linear and nonlinear mode conversion processes from UHR mode waves into L-O and R-X mode electromagnetic waves: That is, at first, the strong UHR mode waves whose wave normal directions are nearly perpendicular to the local magnetic field are excited in the auroral electron beams through the cyclotron type wave-particle interactions. Then, the UHR mode waves are converted into L-O mode electromagnetic waves through the linear mode conversion process. These waves are observed as the fundamental emission. The origin of the second harmonic radiation includes the nonlinear wave-wave interaction processes of excited UHR mode waves. The theoretical calculations of energy conversion rates in this nonlinear mode conversion process have shown that the energy conversion rates from UHR mode waves into R-X mode electromagnetic waves are 20dB larger than those of L-O mode waves; that is in good agreement with the observations. Thus, the observed polarization characteristics of the fundamental and the second harmonic THR and AKR can be explained by the linear and nonlinear mode conversion processes from UHR mode electrostatic plasma waves into L-O mode and R-X mode electromagnetic waves.

GAIII.11/09A/A15-001 0900

A REVIEW OF SPACECRAFT EFFECTS ON PLASMA MEASUREMENTS

Alain HILGERS (ESA-TOS-EMA)

The spacecraft induced environment includes, secondary particles, generated by primary radiation, outgassing material, particles emitted by thrusters or emitters, spacecraft

generated electrical and magnetic fields.All of these components may severely affect the behaviour of sensors and especially scientific instruments. In this presentation the various effects are reviewed and method to copewith or to mitigate them are proposed.

GAIII.11/09A/A15-002   0925

HIGH-ENERGY PARTICLES AND THREATS TO SPACECRAFT

Joe H. ALLEN[1], Daniel N. BAKER[2] ([1]National Oceanic and Atmospheric Administration, [2]LASP/Univ. of Colorado)

Adverse space weather is one of the principal threats to modern human technology. Solar coronal mass ejections, large solar flares, and high-speed solar wind streams often lead to sequences of damaging disturbances within the Earth's magnetosphere, in the atmosphere, and even on the Earth's surface. Powerful and long-lasting geomagnetic storms can develop following solar disturbances and enhancements of the highly relativistic electron populations throughout the outer terrestrial radiation zone can also result. High-energy protons and heavier ions arriving in near-earth space, or trapped in the magnetosphere and having clearest effect in the South Atlantic Anomaly (SAA), can damage satellite solar power panels, confuse optical trackers, and deposit harmful charges into sensitive electronic components. Recent international space science programs have made a concerted effort to study activity on the Sun, the propagation of energy bursts from the Sun to near-Earth space, energy coupling into the magnetosphere, and its redistribution and deposition in the upper and middle atmosphere. Extreme solar, geomagnetic and solar wind conditions can be observed by a large array of international satellites and ground-based sensors. We discuss many of the types of space weather-related problems that have been identified in recent years. We present examples of space weather-induced spacecraft (and ground-based) anomalies and failures. An important effort is to propose technical and operational solutions to space weather problems and we discuss this aspect of space weather in this talk.

GAIII.11/09A/A15-003   0940

INVESTIGATION OF SPACECRAFT/PLASMA INTERACTIONS USING ASPOC AND PEACE

Knut SVENES[1], Bjorn NARHEIM[1], Klaus TORKAR[2], Andrew FAZAKERLEY[3], Michael FEHRINGER[3], Phillipe ESCOUBET[4] ([1]Norwegian Defence Research Establishment, [2]Space Research Institute, Austrian Academy of Sciences, [3]Mullard Space Science Laboratory, University College of London, [4]Research and Scientific Support Department, ESA/ESTEC)

The Cluster satellites are equipped with instruments to actively control the spacecraft potential relative to the ambient plasma. The instruments emit an Indium ion beam of 5 to 50 µA (typically 10 µA), with energies between 5 and 9 keV centered on the direction of the spacecraft spin axis.The ion emitter ASPOC (Active Spacecraft Potential Control) and the electron spectrometer PEACE (Plasma Electron And Current Experiment) have been operating together in a large variety of plasma environments. The main objective of this scheme is twofold: By lowering the magnitude of the spacecraft potential the modification of the ambient plasma before it is measured by on-board sensors are kept at a minimum. Secondly, the controlled conditions allow the escape of a larger fraction of photo-electrons generated at the spacecraft surface into space, whereby the wear of micro-channel plates in the electron detectors due to high count rates is reduced. In addition, the low energy ion measurements by the Cluster Ion Spectrometer (CIS) also gain from active spacecraft potential control. The improvement of the energy resolution of the detectors at low energy is one of the important features for multi-point measurements. These improvements have been achieved on Cluster with negligible disturbance of the plasma environment by the ion beam.The purpose of this presentation of spacecraft/plasma interactions is to systemise the resulting improvement of the Aspoc ion emitter on Cluster observations. In particular, the emphasis is to examine the effects on the Peace electron measurements. This study will be divided into a number of examples showing the effects of Aspoc in various regions of the orbit during different levels of geomagnetic activity. The time period covered is 2001 and 2002.

GAIII.11/09A/A15-004   0955

CHARGING OF THE METALIC ELECTRODE CAUSED BY ENERGETIC ELECTRONS

Yuzo WATANABE (Space Instrument Section, The Institute of Space and Astronautical Science)

Three antarctic rockets S-310JA-3, 5 and 6 were launched at Syowa Station into the auroral ionosphere. Charging of the electrode caused by the energetic electrons precipitated from the magnetosphere was observed on the frequency spectra of the impedance-probe. The measurement of the probe capacitance shows that the ion sheath thickness around the probe increases with enhanced energetic electron flux. A detailed study of the impedance characteristics of the impedance-probe measurement conducted in Antarctica reveals that the charging of the electrode occurred due to energetic electron precipitation from the magnetosphere. The sheath thickness normalized by the local Debye length (S/λ_D) increased with the increase of energetic electron flux as well as the increase of auroral intensity at 557.7 nm observed by the meridian-scanning photometer. Above is the main theme in this short report about charging phenomena on the Impedance-probe. The following is the similar bias effect on the metalic probe in the space plasma by the electron-beam emitted from the rocket to the space. Sudden potential drop of the Impedance-probe due to closed current loop formation with the electron-beam will be described at the oral session. S-310-24 rocket was launched from Kagoshima Space Center at 20 JST on the 11th day of February in 1996. Charging of the probe caused by the electron-beam emitted from the rocket to the space was observed in the frequency spectra of the Impedance-probe. The measurement of the probe capacitance shows that the ion sheath thickness around the probe increases when the electron-beam strikes the probe surface. Probe potential rapidly decreases just after reaching the electron-beam to the probe surface. This negative charging (ΔQ) can be estimated from both the injected electron-beam current (ΔI) to the probe surface and the charging time (ΔT) by the beam as ($\Delta I \cdot \Delta T$). The probe potential (V) is negatively biased to the level of $\Delta Q / C_{PO}$. C_{PO} denotes the equivalent probe capacitance in the vacuum. V is restricted to the minus voltage of the cathode which is used as the electron-beam source of the beam-gun. Above phenomena is interpreted by closed current loop formation, including the electron-beam. The probe is electrically connected with the cathode of the gun when the electron-beam flow from the cathode hits upon the probe surface. The probe potential becomes immediately to the minus voltage applied to the cathode at this moment and then the ion sheath region around the probe expands. Rough estimations will be presented with several figures.

GAIII.11/09A/A15-005   1010

SPACECRAFT CHARGING ANOMALIES AND THEIR RELATION TO THE SPACE ENVIRONMENT

Tateo GOKA[1], Haruhisa MATSUMOTO[1], Kiyokazu KOGA[1], Hitoshi MATSUOKA[1], Hideki KOSHIISHI[1], Masaki AKIOKA[2] ([1]Space Environment Measurement Engineering Group, Office of

R&D, National Space Development Agency of Japan, [2]Hiraiso Solar Observatory, Communications Research Laboratory)

Data concerning satellite anomalies induced by the natural environment, and related space environment measurements obtained by GEO, GTO and LEO satellites in Japan are reviewed. Electrostatic discharges (ESD) in GEO satellites remain the most common cause of anomalies in our database. ESD anomaly statistics show seasonal variations mainly occurring in spring and autumn equinox seasons and also correlate with the solar cycle, mainly in the decline and minimum phase. NASDA has measured surface charging potentials on board ETS-V (GEO, 10 years), ETS-VI (GTO, 2 years), ADEOS (LEO-polar, 10 months). We compare observed surface charging potentials on board ETS-V with substorm onset time, and have found that they are 80% correlated. The semiannual (equinoctial) variations in substorm occurrence are explained by the Russell-McPherron effect. Solar cycle variation matches our observed annual electron fluence data obtained by ETS-V in GEO orbit for 10 years (almost one solar cycle). This could be explained by two mechanisms: solar wind modulation and/or outer belt electron variations. Many satellite anomalies (NOAA-13, ANIK-E1&E2, INTELSAT-K, GOES-8, METEOSAT-3, BS-3a) occurred in the last solar decline and minimum phase (1993-1994). We focus on an ESD anomaly that occurred on BS-3a (22 Feb.1994) as a case study, and conduct a cause-and-effect analysis (a.k.a., cradle-to-grave analysis) using ground-based solar optical and radio data, IMP-8 solar wind data, and ETS-V and Ulysses radiation particle data. We have found that solar wind enhancement occurred around the time of the anomaly, coinciding with the detection of a radiation particle cloud, suggesting that this was the cause. In conclusion, the next solar decline and minimum phase, due in 2005-2007, is expected to lead to electron enhancement in the outer belt, and therefore result in more ESD anomalies in GEO satellites. The history of satellite anomalies should be the basis for uncovering the cause of operational problems. Combining space environment measurement data with satellite anomalies is crucial.

CRITICAL PROBLEMS OF SOLAR POWER STATION FROM SPACE PLASMA PHYSICS VIEW POINT

Hiroshi MATSUMOTO (Radio Science Center for Space and Atmosphere, Kyoto University)

In the 21st century, human activities will expand to near-Earth space. This talk discusses the potential important physical problems to which space plasma and magnetospheric physics should contribute. One of them is an impact of a very large structure on geosynchronous orbit such as Solar Power Station(SPS) on the environment of the magnetosphere and the ionosphere. The impact comes partly from the ion injection of the electric propulsion of the carrier from LEO to GEO. Another interesting issue is a nonlinear behavior of space plasma environment in response to a high density electromagnetic power beam passing through the magnetosphere, ionosphere and atmosphere. The paper also discusses a plasma-body interaction caused by a large solar array and a big phased array antenna for power beaming. The background and state of art of the SPS research in Japan and in the US will also be given as a reference

GAIII.11/09A/A15-007   1120

ANALYTICAL STUDY ON THE APPLICATION OF EXHAUSTED BEAM IONS FROM ION THRUSTER TO ENA OBSERVATION

Yoshiki YAMAGIWA[1], Yukitaka TANAKA[1], Hitoshi KUNINAKA[2] ([1]Faculty of Engineering, Shizuoka University, [2]Institute of Space and Astronautical Science)

The density of neutral particles in the upper atomosphere can be estimated by using ENA (Energetic Neutral Atoms) observation. At present, the ENA observation is done by using the charge exchange collision between the neutrals in upper atomosphere and the ions in the magnetospheric ring current field that is activated by solar wind. But in this method, it is dufficult to separate the informations between neutrals and ions from ENA data because the ions in the magnetospheric ring current field are the natural origin and their energies are not constant. In this study, we propose the new method of ENA observation that uses the ions exhausted from ion thrusters. The ions exhausted from ion thrusters are the artificial ones and are more suitable for ENA observation because their energies and densities can be controlled. We evaluate the possibility of application of exhausted ions from ion thrusters to ENA observation. Analytical results show the range of altitude and the operating conditions of ion thurusters that this method effectively can apply.

GAIII.11/09A/A15-008   1135

COMPUTER EXPERIMENTS ON INTERACTION OF HEAVY ION BEAM FROM A LARGE-SCALE ION ENGINE WITH MAGNETOSPHERIC PLASMA

Yoshiharu OMURA, Toshihiro SAKAKIMA, Hideyuki USUI, Hiroshi MATSUMOTO (RASC, Kyoto University)

We study effects of heavy ions injected from a large scale ion engine to be used to propel large scale space station such as space solar power station in the lowearth orbit to the geo-synchronous orbit. We performed a series of hybrid code simulations where ions are solved as particles, while electrons are treated as a massless fluid. We assume a two-dimensional plane (x, y) where the external magnetic field is taken in the y-direction. We inject an argon beam in the direction perpendicular to the magnetic field, i.e., the direction along the x-axis. We study responses of the surrounding plasma to the heavy ion beam injected with different the density and initial drift velocity. With a sufficiently large injection velocity and high density of the argon beam, there arises a fast shock as the initial response to the injection, followed by gradual formation of tangential discontinuity at the front surface of the ion beam cloud. At the tangential discontinuity we find generation of Alfven waves that propagate along the magnetic field lines, heating up the background thermal protons. We will discuss parametric dependence of the plasma response.

GAIII.11/09A/A15-009   1150

ARTIFICIAL DISTURBANCES OF THE IONOSPHERE OVER THE MILLSTONE HILL RADAR DURING DEDICATED BURNS OF THE SPACE SHUTTLE OMS ENGINES

Paul A. BERNHARDT, Phil J. ERICSON, Frank D. LIND, Bodo REINISCH (Plasma Physics Division, Naval Research Laboratory)

Two of the Shuttle Ionospheric Modification with Pulsed Localized Exhaust (SIMPLEX) experiments were carried out over the incoherent scatter radar (ISR) located at Millstone Hill Massachusetts. These experiments used 10 seconds burns of the dual Orbital Maneuver Subsystem (OMS) engines to produce the injection of high speed molecules in the ionosphere near 380 km altitude. Charge exchange between the high speed exhaust molecules and the ambient oxygen ions produce molecular ion beams that disturb the natural state of the ionosphere. Radar scatter measurements are used to measure the ion

velocity distributions that result from the ion beam interactions. Ground based observations with the University of Lowell Digisonde recorded the ionospheric density depressions resulting from recombination of the molecular ions with electrons. Prompt signatures of a non-equilibrium ion distribution in the OMS engine plume are seen in the data taken during Space Shuttle Flights STS-108 and STS-110 show. The presence of the stimulation of plasma turbulence is seen in the short-time measurements with the ISR for about 30 seconds duration and large scale irregularities are detected by the Digisonde for up to 20 minutes after the engine burn. The SIMPLEX experiments provide localized simulations of naturally occurring disturbances in the ionosphere that can be studied under controlled conditions. The experiment conditions are similar to the strong convection seen with high-latitude plasma during geomagnetically disturbed times.

ION PROPULSION INDUCED PLASMA INTERACTIONS: AN OVERVIEW OF RESULTS FROM DEEP SAPCE 1

Joseph J. WANG (Virginia Polytechnic Institute and State University)

NASA´s New Millennium Deep Space One (DS1) is the first interplanetary spacecraft operated on solar electric propulsion. Using a 30cm diameter Xenon ion thruster as its primary propulsion system, DS1 successfully flew by asteroid Braille in July 1999 and Comet Borrelly in Sept. 2001. One of the primary investigations on DS1 is to characterize ion propulsion induced plasma interactions and their effects on spacecraft and solar wind measurements. DS1 carried an integrated set of ion propulsion diagnostics sensors, Ion Propulsion Diagnostics System (IDS), and a state-of-the-art plasma sensor, The Plasma Experiment for Planetary Exploration (PEPE). 3-dimensional particle-in-cell simulations were also performed to assist data analysis and interpretation. This paper presents an overview of ion propulsion induced plasma interactions based on the results from DS1 investigations. Specifically we examine three major interaction problems: beam neutralization, plume-spacecraft interaction, and plume-solar wind coupling. Both in-flight measurements and modeling results will be discussed.

GAIII.11/09P/A15-001 Invited **1400**

ELECTRODYNAMIC TETHERS FOR IN-ORBIT PROPULSION: STATUS AND TECHNOLOGICAL ISSUES

Brian E. GILCHRIST (Space Physics Research Laboratory, University of Michigan)

Electrodynamic (ED) tether "propellantless" propulsion is accomplished through a magnetic force acting on an electrical current in the conducting tether to transform between electrical and mechanical energy. Orbit raising, lowering and possibly inclination change are all possible. The efficiency with which this is accomplished depends heavily on the ability of the tether system to extract current from and inject into the local magnetoplasma while moving at mesosonic speeds relative to the plasma. The key technologies include the electron collector configurations and low-power, propellantless electron emission technologies, and low-loss, long-life tethers.Both space flight experiments and ground chamber testing using high speed plasmas are helping to reveal details of ED tether operations that will be important for specifying future ED tether system designs. Here, results from the NASA Propulsive Small Expendable Deployer System (ProSEDS) experiment will be described. ProSEDS uses a 5-km bare aluminum tether (multiple strands) deployed from a Delta II second stage. Overall and individual sub-system performance will be reviewed. Ground chamber plasma tests of representative (scaled) geometries of future bare tethers will be described.Other technological issues and representative applications will also be discussed.

GAIII.11/09P/A15-002 **1425**

GROUND EXPERIMENTS OF ELECTRODYNAMIC TETHER USING HOLLOW CATHODE PLASMA CONTACTORS

Masaya KOZAKAI, Naoyuki HIROSE, Tetsuya AOYAMA, Haruki TAKEGAHARA (Department of Aerospace Engineering, Tokyo Metropolitan Institute of Technology)

Plasma contactors are proposed as making good electrical contact devices between spacecraft and ambient ionospheric plasma. Especially, it has been studied as the one of key components of electrodynamic tether. The performance of electrodynamic tether depends on these devices because the current through the tether form a closed loop via space plasma. In this study, hollow cathode plasma contactor was used for both electron emitter and collector. The largest advantage of using hollow cathode is that the same device can both emit and collect electrons. Thus, the electrodynamic tether, which mounts hollow cathode plasma contactors both ends of tether, is possible to change the direction of current and it can generate thrust force and drag force. Since electrodynamic tether system that include current path through the space plasma is very huge, it is necessary to consider a scaling law between space operation and ground experiments to simulate the electrodynamic tether system. This study aims for ground simulation of electrodynamic tether system that is considered near-field and far-field plasma interaction. There are many factors for design a scaling law, such as tether length, geomagnetic field intensity, plasma environment (electron density, neutral density, gas species, and vacuum level), plasma cloud size, etc. However, all of the conditions are not necessary to conduct the ground experiments. Most of study have not been met these conditions. It is necessary to distinguish the dominant factors. Effective electrical connection between collector and ambient ionospheric plasma via luminous plasma cloud is most dominant for gathering enough current. For the understanding of the physical phenomena in plasma contactor operation, the experiment used hollow cathode was conducted in 3.2 m length by 1.5 m in diameter cylinder vacuum chamber. Experimental apparatus consists of three plasma sources. Two of them are the hollow cathode plasma contactors that are connected each other and separated from ground potential. And the other device is plasma simulator used ion thruster without ion beam extraction that simulates ionospheric plasma environment. Xenon was fed to the plasma contactors but argon was fed to the plasma simulator to minimize the ionization of background neutrals. It was confirmed that two functions (electron emission or collection) with one device could be changed in the simultaneous operation experiments. Probe measurement, mass spectrometry and emission spectrometry were performed to verify the elements of plasma cloud at the electron collector. We will describe the constitution elements of plasma cloud and validity of the ground experiments.

GAIII.11/09P/A15-003 **1440**

DETERMINATION OF ESD GROUND TEST CONDITIONS FOR HIGH POWER GEO SATELLITE SOLAR ARRAY

Mengu CHO, Toshiaki MATSUMOTO, Emanuel AMORIM, Kazuhiro TOYODA (Department of

Electrical Engineering, Kyushu Institute of Technology)

Since the last decade, the power level of Geosynchronous Orbit (GEO) satellite has increased dramatically to nearly 10 kW or even higher. To manage the large amount of power efficiently, the satellite bus voltage has increased to 100V. Nowadays many commercial telecommunication satellites employ solar arrays that generate the electricity at 100V.As the voltage of solar array increases to 100V, the problems of arcing during the substorm condition have been recognized as serious hazard that sometimes threatens the stable supply of the solar array power. In the present paper, we report the results of ESD (electrostatic discharge) test carried out on solar arrays for Japanese telecommunication satellites. We have placed solar array coupons made with the same procedure as the flight model inside a vacuum chamber, where we have irradiated a test coupon by high energy electron beam to simulate the charging condition during the subsorm in GEO. The threshold for the trigger arc inception and the sustained arc formation has been studied. The dependence on the coverglass material has been also studied. We have also used test coupons made only with two solar cells but with different gap distances. We have used many of this coupon type to statistically determine the threshold condition for the sustained arc formation. The test result is used to derive the safety margin for the potential difference between adjacent cells. During the tests, the amount of external capacitance simulating the coverglass capacitance of solar array paddle has been changed and the effect of external capacitance on the test results has been studied. We have analyzed the magnetospheric plasma data collected by LANL satellites. From the data of plasma temperature, density, and satellite potential, the duration during which a satellite is under the inverted-potential gradient condition is estimated. Then the total duration of inverted-potential gradient during the operational life time of a satellite is calculated to give a reasonable test duration on the ground. These results are used to determine the appropriate ESD test condition for the ground test of solar array for GEO satellites.

GAIII.11/09P/A15-004 **1455**

EFFECT OF SPACE PLASMA ON HIGH VOLTAGE SOLAR ARRAY

Koji TANAKA[1], Minoru IWASA[2], Susumu SASAKI[1], Haruhisa FUJII[4], Masahiro MORI[3] ([1]The Institute of Space and Astronautical Science, [2]Tokyo Institute of Technology, [3]NASDA, [4]Mitsubishi Electric CO.)

The design and operation of the spacecraft power system will be affected by elements of the space environments. Increasing with power requirements of the spacecraft, a solar array is required to generate high voltage in order to reduce a power loss in a cable and a power system. Especially, a solar power satellite (SPS) will be operated above several kV or several ten kV. Though SPS2000 is a relatively small SPS, its array modules were designed to generate 1kV. A conventional solar paddle of the spacecraft exposes interconnectors to the space environment. When solar arrays generate electricity, interconnectors of the photovoltaic cells collect electrons from the ambient plasma, and spacecraft potential is biased to negative voltage. When spacecraft is negatively biased, the ionospheric ions attack the spacecraft surface. Spacecraft is possibly caused serious damages by ion bombardments. Also, the discharge occurs when the solar array has a negative potential below -200 V with respect to the plasma. The discharge causes various undesired effects, such as electromagnetic interference and surface deterioration, and leads to the permanent loss of the spacecraft power. In this paper, we describe results of the laboratory experiments concerning the interaction between ambient plasma, which simulates the low earth orbit conditions, and the high voltage solar array. We made a two dimensional electrode array that was consisted one hundred electrodes (10×10) on the CFRP honeycomb panel that simulated a solar paddle of the spacecraft. The vacuum chamber with 4.0 m in length and 2.5 m in diameter was used in this experiment. The chamber had a diffusive argon plasma source located at one end, which generated plasma conditions of ne ~1×1010 m-3 and κTe~3 eV. Each electrode on the panel was biased up to 1.5 kV by the solar array simulator that was consisted of the high voltage DC power supplies and voltage dividers. Plasma current from each electrode that was grounded through a 1 kΩ resistance was measured under the same condition and acquired by a mobile computer through the multiplexer. Also, the chamber is equipped with a spherical Langmiur probe with a radius of 1 cm that can be moved in the three axes. Our preliminary results of the plasma experiments using the electrode array show that electron collection currents increase rapidly with increasing bias voltage over several hundred V and saturates in some conditions. These phenomena may be involved in growth of the electron sheath.

GAIII.11/09P/A15-005 **1510**

STUDY OF SPACECRAFT ARCING IN AMBIENT PLASMA ENVIRONMENTS

Takahisa MASUYAMA, Masato NAGATA, Tatuo ONISHI, Hirokazu TAHARA, Takao YOSHIKAWA (Graduate School of Engineering Science, Osaka University)

Spacecraft are in a severe environment in space. Their surfaces are exposed to energetic and reactive particles, such as electrons, ions, protons and oxygen atoms and ultraviolet light, including particles exhausted from plasma thrusters, during space missions. Then, electrostatic interactions between the surface materials and the ambient plasma, such as negative or positive sheath creation, and charging and arcing phenomena, frequently occur.In satellites, the current generated by a solar array is leaked by impact of ions, and the solar array is still degraded by sputtering and arcing due to the collected ions. The electrical breakdown of negative charging on insulating surfaces causes intensive damages in the satellite systems. Furthermore, in plasma contactor operations, negative charging is expected to be mitigated by ions attracted from the plasma, resulting in surface degradation as well as in the case of high voltage solar arrays. The mechanism of the material degradation, the structure of electrical sheaths, and the charging and arcing processes must be understood. In Osaka University, a ground facility was developed for simulation of space plasma and material interaction. Using the simulator, the structure of an ion sheath created around a high voltage solar array and the degradation of surface materials near the array due to high energy ion bombardment were investigated. The mitigation of negative charging by plasma flow, i.e., the feature of plasma contactor operations, has also been studied.In the future, spacecraft will be larger and higher powered. Because of the balance of leakage currents through the ambient space plasma, they will have higher negative potential without plasma contactor operation. When spacecraft operate with higher voltage, more intensive arcing is suspected to occur on the surface. In this study, ground experiment and PIC plasma similation were carried out to understand this phenomenon and to examine effects of the ambient space plasma on the arcing process. Plasmas were generated by electron cyclotron resonance (ECR) discharge. When arcing occurred, the time variations in arc current and bias voltage were measured. Both peak arc current and total charge emitted by arcing increased with bias voltage and plasma number density. The diameter of arc spots also increased. Neutral particles in addition to charged particles around spacecraft are considered to play the important role for expanding of arc plasma.

GAIII.11/09P/A15-006   1525
COMPUTER EXPERIMENTS OF TRANSIENT CHARGING PROCESS OF A PLASMA EMITTING BODY

Hideyuki USUI[1], Ikkoh FUNAKI[2], Hayato TASHIMA[1], Hitoshi KUNINAKA[3], Masaki OKADA[4], Yoshinori NAKAYAMA[5] ([1]Radio Science Center for Space and Atmosphere, Kyoto University, [2]University of Tsukuba, [3]Institute of Space and Astronautical Science, [4]National Institute of Polar Reseach, [5]National Defense Academy)

For the assessment of the spacecraft with active plasma emission and its surrounding plasma environment, we are planning to propose an plasma experimental space platform for the JEM (Japan Experimental Module) exposed unit ofthe international space station (ISS). By using this platform, we will be able to examine the transient processes in non-steady interferencewith plasma and charging/discharge in association with turn-on/off or unexpected failure of the plasma emission facility. In order to design the new platform, we started testing the charging process of a floating body with active ion emission in a vacuum chamber. In parallel to the ground experiment, we also started performing computer simulations with Particle-In-Cell (PIC) model in order to examine the detail of the charging process. In the simulations, we particularly focus on the transient response of a floating ion-emitting body in a situation where a neutralizer which emits electrons from the body is abruptly turned off by accident. In the present paper, in addition to the brief introduction of the concept of plasma experimental module for JEM, we will show some results obtained in the PIC simulationsand discuss the body charging process, the spatial distribution of emitted ions and the response of the background plasma.

DEVELOPMENTS IN MINI-MAGNETOSPHERIC PLASMA PROPULSION

Robert WINGLEE[1], Tim ZIEMBA[2], Peter EURIPIDES[1], Louis GIERSCH[1], John SLOUGH[2] ([1]Dept. of Earth and Space Sciences, Univ. of Washington, [2]Aeronautics and Astronautics, Univ. of Washington)

Mini-Magnetospheric Plasma Propulsion (M2P2) seeks the creation of a large-scale(10 km radius) magnetic wall or bubble (i.e. a magnetosphere) by the electromagnetic inflation of a small-scale dipole magnet. The inflated magnetosphere will intercept the solar wind and thereby provide high-speed propulsion with modest power and fuel requirements due to the gain provided by the ambient medium. Magnetic field inflation is produced by the injection of plasma onto the dipole magnetic field eliminating the need for large mechanical structures and added material weight at launch. Results are presented from the laboratory prototype that shown the production of plasma and in a dipole and the expansion of the magnetic field. It is shown that the observed characteristics are very close to that predicted by computational models. The outcome though is very dependent on the presence of chamber walls which are shown to be limit the expansion of plasma and magnetic field. Possible applications from extrapolating the laboratory and simulations results show substantial savings in mission times spacecraft with a much larger payload to fuel ratio.

GAIII.11/09P/A15-008   Invited   1620
THE CLUSTER DOUBLE PROBE ELECTRIC FIELD EXPERIMENT (EFW)

Arne PEDERSEN[1], Mats ANDRE[2], Andre BALOGH[3], Anders ERIKSSON[2], Per-Arne LINDQVIST[4], Forrest MOZER[5], Goetz PASCHMANN[6], Henri REME[7], Jack QUINN[8] ([1]Dept. of Physics, University of Oslo, [2]Swedish Institute of Space Physics, Uppsala, [3]Imperial College, London, [4]Alfven Laboratory, Royal Institute of Technology, Stockholm, [5]Space Science Laboratory, University of California, Berkeley, [6]Max Planck Institute for Extraterrestrial Physics, Garching, [7]CESR/CNRS, Toulouse, [8]Space Science Center, University of New Hampshire, Durham)

Each of the four Cluster spacecraft has two double probes at the tips of four 44 m long radial booms. The experiments allow for high time resolution measurements of the quasistatic electric field component in the spin plane of the spacecraft. The full electric field vector can be calculated with knowledge of the magnetic field under the assumption that the parallel electric field can be neglected. EFW has the unique possibility to compare data with the Electron Drift Instrument (EDI) which has good mesurements in the inner magnetosphere. This comparison has demonstrated agreements, but has also uncovered problems with EFW over the polar caps. Outflow of low energy ions, some of which do not reach the positively charged spacecraft, creates wakes which disturb EFW. Comparisons with **v x B** , from the magnetic field and the ion experiment, has demonstrated good agreements in the plasmasheet. The force of EFW is the high time resolution of the measurements and the capability to measure spiky large amplitude electric fields. In many studies it is necessary to consider data from all the above experiments as complementary in order to get the full information. Other capabilites of EFW is the high time resolution measurements of the spacecraft potential and its connection to plasma density. EFW also provides high quality wave data; this will be briefly outlined.

GAIII.11/09P/A15-009   1645
RHEOMETRY EXPERIMENT OF THE WIRE ANTENNA ABOARD SCIENTIFIC SPACECRAFTS

Tomohiko IMACHI[1], Satoshi YAGITANI[1], Isamu NAGANO[1], Ryoichi HIGASHI[1], Satoshi ESAKI[1], Minoru TSUTSUI[2], Hiroshi MATSUMOTO[3] ([1]Department of information and system engineering, Faculty of engineering, Kanazawa University, [2]Kyoto Sangyo University, [3]Radio Science Center for Space & Atmosphere, Kyoto University)

Observation of plasma waves in the space is an important subject ofscientific spacecraft missions.The sensor frequently used to measure the low frequency AC electric fieldof plasma waves is a wire antenna.It is necessary for an accurate measurement to estimate the effective lengthof each wire antenna accurately, because it is closely relatedto the gain of the sensor, and the inaccuracy of it affects greatly to thequantitative studies of plasma waves.The effective length of an ideal short wire antenna in free space isconsidered to be a half of its physical length when the wavelength is muchlonger than the antenna, because a theory of short dipole antenna informsthat current distribution along the wire becomes a triangular in lowfrequencies.So far, in most researches related to plasma waves, the effective lengthof a wire antenna has been assumed to be a half of its physical length.However, on the other hand, when we measure electrostatic or quasi-staticfield, the intensity is calculated from a voltage between probes, placed atboth tips of the antenna, divided by the distance between them.In this case the antenna effective length is treated as the same as thephysical length of the wire.What makes difference between them?To investigate this problem, we estimated frequency dependency of the effective length in quasi-static frequency range, by using ``Rheometryexperiment´´[1]. Rheometry is an experimental method to determine the effective lengthof a short antenna by using a water tank.We generate a quasi-static electric field uniformly in the water tank.The intensity of the generated electric field is exactly known so thatwe can estimate the effective length of a small ``scale-model´´wire antenna in the water from its output voltage.It would not be possible to make such a measurement in the air,because the impedance of the antenna is

very high in the quasi-staticfrequency range, and the voltage at the antenna terminals would be changedwhen a voltmeter is connected.However we can make the impedance low in the water because of waterconductivity, and the electric field in the water surrounded by the airbecomes homogeneous because the dielectricity of the water is much higherthan that of the air.A homogeneous quasi-static electric field can be used to simulate theelectromagnetic plane wave observed by the antenna. The result shows that the effective length is a half of their physicallength in higher frequencies (＞ several kHz).However, in very low frequencies(＜ several hundred Hz), it depends on thestructure of the antenna.We will show the detailed result. STUDY OF SPACECRAFT-PLASMA INTERACTION VIA 3D UNSTRUCTURED-GRID EM PARTICLE SIMULATION

Masaki OKADA[1], Hiroshi MATSUMOTO[2] ([1]National Institute of Polar Research, [2]Kyoto University)

We have developed a 3-dimensional electromagnetic particle simulation code with an unstructred-grid system. This code solves Maxwell´s equations which is discretized with triangular elements in 3D simulation space. Plasma particles are also traced by solving the equations of motion with the Buneman-Boris method. The main advantage of this code is the adaptability of modeling more realistic shape of a spacecraft than the orthogonal grid code. Thus, this simulation code is suitable for analyzing the plasma environment in the vicinity of a spacecraft especially in the region within a Debye length from the surface of the spacecraft as well as the spacecraft charging phenomena. We will show the scheme of this code and also show a couple of results from the test simulation runs taking into account of a realistic shape of a spacecraft.

COMPUTER EXPERIMENTS ON ANTENNA CHARACTERISTICS IN SPACE PLASMA

Nobuyuki NAKAMURA, Hideyuki USUI, Hirotsugu KOJIMA, Hajime KAISHIMA, Hiroshi MATSUMOTO, Yoshiharu OMURA (Kyoto University)

Antenna characteristics in a magnetized plasma such as inputimpedance, effective length and pickup factor are important in theplasma wave observation, partcularly for calibration of wavedata obtained from spacecraft. However, it is difficult to evaluateantenna characteristics in space plasma accurately because of complexinteraction among antenna itself, plasma waves, background plasma andphotoelectron sheath. For last several decades, many studies on antenna characteristics havebeen done. In terms of antenna impedance, theoretical analyses weredone with the assumption of the antenna surface current. Simultaneously analysis of antenna impedance was carried outby real observation with spacecraft and antenna equivalent circuitwhich is parallel circuit of resistance and capacitance was used. However there are some discrepancy between the observational results and the analysis with antenna equivalent circuit, which may be caused by the effect of sheath and photoelectron. In the present study, we focused on a dipole antenna and examined itscharacteristics in space plasma by performing three dimensionalelectromagnetic PIC(Particle-In-Cell) simulation. In three dimensionalPIC simulation as a antenna analysis we put a conducting dipoleantenna immersed in a magnetized plasma and examine its impedance,effective length including plasma kinetic effects under a variety ofplasma environments. Firstly, we performed simulations to obtain theantenna impedance. In these simulations impedance resonance at theplasma frequency was recognized and the resonance becomes duller asthermal velocity of background plasma became larger. These resultswere consitent with theory qualitaively and we will proceed to thequantitative analysis. Next, we performed simulations to obtaineffective length. We investigated the effective length by using areceiveing antenna and calculated effective length from antennasurface current under the circumstances an electrostatic wave wasexcited by the beaminstability. When wave length was comparable toantenna length antenna surface current can be approximated as sinewave. However, if load impedance is far higher compared to the antennaimpedance it can be considered that the current flowing over theantenna becomes very little and the voltage induced on antenna becomesdominant. We are investigating the association between effectivelength and current distribution on antenna. The above simulations are performed in only case that antenna length islarger than the local Debye length. Therefore we also focus on thesituation where the local Debye length is larger than or comparable tothe antenna length.

GAIII.11/09P/A15-012   1730
PIC MODELLING OF THE PHOTO-ELECTRON CLOUD AROUND A SPACECRAFT

Alain M.F. HILGERS[1], Benoit THIEBAULT[1], Julien FOREST[1], Olivier CHANRION[1], Philippe ESCOUBET[2], Michael FEHRINGER[2], Harri LAAKSO[2] ([1]ESA-TOS-EMA, [2]ESA-SCI)

Photo-electrons emitted from sunlit surfaces in space may affect plasma measurements by several processes, e.g., via the resulting (i) surface potential, (ii) space charge effects, or/and (iii) direct propagation to detectors. We have used a fully kinetic particle-in-cell code, PicUp3D which is now made available in public domain, for modelling in three dimensions the electrostatic sheath and photo-electron cloud around a conductive volume representative of a spacecraft like Cluster in a typical magnetospheric plasma environment. The model shows several features of key interest for the interpretation of the measurements and for optimizing the design of future instruments. It is found that photo-electrons fill a large volume around the spacecraft where they can dominate over the ambient environment and a significant part of photo-electrons propagates to the antisunward sector. The resulting space charge has been found to generate negative potential barriers under certain conditions. Also long wire booms which are generally used for mounting electrostatic sensors away from the influence of the spacecraft are found to induce significant transport of the spacecraft generated photo-electrons toward the boom mounted detectors. In this presentation the feature of the computer code and the results of the numerical model are reviewed and the implications for plasma instruments are discussed.

ELECTRICAL CHARGING OF THE ROSETTA ORBITER, (1) NUMERICAL SIMULATION

Jean-François ROUSSEL[1], Jean-Jacques BERTHELIER[2] ([1]ONERA, DESP, [2]CETP/IPSL)

One of the objectives of the ROSETTA missions is to investigate the various processes which are responsible for the development and evolution of the cometary neutral and ionised atmosphere. The main problem in measuring the characteristics of the plasma in the coma stems from the very low energy of thermal particles, from less than 10 meV for the electrons to about 100 meV for the outflowing ions. Besides the instrumental difficulties, the possible charging of the orbiter appears of major concern. For this reason, we have undertaken a numerical simulation study of the electrical equilibrium of the ROSETTA spacecraft. The model takes accurately into account the photo-emission and the anticipated characteristics of the cometary plasma, in particular its outflow from the nucleus. It provides the floating

A

potential of the orbiter and the structure of the plasma sheath for the various conditions expected during the operational phase that mainly depend on the distance of the orbiter to the nucleus. The results of this study demonstrate that the electric equilibrium of the spacecraft is essentially controlled by the photo-electron current emitted by its very large solar panels, leading to a positive floating potential. Only very close to the nucleus is the expected plasma density high enough to allow the collected thermal electrons to maintain the floating potential within a few kTe from the plasma potential. At larger distances it will float positive and at high potentials compared to the characteristic energy of cometary particles thus making questionable to obtain reliable measurements of the thermal plasma. A possible way to circumvent this effect, disconnecting the sunlit surface of the solar panels from the spacecraft ground, was suggested by our results.

EFFECTIVE LENGTHS OF CROSSED WIRE ANTENNAS ONBOARD AKEBONO

Ryoichi HIGASHI[1], Tomohiko IMACHI[1], Satoshi YAGITANI[1], Isamu NAGANO[1], Iwane KIMURA[2] ([1]Graduate School of Natural Science and Technology, Kanazawa University, [2]Faculty of Informaton Science and Technology, Osaka Institute of Technology)

The effective length of a dipole antenna designed to pick up low frequency electric fields onboard satellite has been assumed equal to a half of its physical length. However the effective length may change under the influence of plasma sheath surrounding the antenna. To observe the electric field accurately, we must estimate the accurate effective length of the antenna in space plasmas. In this study, we evaluate the effective lengths of crossed wire antennas onboard Akebono satellite by using in-situ observations of OMEGA signals. The VLF instruments onboard Akebono are designed to observe VLF plasma waves and to determine wave normal direction of the waves. Two pairs of wire dipole antennas (tip-to-tip 60m) crossing each other are used for the VLF electric field, and triaxial loop antennas and search coils are used for the VLF magnetic field [1]. The absolute intensities of the electromagnetic fields measured by these antennas are calculated from their induced voltages and effective lengths. However the effective lengths of the wire antennas in space are difficult to be estimated generally because of the plasma sheath surrounding the antennas. So we evaluate the effective lengths by making use of OMEGA navigation signals observed as the whistler mode waves in the magnetosphere and the theory of cold plasma. The frequency and transmitting sequence of OMEGA signals are exactly known. We obtain the electron cyclotron frequency from MGF and the plasma frequency from PWS. The k-vectors of OMEGA signals are calculated from only the wave magnetic field under a cold plasma approximation of whistler mode propagation. For an OMEGA signal, we can calculate its electric field components theoretically from its observed magnetic field components, k-vectors and plasma parameters using the dispersion equation of the cold plasma and Maxwell´s equations [2]. Finally, by comparing such calculated values with the actually observed electric fields that have been calibrated using the assumed effective length, we can determine the effective lengths of each of the two dipole antennas separately. We calculate effective lengths of the two dipole antennas separately by using Australian OMEGA signals (10.2kHz) observed along the two paths, Dec. 14, 1989, and Aug. 3, 1990. Results show that each of their average effective lengths is almost a half of the actual length (60m) of the dipole antennas, 30.8m and 31.5m for x- and y-antennas for the data of Dec. 14, 1989, and 31.4m for both antennas for Aug. 3, 1990. We will present the more detailed analysis results and discuss them statistically. [1] I. Kimura, et al., ˝VLF Observation by AKEBONO satellite,˝ Geophys. Res. INFLUENCE OF THE SHEATH IMPEDANCE OF THE BIASED PROBE ON THE MEASUREMENTS OF THE SPACECRAFT POTENTIAL

Keigo ISHISAKA[1], Yasumasa KASABA[2], Toshimi OKADA[1], Hajime HAYAKAWA[2], Toshifumi MUKAI[2] ([1]Toyama Prefectural Univ., [2]Institute of Space and Astronautical Science)

The spacecraft potential is determined by the balance of the photoelectron current from the spacecraft surface and the incoming ambient electron current and is given by a function related to the photoelectron emitted from the surface and the ambient plasma density. Therefore the spacecraft potential has been used to derive the electron density surrounding the spacecraft in the magnetosphere and the solar wind. The spacecraft potential of the Geotail spacecraft is measured by the single probe system, which is one of the subsystems of the electric field detector (EFD). The single probe system measures the difference of potential between the spacecraft and the spherical probe at the top of long wire boom. The probe potential can be set nearly equal to the ambient plasma potential by feeding a proper bias current to the probe. Therefore the voltage measured by the single probe system is approximately equal to the spacecraft potential for ambient plasma. In order to measure the spacecraft potential accurately, the amount of the bias current is determined to reduce the impedance between the probe and the surrounding plasma below the input impedance of the electronics. However the bias current is determined experimentally in orbit and the bias current actually set -225 nA constantly, while the plasma density and temperature may change from place to place in the magnetosphere. In this case, due to the low density and high temperature of the magnetospheric plasma, the impedance between the probe and the surrounding plasma is very high, especially near the floating voltage at which no current flows between the probe and the plasma. It is difficult to measure the spacecraft potential using the probe technique because the probe potential cannot be measured accurately. In this study, using the data of the Geotail spacecraft measurement, we investigate the sheath impedance between the probe and the ambient plasma in the magnetosphere and solar wind when the bias current is changed variously. We discuss the influence of the sheath impedance of the biased probe on the measurements of the spacecraft potential and demonstrate the method of feeding the proper bias current in the various regions. The spacecraft potential can be measured accurately using the revised bias current. And furthermore, we demonstrate that the spacecraft potential measured by the revised bias current is very useful for obtaining the electron density in the magnetosphere and solar wind.

EXPERIMENTAL STUDY OF TRANSIENT CHARGING PHENOMENA OF A FLOATING BODY WITH ION BEAM EMISSION

Ikkoh FUNAKI[1], Hideyuki USUI[2], Hitoshi KUNINAKA[3], Masaki OKADA[4], Yoshinori NAKAYAMA[5] ([1]Institute of Engineering Mechanics and Systems, University of Tsukuba, [2]Radio Science Center For Space and Atmosphere, Kyoto University, [3]Institute of Space and Astronautical Science, [4]National Institute of Polar Reseach, [5]National Defense Academy)

Since 1960s, there were many space plasma experiments that actively emit charged particles in such forms as electron- or ion-beam from the satellites. Among them, spacecraft charging experiment by such projects as SCATTA, ATS6, in which the first spacecraft charging, and even successful control by those plasma beams were completed. However, it is regrettable these experiments require a whole spacecraft system that is developed for the specific experiments and available for only a short-term mission period. If a platform for plasma experiment is continuously executable in ISS, international space station, these opportunities will place a great impact on both scientific as well as engineering point of view. Based on such an idea, we are proposing a plasma experimental module for Japanese Experimental Module (JEM) ,that utilizes JEM´s unique feature, whose experimental module is directly exposed to space, accordingly, idealistic plasma experiment in semi-infinite space becomes possible. However, before realizing such a plasma experimental facility, strict assessment on the plasma environment around the plasma emitting device should be finished. Plasma experimental module onboard JEM, which we propose, is focused on such assessment, starting from a very small experiment on spacecraft to artificial plasma interaction. In this paper, the need and concept of the plasma experimental module for JEM are described with some initial test results, preliminary numerical analysis and future plans.

MHD SIMULATION OF THE EXHAUST PLASMA PLUME IN THE VASIMR ADVANCED PROPULSION CONCEPT

Alfonso G. TARDITI[1], John V. SHEBALIN[1], Edgar A. BERING[2] ([1]Advanced Space Propulsion Laboratory, NASA Johnson Space Center, Houston, TX (USA), [2]Dept. of Physics, Univ. of Houston, Houston, TX (USA))

VASIMR (Variable Specific Impulse Magnetoplasma Rocket, [1]) is an electric propulsion concept currently under experimental development at the Advanced Space Propulsion Laboratory, NASA Johnson Space Center. An RF (Helicon) discharge generates plasma (typically ionized Hydrogen or Helium) confined by a solenoidal magnetic field. The plasma is then further heated by a RF booster (in the ion cyclotron resonance frequency range) and finally flows through a magnetic nozzle where the thermal plasma energy is converted into kinetic energy along the longitudinal direction, enabling plasma detachment to produce thrust. The system has no electrodes and the magnetic field ensures magnetic insulation of the plasma from the material surfaces. By powering the plasma source and the heating antenna at different levels it is possible to vary smoothly of the thrust-to-specific impulse ratio while maintaining maximum power utilization. A MHD simulation modeling effort (NIMROD code [2,3]) is being carried on to study the plasma parameters and the detachment process of the plasma plume in the magnetic nozzle. In the model, a plasma source feeds a continuous flow through a nozzle-shaped magnetic field. Profiles of plasma density, temperature and flow velocity are then recorded at different times, while the plasma plume is formed in the magnetic field. Current simulations are set to model the plasma environment up to few meters from the nozzle throat: at that distance the plasma exhaust parameters reach values comparable with the ionospheric plasma background [4]. First, two-dimensional results (in cylindrical geometry) from simulation runs specifically designed for obtaining comparisons with laboratory measurements of the VASIMR experiment and first simulations of the plasma exhaust in 3D are here reported. USING THE HISTORICAL RECORDS OF SPACECRAFT MALFUNCTION DATA TO STUDY THE IMPACTS OF FUTURE SPACECRAFT OPERATION IN THE SPACE PLASMA ENVIRONMENT VERSUS THE SPACE DEBRIS ENVIRONMENT

Shin-Yi SU (NRC Senior Research Associate at NASA/JSC, Houston, Texas, U.S.A., On sabbatical leave from National Central University, Taiwan, R.O.C.)

There are many different kinds of spacecraft anomalies caused by the space environment. For the geosynchronous (GEO) satellites, the electrostatic discharge (ESD) has the most serious impact on the spacecraft operation. However, for the low Earth orbit (LEO) satellites, the impact of ESD has greatly diminished so that all the effects from the space plasma environment and the space debris environment will have equal impact. Although the published NASA/GSFC spacecraft operation records (Timmins, 1971; 1974; and 1975) have been studied with the Weibull distribution for the spacecraft operation lifetimes (Baker and

Baker, 1980), we have reanalyzed these records to obtain the average occurrence rate of malfunctions per satellite. A Monte-Carlo simulation is then performed to compare the malfunction occurrences in the space plasma environment with the impacts from the space debris environment. It is noted that although the current miniaturization of the electronic circuits in the spacecraft bus system will increase the vulnerability of the spacecraft operation in the space plasma environment as compared with the operation in the space debris environment, this report should still be valuable for comparison of the impacts from the two different environments to assess the future spacecraft operation.

THE IONOSPHERES OF VENUS AND MARS AND THEIR INTERACTIONS WITH THE SOLAR WIND

Hiroyuki SHINAGAWA (Solar-Terrestrial Environment Laboratory, Nagoya University)

Both Venus and Mars have no significant intrinsic magnetic field, and the solar wind interacts directly with the ionospheres. Previous studies of Venus suggest that the ionospheric thermal pressure (Pi) and the solar wind dynamics pressure (Psw) are the most important parameters, which determine the nature of the solar wind-ionosphere interaction. At Venus, when Pi is larger than Psw, the solar wind flow is deflected at high altitudes. The magnetic field pile-up region (the magnetic barrier) and the ionospheric plasma region are usually clearly separated by a sharp boundary, which is called the ionopause. However, when Psw is larger than Pi, the whole ionosphere is magnetized. Under such conditions, the ionopause tends to be thicker, and a magnetic field belt is formed in the lower ionosphere.The solar wind interaction with Mars appears to be more complicated than that of Venus. The magnetometer and electron reflectometer (MAG/ER) on Mars Global Surveyor (MGS) obtained magnetic field and plasma data throughout the near-Mars environment, from the solar wind to the bottom of the ionosphere (~110 km). It is found that the surface magnetic field of core origin is likely to be smaller than about 5 nT, indicating that the global intrinsic magnetic field at Mars does not play an important role in the solar wind interaction with Mars. Instead, MGS detected fairly strong (B <=1600 nT) magnetic anomalies which are considered to be of crustal origin. It is expected that the crustal magnetic field significantly affects the structure of the ionosphere.The ionospheres of Venus and Mars and their interactions with the solar wind are reviewed in light of recent observations as well as theoretical studies.

ELECTRIC FIELDS AT MERCURY

Lars G. BLOMBERG[1], Judy A. CUMNOCK[1] ([1]Alfven Laboratory, [2]Center for Space Sciences, University of Texas at Dallas)

Returning to Mercury with the BepiColombo mission will provide a unique opportunityto obtain in situ information on the electric field in Mercury's magnetosphere.The electric field plays a crucial role for plasma transport in the magnetoshere, fortransfer of energy between different parts of the system, and for propagation of information.Measuring the electric field, we will be able to better understand plasmamotion and wave propagation in Mercurys magnetosphere. Together with knowledgeof the magnetic field a better understanding will be derived of the magnetosphericcurrent systems and their closure at or near the planetary surface. Further insight intopossible substorms at Mercury will be gained. We summarize the scientific case forelectric field measurements on BepiColombo and outline the instrument design which,because of the harsh environment, is a challenging task.

HYBRID SIMULATIONS OF THE INTERACTIONBETWEEN SOLAR WIND FLOW AND THE HERMEAN MAGNETOSPHERE

Pavel TRAVNICEK[1], Petr HELLINGER[1], David SCHRIVER[2] ([1]Department of Space Physics, Institute of Atmospheric Physics, Czech Academy of Sciences, Bocni II. cp. 1401, 14131 Prague 4, Czech Republic., [2]Institute of Geophysics and Planetary Physics, University of California Los Angeles, Los Angeles, 90095-1567, U.S.A.)

We will examine the magnetosphere of Mercury using global three dimensional hybrid plasmasimulations. Hybrid simulations treat ions as particles and electrons as a fluid. Having ions as particles allows ion kinetic behavior and waves to be included in the physical treatment of theplasma as compared to magnetohydrodynamic (MHD) modeling that treats the plasma as a singlemagnetized fluid and does not include such kinetic effects. Kinetic effects are essential for understanding magnetospheric physics. Hybrid simulations scale to the ion inertial length and thus on a global scale are somewhat limited in spatial extent compared to an MHD simulation.The overal structure of the interaction between a magnetized obstacle in the solar wind flow isdetermined by few basic parameters (namely the solar wind density, background magnetic field,and the speed of solar wind, and also the strength of the magnetic dipole of the obstacle and its radius).The structure of the interaction of the solar wind flow with Mercury is to a large extend uniquewhen compared to other planets. For example, the magnetic moment of the Mercury is over1000 times smaller than that of the Earth and also the solar wind is stronger nearby Mercury thanat Earth´s vicinity. The typical magnetosperic scales are comparable to the ion gyroradii and hence kinetic effects are important for the overall structure of the interaction between the Hermean magnetospere and the solar wind.In this paper we shall focus on the study of structure of the bow shock formed in front of Mercuryunder different conditions of the solar wind flow. The existence of shocklets (multiple shocks) iswell known from observations of comets and it was also noticed in the Martian bow shock inmeasurements of Phobos spacecraft (not seen in Viking observations). The shocklets structurehas been subject of several two and three dimensional numerical studies of considering mainlyunmagnetized obstacles in the solar wind using hybrid code with different spatial resolution.We shall examine the overal structure of the Hermean magnetosphere describing most of the structures formed due to the interaction with the solar wind like the bow shock, protonforeshock, magnetopause, magnetosheath, northern and southern cusps and the currentsheath.

THE INTRIGUING MAGNETOSPHERE OF MERCURY

Michel MONCUQUET, Jean-Louis BOUGERET (LESIA, Observatoire de Paris)

The magnetosphere of Mercury is very different from all other known magnetospheres:Mercury has very rarefied atmosphere, with almost no ionosphere; he has also the smallest known magnetosphere (1/7 of that of Earth), that implies especially small scale size and short characteristic times of the magnetospheric processes.The planet occupies a much larger fractional volume of its magnetosphere than the Earth, and other planets. The magnetosphere of Mercury is exposed to much denser and hotter solar wind plasma and more intense interplanetary magnetic fields than any other planetary magnetosphere. These particular aspects of the Hermean Magnetosphere will be reviewed and some of associated magnetospheric processes will be compared to those at work in the Earth Magnetosphere. We will finally discuss how the BepiColombo/Mercury Magnetospheric Orbiter (MMO), and especially the radio experiment, should answer some of the questions asked by this intriguing magnetosphere of Mercury.

ENERGETIC PARTICLE DISTRIBUTIONS IN THE VICINITY OF IO

Richard M. THORNE[1], Donald J. WILLIAMS[2] ([1]Atmospheric Sciences, [2]Applied Physics Laboratory)

The Galileo Spacecraft has made several close passages of the moon Io. Pronounced changes in the energetic particle distributions were observed during each encounter. Some of these changes can be explained simply as an adiabatic response to changes in the magnetic and electric fields surrounding the moon. The two passes over the polar cap region of Io clearly demonstrate that the Jovian magnetic field is connected to the poles of Io and that most energetic particles are lost by collision with the moon. There is, however, a residual trapped population that mirrors between the enhanced field at the surface of Io and some point further up the field line towards Jupiter. A detailed analysis of the development of such trapped distributions indicates that the convective motion over the poles is dramatically reduced from that in the corotation flow upstream of the moon. Energetic electron beams arriving in a narrow cone from the direction of Jupiter indicate pronounced field-aligned acceleration in the region close to the planet. Such beams, which are found over each polar cap and within the wake region downstream of Io, provide an estimate of the spatial region of field-aligned currents that connect Io to Jupiter.

RELATION BETWEEN EXTENDED SODIUM DISTRIBUTION ORIGINATED FROM IO AND AROUND IO

Shin TAKAHASHI, Akira MORIOKA, Shoichi OKANO, Hiroaki MISAWA, Hiromasa NOZAWA, Masato KAGITANI (Planetary Plasma and Atmospheric Research Center, Tohoku University)

We have performed imaging observations of the D-line emissions of Iogenic sodium atoms. The method of the observation is the 2-dimensional imaging observations whose field of views are 20Rj (narrow FOV) and 400Rj (wide FOV) around Jupiter. From these observations, we investigated the characteristics of the emission distribution and its time variation. Based on these observations, we have also performed model analyses to investigate source processes of sodium atoms and time variation of sodium distribution, and presented the comprehensive source process which can consistently reproduce the observed characteristics. From these studies, we concluded that the composition of both charge exchange and molecular ion destruction processes are appropriate as source mechanisms of extended distribution of sodium atoms. The initial conditions of released sodium atoms through these two processes depend on the plasma environment around Io, so that we can investigate interaction between Io and the Jovian magnetospheric plasma by using spatial and temporal variation of extended sodium distribution.

IMPLICATION FOR THE SOLAR WIND EFFECT ON THE IO PLASMA TORUS

Hiromasa NOZAWA, Hiroaki MISAWA, Shin TAKAHASHI, Akira MORIOKA, Shoichi OKANO (Planetary Plasma and Atmospheric Research Center, Tohoku University, Aoba, Aramaki-aza, Aoba-ku, Sendai, 980-8578, JAPAN)

Jovian inner magnetosphere is characterized by strong magnetic field and fast rigid-rotation. Hence, it is considered that there is little solar wind effect in the inner magnetosphere and also around the Io plasma torus (IPT). However, the narrow band kilometric (nKOM) radio emissions whose sources are thought to be at the outer edge of the IPT showed solar wind dependence at the time of the Ulysses observation (Reiner et al. 2000). Therefore, it is suggested that there may be some relations between the solar wind and the IPT. Between September 4 and 22 in 1999, we carried out ground-based optical observation of the IPT. In this period, the Galileo orbiter was in the Callisto 23 Orbit and made observations of planetary radio emissions with the Plasma wave system (PWS) between September 13 and 27. From the comparison between the ground-based and Galileo/PWS observations, it was found that sudden enhancement of the IPT emission was concurrent with the appearance of nKOM. In addition, just prior to the IPT enhancement, we detected the enhancement of the hectometric (HOM) radio emission that would be related to the solar wind. From these evidences, it can be supposed that the IPT is affected by the solar wind.

OBSERVATION OF [SII] EMISSION IN IO PLASAMA TORUS USING AN IMAGING FABRY-PEROT INTERFEROMETER

Masato KAGITANI, Takeshi SAKANOI, Shoichi OKANO (Planetary Plasma and Atmospheric Research Center, Tohoku University)

Plasma originated from volcanic eruption on Jovian satellite Io forms a donut-shaped region of dense plasma along Io´s orbit, which is called Io plasma torus (IPT). Spectral line emission from singly charged sulfur ions, [SII], at 671.6 nm and 673.1 nm in IPT is strong enough to be observable from the ground. Imaging observation of sulfur ion emission with sufficient spectral resolution will enable us to monitor two-dimensional distributions of ion temperatures, line-of-sight velocities of ions, and emission intensity. In order to attain such purpose, we have developed an imaging Fabry-Perot interferometer (IFPI) for continuous observation of Io plasma torus. The IFPI is coupled to a 60-cm Coude telescope of our Iitate observatory (37.7ºN, 140.7ºE). Fabry-Perot etalon of the IFPI is characterized by wavelength resolution of .011nm and finesse of 40 at 671.6 nm. The gap of etalon is scanned in order to obtain two-dimensional distributions of above mentioned physical quantities, and spectral profile is recorded at each pixel of a CCD detector. Before starting actual observation, the best combination of observation parameters; the etalon scanning step, number of scanning

A

points, and exposure time, were determined based on simulation. Calibration of the IFPI was made using Ne spectral lamp, whose wavelength (671.704 nm) is within one free spectral range of the Doppler-shifted sulfur ion line, as a light source for determination of absolute wavelength, and a frequency stabilized He-Ne laser as a light source for determination of etalon finesse. Preliminary observation was made on November 23, 2002 (JST). Although the nature of observation is very preliminary, following results were obtained from analysis of the recorded data for the east ansa of IPT; (1) emission intensity at $6.05R_J$ was $600R$, (2) regarding line-of-sight velocity, slowing down from the corotation velocity at $6.05R_J$ was 5 km/sec, (3) ion temperatures perpendicular to the field line showed increase from $5.7R_J$ to $6.05R_J$, where the value was approximately 2×10^6K. From these results, it has been shown that the method is encouraging and we are going to continue monitoring observation of IPT.

A COMPARISON OF THE GANYMEDE MAGNETOSPHERE WITH THE EARTH'S MAGNETOSPHERE UNDER EXTREME SOLAR WIND AND IMF CONDITIONS

Aaron J. RIDLEY[1], K.C. HANSEN[1], F.J. CRARY[2] ([1]Center for Space Environment Research, University of Michigan, [2]Southwest Research Institute, San Antonio, Texas)

Ganymede has an intrinsic dipolar magnetic field. Because of the orbit of Ganymede in Jupiter´s magnetic field, it is constantly in a magnetic field dominated plasma. Earth is sometimes in this type of flow also - when the solar wind density is quite low and the magnetic field is quite high. This talk will show MHD simulation results of Ganymede´s magnetosphere in nominal conditions above and below Jupiter´s current sheet, and compare those simulation results to MHD simulation results of the Earth´s magnetosphere during very strong interplanetary magnetic field conditions. The relative size and structure of the different magnetospheres will be discussed. The solar wind and IMF conditions which produce a Ganymede-like Earth magnetosphere will be discussed. In addition, the frequency of such events at the Earth will be discussed.

THE MAGNETOSPHERES OF JUPITER AND THE EARTH: A COMPARATIVE ASSESSMENT

Margaret G. KIVELSON (Inst. of Geophysics and Planetary Physics)

The planetary magnetic fields of Earth and Jupiter exclude the solar wind from large volumes of space, the magnetospheres that surround these planets. Our knowledge of the Earth's magnetosphere relies on many decades of data from orbiting spacecraft supplemented by data from ground-based instruments from which a basic description of the structure and dynamics of this plasma regime has evolved. Galileo has recently completed a survey of the field and plasma properties of the Jovian system over a large range of radial distances (6-150 R_J) in the near equatorial regions and at all local times. These data, supplemented by remote observations of the aurora and complemented by data from previous spacecraft flyby missions, provide considerable insight into the structures and processes that control Jupiter's magnetosphere. After introducing selected salient features of both of these magnetospheres, I will first discuss the properties that these systems share in spite of the vast differences in their scale sizes and sources of plasma and energy. Next, I will touch on some features unique to each of the magnetospheres. I will discuss the roles of reconnection, planetary rotation and ionospheric conductivity in driving and maintaining plasma convection. The differences and similarities in the processes that generate aurorae in the atmospheres of these planets will also be examined. The evidence for intermittent processes that may be similar to terrestrial substorms in the magnetosphere of Jupiter will be presented and I shall comment on their relation to plasma convection and magnetospheric reconfiguration. I will first discuss the properties that these systems share in spite of the vast differences in their scale sizes and sources of plasma and energy. MAGNETOSPHERE-IONOSPHERE COUPLING CURRENTS IN JUPITER'S MIDDLE MAGNETOSPHERE

Jonathan D. NICHOLS, Stan W.H. COWLEY, Emma J. BUNCE (Department of Physics and Astronomy, University of Leicester)

The dynamics of Jupiter's plasma environment is dominated by the outflow of material originating from the moon Io, which orbits deep within the magnetospheric cavity. Breakdown of corotation associated with this radial transport results in the formation of a magnetosphere-ionosphere coupling current system which transfers angular momentum to the magnetospheric plasma and has been linked to the formation of the main jovian auroral oval. It has been shown that the amplitude and spatial distribution of the currents, and the related profile of the plasma angular velocity, depend on the values of the effective Pedersen conductivity of the jovian ionosphere and the mass outflow rate of iogenic plasma. In this talk we compute self-consistent solutions for this current system based on steady plasma outflow from the Io torus, and present our latest results.

GAIII.14/07P/A12-003   1445
DIPOLAR MAGNETOSPHERES: CHARACTERIZATION AND SCALES

Nick OMIDI[1], Homa KARIMABADI[1], X. BLANCO-CANO[2], Christopher RUSSELL[3] ([1]UCSD, [2]UNAM, [3]UCLA)

Hybrid simulations (kinetic ions, fluid electrons) of solar wind interaction with dipoles of various strength are used to characterize the resulting magnetospheres and establish the scales associated with the formation of various magnetopsheric boundaries and regions. It is shown that depending on the dipole strength, a spectrum of magnetospheric structures exist which can be characterized in terms of the distance ahead of the dipole where the magnetic field pressure balances the solar wind ram pressure (Dp). At low dipole strengths, the magnetosphere is fairly simple and consists of whistler and/or magnetosonic wakes. Increasing the dipole field results in the formation of progressively more complex magnetospheres with a number of different plasma regions separated by various types of waves or discontinuities. When Dp approaches ~ 20 ion inertial length, the resulting

magnetosphere exhibits a terrestrial type behavior. This result explains why despite their major differences in size, all magnetospheres in the solar system (e.g. Hermean and Jovian) have characteristics similar to the Earth's. Despite similarities, however, differences due to scale sizes are also expected. Implication of these results for the various bodies in the solar system ranging from magnetized asteroids to planets and moons are discussed.

EXTERNAL AND INTERNAL CONTROL OF THE MAGNETOSPHERIC CONFIGURATIONS AND DYNAMICS AT THE EARTH AND JUPITER

Raymond John WALKER[1], Tatsuki OGINO[2] ([1]Institude of Geophysics and Planetary Physics and Department of Earth and Space Physics, UCLA, [2]Solar Terrestrial Environment Laboratory, Nagoya University)

At the Earth magnetospheric dynamics are largely controlled by the solar wind and interplanetary magnetic field. Internal processes contribute to the details of magnetospheric dynamics but the energy required to power the system comes from the solar wind. At Jupiter the dominant energy reservoir is within Jupiter's magnetosphere. That energy reservoir is Jupiter's plasma disk which is powered by Jupiter's rotation. The existence of the magnetodisk is a major difference between the Earth's magnetosphere and that at Jupiter. On the dayside it is located between the inner magnetosphere where Jovian effects are dominant and the outer magnetosphere or cushion region where the solar wind influence is great. We have used a three dimensional global magnetohydrodynamic simulation of the interaction of Jupiter's magnetosphere with the solar wind to investigate the structure of Jupiter's magnetosphere. The emphasis in this study is on the extent to which the solar wind affects the structure and dynamics of the magnetodisk. The plasma in the magnetodisk flows around Jupiter. The azimuthal flow is largest in a band from 1800 LT across the night side magnetosphere to noon and between $30R_J$ and $50R_J$ from Jupiter. Between noon and dusk the azimuthal flow decreases. The region of largest azimuthal flow is also characterized by smaller flows away from Jupiter with maximum outflow predawn. The region where the azimuthal flow decreases contains radial flow toward Jupiter. The simulated equatorial plasma sheet is much thinner in the morning magnetosphere than in the afternoon magnetosphere as has been inferred from observations. The plasma sheet is thickest where the radial flow is toward Jupiter. The configuration of the middle magnetosphere is only weakly dependent on solar wind dynamic pressure. However, the radial inflow decreases when the IMF turns from northward to southward.

PARTICLE MOTION IN JUPITER'S MAGNETOSPHERE COMPARED TO THE EARTH'S CASE

Norbert KRUPP[1], Joachim WOCH[1], Andreas LAGG[1], Krishan KHURANA[2] ([1]Max-Planck-Institut f. Aeronomie, [2]IGPP, UCLA)

Comparing the motion of plasma and energetic particles in different planetary magnetospheres provides new insights into the physical processes of these large-scale plasma laboratories in space and extends our knowledge of the solar system as a whole. Especially important information is obtained about the steady-state configuration and the dynamic processes of these magnetospheres. In this paper the observational facts of particle motion in Jupiter's magnetosphere is reviewed and compared with the well known pattern in the Earth's case. This study is essentially based on in-situ measurements from Galileo which is orbiting Jupiter since 1995 obtaining the most complete data set of the Jovian system. For the first time it was possible to determine details about the particle motion in the equatorial plane of Jupiter's magnetosphere. These results will be compared with the well-known processes in the Earth's magnetosphere achieved over the last decades. A comparison of the particle motion in both magnetospheres revealed both similarities and significant differences. At Earth, magnetospheric convection is driven by the solar wind whereas in the Jovian case planetary rotation is far more important. Another very important difference lies in the particle sources and in the composition of magnetospheric plasma - solar wind and ionosphere in the Earth's case and mainly the moon Io for Jupiter ÅElead to completely different global flow pattern. Similarities are also found in the comparison between both magnetospheres. The well-known substorm scenario at Earth could have its counterpart at Jupiter where flow bursts together with magnetic field rotations and auroral emissions were observed. This suggests that substorm-like events (eventually internally triggered) have been observed at Jupiter.

PLASMA SOURCES FOR SATURN'S MAGNETOSPHERE

John d RICHARDSON, Slobodan JURAC (Center for Space Research, M.I.T.)

The magnetosphere of Saturn, in contrast to that of Earth, has numerous orbiting sources of plasma. The rings and inner icy satellites are sources of water group neutrals which become ionized and contributed to the plasma population. Titan´s atmosphere is a source of H and N. The main sources of plasma in Earth´s magnetosphere are the solar wind and ionosphere; while these sources provide plasma at Saturn, they provide only a small percentage of the total plasma. We present models of the sputtering of water from Saturn´s orbiting icy bodies, formation of the neutral cloud surrounding Saturn, and the transport and energy balance of the plasma. The model results match well observations of OH by the Hubble Space Telescope and of plasma by Voyager. The required source of neutrals is larger than sputtering theory predicts. A possible solution to this problem is suggested; a large number of small ice grains providing additional surface area for sputtering.

GAIII.14/07P/A12-007   Invited   1625
PLANETARY AURORAE

Renée M. PRANGE, Philippe ZARKA (LESIA, Observatoire de Paris)

The Voyager missions have revealed the presence of auroral features surrounding the magnetic poles for all the magnetized planets in the solar system which also possess an atmosphere. Since then, planetary aurorae have been thoroughly studied on Jupiter, from Earth orbit and by means of the visible camera and of the UV spectrometer on board the Jupiter orbiting Galileo spacecraft. Increased performances of the Hubble Space Telescope instruments have also recently allowed to take very good images and spectra of the UV aurorae on Saturn in the prospect of Cassini's arrival in the planet vicinity. At all planets counterparts of these auroral emissions are found, from earth-based receivers and from space, in the radio spectral range. Taking advantage of these two complementary diagnostic tools, I will give an overview of the morphology, temporal behavior, and suggested auroral processes in the magnetosphere for the Earth, Jupiter and Saturn, taking a comparative point of view approach.

GAIII.14/07P/A12-008   1650

COMPARISON OF AURORAL PROCESSESON JUPITER AND THE EARTH

John T. CLARKE (Center for Space Physics, Boston University)

High resolution images of Jupiter´s UV aurora obtained over thepast 4-8 years have revealed with increasing detail and sensitivity the auroral patterns on that planet. We are now beginning to learnthe relationships between the auroral emissions and other propertiesof Jupiter´s giant magnetosphere. Jupiter´s aurora include a mainoval related to the breakdown of corotation of outwardly driftingplasma in the middle magnetosphere. This region is most analogousto the outer boundary of the Earth´s plasmasphere. Jupiter also displays auroral emissions from the magnetic footprints of at least 3 satellites, for which there is no analogous process at the Earth.Finally, the polar regions of Jupiter´s aurora, which are also the most rapidly variable, are most analogous to the Earth´s auroralregions, in the sense that they must map to the general vicinityof the magnetosphere/solar wind boundary. The characteristics ofJupiter´s polar emissions are nonetheless quite different fromthose of the Earth´s aurora. These analogies will be discussedand expanded upon in this presentation, supported by images ofJupiter´s aurora obtained from the Hubble Space Telescope.

GAIII.14/07P/A12-009   1705

SPECTRUM OBSERVATION OF JUPITER'S SYNCHROTRON RADIATION AT THE FREQUENCIES OF 325, 929 AND 2295MHZ

Hiroaki MISAWA[1], Fuminori TSUCHIYA[1], Yoshizumi MIYOSHI[1], Akira MORIOKA[1], Tetsuro KONDO[2] ([1]Planetary Plasma and Atmospheric Research Center, Tohoku University, [2]Communications Research Laboratory, Independent Administrative Institution)

Jupiter's synchrotron radiation (JSR) is generated by the relativistic electrons trapped in Jupiter´s radiation belt. Variation of JSR is, therefore, an important probe to investigate generation and dissipation processes of the relativistic electrons and deformation of their global distribution in Jupiter´s inner magnetosphere. For more than 40 years since its discovery, JSR has been thought to be quite stable emission except for a long-term variation at a time scale of nearly the solar-cycle. However regular and systematic JSR observations have been made by several groups particularly after the event of the comet P/SL9 impacts to Jupiter, and revealed the existence of short term variations at a time scale of several days to months inferring some electro-magnetic activities in the inner magnetosphere. Nowadays it's the time to investigate the details of variation characteristics and origin of the time variation. A program of a multi-frequency observation for JSR has been started since 2001. The JSR spectrum measurements give us information of variations of pitch angle and/or characteristics of radial diffusion of the relativistic electrons. In this program three observation frequencies measured with different facilities are adopted; i.e., 325MHz at Tohoku Univ. and Nagoya Univ., Japan, 929MHz at EISCAT, and 2295MHz at Comm. Res. Lab.(CRL), Japan. As for the 325MHz observation, although the Tohoku Univ. system will start the regular JSR observation in the middle of 2003, the Nagoya Univ. system has made the JSR observations for about three months a year since 1995. The observation method has been already established at 2295MHz using the CRL system by our group. On the other hand, we made test experiments for JSR using the EISCAT 929MHz system in the autumn of 2001 and made ten successive day observation in the end of November of 2002. Now we plan to make the spectrum observation with these there frequencies in this autumn. In the presentation, outline of the spectrum observation and present status will be shown with the objectives of this program.

GAIII.14/07P/A12-010   1720

ON THE ORIGIN OF THE POLARIZATION CHARACTERISTICS OF JUPITER'S DECAMETRIC RADIATION

Hiroaki MISAWA (Planetary Plasma and Atmospheric Research Center, Tohoku University)

The Io-related Jupiter´s decameter wave emission (Io-DAM) is known to show two clear occurrence characteristics. One is the occurrence periodicity and another one is the polarization characteristics. The former is that the Io-DAM events occur in specific geometric combinations of the central meridian magnetic longitude and Io phase angle. The latter is the theme of this study, and shows following somewhat unique nature. 1)The Io-DAM events show highly elliptical polarization, which is observed only for certain pulsars except Io-DAM. 2)The degree of polarization of one Io-DAM event doesn´t show a significant time variation for a few hours. 3)Although the degree of circular polarization decreases slightly with frequency, in most cases, the degree of polarization changes very little with frequency. 4)The degrees of circular or linear polarization between Io-A and Io-B DAM events show slight difference; i.e., the Io-A events are slightly more circular than the Io-B events. The elliptical polarization of the Io-DAM events was explained by Melrose and Dulk[1991, 1993] based on the cyclotron maser theory and strong magneto-ionic mode coupling assumption in and near the source region: 1)the Io-DAM wave is generated at an angle (T) of 60 to 80 degrees with respect to the local magnetic field and starts out in elliptical polarization. 2)the plasma in and near source region is quite tenuous, say less than 5 per cc, then, the elliptical polarization retained during propagation. If the idea is correct, the expected axial ratio (AR) of an event is denoted as AR=cos(T). Misawa et al.[1997] examined this explanation by comparing the observed AR with the AR value calculated from the angle between the local magnetic field of the expected source region and the direction of an observer (the earth) for each datum, and showed that the observed AR values are not interpreted by the idea. Instead of the idea of Melrose and Dulk[1991], Shaposhnikov et al.[1997] took into account the effect of plasma continuity (weak or no mode coupling condition) in and near the source region and showed the possibility of polarization variation of the Io-DAM wave during ray propagation using a simple models of the Jovian magnetosphere and ionosphere. We have made a 3D ray tracing analysis for Io-DAM to investigate the observed occurrence periodicity and polarization characteristics of Io-DAM by using the GSFC VIP4 magnetic field model. In this study, we have evaluated polarization characteristic based on the assumption of plasma continuity in and near source regions and have traced variation of polarization along a ray path. Preliminary results show some possibilities for explaining some of the above mentioned unique polarization characteristics of Io-DAM with the assumption of plasma continuity.

GAIII.14/07P/A12-011   1735

ELECTRIC FIELDS IN THE JUPITER'S MAGNETOSPHERE (COMPARISON WITH THE CASE OF THE EARTH)

Elena Semenovna BELENKAYA (Institute of Nuclear Physics, Moscow State University)

In a constructed model of the jovian magnetosphere the magnetospheric magnetic field consists of Jupiter´s dipole field, the magnetodisc field, and the field of the magnetotail current system. All magnetospheric magnetic fields are screened by the magnetopause currents.Interplanetary magnetic field partially penetrates into the magnetosphere. The

electric fields and plasma motions caused by the Jupiter´s rotation and the solar wind MHD generator are studied. The comparison with the case of the Earth is fulfiled.

WHAT CAN SEE A MAGNETOMETER ON NOZOMI MISSION AT THE VICINITY OF PHOBOS?

Valentina G. MORDOVSKAYA, Victor N. ORAEVSKY (Institute of Terrestrial Magnetism, Ionosphere, and Radiowave Propagation (IZMIRAN))

In this communication, we examine in situ observations of the magneticfield in the vicinity of Phobos on the ˝Phobos-2˝ mission and givesome analysis of the data during a unique experiment ``CelestialMechanics,´´ which leads to the evidence of the Phobosmagnetic field. In particular, it is suggested that the peculiarity ofthe solar wind interaction with Phobos and rotating direction of themagnetic field obtained on the circular orbits around Mars are theevidence for the existence of an intrinsic planetary field of Phobos.Vector magnetic field observations of the solar wind interaction with Phobos were acquired by MAGMA and FGMM during Phobos-2 mission inregions which have not been explored before. Phobos deflects the flowof the solar wind and the subsolar stand-off distance of the deflectionis about 16-17 Phobos radii. Source with equivalent magnetic momentM´= 10^(15) A\m^2 in Phobos leads to the development ofsuch an obstacle for solar wind flow around Phobos.1. THE PECULIARITIES OF THE INTERACTION OF PHOBOS WITH THE SOLARWIND ARE EVIDENCE OF THE PHOBOS MAGNETIC OBSTACLE (FROM PHOBOS-2 DATA)V.G. Mordovskaya, V.N. Oraevsky, and V.A. AN ENA INSTRUMENT FOR MERCURY MAGNETOSPHERIC ORBITER OF THE BEPICOLOMBO MISSION

Yoichi KAZAMA[1], Stas BARABASH[1], Kazushi ASAMURA[2], Andrei FEDOROV[3], Peter WURZ[4] ([1]Swedish Institute of Space Physics, [2]Institute of Space and Astronautical Science, [3]Centre d'Etude Spatiale des Rayonnements, [4]University of Bern)

It is known that Mercury has an intrinsic magnetic field, which formsthe Hermean magnetosphere. Energetic magnetospheric ions and the solarwind directly hit the surface, and sputter material to populate theexosphere. Since the spectrum of the sputtering neutral atom isrelatively hard, neutrals with energies above tens eV are produced inlarge amount. Therefore the interaction region between precipitatingions and the Mercury surface is a strong source of low energy ENAs(energetic neutral atoms). Some exospheric neutrals are ionized bycharge-exchange process with magnetospheric ions and the solarwind. Once a particle is ionized, the particle is acceleratedimmediately due to electric field up to keV range. The energeticparticle strikes again the Hermean surface, constituting a cyclicprocess. The energetic ions are re-neutralized with some probability,resulting in high-energy ENAs around Mercury. Mentioned above, themagnetosphere, exosphere, and the surface are tightly coupled throughneutral particles at Mercury. Therefore, neutral particle measurementis one of the important targets of the BepiColombo mission to gainknowledge about the particle environment around Mercury. The solarwind ions injected from the tail in the sub-storm/storm alikeprocesses as well as from direct penetration of the solar wind can bealso charged-exchanged to ENA. Therefore, the ENA measurements providemagnetospheric imagery , that give us important information on thedynamics and structure of the Hermean magnetosphere, as has theterrestrial ENA. To observe ENAs comprehensively around Mercury, wepropose an instrument on MMO in the BepiColombo mission. Theinstrument can cover neutrals in a wide range of energies, fromsputtered particles to accelerated neutrals with sufficient time andangular resolutions. Following very tight mass budget the priority,however, will be given to the mass resolution capability of theinstrument (ENA mass spectroscopy) to fully investigatemagnetosphere-exosphere-surface relations taking place at Mercury.Neutrals entering the instrument are ionized by carefully producedsurfaces at first, and then selected in energy by well-designedelectrostatic multiple reflections, in which a huge number of solarphotons are rejected. Mass analysis is done by permanent magnets, andfinally the particle is detected by an imaging MCP detector.

THE MAGNETIC FIELD EXPERIMENT FOR BEPI-COLOMBO MMO

Ayako MATSUOKA[1], Wolfgang BAUMJOHANN[2], The MERMAG-M CONSORTIUM[3] ([1]Institute of Space and Astronautical Science, [2]Institut fur Weltraumforschung, Graz)

The MERMAG-M consortium is now preparing to propose a magnetic field experiment for Bepi-Colombo MMO. We have examined the design and performance of magnetometers to measure fields around Mercury with good accuracy. It consists of two sets of ring-core geometry sensor and electronic system with an extensible arm. One of the sensors (outboard) is mounted at the top of the arm and the another one (inboard) is at the 1/3 distance of the arm length from the top. The dual measurement enables not only good evaluation of the magnetic interference caused by the satellite body, but also a reliable redundancy of the measurement. Because the instruments on board MMO are expected to suffer acute radiation and heat inflow from the sun, measures against them without additional weight have been particularly examined. For the outboard sensor, the electronics is designed so that most signal processing is done digitally in the field programmable gate array (FPGA). It resolves the problem of the offset drifting which is caused by the change of temperature in the conventional analogue electronics. For the inboard sensor, the electronics is relatively similar to the conventional analogue circuit, but the robustness against the radiation is highly increased. An international collaboration has worked very well to proceed the examinations described above.

BEPICOLOMBO MISSION: SCIENTIFIC EXPECTATIONS AND CURRENT STATUS OF MERCURY MAGNETOSPHERIC ORBITER (MMO)

Hajime HAYAKAWA[1], Yasumasa KASABA[1], Hiroshi YAMAKAWA[1], Hiroyuki OGAWA[1], Toshifumi MUKAI[1], Masaki ADACHI[1], Mercury Exploration WG[1] ([1]Institute of Space and Astronautical Science, [2]NEC-TOSHIBA Space Systems, Ltd.)

BepiColombo for the exploration of Mercury is the first collaborated mission between Europe (ESA) and Japan (ISAS). The aim of this mission is to clarify present and past of Mercury by investigating interior, surface, atmosphere, and magnetosphere, by 2 orbiters and 1 lander, which are MPO (Mercury Planetary Orbiter), MMO (Mercury Magnetospheric Orbiter), and MSE (Mercury Surface Element). Intensive contribution to this project is essentially expected for Japanese earth \& planetary science community. ISAS will provide the MMO spacecraft. In this paper, we report our scientific expectations for and current status of the MMO mission study, which was conducted by the ISAS Mercury Exploration Working Group. Main scientific targets of MMO are 1) Structure and origin of Herman magnetic field, 2) Structure, dynamics, and physical processes of Herman magnetosphere, 3) Structure, variation, and origin of Herman Na atmosphere, 4) Macroscopic structure of Herman crust, and 5) Physical environment of inner solar system. For these targets, MMO will have 10 model payloads: Electron Spectrum Analyzer (ESA), Mass Spectrum Analyzer (MSA), Solar Wind Analyzer (SWA), High Energy Particle (HEP), Energetic Neutral Atoms (ENA), Magnetic Field sensor (MGF), Plasma Wave Instrument (PWI), Mercury Dust Monitor (MDM), and Mercury Imaging Camera for Atmosphere (MIC-A) & for Surface (MIC-S).For these targets, MMO, which weighs about 200kg, is as a spinning spacecraft at 15 rpm whose spin axis is perpendicular to the Mercury orbital plane. MMO will be at polar orbit with the period of 9.2hour, the periherm of 400km and the apoherm of 12,000km (~6RM). It is selected for the observations of large regions in the Herman magnetosphere, mappings of magnetic field and surface, and macroscopic imaging of the Na atmosphere. The telemetry ability will be 20~160Mbytes/day (~40Mbytes/day [ave]). Data production rate will show large seasonal variation, because the data rate of in-situ plasma instruments is correlated to the duration staying in the magnetosphere and varies in 20~75MB/day. So basic policy of the operation is storing in the high-production term and reproducing in the low-production term. Mission life is 1 Earth year (~4 Mercury year). The specifications of the model instruments in this paper are for the basis of spacecraft investigations and not final ones. Actual selection of the instruments is based on the results of Announcement of Opportunity (A/O) in Japan and Europe. In the current plan (Jan 2003), the A/O for MPO (from ESA) and MMO (from ISAS) payloads will be issued in June 2003.

MERCURY MAGNETOSPHERE: EXPECTED PROGRESS BY BEPICOLOMBO/MMO

Hajime HAYAKAWA, Yasumasa KASABA, Toshifumi MUKAI, Hiroshi YAMAKAWA, Hiroyuki OGAWA, Mercury WG (Institute of Space and Astronautical Science)

More than 25 years ago the Mariner 10 observations discovered the presence of the intrinsic magnetic field which was strong enough to stand off the solar wind and form the magnetosphere. According to the limited data from Mariner 10, the Mercury´s magnetosphere has been drawn schematically by analogy from the Earth´s one, so that it is apparently similar to the Earth´s magnetosphere, being scaled down by a factor of 7-8 with normalization by the planetary radius, or by a factor of 20 in the real dimension. There have also been addressed several unique features, such as large occupation of the planetary body in the magnetosphere, no significant atmosphere and ionosphere, and the direct interaction of magnetospheric plasma with the planetary surface. Thus the Mercury has long been one of the most interesting objects in the field of comparative magnetospheric physics. For example, we should note that the scaling with the Earth´s viewpoint may not necessarily hold in the internal structure of the magnetosphere. There are difficulties to adopt the simple scaling-law to the Mercury´s magnetosphere. Average solar wind dynamic pressure at Murcury orbit is 7-8 times lager than that of Earth orbit. This requires stronger magnetopause current which is same as plasma sheet current than earth´s magnetosphere case, if flaring angle of the magnetosphere is same as earth´s magnetosphere. Also thickness of the Mercury´s plasma sheet expected from the scaling-law is only several hundred km which is comparable to the so-called ˝very thin plasma sheet˝ in the earth´s magnetosphere. These facts suggest that the Mercury´s plasma sheet current layer may be unstable if the scaling-law is correct, or the current sheet thickness is much larger than that expected from the scaling-law. Furthermore in the Earth´s magnetosphere, when magnetic reconnection occures, reducedcross tail current generates FAC and flows in the ionosphere to close the currentcircuit. But in the Mercury´s magnetosphere this bipass circuit may not be possiblesince there is no ionosphere. The planetary body acts as a large plasma sink and the source of heavy ions, so this also provides us other ambiguous aspects. We do not know yet what is really happened in the Mercury´smagnetosphere and how the structure is BepiColombo/MMO will reveal these misteries and provide essensial keys for the magnetospheric physics.

DEVELOPMENT OF IITATE PLANETARY RADIO TELESCOPE (IPRT) FOR THE INVESTIGATION OF THE JOVIAN INNER MAGNETOSPHERE

Fuminori TSUCHIYA[1], Hiroaki MISAWA[1], Riichi KUDOU[1], Yoshizumi MIYOSHI[1], Takuo WATANABE[1], Akira MORIOKA[1], Tetsuro KONDO[2] ([1]Graduate School of Science, Tohoku University, [2]Communications Research Laboratory)

Iitate Planetary Radio Telescope (IPRT) which measures meter to decimeter radio waves has been developed at the Iitate village in Fukushima Prefecture, Japan. Primary purpose of IPRT is continuous monitoring of Jovian synchrotron radiation (JSR) and research of the dynamics in the Jovian inner magnetosphere by detecting short-term variations of JSR with the time scale of a few days to a few months. The short term variation reflects dynamic transport and acceleration processes of relativistic electrons in the inner radiation belt of Jupiter. The total flux observation of JSR by using a single dish telescope is a useful tool for the investigation of the acceleration and transport of relativistic electrons because the spectrum and polarization of JSR reflect energy spectrum and pitch angle distribution of the relativistic electrons in the Jovian inner radiation belt, respectively. IPRT is an offset parabola antenna whose physical aperture area of 1023 m². The front-end receivers and normal half-wave dipole feed system for 325MHz were already set up. The test observations of some calibration stars showed that the noise temperature of the receiver system and the aperture efficiency of the telescope achieved 83K and 50%, respectively. The shape of IPRT is very unique; the primary reflector is composed of two separate but same-shaped parabolic rectangle sections and installed on one altitude-azimuth mount. In order to match a beam pattern of the feed system with the rectangular shaped reflector, we developed beam forming technique and applied it to a dipole feed system. The numerical simulation and the experiment in a radio anechoic chamber showed that the beam forming feed system achieved high aperture efficiency of 70%, which makes possible highly sensitive measurement radio emission of Jupiter and other radio stars. The back-end receiver system

for the total power measurement and the new beam forming feed system for 325 MHz will be set up in February 2003, and continuous monitoring of JSR will be started from this spring.

THE DUAL FREQUENCY INTERFEROMETER OBSERVATION FOR JOVIAN DECAMETRIC RADIATION

Tomoyuki NAKAJO[1], Takayuki ONO[1], Masahide IIZIMA[1], Hiroshi OYA[2] ([1]Department of Geophysics, Graduate School of Science, Tohoku University, [2]Fukui University of Technology)

For understanding the generation mechanism of the Jovian decametric radiation (DAM), identification of the propagation mode by clarifying the source location as well as the polarization character is one of the most important observations. Although a long baseline interferometry is a unique method to identify the source location directly (whether the DAM source is located in northern or southern ionosphere of Jupiter), the method is significantly suffered from the effect of irregularities of the earth´s ionosphere. To solve this difficulty, we have developed the double frequency long baseline interferometer system. The new observation system has been developed in Tohoku university in Japan by employing three member stations, Zao, Yoneyama and Iitate. These stations are adequate to identify whether the DAM source is located in northern or southern ionosphere of Jupiter because the baseline length is ranging from 50 to 116km. The receiving system consists of three parts, i.e. the front-end, the main receiver and the data recording system. The front-end consists of a log-periodic antenna, a band pass filter whose passband is 20-30MHz, and a low noise wide-band pre-amplifier. The main receiver consists of two sets of double super-heterodyne receivers to carry out the double frequency observation and the received RF signal is converted into the frequency range from 5 to 15kHz and this output signals are digitized directly by the data recording system. The phase stability of the observation system is essentially decided by the stability of main receiver. The stability is achieved to be 1.0 (degree/C) by using Direct Digital Synthesizer (DDS) whose reference signal is fed by the cesium frequency standard (the phase stability of band pass filter and pre-amplifer is about 0.1degree/C). In order to evaluate the quality of the data, the temperature measurements and the phase calibration is carried out. From the results of performance evaluation by the simulation study, it has been estimated that this observation system will allow us to decide the source location of DAM with an accuracy of 25 arcsec (about 0.5 Jovian radii) under the condition of temperature fluctuation less than 5.0 degree under the condition of TEC fluctuation less than $1.0{\times}10^{16}$ [el/m^2] which is typical for the observation time interval of DAM (within a few ten minutes).

THE ORIGIN OF WHISTLER WAVES AT INTERPLANETARY SHOCKS

Kouta NAKATA[1], Toshio TERASAWA[1], Nobue SHIMADA[2], Hiroshi MATSUI[3], Iku SHINOHARA[4] ([1]Department of Earth and Planetary Science, University of Tokyo, [2]Communication Research Laboratory, [3]University of New Hampshire, [4]Institute of Space and Astronautical Science)

Whistler waves are generally considered to play important roles in the electron dynamics at collisionless shocks. However, generation problem of these waves is not yet completely solved. In this report, we first introduce GEOTAIL observations of whistler wave enhancement in the foreshock region of several interplanetary CME shocks, where energetic electrons (several hundred eV - several tens of keV) are seen to be accelerated through the shock Fermi mechanism. Next we show that these whistler waves are responsible for pitch-angle scattering of low energy electrons ($<$~1keV), namely the injection process needed for the Fermi mechanism to work. For the origin of these whistler waves, we consider (1) generation at the shock front or in the downstream region and successive upstream propagation, as well as (2) the nonlinear cascading process of the lower frequency MHD waves, which are excited by nonthermal ions accelerated at the same CME shocks. We will discuss the relative importance of these two processes.

GAIV.02/07A/A07-002 — 0930

STRUCTURE, FORMATION AND DYNAMICS OF SHOCK WAVES

Bertrand LEMBEGE (CETP/IPSL/UVSQ)

Collisionless shocks are quite common throughout the heliosphere in association to coronal mass ejection, to travelling and planetary bowshocks and to the outer heliosphere. These represent excellent energyconverters from bulk energy to particles kinetic energy. A large part ofthis conversion takes place at and/or around the shock front itself. Forthis reason, shocks are quite often invoked as attractive candidates forbeing responsible for particles acceleration; in a second step, someaccelerated particles may reach energies large enough to representnoticeable sources of radiation. The difficulty is (i) to determine whichacceleration process is dominant around the front and (ii) to verifywhether appropriate conditions are satisfied for particles to getsignificant energies during the process of concern. Recent works based onnumerical simulations and motivated by sophisticated mono- and/ormulti-spacecrafts missions (as CLUSTER-2) have clearly stressed that : (i) shocks front is highly nonstationary and nonuniform. Thenonstationarity takes place over quite different spatial/time scales whichhave been partially identified at present time. Moreover, the mechanismsresponsible for the nonstationarity totally differ from quasi-perpendicularto quasiparallel shocks. (ii) the efficiency of the particles acceleration strongly dependsnot only on the spatial width of the front itself but also on itsnonuniformity features (i.e. front rippling) and on its nonstationarydynamics. This suggests that simplified stationary shock models are notappropriate and that multidimensionality plays an important role.. This presentation will review results of these recent works andwill try to identify the key questions which are still open.

NONLINEAR REPLENISHMENT OF THE DISSIPATION RANGE AND STOCHASTIC ION HEATING IN THE SOLAR CORONA AND WIND

Yuriy M. VOYTENKO, Marcel GOOSSENS (Centre for Plasma Astrophysics, K.U.Leuven)

The perpendicular energization of the ions in the solar corona and solar wind has been mainly attributed to MHD waves that undergo either turbulent cascade or cyclotron sweep, transporting the wave energy in the dissipation range of ion-cyclotron waves. However, the ion-cyclotron scenario is not free from difficulties and is not unique. We study an alternative possibility that the dissipation range is formed by the kinetic Alfven waves, which have a sufficiently short wavelength across the magnetic field for the dissipative effects to become significant. The energy reservoir is provided by the large-scale MHD waves launched by the photospheric motions or magnetic restructuring at the coronal base. However, instead of following local nonlinear interactions among MHD waves, which are rather slow, we study the nonlinear excitation of KAWs via three-wave resonant interaction. We show that the presence of the finite-amplitude MHD waves, polarized in the sense of fast and/or Alfven wave, gives rise to the nonlinear excitation of KAWs via three-wave resonant interaction (jump-like transport of MHD wave energy directly in the dissipation range). Short transversal wavelengths of the order of the proton gyroradius make KAWs accessible for the stochastic heating of ions if the wave/background magnetic field ratio exceeds a critical value, proportional to the charge-to-mass ratio q/m of the ion. The resulting ion energization is primarily in the direction perpendicular to the background magnetic field. This process provides an alternative to the ion-cyclotron explanation for the transverse energization of ions (in particular, observed by SOHO at 2-4 solar radii). References: [1] Voitenko Yu.M., Goossens M. Nonlinear excitation of small-scale Alfvén waves by fast waves and plasma heating in the solar atmosphere. Solar Phys., 209, 37-60 (2002).

MHD INTERACTION OF THE SOLAR WIND AND LISM

Haruichi WASHIMI[1], Takashi TANAKA[2] ([1]Shonan Institute of Technology, [2]Kyushu Univ.)

The global structure of the heliosphere under the interaction between the solar wind plasma and the local interstellar medium is studied by MHD computer simulation. A new type structure, i.e., a V-shaped gutter on the nose-cone surface of the heliopause caused by MHD processes is found in this simulation. The V-shaped gutter is also found on the termination shock surface, and both gutters are found to almost touch on the ecliptic. Hence the width of the heliosheath near the ecliptic becomes negligibly thin in our new model.

GAIV.02/07A/A07-005   1130

SOLAR WIND ENCOUNTER WITH STRONGLY MAGNETIZED INTERSTELLAR MEDIUM:PURELY MHD AND MULTIFLUID MODELLING

Nikolai V. POGORELOV[1], Vladimir FLORINSKI[2], Gary P. ZANK[2], Donald P. COX[3] ([1]Institute for Problems in Mechanics, Russian Academy of Sciences, Vernadskii Avenue 101-1, Moscow 119526, RUSSIA, [2]Institute of Geophysics and Planetary Physics, University of California, Riverside, CA-92521, U.S.A., [3]Physics Department, University of Wisconsin-Madison, University Avenue 1150, Madison, WI 53706, U.S.A.)

Uncertainties in the value of the magnetic field in the local interstellar cloud and its direction with respect to the solar system ecliptic plane stimulate the analysis of the solar wind (SW)--interstellar medium (LISM) interaction problem, where these quantities act as free parameters. The range of their variation is defined by available observational data interpreted on the basis of theoretical models describing the origin and evolution of the interstellar cloud. Most previously obtained results dealt with magnetic field values below 3 microgauss. Since the LISM flow is super-fast magnetosonic in this case, the heliospheric interface involves two shock waves: a SW termination shock and a bow shock. Conversely, for stronger magnetic fields Parker´s solution for the supersonic source inflow into the uniformly magnetized interstellar gas at rest contains only a termination shock. Crossing it, the solar wind moves along the symmetry axis to infinity pushing aside magnetic field lines. There exist strong physical arguments in favor of substantially sub-Alfvenic LISM velocities nearly parallel to the magnetic field direction. We study an axially symmetric and a three-dimensional SW--LISM interaction under such conditions both in a purely MHD statement and in the framework of a newly developed four-fluid model. The latter includes protons and various populations of neutral hydrogen atoms. Simulation of a plasma-alone flow gives a solution in many aspects similar to Parker´s. It is no longer correct if neutral atoms are added, since under certain circumstances the bow shock remains even in the case of a sub-Alfvenic LISM flow. Lyman-alpha absorbtion profiles are calculated in order to reveal consistency of the developed models with the currently available observational data.

GAIV.02/07A/A07-006   1200

COMPLEXITY: NEW INSIGHTS FOR SPACE PHYSICS

Tom T.S. CHANG (Center for Space Research, Massachusetts Institute of Technology)

˝Complexity˝ has become a hot topic in nearly every field of modern physics. Solar wind plasmas are of no exception. Recently, Chang [2002], in analogy with theories developed for phenomena observed in the magnetotail and the auroral zone [Chang, 1999; 2001], demonstrated that the sporadic and localized interactions of magnetic coherent structures arising from plasma resonances could be the origin of ˝complexity˝ of the coexistence of non-propagating pseudo-2D spatiotemporal fluctuations and propagating modes in solar wind turbulence. Such coexistence of two types of fluctuations were detected in the solar wind by Matthaeus et al. [1990] in terms of the two-dimensional correlation as a function of distance parallel and perpendicular to the mean magnetic field based on the ISEE-3 magnetometer data. Other supporting evidences have been reported by Tu et al. [1989], Tu and Marsch [1990, 1991], Bruno and Bavassano [1991], Bavassano and Bruno [1992], Bruno et al. [2001], and others. The above observational results are also consistent with the conclusions obtained from 2D MHD numerical simulations [Matthaeus and Lamkin, 1986, Roberts and Goldstein, 1988, Goldstein et al., 1989, Roberts et al., 1991, and Roberts, 1992]. These findings have led Chang [2002] to suggest the following evolutionary scenario for the plasma turbulence in the generic fast solar wind. In and near the coronal hole base, the turbulent fluctuations are predominantly generated by pseudo-2D nonlinear interactions. As the fluctuations emerge from the coronal hole base, they propagate in the field-aligned direction primarily as Alfvén waves. At the same time, field-aligned coherent structures in the form of flux tubes are generated. ˝Alfvénic flux tubes˝ have been observed and reported recently by Bruno et al. [2001]. Then these flux tubes begin to interact nonlinearly and intermittently; thereby generating new pseudo-2D transverse fluctuations. Some of these fluctuations then propagate along the field-aligned direction as newly generated Alfvén waves. Other non-propagating fluctuations, on the other hand, begin to generate new coherent structures of varied sizes and new flux tubes are then formed. Ultimately, some sort of a balance of the non-propagating pseudo-2D fluctuations and field-aligned

propagating fluctuations is developed. Consequently, the Alfvén ratio of the fast solar wind turbulence generally will have a value less than one at the space range sufficiently far away from the coronal hole base. It has been demonstrated by Tam and Chang [1999; 2001; 2002] that resonant wave-particle interactions can be the primary driving mechanism for the fast solar wind. We suggest that the additional particle interactions with the non-propagating portion of the solar wind fluctuations near the coronal hole base may significantly increase the efficiency of the energization process as the solar wind emerges from the coronal hole base. The solar wind fluctuations in the solar wind generally may be accompanied by an electrostatic component. Both the electrostatic and electromagnetic fluctuations can energize the local charged particle distributions in magnetized plasmas selectively and intermittently, particularly in the transverse direction to the ambient magnetic field [Chang et al., 1981;Chang, 1993; Tam and Chang; 1999; Chang, 2002].

MULTI-FLUID SIMULATIONS OF PLANETARY MAGNETOSPHERES

Robert M. WINGLEE, Erika HARNETT, Carol PATY (Dept. of Earth and Space Sciences, University of Washington)

Planetary magnetospheres development substantial structure due to the presence of multi-ion species, some of which originate from the solar wind and some from the planet's ionosphere and in the case of the Jovian magnetosphere, from moons within the system.In these mixed plasma systems, ion cyclotron effects can lead to preferential acceleration of heavy ions, and velocity filtering effects can lead to mass fractionation and the formation of boundary layers as well limit access to key regions such as current sheets and reconnection regions. To date the most common tool to investigate the global structure of planetary magnetosphere is MHD simulations, but this method treats the plasma as a single fluid and ion cyclotron effects such as the formation of a ring current are missing. To address these issues on ion-cyclotron and ion-species effects, a full treatment of the fluid equations for the different ion components has to be developed. In this paper, we present such a formalism and show how these effects modify our understanding of tail reconnection in the Earth's magnetosphere, in association with the development of filamented flux ropes and the heavy ion hot spots on the dusk flank.For the Jovian magnetosphere, the heavy ions control the energy transport and like the Earth's magnetosphere, dawn/dusk asymmetries develop and modify the reconnection geometry in the near-Jovian region.

GAIV.02/07P/A07-002   1440

THE PERIODICITIES OF SOLAR FLARES AND CORONAL MASS EGECTIONS DURING SOLAR CYCLE 23

Ahmed Abdel HADY (Cairo University)

The Events of energetic particles from solar flares have been studied.The data were taken from National Geophysical data center (NGDC) in Boulder,Colorado, USA. The data of these events were given during the solar cycle 23rd.The 23rd cycle is the present one, started in April 1996, and its maximum was in May 2001, and will be decayed during year 2007. Power spectrum methods have been applied for analysis of the data given, to find the short and intermediateperiodicities. The periodicity around 14 days has been appeared in thisanalysis. This has important implications for understanding and predicting the effects of solar activity on the Earth and earth's atmosphere. If a CME' hit the Earth, it can excite a geomagnetic storm. Large geomagneticstorms have, among other things, will cause electrical power which damage satellites communications. In space CME typically drive shock waves thatproduce energetic particles that can damag both electronic equipment andastronauts that are outside the protection of the Earth´´s magnetic field.So, the prediction of the high energetic particle events is of vitalimportance for space navigation and airline disasters.

GAIV.02/07P/A07-003   1510

THE EARTH'S BOW SHOCK AS A NONLINEAR PARTICLE ACCELERATOR

Toshio TERASAWA[1], Hirotomo NODA[2], Mitsuo OKA[1], Yoshifumi SAITO[3], Toshifumi MUKAI[3] ([1]Dept. Earth & Planetary Science, Univ Tokyo, [2]National Astronomical Observatory, Japan, [3]Institute of Space and Astronautical Science, Japan)

The earth´s bow shock has been known to be an efficient particle accelerator in several different ways, such as shock-drift-acceleration of reflected ions/electrons, and diffusive-shock-acceleration (DSA) of diffuse upstream ions. From the view of nonlinear physics involved, the DSA process for diffuse ions is most prominent, since (1) the low frequency MHD waves self-excited by these diffuse ions havea large amplitude (10-50% of the background field), and show variouskinds of nonlinear wave phenomena, and (2) the pressure exerted by the diffuse ions becomes non-negligible with respect to the solar wind ram pressure, and the internal structure of the bow shocktransition region is modified by the existence of these ions(´Cosmic-Ray-Modified´ nature of the bow shock). We will present our recent observational results on the above two properties,and discuss their relevance in the general study of nonlinear shock acceleration problems in cosmic shock environments. In addition, we will also discuss the dependence of the bow shock acceleration efficiency on the distance from the nose region of the bow shock. (The nose bow shock has the larger compression ratio than any other part of the bow shock, and thus has the largest acceleration efficiency.)

RADIO EMISSIONS ASSOCIATED WITH SHOCKS: COUPLING MICROPHYSICS WITHMACROPHYSICS

Iver H. CAIRNS, Peter A. ROBINSON, Stuart A. KNOCK, Zdenka KUNCIC, Jeremy J. MITCHELL (School of Physics, University of Sydney)

Type II solar radio bursts, radiation near the electron plasma frequency f_{pe} and near $2f_{pe}$ from Earth´s foreshock, and the 2-3 kHz radiation observed by the Voyager spacecraft in the outer heliosphere are well known examples of radio emissions associated with shocks. These are widely interpreted in terms of electron reflection at the shock, generation of Langmuir waves, and coupling of Langmuir energy into f_{pe} and $2f_{pe}$ radio emission. Recent observations and simulations provide evidence that macroscopic shocks are rippled on scales ranging from the thermal ion gyroradius to those of the ambient MHD turbulence and the shock´s driver itself. Ripples affect electron reflection and acceleration at the shock, resulting in time variable electron beams upstream, and lead to multiple simultaneous, time-varying foreshock regions upstream from the overall shock. Similarly, the observed Langmuir waves are bursty on small time and distance scales but persist with the driving electron beams for macroscopic distances. These characteristics and the observed field statistics are consistent with stochastic growth theory (SGT), which describes the development of a

macroscopic state near marginal stability that retains microscopic burstyness. Finally, the radiation is generated by nonlinear coupling and/or linear mode conversion of Langmuir waves, described using microphysical theory. This paper reviews quantitative analytic theories for type II bursts, Earth´s foreshock radiation, and the 2-3 kHz emissions that combine the above microphysics to predict the properties of the electron beams and radio emission throughout the foreshocks of macroscopic rippled shocks.

GAIV.02/07P/A07-005   1640

ON THE RADIAL HELIOSPHERIC MAGNETIC FIELDS: VOYAGER 2 OBSERVATION AND MODEL

Chi WANG[1], J.D. RICHARDSON[2], L.F. BURLAGA[3], N.F. NESS[4] ([1]Lab. for Space Weather, Chinese Academy of Sciences, [2]MIT Center for Space Research, [3]NASA Goddard Space Flight Center, [4]Bartol Research Institute)

The heliospheric magnetic field (HMF) direction, on average, conforms well to the Parker spiral. However, numerous examples of events where the HMF is oriented in near-radial directions for many hours have been reported based on observations inside 5 AU from spacecraft such as ISEE-3 and Ulysses. The magnetic field data observed by Voyager 2 from launch in 1977 through the end of 1982 (i.e. between 1 and ~10 AU) were searched for all instances of radial fields with durations of 6 hours or more. Radial fields of significant durations at large distances are unusual as the Parker spiral is very tightly wound. The radial HMF events in the inner heliosphere typically occur at times when the solar wind speed is declining gradually, while they tend tobe associated with steady wind speeds at distances beyond ~6 AU. The durations of these events appear to be independent of distance and solar cycle, with an average duration of ~11 hours. They generally are not associated with interplanetary coronal mass ejections (ICMEs). Possible generation mechanisms of the radial field events related to speed variations near the Sun are investigated by use of a MHD model. We find that a noticeable low-speed plateau of limited duration in solar wind speed near the Sun can produce radial field events having durations of the order of 10 hours in the heliosphere as observed by Voyager 2.

GAIV.02/07P/A07-006   1710

FULL PARTICLE SIMULATIONS OF QUASI-PARALLEL SHOCKS AND SLAMS FORMATION: A PARAMETRIC STUDY

Ken TSUBOUCHI, Bertrand LEMBEGE (CETP/IPSL/UVSQ)

The dynamics of quasi-parallel shocks and the formation of associated SLAMS (Short Large Amplitude Magnetic Structures) have been analyzed via a parametric study based on the use of 1D full particle simulation. Recent works (Tsubouchi and Lembege, 2003) have focussed on the characteristics of the SLAMS which have been shown to be in good agreement with experimental space observations. These works have confirmed that typical SLAMS patterns result from the steepening of a nonlinear magnetosonic waves excited by reflected ion beam-ambient plasma instability as proposed by Scholer (1993) with hybrid simulations; when the wavelength of these waves is of the order of reflected ions density gradient, it shrinks to lower values which contributes to the wave steepening and leads to the SLAMS formation. The present parametric study is an extension of this previous work and shows that such structures are very sensitive to the shock regime. This could explain the variety of SLAMS (isolated, embedded) identified in experimental spacecrafts observations; the form and the occurrence frequency of SLAMS strongly varies with Mach number. In addition, present results suggest that a small variation in the Mach regime not only has a strong impact in the mechanisms responsible for SLAMS formation, but may also contribute to make dominant some mechanisms other than ion beam-plasma instability; these mechanisms lead also to a large variety of field patterns. Some intermittent spiky (short time life soliton-like) patterns in the electrostatic field have been identified but not always in association with well formed SLAMS. The mixing of these field patterns varieties developping over quite different time scales could account for the turbulent dynamics of quasi-parallel shocks .

GAIV.03/08A/A16-001   0830

THE MAGNETIZED CRUST OF MARS - THE FINDINGS OF MARS GLOBAL SURVEYOR

Mario H. ACUNA (NASA-GSFC)

Mars Global Surveyor discovered intense crustal magnetization associated with the ancient, cratered highlands and provided new and fundamental views into Mars´ early history, its interior evolution, ionosphere, tectonics, the loss of volatiles from the atmosphere and the planet´s interaction with the solar wind. In many respects the MGS observations have changed our basic understanding of the planet. Fundamental questions remain about the processes that led to the formation of the magnetic anomalies. We now know that Mars has lacked a global magnetic field for >4 billion years and solar wind erosion is believed to be an important and possibly the dominant atmospheric loss process. The crustal magnetic sources lead to the formation of ˝mini-magnetospheres˝ and a complex ionospheric structure. This paper will review the MGS magnetic field and electron observations and selected results obtained to date.

Planck Institute for Aeronomy, Klatenburg-Lindau, Germany.)

For a number of years a great deal of uncertainty has existed concerning the nature of the solar wind interaction at Mars, because of the lack of relevant plasma and field observations. However, measurements by the Phobos-2 and the Mars Global Surveyor spacecraft, with different instrument complements and orbital parameters, led to a significant improvement of our knowledge about the regions and boundaries surrounding Mars. The main signatures, defined by the different plasma processes at work, can be summarized as follows: (1) The bow shock stands off an effective obstacle at a distance expected from gas-dynamic and/or magnetohydrodynamic approximations. (2) The Magnetic Pile-up Region (MPR) is a region dominated by planetary ions. The region is separated from the magnetosheath by the Magnetic Pile-up Boundary (MPB). (3) A plasma boundary is observed in the supra-thermal electrons (> 10 eV, MGS data), which hints at the existence of a boundary between the MPR and the ionosphere below. In this review the magnetosheath, the Magnetic Pile-up Region, and the Magnetic Pile-up Boundary will be discussed, as well as the observations of a possible ionopause.

THE MAGNETIC PILEUP BOUNDARY: A COMMON FEATURE FOR WEAKLY MAGNETIZED BODIES?

Cesar L. BERTUCCI[1], Christian MAZELLE[1], Mario H. ACUÑA[2] ([1]CESR, CNRS/UPS, France, [2]NASA GSFC, USA)

The lack of an intrinsic magnetic field at Venus, Mars and comets makes their interaction with the solar wind very similar, with the formation of a magnetic barrier in front of a highly conducting obstacle and an induced magnetic tail as their most characteristic peculiarities. The Magnetic Pileup Boundary (MPB) is the plasma boundary that marks the entrance into the magnetic barrier at Mars and comets. This boundary can be identified by clear observational signatures: a gradient in the magnetic field magnitude (often as a sharp jump) accompanied by a decrease in the magnetic field fluctuations, and a simultaneous drastic decrease in the solar wind electron and proton densities as the obstacle is approached. Recently, an enhancement of the magnetic field draping has been reported at the Martian MPB from Mars Global Surveyor magnetometer data as a new ubiquitous characteristic of this boundary. As a result of the application of the same technique to magnetometer data acquired near comets and Venus, we confirm that the MPB is the dayside counterpart of the magnetic tail boundary and present new evidence in favor of the existence of a MPB at Venus, where the boundary has never been reported.

GAIV.03/08A/A16-004   1000

THE MAGNETIC PILE-UP BOUNDARY AT MARS AND RELATED ION DYNAMICS

Konrad SAUER[1], Eduard DUBININ[1], Christian MAZELLE[2] ([1]Max-Planck-Institut fuer Aeronomie, Katlenburg-Lindau, Germany, [2]CESR, Toulouse, France)

The recent magnetic field measurements aboard Mars Global Surveyor at Mars have clearly shown that a permanent plasma boundary exist between the bow shock and the ionopause which is characterized by strong magnetic pile-up. The evidence of this ´Magnetic Pile-up Boundary´ (MPB) confirms the outcome of earlier Phobos-2 measurements in which the presence of an ´obstacle boundary´ was seen by different instruments. Especially, the observed change of ion composition at this boundary by ASPERA and TAUS seems to be of great importance to understand the physical nature of the MPB. Hitherto unpublished Phobos-2 data of MPB crossings at large distances (~10 RM) are discussed. The results are compared with simple 2D bi-ion simulations considering exclusively electrostatic coupling between solar wind protons and newly generated planetary ions by the charge separation field. The good agreement with the observations indicate that the different dynamics of both ion populations is essentially for the sharp magnetic field increase at the MPB.

GAIV.03/08A/A16-005   1040

MARTIAN SHOCK AND MAGNETIC PILE-UP BOUNDARY POSITIONS AND SHAPES REVISITED AFTER MARS GLOBAL SURVEYOR

Jean Gabriel TROTIGNON[1], Christian MAZELLE[2], Cesar BERTUCCI[2], Mario H. ACUNA[3] ([1]LPCE/CNRS, Orleans, France, [2]CESR/CNRS/UPS, Toulouse, France, [3]GSFC, Greenbelt, Maryland, USA)

A lot of Martian bow shock and magnetic pile-up boundary crossings have been unambiguously identified in the Phobos-2 and Mars Global Surveyor, MGS, data. From these observations the positions and shapes of the bow shock and magnetic pile-up boundary, MPB, have been derived and modeled, using curve-fitting techniques. The models derived separately from the Phobos-2 and MGS data sets do not differ drastically, despite the different time and space data coverages. The purpose of the presentation is to show the results obtained in mixing the Phobos-2 and MGS data sets and to compare the derived bow shock and MPB models with the ones obtained in considering the two data sets separately. The underlying objective is to see whether it is possible to determine general bow shock and MPB models or not.

THE IONOSPHERE OF MARS

Hiroyuki SHINAGAWA (Solar-Terrestrial Environment Laboratory, Nagoya University)

Observations relevant to the ionosphere of Mars have been made by a number of missions. It is expected that structure and dynamics of the ionosphere of Mars are significantly affected by the solar wind interaction. The Mars Global Surveyor has detected a fairly strong but localized magnetic field which is of crust origin. It was also found that the surface magnetic field is likely to be insignificant. Although the solar wind interaction with Mars is basically similar to the solar wind interaction with Venus or comets, the crustal magnetic field appears to play an important role in the structure and dynamics of the Martian ionosphere. To study the ionospheric processes at Mars, many theoretical studies have been done using various kinds of numerical models. Our current understanding of the ionospheres of Mars is reviewed, and outstanding problems to be solved are summarized.

GAIV.03/08A/A16-007   1130

PROBING MARS' CRUSTAL MAGNETIC FIELDS AND IONOSPHERE WITH THE MGS ELECTRON REFLECTOMETER

David L. MITCHELL[1], Christina O. LEE[1], Sherry CHOU[1], Robert P. LIN[1], Henri REME[2], Paul A. CLOUTIER[3], Mario H. ACUNA[4] ([1]Space Sciences Laboratory, U.C.-Berkeley, [2]CESR, Toulouse,

France, [3]Rice University, Houston, Texas, [4]NASA Goddard Space Flight Center)

Mars´ magnetic field is dominated by remanent magnetization of the crust, which is distributed non-uniformly over the surface. In the northern hemisphere, crustal magnetic fields are so weak that the solar wind interacts directly with the atmosphere and ionosphere in a manner similar to that observed at Venus and active comets. However, in the most strongly magnetized regions of the southern hemisphere, the crustal field is strong and coherent enough to stand off the solar wind up to altitudes of ~800 km, forming localized ″magnetospheres,″ which are elongated in the east-west direction following the pattern of magnetization. In sunlight, these mini-magnetospheres contain trapped ionospheric plasma, and in some locations form cusps, where the crustal field is connected to the interplanetary magnetic field. In darkness (2 am local time), trapped populations persist only on field lines that are nearly vertically oriented at 400 km altitude, and thus extend far downstream of the planet. The Electron Reflectometer (ER) onboard Mars Global Surveyor (MGS) detected a plasma boundary between the ionosphere and the solar wind as the latter is diverted around and past the planet. Above this boundary the 10-1000 eV electron population is dominated by solar wind electrons, while below the boundary it is dominated by ionospheric photoelectrons. We show that this ″photoelectron boundary,″ or PEB, is sensitive to pressure variations and moves vertically in response to changes in the ionospheric pressure from below and the solar wind pressure from above. The PEB is also sensitive to crustal magnetic fields, which locally increase the total ionospheric pressure and positively bias the PEB altitude. We have analyzed more than five million electron spectra obtained in the mapping orbit, spanning two Martian years. We have empirically modeled and removed systematic variations in the PEB altitude associated with the solar wind interaction, thus isolating perturbations caused by crustal magnetic fields. A map of these PEB perturbations closely resembles a map of the horizontal component of the crustal magnetic field measured at 400 km by the MGS Magnetometer. This technique allows us to extend the sensitivity of existing magnetic field maps and reliably identify crustal fields with an intensity of only ~5 nT at 400 km altitude.

THE EFFECTS OF CRUSTAL MAGNETIC FIELDS AND THE PRESSURE BALANCE IN THE HIGH LATITUDE IONOSPHERE/ATMOSPHERE AT MARS

Tamara K. BREUS, Norman F NESS, Alexander M KRYMSKII, Mario H ACUNA, Jack E.P. CONNERNEY, David HINSON, Konstantin K BARASHAYN (Space Research Institute, Moscow, Russia)

The intensely and nonuniformly magnetized crustal sources generate an effective large-scale magnetic field. Re-connection with the interplanetary magnetic field can possibly take place in many localized regions. This will permit solar wind (SW) and more energetic particles to precipitate into and heat neutral atmosphere in cusp-like structures. The strongest crustal fields are l located in certain regions in the Southern hemisphere and lead to the formation of large-scale mini-magnetospheres. In the Northern hemisphere, the crustal fields are rather weak and usually do not prevent direct interaction between the SW and the Martian ionosphere/atmosphere. Exceptions occur in the isolated mini-magnetospheres formed by the crustal anomalies. Electron density profiles of the ionosphere of Mars derived from radio occultation data obtained by the Radio Science Mars Global Surveyor (MGS) experiment have been compared with the crustal magnetic fields measured by the MGS Magmetometer/Electron reflectometer (MAG/ER) experiment. A study of 523 electron density profiles obtained at latitudes from 67o till 77o has been conducted. The effective scale- height of the electron density for two altitude ranges, 145-165 km and 165-185 km, and the effective scale-height of the neutral atmosphere density in the vicinity of the ionization peak have been derived for each of the profiles studied. A significant difference between the large-scale mini-magnetospheres and regions outside of them has been found. The neutral atmosphere is cooler inside the large-scale mini-magnetospheres. It appears that outside of the cusps the strong crustal magnetic fields prevent additional heating of the neutral atmosphere by direct interaction of the SW. For the regions outside of the mini-magnetospheres the thermal pressure of the ionospheric plasma for the altitude range 145-185 km has been derived. The pressure balance in the high latitude ionosphere at Mars has been studied.

MHD SIMULATION STUDY ON IMF PENETRATION INTO THE IONOSPHERE OF MARS AND VENUS

Hidekatsu JIN, Kiyoshi MAEZAWA, Toshifumi MUKAI (ISAS)

Since Mars and Venus do not have a global intrinsic magnetic field, the solar wind directly interacts with the ionosphere of these planets. PVO (Pioneer Venus Orbiter) observed a sharp boundary between the solar wind and Venus ionosphere when dynamic pressure of the solar wind does not exceed ionospheric pressure. But in the case where the solar wind dynamic pressure is large, ionopause becomes rather obscure with its altitude lower and its thickness thicker. During this phase, a large-scale magnetic field is observed in the subsolar region of the ionosphere. Recently, MGS (Mars Global Surveyor) also observed the IMF penetration into the Martian ionosphere. The large-scale field as well as the ionopause behavior have caught a great deal of attention and have been studied by many scientists. The altitude profile of the large-scale field has been explained by using the model in which the field is transported by downward convection and accumulated in collision-dominant region. There are, however, some problems that still remain unclear. Especially, the key physics behind IMF penetration into the ionosphere and its altitude profile is not well understood. For example, it is not obvious how the altitude profile of the vertical ionospheric flow is formed, which is important for the altitude profile of the field. We study the mechanism for the penetration of IMF into Venus/Mars ionosphere and the altitude profile of the large-scale field, by using a 2D global MHD simulation model. The purpose of our study is to understand key physics behind those phenomena. We will report effects of physical processes such as ionospheric production and loss, gravity, collision, and magnetic diffusion due to collision in detail. We will clarify the differences between the physical processes operating at Mars and Venus.

THE MARTIAN MAGNETOSPHERE BASED ON PHOBOS-2 - IMPLICATIONS FOR THE UPCOMING NOZOMI AND MARS EXPRESS MISSIONS

Rickard N.A. LUNDIN, Stanislav BARABASH (Swedish Institute of Space Physics)

The solar wind interaction with Mars, its atmosphere, ionosphere and magnetosphere, was first investigated by the Soviet Mars-2, 3 and 5 orbiters in the 1970ies. It took until the late 1980ies (1989) before another mission to Mars, the Soviet Phobos-2, wasable to carry out more detailed measurements in the martian magnetosphere. The Phobos-2 mission provided detailed measurements on the Sun-Mars interaction during its 2 months in orbit around Mars, substantially improving our understanding of the martian magnetosphere morphology and the atmospheric outflow/escape from a nonmagnetized planet. However, the Phobos-2 mission also left us with a number of unsolved issues. Subsequent MGS-results of e.g. magnetization regions at Mars have added to the ″mystique″ on the evolution of Mars. The investigations on the two missions Nozomi and Mars Express were designed to specifically address the above unsolved issues. For instance the IMI experiment on Nozomi were designed to analyze the magnetospheric structure, the ionospheric escape mechanisms and the potential occurrence of charged dust near the Phobos and Deimos orbits. ASPERA-3 on Mars Express will focus on the overall plasma outflow and its correspondance with the energetic neutral atoms produced as a result of charge exchange. This report will discuss some of the unsolved issues about the solar wind interaction with Mars and how we plan to address these issues with Nozomi and Mars Express.

GLOBAL HYBRID SIMULATIONS OF THE MARTIAN PLASMA ENVIRONMENT

Gerard M. CHANTEUR[1], Ronan MODOLO[1], Allan P. MATTHEWS[2] ([1]CETP / IPSL / CNRS, [2]University of Natal, Durban, South Africa)

Two- and three-dimensional hybrid simulations of the global plasma environmentof Mars, including the night side of the planet and the near wake, have beenmade on uniform grids with varying resolutions. The simulation code includesphotooionisation and electron impact ionisation of neutral hydrogen and oxygencoronae although with a simplistic modelisation of the second process based onan adiabatic behaviour of the electron fluid. The densities of the neutralspecies are supposed to vary only with respect to the planetocentric distanceaccordingly to theoretical profiles. The simulation model also includes chargeexchange processes between protons or oxygen ions both with neutral hydrogenand oxygen. Both two- and three-dimensional simulations clearly exhibit a wellresolved bow shock, a pile-up region of the magnetic flux and a wake depletedof solar wind ions but partially filled with planetary ions. Spatial variationsof densities of planetary or solar wind ions (protons and alphas) around theplanet extend over four decades. The spatial scales of the simulated Martianenvironment are reasonable but due to a presently insufficient spatialresolution the bow shock, in the three-dimensional simulations, is located toofar away from the planet but more realistic results are expected fromsimulations on supercomputers.

GAIV.03/08P/A16-003 **1500**

ANALYSIS OF THE MARTIAN OBSTACLE AND BOW SHOCK TERMINATOR ANISOTROPY ORIGINS USING PHOBOS 2 AND MGS DATA

M.I. VERIGIN[1], G. KOTOVA[1], A. REMIZOV[1], J. SLAVIN[2], M. ACUNA[2], T.-L. ZHANG[3], K. SCHWINGENSCHUH[3], K. K. SZEGO[4], M. TATRALLYAY[4] ([1]Space Research Institute of Russian Academy of Sciences, [2]NASA Goddard Space Flight Center, Greenbelt, Maryland, USA, [3]Space Research Institute of Austrian Academy of Sciences, Graz, Austria, [4]KFKI Research Institute for Particle and Nuclear Physics, Budapest, Hungary)

The Phobos 2 and MGS data sets on positions of the Martian obstacle and bowshock are analyzed by uniform method for checking of their mutual consistency and for analysis of anisotropy of these boundaries. New Martian obstacle model dependent on the solar wind ram pressure and based on recently introduced ram pressure proxies, is used for the obstacle tracing to terminator plane in the period of MGS observations. This model as well as earlier obstacle model constructed for the period of Phobos 2 observations, is applied to trace the Phobos 2 obstacle crossings. MHD model of the planetary bow shock taking into account the obstacle shape, solar wind sonic and Alfvenic Mach numbers, and interplanetary magnetic field direction, is used to trace bow shock positions observed by both orbiters to terminator plane. Thus traced terminator obstacle and bow shock positions are studied for the search of MHD, picked-up ion, crustal magnetization effects on position of both boundaries. It is found that localized Martian crustal magnetization increases the height of the terminator obstacle by several hundreds of kilometers while the influence of MHD or ion pick-up effects on Martian obstacle position is small. Elongation of the Martian bow shock cross-section in the direction perpendicular to the interplanetary magnetic field and the shift of this cross section in the +Y direction of the Martian interplanetary medium reference frame were clearly observed while the shift of bow shock cross section in the direction of the interplanetary electric field was not revealed thus not conforming the idea that mass-loading play any role in this boundary controlling.

MAGNETIC FIELD INVESTIGATION OF THE VENUS PLASMA ENVIRONMENT: WHAT DO WE EXPECT FROM THE VENUS EXPRESS MISSION

Wolfgang BAUMJOHANN, Tielong ZHANG (Space Research Institute, Graz, Austria)

The Venus Express mission is scheduled to launch in 2005. Among other instruments, it carries a magnetometer to investigate the Venus plasma environment. Although Venus has intrinsic magnetic moment, magnetic field measurements are essential to studying the solar wind interaction with Venus. Our current understanding of the solar wind interaction with Venus is mainly from the long lasting Pioneer Venus Orbiter observations. In this paper, we describe the magnetic field experiment of the Venus Express mission. We assess the current understanding and find out what we will achieve with the upcoming Venus Express mission.

GAIV.03/08P/A16-005 **1610**

SOLAR WIND CONTROL OF THE VENUSIAN AND MARTIAN IONOTAILS

Naoki TERADA, Hiroyuki SHINAGAWA (Solar-Terrestrial Environment Laboratory, Nagoya University)

Comprehensive two-dimensional global hybrid (particle ions, massless fluidelectrons) simulations of the solar wind interaction with the ionosphereof the unmagnetized planets, Venus and Mars, are conducted.The hybrid code successfully models the entire solar wind-planet interactionregion including the planetary ionosphere, magnetosheath, and solar windregions simultaneously by applying boundary-fitted coordinates to theparticle-in-cell code.The model predicts strong dependence of the ionotailconfigurations on the solar wind dynamic pressure.Asymmetry in the ionotail configurations with respect to the direction ofthe solar wind motional electric field becomes prominent as the dynamicpressure increases.We will show that the momentum transfer between magnetosheath protons andpickup planetary ions as well as the asymmetrical transterminator transportof ionospheric ions plays an important role in producing the asymmetricalionotail configurations.Development of the ionotails appears quite dynamic.We will also discuss the time evolution of the ionotails.

PLASMA EFFECTS OF INTERACTION OF SMALL BODIES WITH SOLAR WIND

Valentina G. MORDOVSKAYA (Institute of Terrestrial Magnetism, Ionosphere, and Radiowave Propagation (IZMIRAN))

The last planetary explorations have witnessed an increase of importance of investigations of small bodies of the Solar System because its substance may carry the information on an origin and evolution of Solar system. Interplanetary spacecrafts have passed near asteroidal bodies: Gaspra, Ida, Braille, Eros, and Martian moons (Phobos and Deimos). The small characteristic sizes of the obstacle to the solar wind have to give specific signatures of the solar wind-asteroid interaction. The typical length of the free motion of particles of the solar wind is much more enhanced than the sizes of the bodies; therefore, a hydrodynamic formulation is invalid for such solar wind-asteroid interaction. It is necessary to use a kinetic theory for the consideration of phenomena near the bodies. As an application of the kinetic theory, the solar wind interaction with Phobos is studied in this work both from the theoretical standpoint and from using the data of Phobos mission. The size of Phobos and the solar wind ion gyroradius are alike. That leads to a large-scale structure of the plasma in the Phobos tail. Just the modulation is responsible for the phenomenon observed by spacecraft Phobos-2 on February 1, 1989. The speculations about the dust\gas nature of the phenomenon are erroneous.

THE SOLAR WIND INTERACTION WITH MARS

Yingjuan MA, Andrew F. NAGY, Igor SOKOLOV (Dept. Atmos., Ocean. & Space Sci.)

We have modified our multi-species, 3D, MHD model of the interaction of the solar windwith Mars. We have moved from a Cartesian coordinate system to a spherical one, in order to achieve better radial resolution and to achieve a better fit to the shape of theionosphere-magnetosheath interface in our calculations. This is especially important inorder to assess the role of the interaction processes on the ionosphere and the inner magnetosheath. We will be presenting the first results of these new calculations, whichalso include the effects of the crustal magnetic field.

GAIV.03/09A/A16-002   0930

EXAMINING THE CRUSTAL FIELD TOPOLOGY AT MARS WITH THE MGS MAG/ER DATA: COMPARISONS WITH A B-FIELD DEPENDENT TRANSPORT CODE

Michael W. LIEMOHN[1], David L. MITCHELL[2], Andrew F. NAGY[1], Stephen W. BOUGHER[1], Jane L. FOX[3], Jacki M. FRANK[1], Tamara W. REIMER[4] ([1]SPRL, University of Michigan, [2]Space Science Laboratory, University of California Berkeley, [3]Department of Physics, Wright State University, [4]Department of Physics, Harvey Mudd College)

We compare MGS MAG/ER data with results from a B-field dependent kinetic transport code for electrons in the 10-1000 eV energy range. The photoelectrons created on the dayside, in regions where crustal fields are strong, allow for the exploration of the magnetic topology. By comparing the observed velocity space distributions of the electrons with the simulation results, in particular the depth and structure of the trapped zone fluxes, the integral "scattering depth" can be determined. This constrains both the topology of the field line as well as the thermospheric/ionospheric densities in the upper atmosphere of Mars. Case studies of typical MGS mapping phase orbits through the strong crustal field region in the southern hemisphere of Mars are examined.

GAIV.03/09A/A16-003   0950

INTERACTION BETWEEN THE SOLAR WIND AND A ˝MARS-TYPE˝ PLANET HAVING A SMALL-SCALE LOCAL MAGNETIC STRUCTURE ON ITS SURFACE

Kiyoshi MAEZAWA, Hidekatsu JIN, Akinori SHIGA (Institute of Space and Astronautical Science)

We present the result of our MHD simulations on the interaction between the solar wind and a planet having small-scale magnetic structures as in the case of Mars. In order to see the influence of the spatial scale of the surface magnetic field, various forms of local magnetic fields are examined, including the cases with a single dipole(s) below the surface, the ones with linearly aligned magnetic structures, and the ones expressed by several different spherical harmonic functions. In order to see the effects of the magnetic field clearly, a very simple ionospheric model is adopted for a generic case, where MHD equations include only two ion species (ionospheric Oxygen and the solar wind proton). In addition, our model incorporates the effects of the mass-loading processes on the local/global-scale solar wind flow around the planet by assuming a hot Oxygen corona. Our simulation code is TVD with source terms and a polar coordinate mesh is used. We compare the results for individual magnetic models and show that the effect of magnetic reconnection on the global-scale flow structure around the planet is strongly dependent on the spatial scale of the magnetic field. We also comment on the difficulty of MHD simulations for some of the cases where a very high Mach number flow can be produced by magnetic reconnection in a low-temperature planetary plasma. We finally comment on the possibility of obtaining observational clues for the simulated interaction processes with the instruments flown on the Nozomi spacecraft.

GAIV.03/09A/A16-004   1010

WAVES AT MARS: A TENTATIVE REVIEW

Jean Gabriel TROTIGNON (LPCE/CNRS, Orleans, France)

Despite the great number of missions devoted to the exploration of the Martian environment, a very few space probes carried instruments designed to study waves. The best equipped spacecraft was indisputably Phobos-2 which allowed, in 1989, electric field in the 5 Hz-150 kHz frequency range and high temporal resolution DC magnetic field to be monitored. Unfortunately, the lowest Phobos-2 perigee altitude was too high, about 850 km, to allow investigation of the ionosphere of Mars. More recently, the high quality DC magnetic field measurements performed onboard the Mars Global Surveyor, MGS, spacecraft have been used to derive valuable information on low frequency waves upstream of the Martian bow shock. The subject of the presentation is to tentatively review the wave observations made by both the Phobos-2 and MGS spacecraft. In a next future, we hope that NOZOMI and Mars Express will increase our poor knowledge of waves at Mars.

GAIV.03/09A/A16-005   1100

REFLECTED IONS UPSTREAM OF A CURVED QUASI-PERPENDICULAR SHOCK

Ronan MODOLO[1], Gerard M. CHANTEUR[1], Allan P. MATTHEWS[2] ([1]CETP / IPSL / CNRS, [2]University of Natal, Durban, South Africa)

Self-consistent data from two-dimensional hybrid simulations are used to investigate the reflection of solar wind ions (protons and alphas) by a curved quasi-perpendicular shock created by a small planetary obstacle having typically the size of Mars or slightly larger. All incoming alpha particles aretransmitted downstream of the shock and reflected alphas are not observed in these simulations. A few percent of incoming protons are reflected on one side of the shock depending upon the orientation of the motional electric field of the solar wind as expected from theoretical considerations. The localisation of the reflection process is illustrated by maps of the acceleration sites built from the analysis of the self-consistent motion of the ions. The flux of reflected protons versus energy is exponential with a characteristic energy depending mainly upon the velocity of the solar wind and only slightly upon the size of the obstacle for the investigated range of sizes. Coarse pitch-angle distributions of reflected protons will also be presented.

GAIV.03/09A/A16-006   Invited   1120

STATIONARY NONLINEAR LF ELECTROMAGNETICWAVES IN A BEAM-PLASMA: APPLICATION TO UPSTREAM PHENOMENA AT EARTH AND MARS

Konrad SAUER[1], Eduard DUBININ[1], Christian MAZELLE[2] ([1]Max-Planck-Institut für Aeronomie, [2]CNESR, Toulouse, France)

Using the full nonlinear system of fluid and Maxwell equations for a beam-plasma configuration, where the beam is thought to be formed by shock-reflected protons or exospheric ions (at Mars), stationary nonlinear electromagnetic waves near and below the proton cyclotron frequency are described.Depending on the beam parameters, coherent structures in form of ´oscillitons´ (Sauer et al., 2002) and solitons have been obtained. The results are applied to different upstream phenomena seen at Earth and Mars.

GAIV.03/09A/A16-007   Invited   1150

OBSERVATION OF THE MARTIAN UPPER ATOMOSPHERE BY JAPANESE MARS ORBITER NOZOMI

Yoshifumi SAITO, Hajime HAYAKAWA, Kiyoshi MAEZAWA (Institute of Space and Astronautical Science)

Japanese Mars Orbiter NOZOMI launched in 1998 from Kagoshima Space Center is now on its way to Mars. Fourteen science instruments are onboard the NOZOMI spacecraft in order to observe the interaction between the solar wind and the Martian upper atmosphere. At the moment, NOZOMI is expected to arrive at Mars in the end of 2003. Similar to Venus, Mars has no strong intrinsic magnetic field that makes the structure and dynamics of the Martian upper atmosphere quite different from that of the Earth. Strong intrinsic magnetic field of the Earth prevents solar wind to directly enter into the Earth's magnetosphere. On the contrary, Martian upper atmosphere is directly exposed to the solar wind. The interaction between the solar wind and Venus upper atmosphere has been intensively investigated using the data obtained by the Pioneer Venus Orbiter (PVO). Most of our knowledge concerning the interaction between the solar wind and the planets without strong intrinsic magnetic field is based on the results obtained by the research of the Venus upper atmosphere. However, even the piecemeal data of the Martian upper atmosphere so far obtained cannot be fully explained by our current knowledge based on the Venus upper atmosphere. The Phobos-2 spacecraft discovered the significant amount of the oxygen outflow in the Martian tail region. According to this observation, the oxygen in the Martian atmosphere will be fully replaced in 10^8 years. If the interaction between the solar wind and the Martian upper atmosphere causes this outflow, this interaction is very important to understand the history and evolution of the Martian atmosphere. Recently, Mars Global Surveyor (MGS) discovered the existence of the strong crustal magnetic anomaly in the southern hemisphere of Mars. The existence of the strong magnetic anomaly clearly differentiates Venus and Mars from the viewpoint of the solar wind interaction. The interaction between the solar wind and the localized magnetic field may be greatly different from the interaction between the solar wind and the global magnetosphere. There is a possibility that the localized magnetic field significantly affects the ion transport in the Martian upper atmosphere. So far, no systematic observation of the Martian upper atmosphere has been performed. The most important tasks of NOZOMI are to measure the basic plasma parameters of the Martian upper atmosphere, to elucidate the composition of the Martian neutral atmosphere, and to survey the magnetic field distributions in detail. In order to answer the several questions brought up by the previous observations, NOZOMI will systematically observe the key parameters of the Martian upper atmosphere.

GAIV.03/09A/A16-008   1220

ABOUT A MAGNETIC TOPOLOGY OF THE MARS WAKE IN THE PLANE OF PHOBOS ORBIT

Valentina G. MORDOVSKAYA, Victor N. ORAEVSKY (Institute of Terrestrial Magnetism, Ionosphere, and Radiowave Propagation (IZMIRAN))

The plane of the ˝Phobos-2 ˝spacecraft orbit coincided with that of Phobos. This led to sophisticated magneticsignatures of the Mars wake, which were acquired by the spacecraft. Themeasurements made on the circular orbits demonstrated an influenceof the Phobos magnetic field on the topology of the Mars wake.Depending on location of Phobos during manoeuvres, a filamentation ofthe Mars magnetic tail was observed. The magnitude of themagnetic field observed varied from several nT to tens nT.The adopted rule that the orientation of the field in the Martian wake is governed by the direction of the solar wind magnetic field is not confirm by the data. To obtain the expected change in polarity of magnetic field components in the Mars wake we must except the data obtained near Phobos and consider only ˝pure˝ measurements of the magnetic field in the Mars wake. Three types of magnetic field lines, acquired by the ˝Phobos-2 ˝spacecraft, are revealed in the Mars wake. They refer to1. Phobos magnetic field.2. The Mars magnetic field of an internal origin.3. The observation of the draping of the interplanetary field around Mars or/and the induced magnetic field of Mars for two directions of the interplanetary field which is governed by the interplanetary magnetic field points away the Sun and toward the Sun.

DISTRIBUTION OF CRUSTAL MAGNETIC FIELDSON MARS: SHOCK EFFECTS OF BASIN-FORMINGIMPACTS

Lon L. HOOD[1], Nicola C. RICHMOND[1], Elisabetta PIERAZZO[2], Pierre ROCHETTE[3] ([1]Lunar and Planetary Laboratory, University of Arizona, [2]Lunar and Planetary Institute, Tucson, Arizona, [3]University of Aix-Marseille, France)

Crustal magnetic fields on Mars are inhomogeneously distributedwith the strongest fields occurring over the southern highlandsin a longitude sector between approximately 130E and 240E.Here we investigate whether radially extended shock demagnetizationassociated with the Hellas and Argyre basin impacts (in additionto thermal demagnetization associated with the northern resurfacingevent and the formation of the Tharsis volcanic complex) may largelyexplain this distribution.Using analytic approximations and empirical scaling laws,it is estimated that much of the weaklymagnetized southern highlands (i.e., that between 110W and 130E)was shocked to pressures exceeding 1-2 GPa during the Hellas and Argyreimpacts. Possible primary remanencecarriers in the martian crust include iron oxidesand iron sulfides (pyrrhotite). If pyrrhotite is the main remanencecarrier, extensive demagnetization of crustal regions (about 90%) mayoccur at shock pressures of 2 GPa or more. Thus, at least for thisremanence carrier, impact shock demagnetization can potentially explainthe distribution of crustal fields in the southern highlands.

THE ORIGIN OF THE SOLAR MAGNETIC FIELD

Arnab R. CHOUDHURI (Dept of Physics, Indian Institute of Science)

One of the most outstanding questions in the field ofsolar system studies is to understand the origin ofthe Sun´s magnetic field varying with a cycle of 22years. Some of the fundamental ideas in dynamo theorywere developed nearly half a century ago. However,one needs fairly detailed information about the flowsand magnetic fields in the interior of the Sun tomake a realistic model of the solar dynamo. Suchinformation was not available till a decade ago. Twodevelopments within the last one decade have changedthe scenario completely. (1) Helioseismology hasmapped the internal differential rotation of the Sun,which is now a crucial ingredient in developingdynamo models. (2) MHD simulations of sunspotformation have put important constraints on themagnetic field in the solar interior. Only veryrecently solar dynamo models are being built whichaddress these issues. I shall present a review ofwhere we stand now on this subject.

RECENT ADVANCES IN THE STUDY OF SOLAR ACTIVITY: REPORTER REVIEW

Barbara J. THOMPSON (NASA Goddard Space Flight Center, Greenbelt MD, USA)

Recent advances in the study of solar activity have been spurred byseveral new missions and ground-based research initiatives, as wellas widespread collaboration of theorists and modelers. Progress has beenmade in our ability to anticipate and react to nearly all types ofsolar variability which impact the heliosphere and Earth; studiesof the origin, flow, storage and release of energy have paved the way for significant advances in our predictive abilities. The review willcover advances ranging from deep into the solar interior, to the study of impulsive releases of energy such as flares and coronal mass ejections, to the interaction of energetic shocks in the inner heliosphere.

ORIGIN OF THE FAST SOLAR WIND: OUR CURRENT UNDERSTANDING AND HOW WE GOT HERE

Joseph V. HOLLWEG (Space Science Center, Univ. of New Hampshire)

Before the discovery of the fast solar wind in the mid - 1970s, it was known that even the average solar wind could not be well explained by models in which electron heat conduction was the energy source and the electron pressure gradient was the principal accelerating force. The Alfven waves discovered around 1970 were thought for a while to provide the sought - after additional energy and momentum, but their wave pressure ultimately failed to explain the rapid acceleration of the fast wind close to the Sun. By the late 1970s, various in situ data were suggesting that protons and heavy ions were being heated and accelerated by the ion - cyclotron resonance far from the Sun. This notion was soon applied to the acceleration region in coronal holes close to the Sun. The models which resulted suggested that the fast wind could be driven mainly by the proton pressure gradient (which is mainly the mirror force if the anisotropy is large), and that the high temperatures and flow speeds of heavy ions could originate within a few solar radii of the coronal base; these models also emphasized the importance of treating the extended coronal heating and solar wind acceleration on an equal footing. By the mid 1990s, SOHO, especially the UVCS (Ultraviolet Coronagraph Spectrometer), provided remarkable data which have given great impetus to studies of the ion cyclotron resonance as the principal mechanism for heating the plasma in coronal holes, and ultimately driving the fast wind. We will discuss the basic ideas behind current research, emphasizing the particle kinetics. We will discuss remaining problems such as the source of the ion - cyclotron resonant waves (direct launching, turbulence, microinstabilities), problems concerning OVI and MgX, the roles of inward - propagating waves and instabilities, the importance of oblique propagation, and the electron heating. Some alternatives, such as shock heating and turbulence - driven magnetic reconnection, will also be mentioned.

THREE-DIMENSIONAL STRUCTURE OF THE OUTER HELIOSPHERE

Nikolai V. POGORELOV (Institute for Problems in Mechanics, Russian Academy of Sciences, Vernadskii Avenue 101-1, Moscow 119526, RUSSIA)

The review is presented of modern three-dimensional models of the outer heliosphere that confines the solar wind (SW) during its interaction with the local interstellar medium (LISM). Among many reasons determining spatial features of the heliospheric interface, the most important are those related to asphericity of the solar wind, prominently manifesting itself during solar activity minima, inhomogeneities in the LISM, and the presence of the interplanetary and interstellar magnetic fields. Starting from the seminal work of E.N. Parker (1961), the SW--LISM interaction is analyzed in the framework of mechanics of continuous media. Once this assumption is made, the heliopause acquires the form of a tangential discontinuity separating two flows and various shock waves can originate. Due to collective processes occurring in plasma, normally only the plasma component of the winds has a mean free path considerably smaller than the characteristic size of the heliosphere. However, the neutral component of the LISM substantially modifies the interface by a charge exchange with plasma particles. This process strongly affects distributions of the plasma and neutral components and substantially changes geometrical parameters of the heliopause and stand-off distances of the principal shock waves from the Sun. The charge exchange also contributes to breaking the spherical symmetry of the solar wind ahead of the termination shock. We analyze the current state of knowledge on the above-mentioned phenomena and discuss interrelations between the Lyman-alpha absorption in directions to nearby stars and possible three-dimensional features of the heliospheric interface. Different theoretical models of the local interstellar cloud are reviewed in order to extract information on the interstellar magnetic field strength and direction. Galactic cosmic ray diffusion into the heliosphere is discussed from the viewpoint of its necessarily three-dimensional character in the presence of the interplanetary magnetic field. New theoretical and computational challenges are set forth, which are critical for obtaining adequate reliable information about processes occurring the heliosphere.

SOLAR WIND INTERACTION WITH WEAKLY MAGNETIZED PLANETS AND COMETS

Christian MAZELLE (CESR / CNRS)

Among solar system bodies, planets like Mars and Venus on one side and active comets on the other side share both the lack of any measurable large-scale magnetic field and the existence of a dense expanding neutral atmosphere. Therefore, it is not surprising that, despite their obvious different physical nature and different characteristic scales, their interaction with the solar wind exhibits many similarities. The most important are the formation of a magnetic barrier in front of the highly conducting ionosphere and an induced magnetic tail, often described by models, e.g., in the frame of gas-dynamics, MHD or kinetic hybrid simulations. The review will cover recent advances in the understanding of this type of interaction with the solar wind both from recent observations, e.g. by Mars Global Surveyor within the Martian environment, and from recent modeling efforts.

COLLISIONLESS SHOCKS AND MAGNETOSHEATH: RECENT RESULTS FROM MULTIPOINT MEASUREMENTS IN SPACE

Vladimir KRASNOSELSKIKH (LPCE/CNRS-Universite d'Orleans)

Several problems of collisionless shocks physics felt the lack of direct measurements of crucial parameters. To study electron heating or acceleration in quasiperpendicular shocks one needs detailed information about spatial and temporal fine structure of electric and magnetic fields across the front of the shock. Until recently, there were only two attempts to evaluate the distribution of electric field potential across the shock front based on the data of ISEE 1,2. The fine spatial structure of the shock front and its time variations were intensively studied in 2D computer simulations but there were no serious effort to study these characteristics experimentally. Some problems such as shock front variations could not be studied using one satellite and even two satellites measurements, which were not sufficient to perform such a research program. Serious improvement of the electric field measurements and multipoint measurements by the Cluster satellites offered the possibility to get new important income to our knowledge of physical processes in the front of quasiperpendicular shocks. Electric field measurements onboard of the Wind satellite allowed to establish the presence of the small scale electric field structures similar to double layers in the ramp region of the quasiperpendicular shock. Similar measurements onboard of Cluster satellites have demonstrated the presence of the small scale electric field structures in the front of low Mach number quasiperpendicular shocks. Analysis of characteristic scales of electric and magnetic fields was performed for many shock front crossings by Cluster satellites. Several shock crossings were studied that gave an evidence of the nonstationary dynamics of the shock front of high Mach number quasiperpendicular shocks. Multiple crossings of quasiparallel shocks have allowed to study in more detail three dimensional characteristics of short large amplitude magnetic field structures (SLAMS). The detailed study of their role for the process of particle acceleration is still to be performed. The combination of the multipoint measurements with the modern methods of data analysis have allowed to perform wave identification in the magnetosheath region. It was unambiguously established the presence of mirror mode waves in the downstrem region of the moderate Mach number high betha shock. Intensive theoretical studies of these waves have provided the possibility to perform more detailed comparison of wave characteristics with theoretical predictions. There were new interesting results obtained onboard of Ulysses satellite that clarify the special role of shocks in particle acceleration. It was clearly shown that the enhanced fluxes of energetic electrons are associated with the crossings of reversed shocks in the vicinity of corotating interaction regions (CIR).

SWARM, A CONSTELLATION MISSION TO IMPROVE OUR UNDERSTANDING OF THE GEOMAGNETIC FIELD

Eigil FRIIS-CHRISTENSEN (Danish Space Research Institute)

A new era in geomagnetic research began with the launch of the Oersted satellite in February 1999. Oersted is the first of a series of geomagnetic mapping missions during the International Decade of Geopotential Research. CHAMP (launched in July 2000) and the Oersted-2 experiment on board the SAC-C satellite (launched in November 2000) will continue to deliver high-precision geomagnetic data during the first years of the new millennium.However, these three satellites have been conceived as single-satellite missions. Recent progress in geomagnetic research indicates that the limiting factor in the accuracy of present geomagnetic field models is the dynamic behaviour of the external current configuration. Single satellite missions are not able to take advantage of the impressive instrument improvement, which has been achieved during the last couple of years. Multiple satellite missions measuring simultaneously over different regions of the Earth offer the only way to take full advantage of this new generation of instruments.A proposal with exactly this aim was submitted to ESA's Earth Explorer Opportunity Mission programme and has been selected for an industrial Phase A Study to be conducted during 2003. The swarm concept consists of a constellation of four satellites in two different polar low altitude orbits. Each satellite will provide high-precision and high-resolution measurements of the vector magnetic field. A few additional instruments like GPS receivers, an accelerometer, and an electric field instrument provide supplementary information for studying the interaction of the magnetic field with other physical quantities describing the Earth system.

GAV.04/07A/A11-002   0930

THE SWARM END-TO-END SIMULATOR STUDY: SEPARATING THE VARIOUS CONTRIBUTIONS TO EARTH'S MAGNETIC FIELD USING SYNTHETIC DATA FROM A SIMULATED MISSION

Nils OLSEN[1], Eigil FRIIS-CHRISTENSEN[1], Roger HAAGMANS[2], Gauthier HULOT[3], Hermann LUEHR[4], Stefan MAUS[4], Michael PURUCKER[5], Terence SABAKA[5], Pascal TARITS[6], Alan THOMSON[7] ([1]Danish Space Research Institute, [2]ESA, ESTEC Earth Sciences Division, [3]Institut de Physique du Globe de Paris, [4]GeoForschungsZentrum Potsdam, [5]NASA GSFC, Geodynamics Branch, [6]Universite de Bretagne Occidentale, [7]British Geological Survey)

The *swarm* mission concept consists of a constellation of foursatellites for studying the Earth´s magnetic field and its interactionwith the Earth environment. Each satellite will provide high-precisionmeasurements of the magnetic field; in combination, they will providethe necessary observations that are required to separate the varioussources of the geomagnetic field. GPS receivers, an accelerometer andan electric field instrument will provide supplementary informationfor studying the interaction of the magnetic field with other physicalquantities characterizing the Earth system. *swarm* has been selected by ESA for a Phase-A study. In parallel withthis Phase-A, an End-To-End simulation of the mission has started.The objective of this End-To-End simulator is to evaluate variousmission and constellation scenarios. This will be done by analyzingsynthetic data in much the same way that will be used regarding thereal data. We will report on the various approaches used for this End-to-Endstudy, and on first results.

GAV.04/07A/A11-003   0950

FIRST MAGNETOMETER RESULTS FROM THE AUSTRALIAN MICRO-SATELLITE FEDSAT

Brian J. FRASER[1], Fred W. MENK[1], Colin L. WATERS[1], Andrew BISH[1], C.T. RUSSELL[2], J.D. MEANS[2] ([1]Cooperative Research Centre for Satellite Systems, University of Newcastle, School of Mathematical & Physical Sciences, [2]IGPP/UCLA, Los Angeles, CA, USA)

In December 2002 FedSat, an Australian scientific microsatellite (58 kg) was launched from the NASDA Tanegashima Space Centre on the HIIA-F4 rocket. FedSat was placed in an 800 km altitude 98.7° inclination polar orbit, sun-synchronous at 10:30 LT. The primary scientific experiment is NewMag a triaxial fluxgate magnetometer designed to study magnetosphere- ionosphere coupling through measurements of the Earth's magnetic field and its variations. NewMag observes field aligned current structures in the auroral zones and ultra-low frequency (ULF) plasma waves in the upper ionosphere. This paper will describe the NewMag instrumentation, and initial data initial reduction. The FedSat orbit period is ~ 101 minutes and during this time NewMag passes through the auroral zone current systems four times. It is anticipated that initial results from NewMag showing field aligned current signatures in the geomagnetic field and ULF waves associated with field line resonance and compressional cavity mode waves, will be presented.

GAV.04/07A/A11-004   Invited   1030

NET FIELD-ALIGNED CURRENT SYSTEMS AND THEIR EFFECTS ON THE GROUND

Toshihiko IYEMORI[1], Shin'ya NAKANO[2], Satoru YAMASHITA[2] ([1]Data Analysis Center for Geomagnetism and Space Magnetism, Graduate School of Science, Kyoto University, [2]Geophysical Institute, Graduate School of Science, Kyoto University)

Field-aligned currents normally appear as a pair of upward and downward currents and close in the ionosphere. If the amount of upward and downward currents balances, the magnetic effects generated by the currents would be mostly confined in the current flowing region. However, if there exists some imbalance, i.e., ´net´ field-aligned current, the magnetic effects reach to distant region. This effect appears even at mid- or low- latitudes in midnight and could be a source of significant errors in modeling geomagnetic main field. For example, a pair of net field-aligned currents which flow into the ionosphere on the dayside and flows out from night side generates east-west disturbance fields in middle latitudes. We present the net current systems estimated from satellites and ground geomagnetic field observations and estimate their quantitative effects.

GAV.04/07A/A11-005   1100

MODELLING OF POLAR FIELD-ALIGNED CURRENT SYSTEMS

Peter STAUNING[1], Dan WEIMER[2], Vladimir PAPITASHVILI[3], Freddy CHRISTIANSEN[1] ([1]Solar-Terrestrial Physics Division of Danish Meteorological Institute, [2]Mission Research Corporation, [3]SPRL, University of Michigan)

Compared to the earlier high-precision Magsat magnetometry mission (1979-80) the Oersted and CHAMP satellites have since 1999 provided much more complete coverage with respect to local time and geophysical conditions. The Magsat satellite had a fixed dawn-dusk orbit and even with the added spread in local magnetic time Magsat still gave poor coverage of the noon and the midnight sectors. With data from Oersted and CHAMP in their drifting orbits it has been possible to investigate the important high-latitude field-aligned current (FAC) and ionospheric current systems, like the cusp currents and the substorm current systems, located in these sectors. The added local time coverage has enabled a more complete determination of the local time dependencies in further ionospheric, magnetospheric and field-aligned current systems like the the auroral electrojet currents and the region 1 and region 2 high-latitude field-aligned current systems. With the abundance of high-quality data the comprehensive statistical basis has now enabled the development of sophisticated models for the current distribution and intensities in dependence of solar wind and magnetospheric parameters. Three models for the polar FAC distribution based on different procedures for relating the observed magnetic perturbations to FAC´s shall be presented and their predictions will be compared to each other and to actual observations. There are still large uncertainties involved in using the new models primarily due to the lack of precise knowledge of the temporal development of the currents in relation to the highly variable solar wind parameters and the still unpredictable effects of magnetospheric substorms.

GAV.04/07A/A11-006   1120

MAGNETIC SIGNATURE OF MAGNETOSPHERIC SOURCES IN CHAMP DATA

Judith SCHWARTE[1], Aude CHAMBODUT[2], Hermann LUEHR[1], Mioara MANDEA[2] ([1]GeoForschungsZentrum Potsdam, Div. 2.3, [2]IPG Paris, Laboratoire Geomagnetisme)

For modeling the main and crustal fields it is necessary to describethe magnetic field contributions from large-scale magnetosphericcurrent systems, as the ring current. In general, the satellite dataare corrected using the D_{st} index. However, a firstparameterisation of the external magnetic fields using CHAMP scalardata suggests that some problems may occur with this commoncorrection, specially near the poles and in modeling the local timedependences. For a better description of the effects caused by thering-current, CHAMP vector data are used in a second approach. From time to time the satellite is flying in resonance with theEarth´s rotation, and we just took advantage of these orbital repeattracks. While the contribution of magnetospheric effects isemphasised, the lithospheric contributions and model errors areeliminated by this technique. The differences of such two sucessiverepeat tracks are taken as input data. In order to minimise non-scalarpotential contributions, before applying the SHA, we determine`Ampere´s law integral´ over one-full orbit and correct the data overa region of ± 20° around the poles. The east component isnot taken into account because it is strongly affected by thefield-aligned currents. We present the used data and technique, andthe obtained results in modeling internal and external magnetic fieldsin a dipole-axis/local time frame.

GAV.04/07A/A11-007   1140

PRELIMINARY CORRELATIONS OF SATELLITE AND GROUND MAGNETIC VARIATIONS TO ESTIMATE SCALE-LENGTHS OF INDUCING FIELDS

Nandini NAGARAJAN[1], Manoj C.[1], Stefan MAUS[2] ([1]National Geophysical Research Institute, [2]GeoForschungsZentrum Potsdam, Telegrafenberg, 14473 Potsdam, Germany)

Natural electromagnetic fields are measured on the earth´s surface to estimate the electrical resistivity of the sub-surface, by means of Magnetotellurics (MT). The phase and amplitude of the E/H ratios, as a function of frequency, are dependent on the Earth´s subsurface electrical resistivity. MT long period source field (>1 second) is generated by the interaction of solar wind with earth´s magnetosphere. Man-made as well as natural distortion corrupts these fields and may result in erroneous estimates of resistivity and phase. Many attempts have been made to reduce the effect of such noise in inducing fields on computed resistivity estimates. Recent studies have shown the coherence of MT magnetic field over distance >500 km. An attempt is made here to examine the coherency of simultaneous measurements of magnetic fields (>1sec period) on the ground and by the CHAMP satellite. Additionally data at a distant magnetic observatory are also examined. A few samples of data have been examined in this preliminary study. The present study, if successful, would aim at reducing noise in MT resistivity estimates using vector magnetic data from CHAMP and distant observatories.Additionally the study of changing time and length-scales of natural magnetic variations that form the inducing fields for all induction studies would be brought out in this study as there are recorded instances where the uniform inducing field changes its length-scale unexpectedly. With the time and effort spent in collecting electromagnetic time series for induction experiments it would be worthwhile to assess the effects of changes in external magnetic field variations as measured at a sufficiently distant source - such as satellite magnetic data.

GAV.04/07A/A11-008   1200

GLOBAL SCALE IONOSPHERIC IRREGULARITIES ASSOCIATED WITH THUNDERSTORM ACTIVITY

Sergey A. PULINETS, Viktor H. DEPUEV, Amando C. LEYVA (Institute of Geophysics, UNAM)

The potential difference near 280 kV exists between ground and ionosphere. This potential difference is generated by thunderstorm discharges all over the world, and return current closes the circuit in the areas of fair weather (so-called fair weather current). The model calculations and experimental measurements clearly demonstrate non-uniform latitude-longitude distribution ofelectric field within the atmosphere. The recent calculations show that the strong large scale vertical atmospheric electric field can penetrate into the ionosphere and create large scale irregularities of the electron concentration.To check this the global distributions of thunderstorm activity obtained with the satellite monitoring for different seasons were compared with the global distributions of ionosphere critical frequency (which is equivalent to peak electron concentration) obtained with the help of satellite topside sounding. The similarity of the obtained global distributions clearly demonstrates the effects of thunderstorm electric fields onto the Earth´s ionosphere.

MODELING OF THE GEOMAGNETIC FIELD FROM THE JERK ASSUMPTION

Anahit Hovhannes SIMONYAN (Institute of Geophysics & Engineering Seismology of the National Academy of Sciences, Armenia)

Elucidating the geomagnetic field behavior for the XX century with construction it up to second time derivatives accuracy models we get appropriate data basis for solving the reverse problem of magnetic hydrodynamics on description of mechanism of core fluid motion system reorganization, which originates the jerks in the Earth's magnetic field.For this goal we have screened out the extended set of geomagnetic field elements annual mean values from 153 worldwide magnetic observatories. In development of jerk investigations we have kept the conception that in large regional scale the geomagnetic field dynamics for a few decades is characterizing by constant values of accelerations, which suffer jump-like changes during the jerk events. Hence meaningful, from physics point of view, method of piecewise linear approximation has been applied to the series of geomagnetic field X, Y and Z strength components annual mean values first time derivatives series. Slops of linear segments in nT a-2 present the geomagnetic field values second time derivatives. These values are input constructing the spatial spherical harmonic models of geomagnetic accelerations field at each central epochs of stable state interval between the successive jerks on the globe. Four harmonic global models dated on 1901, 1909, 1922, 1931, 1943, 1955, 1963, 1975, 1982 and 1992 are constructed for the XX century. It would be noticed however that the model on 1901 has anomalous powerful energy spectrum and is deteriorated by incredible strong foci on south hemisphere, when mapping the accelerations field components computed from this model. Obviously lack of data series from main part of south hemisphere at the beginning of XX century prevent from construction of more accurate model. While power spectrums for all of remainder models are of reasonable amplitudes with domination of first two non-dipole harmonics energy. And on the maps from those models are observed reasonable magnitudes in changeable sign large regional foci, depicting internal nature of mapped field. Furthermore, despite of constant accelerations global models are repeated over a decade, regional patterns from one model to another are not changing everywhere, so well reflecting the observational data, by which their regional feature the neighboring jerks are divided by more than one, or in majority over a three, or even more decades. Construction of 6-, 8-harmonic models for second half of century resulted the similar feature of foci distribution but depicted also small-scale peculiarities, which could not be supported by observational data accuracy and density in their distribution. Hence we rely the homogeneity and better accuracy in modeling the geomagnetic accelerations field while interrupted the expansion series at fourth harmonic. On the basis of IGRF-1980 and IZMIRAN-1985 for geomagnetic field, using the acceleration model on 1982 coefficients set for SV-1980 have been computed. Better accuracy of secular variation computed model is proved by its persistent correlation with data based IGRF and IZM-SV models for 1980. Then that with obtained second time derivative models were used for extension the IGRF-1980 field model forward and back during the XX century transferring from one jerk to another.

THE CONTRIBUTION OF MAGNETIC ANOMALIES TO UNDERSTANDING TECTONIC EVOLUTION AND CRUSTAL STRUCTURE

Colin V. REEVES (International Institute for Geo-information Science and Earth Observation (ITC))

Since shortly after the invention of the electronic magnetometer in the 1940s, airborne systems have been used to map variations in magnetic total field strength (F) over the Earth's surface. From initial naAEe ambitions of finding buried magnetite deposits of economic value, the technique has evolved into one of the most sophisticated (yet inexpensive) tools for rapidly mapping geology over large areas. Reconnaissance surveys of a technical standard achievable in the period until ~1990 cover over half the land area of the Earth and have been systematically compiled for many large (continent-sized) regions. But even the assembly of thousands of individual surveys on land and millions of km of shiptracks at sea, while giving a tantalizing new glimpse of the Precambrian mosaic of the continents, does not yet provide a complete global magnetic anomaly map. The elegant simplicity of the magnetic anomaly patterns over the ocean has, nevertheless, been seminal in the evolution of ideas on ocean-floor spreading and global tectonics. The global uniformity of coverage afforded by satellite magnetometry, meanwhile, is obviously highly attractive. Unfortunately, potential field theory predicts that the resolution of anomalies at satellite altitude will be no better than several hundred kilometres. And experience from Pogo and Magsat over 20 years ago shows that amplitudes of even the largest crustal anomalies are no more than 10-20 nT. Improved technology has overcome the problem of signal-to-noise ratio and hence anomaly reproducibility in the current generation of satellite-borne magnetometer systems. Improved resolution of detail can only be attempted as satellites descend into lower - ultimately fatal - orbit. The GFZ 'Champ' satellite mission has produced a stable picture of crustal magnetic anomalies and their reconciliation with crustal geology has commenced. One of the largest anomalies is coincident with an area of the Arctic Ocean that has a distinctive signature on the marine/aeromagnetic anomaly compilation – probably a large igneous province lying entirely below sea level. Three distinct anomalies, now situated above Early Creataceous oceanic crust off South Africa, Antarctica and Argentina respectively, coalesce when ocean creation is reversed in computer animation, suggesting a common origin off the southern coast of Africa during the early stages of dispersal of the three continents, 120-140 million years ago. Several pairs of anomalies in the South Atlantic and Indian Oceans suggest a similar conjugate origin on now-opposing sides of their respective mid-ocean ridges. Anomalies over the continents at satellite altitude are less easily related to what is known of the Precambrian crust. Suggestions of ancient meteorite impacts are not easily verified from direct observation of the crustal geology, such as in the Bangui region of central Africa.

GAV.04/07P/A11-002   1430

DEPTH OF THE MAGNETIC CRUST IN THE INDIAN SUBCONTINENT

Mita RAJARAM, Anand P. SASHIDHARAN (Indian Institute of Geomagnetism)

Aeromagnetic anomaly map over Indian Peninsula (from 8 to 24 degrees North) is prepared and downward continued to ground level. This is merged with available marine magnetic data and available ground magnetic data to fill gaps in the aeromagnetic data set. Distinct structural trends are identified and some of the features within the continent continue into the offshore area. From the aeromagnetic data combined with the gravity anomaly of the region, the different tectonic blocks are identified. An analytical signal map of the aeromagnetic anomaly is prepared and the different source fields are located; the sources of the magnetic anomaly within the different blocks are distinctly different. The data are also subjected to high pass filtering process. The depths are calculated from the spectral plots, in order to peep into the source depth of the magnetic anomaly in the different blocks like the Southern Granulite Terrain (SGT), Dharwar region, Eastern Ghat Mobile belt, etc. In Dharwar craton the magnetic sources extend up to a depth of around 36 km, possibly reflecting the average Moho depth. Within the SGT the magnetic crust is thin and is confined to within the first 22 km, with the deeper levels not contributing significantly to the magnetic signatures. Kuppam-Palani seismic reflection / refraction profiles also depict a change in velocity around this depth in the SGT. We conclude that below the exhumed crust of the SGT there is a lithological / mineralogical change at around 22 km depth caused possibly by magmatic underplating or the Curie isotherm is shallow when compared to the Dharwar craton. Satellite magnetic anomalies contain information of the long wavelength structures of the magnetic lithosphere above the Curie isotherm. The integrated susceptibility map from Oersted data (Purucker, 2002) depicts a low in the SGT when compared to the Dharwar region. From the Standard Earth Magnetisation Model (SEMM) developed from the global POGO / Magsat data, crustal anomaly depth over the Indian subcontinent is derived. The SGT depicts low crustal thickness values when compared to the Dharwar region. There is a reasonably good comparison between the depth estimates for these two blocks from the satellite derived and aeromagnetic derived crustal depth values. The implications of the depth estimates of the entire region will be discussed.

GAV.04/07P/A11-003   1450

3D GLOBAL INDUCTION EFFECTS ON GEOMAGNETIC FIELD VARIATIONS INFFERED FROM THE RESPONSE TO RING CURRENT AND AURORAL OVAL EXCITATION

Ikuko FUJII[1], Adam SCHULTZ[2] ([1]Kakioka Magnetic Observatory, JMA, [2]Earth Science Dept., Cardiff Univ.)

We report on global-scale induction effects on the geomagnetic field at the surface of the Earth over several decades of observations. We developed a statistically robust form of empirical orthogonal function (EOF) analysis to analyze a spatially and temporally sparse data set. This has resulted in an improved compilation of the functions representing the geoelectromagnetic response of the Earth´s mantle. Fujii & Schultz (2002) presented the first results and an updated version of the functions in the spatial coverage and quality is shown in the present study. The EOF method was applied to a newly assembled global catalogue of magnetic observatory hourly mean values. The analysis indicates that for periods longer than 5 days the geomagnetic field variation can be represented predominantly by a single eigenmode. We have identified that the primary source fields of the dominant mode consist of two current systems in the same direction: an equatorial ring current in the magnetosphere, and two conjugate auroral oval ring currents in the ionosphere. The influence of the auroral current system is seen at surprisingly low latitudes, 40 and 50 degrees for the vertical and northern components, respectively, which results in non-negligible bias in the conventional c response at latitudes higher than 40 degrees. To correct the auroral current effect on the dominant EOF mode, the geomagnetic field by conjugate ring currents at the auroral oval was computed at the surface of a conductive Earth. The height and amplitude of the currents were determined in the least squares sense. Having established the optimal geometry of the auroral currents, the estimated auroral effects were removed from the dominant EOF geomagnetic response mode. Unbiased c responses were obtained for data from more than 50 observatories at latitudes from 60 to 60 at periods from 5 to 106.7 days. A newly defined d response function, which constitutes a sensitive indicator of lateral heterogeneities in conductivity was also estimated. The c and d response functions show significant spatial variations and vary stably with frequency. This is consistent with the view that significant lateral variations of the conductivity are found in the upper- and mid mantle. These new sets of electromagnetic response information are expected to increase the resolving power of the 3D distribution of electrical conductivity in the Earth´s mantle.

GAV.04/07P/A11-004   1510

USING SATELLITE MAGNETIC DATA FOR PROBING THE ELECTRICAL STRUCTURE OF THE EARTH

Pascal TARITS (UMR CNRS Domaines Oceaniques, IUEM/UBO)

The magnetic field of the earth results from two primary sources, convection in a conductive liquid core and the interaction between the planet and solar wind plasma, and from two secondary sources, the local magnetisation and electric currents induced in the planet by the transient magnetic fields of external origin. The external natural fluctuations (the primary source) of the magnetic field induce an internal response (the secondary source) that can be used to infer the electrical conductivity structure of the planet. The maximum depth resolved by the technique is a function of the longest period of variations of the external magnetic sources that may be recovered from the data. The external transient variations result from both the interactions between the planetary environment and the solar wind plasma.Traditionally, induction studies on Earth make use of magnetic data recorded continuously at stations set up at the Earth surface transitionally or permanently (the geomagnetic observatories). The successful launch of several magnetic satellite missions in the last few years (OERSTED, CHAMP, SAC-C) has triggered the interest of the electromagnetic induction community to use satellite data to investigate the electrical conductivity of the Earth. The satellite provides a complete coverage of the planet. Measuring the vector magnetic field in a satellite surveying the planet offers the unique opportunity to investigate at planetary scale the heterogeneous electrical conductivity structure of the Earth´s mantle. Results using data from OERSTED and CHAMP are presented and a new approach to extract the internal induced anomalous magnetic field is discussed.

ELECTRIC AND MAGNETIC FIELDS GENERATED BY OCEAN FLOW

Robert H. TYLER (Ocean Physics Dept., Applied Physics Laboratory, University of Washington)

Through magnetohydrodynamic interaction between ocean flow and the main magnetic field, secondary electric and magnetic fields are generated. It has recently been shown that the

ocean tides generate magnetic fields which are clearly evident in magnetic observations of the CHAMP satellite. We review these results together with other evidence, and discuss the opportunity for identifying other ocean signals in the magnetic records.

CORE DYNAMICS REVEALED BY SPACE MAGNETIC OBSERVATIONS

Gauthier HULOT (Departement de Geomagnetisme et Paleomagnetisme, IPGP/CNRS)

Magsat in 1980, was the first satellite capable of mapping the Earth's magnetic field up to degree and order 13. Oersted, launched in 1999, is the second satellite with similar capability. This offered the first opportunity to study the detailed way the core field had changed in 20 years time (Hulot et al., Nature, 416, 620-623, 2002) and revealed several striking features. First, that the smallest visible scales of the core field can change with time scales as little as 50 years, second that most of the changes have occurred only at polar latitudes or beneath the Atlantic Hemisphere, while very little changes seem to have occurred below the Pacific Hemisphere. This asymmetry echoes the current asymmetric pattern also found in the field itself at the core surface, which displays strong normal polarity values below the Pacific hemisphere, and much weaker, sometimes reversed values below the Atlantic hemisphere. Thanks to the high resolution of the field changes seen between Magsat and Oersted, it is also possible to try and infer core flows accounting for those changes, in very much the same way than has been done with historical data, but with a better resolution. Those maps, together with those of the field and its temporal changes can then be used for comparison with results from recent dynamo simulations. This can lead to stimulating interpretations. However, care must be taken when carrying such comparisons. Numerical simulations are still being run in unrealistic parameter regimes. But also, core flow computations remain limited in resolution. The good news is that this limitation is no longer linked to the quality of the observations. Satellite observations now appear to provide good enough field models (and field change models) as soon as the satellites are up for more than two years (as has been the case since the launch of Oersted, joined more recently by Champ) The bad news is that the limitation is now linked to the fact that we may not have access to the smallest scales of the core field, hidden by the crustal field. This not only stops us from recovering the smallest scales of the core flow, but also means that we should avoid interpreting too much of the smallest scales of the field changes in terms of computable flows. As a consequence, it may for instance be that the weak changes seen below the Pacific Hemisphere could mainly be due to inaccessible small scale flows (Eymin and Hulot, in prep.). This somewhat negative note should however not hide the important fact that continuous observation of the Earth's magnetic field from space has now been proven to provide much better images of the time varying core field, with a temporal resolution already of the order of a couple of years. Smarter missions, such as the Swarm constellation, could help reduce this temporal resolution to less than a year. This will eventually offer the possibility to study short-term dynamics of the core in much more detail than was previously possible.

GAV.04/07P/A11-007 — 1640
SHORT-PERIOD SECULAR VARIATION AND CORE DYNAMICS

Jeremy BLOXHAM, Mathieu DUMBERRY (Department of Earth & Planetary Sciences, Harvard University)

A large part of the short-period secular variation (which we define as the part that is unexplained by steady flow) can be fit by a small number of torsional oscillations in the core. In particular, torsional oscillations provide a simple though unexpected explanation of geomagnetic jerks: unexpected because torsional oscillations have strong symmetry properties(they are both axisymmetric about the rotation axis and symmetric about the equator) while geomagnetic jerks have a highly asymmetric geographical distribution.The fit of torsional oscillations to geomagnetic jerks is not perfect. Given that it is unlikely thata separate physical phenomenon happens to combine with torsional oscillations to produce jerks,we hypothesize that the misfit most likely results from insufficient temporal and spatial complexity in our field and flow models. Here we examine what we can learn about the complexity of the field and flow at the core surface from requiring a more complete fit to the observations.From this we can hope not only to gain an understanding of the spectrum of the field and flow atthe core surface, but also a more complete spectrum of torsional oscillations which will provideimportant insight into the dynamics of the core.

GAV.04/07P/A11-008 — 1700
CHAOS IN THE PRESENT EARTH MAGNETIC FIELD: A SYMPTOM THAT A REVERSAL IS IN PROGRESS?

Angelo DE SANTIS[1], Tozzi ROBERTA[2], Luis R. GAYA-PIQUE'[3] ([1]Istituto Nazionale Geofisica e Vulcanologia, Rome, Italy / Earth Science Department, G. D'Annunzio University, Chieti, Italy, [2]Istituto Nazionale di Geofisica e Vulcanologia, Rome, Italy, [3]Istituto Nazionale di Geofisica e Vulcanologia, Rome, Italy / Observatori de l'Ebre, Roquetes, Spain)

Understanding the spatial and temporal characteristics of the geomagnetic field would allow us to infer important properties of the dynamics in the outer terrestrial core, where the geomagnetic field **B** is produced and maintained. In this contribution we apply the concepts of Information Theory to the geomagnetic field, as represented by global models of the last 100 years, to investigate on the temporal behaviour of a very important quantity for a physical system: its information content. The results support the idea that **B** is in a chaotic state with characteristic times close to those related to the westward drift of the secular variation (~1000 yr) and to the convective overturn time in the outer core (~500 yr). We also show that the dipole field has a characteristic time equal to the time-span (~5000 yr) of a reversal (i.e. the change of polarity of the field), leading us to suspect that loss of memory about its, possibly chaotic, origins plays an important part on geodynamo mechanisms. The main consequence of these results, and of the comparable results obtained from the analysis of the secular variation, is the suggestion that a possible geomagnetic reversal is currently in progress.

GAV.04/07P/A11-009 — 1720
MAGNETIC FIELD SECULAR VARIATION: THE SATELLITE PERSPECTIVE

Benoit LANGLAIS (NAS/NRC at NASA/GSFC)

The temporal changes of the Earth´s magnetic field are usually modeledusing observatory data. Indeed the secular variation models rely onlong-term series of magnetic measurements. Up to now, only theobservatories were able to provide such measurements. The first halfof the Decade of Geopotential Research has seen the launch of threesatellites, Ørsted, CHAMP and SAC-C. These three satellites arededicated to monitoring the space and temporal changes of the Earth´smagnetic field. In this study we present the combined use the vectorand scalar measurements made on-board these satellites to model thesecular variation. First, data are selected with respect to theirlocal time and to the external activity

indices. These data aresorted so that their geographical distribution are as equiangular aspossible. Then, secular variation models are derived using twoapproaches. In the first one, we solve for the main field and thesecular variation Gauss coefficients together. In the second, we firstderive short-time main field models, from which the secular variationis derived by subtracting the coefficients from consecutive models. Acomparison of the methods is presented, in terms of rms behavior andfield spectra. We also discuss the core properties inferred fromthese models, including the core radius estimation, and the diffusivetimes of the magnetic field.

GAV.04/07P/A11-010 — 1740
GLOBAL SPACE-TIME MODELLING OF THE GEOMAGNETIC FIELD UTILIZING NOISY DATA

Vadim P. GOLOVKOV, Tatiana N. BONDAR, Svetlana V. YAKOVLEVA (IZMIRAN)

Most precise data are obtained from magnetic observatories. These data are continuous in time, but very irregular in space. Supposing that exact data from irregular network can be used for obtaining precise model, the noise level of data was investigated as a factor of obtained models distortion. It was shown, that random numbers, taken as pseudodata in the observatory network, produce false anomaly with magnitude two orders more then their rms over large empty areas. A method of randomization was developed to minimize these false anomaly and to increase, in this way, an accuracy of models obtaining from analyses of data from uneven net of magnetic observatories.

SWARM, A NEW OPPORTUNITY TO IMPROVE GLOBAL MAGNETIC FIELD MODELS

Eigil FRIIS-CHRISTENSEN (Danish Space Research Institute)

The Oersted satellite launched in February 1999 was the first in a series of geomagnetic mapping missions during the "International Decade of Geopotential Research". The high accuracy of the observations from these missions resulted in great advancements in geomagnetic field modelling. It was also shown that now the quality of the geomagnetic field models is related to the sophisticated separation of magnetic contributions of internal and external origin. Due to the dynamic nature of the external magnetic field the only way to reduce this ambiguity is to use simultaneous high precision observations from multiple satellites around the Earth.The SWARM concept with a constellation of four satellites in two different polar low altitude orbits has been proposed in response to ESA's Earth Explorer Opportunity Mission programme and was selected for an industrial Phase A Study to be conducted during 2003. Recent investigations have shown the great advantage of modelling the Earth's main field and its secular variation simultaneously with ionospheric and magnetospheric contributions in a comprehensive approach by means of a joint inversion of ground-based and satellite magnetic field measurements. The ability of SWARM to obtain simultaneous measurements at different places in space will allow a better separation of internal and external sources, thereby improving geomagnetic field models.A decision to implement the mission will provide important new knowledge about the Earth´s magnetic field and its variations and create a wealth of new scientific opportunities for the whole science community.

GAV.05/08A/A11-002 — 0900
IMPROVED SEPARATION OF SOURCES USING SATELLITE AND GROUND-BASED DATA AND DAILY DIPOLE ESTIMATES

Susan MACMILLAN, Alan THOMSON, Vincent LESUR (British Geological Survey)

 Using Ørsted satellite data we investigate the effects on model misfits as a result of including ground-based data and daily dipole terms. In general, satellite data are well distributed in space but less so in time whilst observatory data are well distributed in time but poorly distributed in space. However, often only observatory annual and monthly mean values are used in global modelling, or, if hourly mean values are used, estimates of the rate of change of the internal field are made by fitting simple functions to a selection of values. In the models presented here we use observatory hourly mean values directly and solve for the crustal biases. We also make some comments about the use of other ground-based data, in particular repeat station data, for global modelling. In order to characterise the rapidly varying magnetospheric and induced contributions, the external and internal dipole Gauss coefficients are re-calculated for each day where there are sufficient data. This avoids using coefficients for annual and semi-annual periodicity and magnetic activity indices. Preliminary results indicate improvements to the fits of the data when this new technique is used. Thus, by combining satellite and observatory hourly mean data and improving the parameterisation, the resulting models should represent a better description of the contributing sources. In turn, this should lead to a better prediction of secular variation which is important for the IGRF.

GAV.05/08A/A11-003 — Invited — 0920
A COMPARISON OF MAGNETIC FIELDS FROM THE LATEST COMPREHENSIVE MODEL AND OTHER EARTH MODELS, PARTICULARLY OF CORE AND LITHOSPHERIC ORIGIN

Terence John SABAKA[1], Nils OLSEN[2] ([1]Geodynamics Branch, Code 921, NASA/Goddard Space Flight Center, [2]Danish Space Research Institute, Copenhagen, Denmark)

The terrestrial magnetic environment contains field contributions fromseveral major current sources. There are several philosophies as to the bestway to extract these constituent signals. Comprehensive models (CMs)parameterize fields from all these sources and coestimate their coefficients;the premise being that the important cross-correlative information will allowa proper partitioning amongst these signals. However, other methods have alsoenjoyed varying degrees of success. Of course, as the methods vary so do theresultant models. In addition to a brief description of the latest CM, thistalk will attempt to

evaluate some of the differences which exist betweenthese models with respect to the more commonly described portions of the field,such as the core and lithosphere.

GAV.05/08A/A11-004   0950

REALISTIC ESTIMATES OF THE VARIANCES OF SPHERICAL HARMONIC GEOMAGNETIC FIELD MODELS DERIVED FROM SATELLITE DATA

Frank J. LOWES[1], Nils OLSEN ([1]University of Newcastle, [2]Danish Space Research Institute)

We show that conventional estimates of the variances of the spherical harmonic coefficients can be grossly wrong. Because the modelling ignores the presence of along-track serial correlation in the (largely magnetospheric) data ´noise´ it underestimates the variances of the tesseral (m=n) and near-tesseral coefficients by large factors (up to 20 for the Ørsted OSVM model). Conversely, other variances can be overestimated (by a factor of up to 4). Also, an approach which does not adequately model the effect of ionospheric currents can lead to there being large systematic errors in the zonal (m=0) and near-zonal coefficients, together with an enhancement of the variances of these terms.

GAV.05/08A/A11-005   1010

TOWARD IMPROVING THE MODELING OF THE MAIN GEOMAGNETIC FIELD

Crisan DEMETRESCU, Venera DOBRICA (Institute of Geodynamics, J.L. Calderon St., Bucharest 37, R-70201, Romania)

Annual mean values at geomagnetic observatories and annual values at repeat stations contain a well known but forgotten component, namely the solar-cycle-related (SC) variation. The SC variation in the annual means of the horizontal and vertical components of the geomagnetic field at European observatories is used to infer information on the magnetic and electric properties of the interior, characteristic to the observatory location, by identifying and analyzing the magnetic induction component and respectively the electromagnetic induction component of the SC variation. The obtained results and the method can be used to better constrain the anomaly bias in main field modeling. A similar treatment for the Romanian repeat stations network data is presented as well. The analysis of long series of geomagnetic data from several observatories reveals the presence of longer period components, namely the 22 and 80-90 years cycles, also related to the solar activity, which might bias the secular variation model viewed as a linear variation of the main field coefficients between two successive 5-years epochs of IGRF and DGRF.

GAV.05/08A/A11-006   1050

MODELING OF HIGH-LATITUDE GEOMAGNETIC FIELD DISTURBANCES AT SATELLITE ALTITUDES FOR VARIOUS IMF CONDITIONS

Vladimir PAPITASHVILI[1], Freddy CHRISTIANSEN[2] ([1]SPRL, University of Michigan, [2]Danish Meteorological Institute)

We present a new model of high-latitude geomagnetic field disturbances generated by the varying 3-D system of field-aligned and ionospheric currents at satellite altitudes. This model is based on the high-precision magnetic field measurements made onboard of the Ørsted and CHAMP satellites in 1999-2002. The model is parameterized by the interplanetary magnetic field (IMF) strength and direction, as well as by the Earth's dipole tilt angle. Specific attention is paid to determining a set of geomagnetic variations during quiet conditions for different seasons; that is, when IMF nears zero. The latter allows us to better understand how the high-precision magnetic field surveys over high latitudes can be utilized for the main geomagnetic field modeling. We compare our 'disturbance´models for various IMF conditions and seasons with the actual satellite measurements to estimate how well our statistical patterns mimic observations along the orbits.

GAV.05/08A/A11-007   1110

MAIN AND LITHOSPHERIC FIELD MODELS FROM CHAMP VECTOR DATA

Stefan MAUS[1], Monika KORTE[1], George BALASIS[1], Hermann LUEHR[1], Mioara MANDEA[2] ([1]GeoForschungsZentrum, [2]IPGP)

With its low orbit, long life time, high-resolution magnetometers, dual head star camera, and an almost 100% data coverage, CHAMP determines the geomagnetic fieldwith an unprecedented resolution and accuracy. The lithospheric fieldis now resolvable to 500 km wavelength, corresponding to spherical harmonics of degree 80.We argue that further improvements now hinge on the prediction and subtraction of the weak but significant fields generated by ocean flow.CHAMP is also particularly suited for main field studies. Having 2 star camera heads pointing into different directions significantly reducesthe inherent uncertainty in satellite attitude, in particular the errors in the rotationangle about the star camera bore sight.The standard calibration scheme applicable for spinning satellites fails for CHAMP,due to its stable attitude in the presence of non-potential fields.However, we show that by making use of the orbit characteristics and modelling thenon-potential fields, CHAMP´s star camera orientation is well constrained.As inferred from the degree spectrum, the secular variation of our main field model from CHAMP-vector-only data is reliable to degree 11. We plan to furtherconstrain the satellite derived secular variation back in time by including earlier CHAMP scalar and Oersted measurements. The results are verified against data provided by Intermagnet observatories.

GAV.05/08A/A11-008   1130

GLOBAL MODELS OF THE LITHOSPHERIC MAGNETIC FIELD FROM SATELLITE DATA

Kathryn A. WHALER[1], Michael E. PURUCKER[2] ([1]School of GeoSciences, University of Edinburgh, [2]Geodynamics Branch, Goddard Space Flight Center)

Several satellite missions have now provided high quality 3-component magnetic measurements of the Earth´s field from low altitude orbits. Careful data selection and subtraction of models representing external, main and induced field sources give estimates of the magnetic field due to lithospheric sources. Consistent images of the lithospheric field have emerged from the different missions. Consistency is easier to judge, and the results easier to interpret, if the data are reduced to common altitude or modelled in terms of lithospheric magnetisation. We present models of the lithospheric field downward continued to the Earth´s surface and magnetisation models. Both types of model are calculated using a Green´s function basis, and we regularise the solutions. The computational effort of solving a linear system of dimension many tens of thousands is eased by the matrices relating the data to the model parameters being sparse; we are therefore able to employ the conjugate gradient iterative scheme. The resulting maps retain the full resolution of the original data. Our magnetisation models include both induced and remanent magnetisation, with the division between the two determined by the regularisation constraint. The component

consistent with induced magnetisation agrees well with induced magnetisation models based on equivalent source models. Global maps of the downward continued field and lithospheric magnetisation will be presented, and their interpretation discussed.

GAV.05/08A/A11-009   1150

MIX AND MATCH, MULTIPLE SATELLITE DERIVED, GLOBAL AND AUSTRALIAN REGIONAL MAIN FIELD MODELS

Jon TURNER, David IVERS, Denis WINCH (School of Mathematics and Statistics, University of Sydney)

Concurrent satellites, which are widely spaced in orbital radius, offer an opportunity to separate the internal and external potentials of the earth's main field with greater accuracy than normally achievable with a single data source. However, satellite derived global models of the Earth's main field are a necessary compromise of least squares or least modulus criterion with data containing various attitude inaccuracies. A more accurate model may be possible with the inclusion of data from quality ground-based observatories especially when the model is to be used to predict main field evolution over continental sized areas. Champ and Oersted have had attitude determination problems and SAC-C appears to have little chance of yielding vector data. It is possible to use these data in conjunction with data from ground based observatories in a variety of ways, such as excluding certain data in rotation or weighting according to confidence levels, and then compare results both globally and over the greater Australian region. As a test of the accuracy of the satellite attitude solution, some of the vector data can be 'scalarised´ and then 'equatorially biased´ if some knowledge of the dip equator is available. If secular variation is of prime interest then models based on net changes from some defined epoch may be of greater reliability.

GAV.05/08A/A11-010   1210

TWO LONG BALLOON PROFILES ACROSS THE PACIFIC OCEAN AT AN ALTITUDE OF 30 KM

Yves COHEN, Ali LATROUS (Institut de Physique du Globe de Paris)

Stratospheric balloons can be used to measure theEarth magnetic fiield, at an analtitude between 20 and 30 km, bridging the gap between satellite, aeronomic and surface measurements. A 50 kg scientific payload gathering a proton magnetometer, a GPS receiver, and a worldwide transmission system allow a precise determination of the anomaly field. Infra-Red Montgolfiers developped by CNES, can carry such payload over thousands of kilometers between 25 and 30 km altitude. The obtained East-West profiles provide new informations that complement those obtained by the polar orbiting satellites. Two experiments of this kind were launched from South America, and crossed the pacific ocean along the equator at a mean 27 km altitude. The anomaly field is tentatively extracted from these profiles by subtracting the values of the IGRF computed along the profiles, as well as an estimate of the external field. The two profiles are presented and shown to evidence very similar anomalies, thus demonstrating the capacity of this technique. Two anomalies situated along the profiles at the longitudes of 110 and 130° West areclearly evidenced for the first time. The geophysical signal thus detected is shown tobring new information that are tentatively interpreted and modeled.

GEOMAGNETIC REFERENCE FIELD MODELS: A GIVEN TOOL TO DESCRIBE THE MAIN FIELD

Mioara MANDEA (Institut de Physique du Globe de Paris)

The Earth´s magnetic field is used as a basis for navigation, surveying and mapping, mineral exploration, probing the Earth´s crust and deep interior, and understanding solar-terrestrial relationships. Geomagnetic data, indices of activity, numerical field and secular-variation models and charts, advice and information for the geomagnetic field models are prepared by a variety of organizations and countries, all differing somewhat in the manner of processing and in the selection of data for the model fitting (data from surface observatories, from special surveys over land and sea, and from satellites). After an exacting study of the various national field models, a select committee (Working Group 8, Division V) of the International Association of Geomagnetism and Aeronomy agrees upon the best compromise Gauss coefficients for the recorded measurements of the magnetic field about the Earth. That committee fixes what is called the ˝International Geomagnetic Reference Field˝ (IGRF) for every five-year epoch since 1900. An estimate of the change-per-year for each coefficient allows projection of the model to later years. If any IGRF model is subsequently adjusted by agreement, the replacement is called the ˝Definitive Geomagnetic Reference Field˝ (DGRF). A presentation of the IGRF/DGRF models over the 20th century is given and a brief report on where and how these models have been used.

BGS CANDIDATE MODELS FOR DGRF1995 AND DGRF2000 AND A SECULAR VARIATION MODEL FOR 2000.0 TO 2005.0

Susan MACMILLAN, Vincent B.F. LESUR, Alan W.P. THOMSON (British Geological Survey)

The BGS DGRF candidate models for 1995.0 and 2000.0 and a revised constant secular variation model for 2000.0-2005.0 are presented and discussed. We describe the selection and weighting of input satellite and ground data and the model solution process used. Some comparisons with other models for the same epochs are also presented.

GAV.05/08P/A11-003   1445

DGRF CANDIDATES BASED ON OBSERVATIONS FROM OERSTED, CHAMP AND SAC-C

Nils OLSEN[1], Terence SABAKA[2] ([1]Danish Space Research Institute, [2]NASA GSFC, Geodynamics Branch)

The present high-precision geomagnetic missions Oersted, CHAMP andOersted-2/SAC-C provide a unprecedented possibility to derive models ofthe Earth´s magnetic field. We present a candidate for DGRF 2000 that has been derived entirely fromsatellite data, and candidates for DGRF 1995 and 2000 that are derived bya combination of satellite and observatory data and are extracted fromthe latest version of our Comprehensive Model. We also outline the procedure that we plan to use for deriving a candidate for IGRF 2005.

GAV.05/08P/A11-004   1500

GEOMAGNETIC FIELD MODELS FOR EPOCHS 1995 AND 2000

Aude CHAMBODUT[1], Mioara MANDEA[1], Benoit LANGLAIS[2] ([1]Laboratoire de Geomagnetisme, Institut de Physique du Globe de Paris, [2]NAS/NRC at GSFC/NASA, Geodynamics Branch, Greenbelt, Md, USA)

The recent call for revision of the IGRF/DGRF models for 1995 and 2000epochs provides an excellent opportunity for studying the global andregional structure of the main geomagnetic field and of its secularvariation. Available datasets consist of new, high-quality, satellitemeasurements, and of time series of the global magnetic observatorynetwork. A 2000.0 main-field model (up to degree/order 13) andsecular-variation one (up to degree/order 8) are derived using Orstedvector and scalar data spanning twelve months centered on theconsidered epoch. In order to minimize the diurnal disturbanceslinked to the Sun, only satellite measurements made in the shadow regionwere kept. Then data were selected with respect to thegeomagnetic indices: Kp(h) <= 1+; Kp(h +/- 3) <= 2-; |Dst|<=5 nT and|dDst/dt| <= 3nT/h. A series of secular-variation models from 1995 to 2000is also computed using observatory data, weighted by a scheme basedon their geographical distribution. These resulting models are presented,as well as their comparison with other models for the same epochs.

GAV.05/08P/A11-005   1515

NEW INSIGHTS INTO THE SECULAR VARIATION BETWEEN MAGSAT AND CHAMP/ØRSTED

Ingo WARDINSKI[1], Richard HOLME[2] ([1]GFZ Potsdam Section 2.3, [2]Dept. of Earth Sciences, University of Liverpool)

Over the two decades between 1980 to 2000, the secular variation ofthe Earth´s magnetic field demonstrates rich behavior, most obviouslymagnetic jerks in 1991 and around 2000. The 1991 jerk is most clearlyseen in the dY/dt at European observatories, raising questions aboutthe geographical extent of this feature and the processes which mightcaused it. In this study we developed models for the secular variation over thisperiod. Our method is based on an approach proposed by Bloxham andJackson (1992); a decomposition of the magnetic potential in sphericalharmonics and expansion in time of its coefficients on a basis cubicB-Splines. The essential new feature of our method is the use of Mainfield models as constraints for the field at the endpoints, 1980 and2000. These models were derived from high-quality satellite vectordata. For the intervening period our most useful data are secularvariation estimates derived from magnetic observatorymeasurements. External variation is significant, but simpleparameterization of this in terms of an uniform external field provesinadequate, we investigating ways of mitigating the effects ofexternal fields on our model, particularly those from the ringcurrent. Our resulting models are in good agreement with the models developedby Bloxham and Jackson for 1980 until 1990, but reveals more smallscale secular variation structure.

GAV.05/08P/A11-006   1530

SPACE-TIME MODEL FOR OBTAINING CANDIDATE MODELS FOR DGRF 95, AND IGRF SV 00-05

Vadim P. GOLOVKOV, Tatiana N. BONDAR, Svetlana V. YAKOVLEVA (IZMIRAN)

Using DGRF 80 and Olsen's model of the field and SV for 2000.0 a parabolic model of the main field change in the span between satellite epochs. Comparing modeled and observed in magnetic observatories data an unsatisfaction of this model was shown. A space-time model obtained by use data from observatories better describes field changes over regions of a good density of observatories. Expansion of observatory time series in natural orthogonal components has shown that the reason of this phenomenon is a jerk about 1991. To avoid the false anomaly formation dew to uneven distribution of observatories on the Earth's surface the space-time model was improved with adding a number of "artificial" observatories in South Pacific with values, obtained from the satellite parabolic model. This improved model allows calculation of the 1991 yr model. Taking into account the very high stability of the geomagnetic acceleration between the jerk epochs, new parabolic model was designed, using the field models of 1991 yr and Olsen's ones of 2000, including SV of Olsen's model. These parabolic models were used to obtain candidate models of DGRF 1995,0 and IDRF SV 2000.0-2005.0.

GAV.05/08P/A11-007   1620

MODELING THE GEOMAGNETIC SECULAR VARIATION FIELD FOR A TERRITORY WITH A LONG AND IRREGULAR FORM AS VIETNAM

Ha Duyen CHAU[1], Nguyen Thi KIM THOA[1], Jean Louis LE MOUEL[2], Armand GALDEANO[2] ([1]Department of Geomagnetism, Hanoi Institute of Geophysics, [2]Paris Institute of Physics of the Earth)

The construction of a geomagnetic secular variation model from the Vietnam magnetic repeat stations network meets a difficulties due to the irregular geometry of the territory; the shape of this territory looks indeed like an elongated ´´S´´ oriented in the North-South direction. Geomagnetic secular variation charts for magnetic elements D, I, H, X, Y, Z, T have been constructed from the 56 repeat stations of the Vietnamese network. At each station, the absolute measurements of the geomagnetic field are made in 1991 and 1997. The used method is based on an analytic approximation (a second degree polynomial) of the real magnetic secular variation field. The computation is based on the values from different number of secular variation stations, sparsely distributed all over the territory of Vietnam, and in addition, on some weighted values of IGRF 1995 outside the territory of Vietnam. One discusses this technique and infer some criteria to take into account the minimum number of added IGRF values.The characteristics of the magnetic secular variation field were shown for 4 elements T, X, Y, Z. The secular variation of the total magnetic field and of its components in Vietnam varie in the following ranges : 20 nT/year < or = dT/dt < or = 33 nT/year; -9 nT/year < or = dX/dt < or = 14 nT/year; 0 nT/year < or = dY/dt < or = 28 nT/year; 60 nT/year < or = dZ/dt < or = 76 nT/year.

GAV.05/08P/A11-008   1640

ØRSTED/CHAMP-BASED SPHERICAL CAP MODEL FOR SOUTHERN AFRICA

Pieter Benjamin KOTZE (Hermanus Magnetic Observatory, South Africa)

Vector magnetic field measurements by both the Ørsted and CHAMP satellites havebeen employed to derive a Spherical Cap Harmonic geomagnetic field model for the southern African region between 10º and 45º South in latitude and between10º and 45º East in longitude. In the process only data obtained duringgeomagnetic quiet conditions (| Dst | ≤ 10) were selected for modeling purposes, enabling us to derive a field model with minimum

wavelength resolutionapproximately 1200 km. This model is compared with other global magnetic fieldmodels in terms of a fit to observatory and repeat station data over thesouthern African subcontinent where the Hermanus Magnetic Observatory conductsfield surveys at regular intervals. In addition, this model will also be compared to other Spherical Cap models based on only Ørsted vector data and POGS scalar data respectively. The inclusion of ground magnetic field data willbe discussed when deriving a regional magnetic field model, especially towards the borders of the cap where such a model is most sensitive to the lack of ground data.

SPHERICAL CAP HARMONIC ANALYSIS REVISITED

Erwan THEBAULT[1], Jean-Jacques SCHOTT[1], Mioara MANDEA[2] ([1]Ecole et Observatoire des Sciences de la Terre, Strasbourg, France, [2]Institut de Physique du Globe de Paris)

Spherical Cap Harmonic modelling is an attractive regional modelling of the geomagnetic field, widely used since the pioneer work of Haines (1985). It should offer many of the properties of the global Spherical Harmonic Analysis, particularly a straightforward upper continuation allowing to incorporate easily satellite data in the modelling. Yet, it may be shown that the bases proposed by Haines are hampered by the following drawbacks: actually they are not suitable for upper continuation; they lead to relationship between global and local Gauss coefficients dependent on the radial distance. Yet, the calculation of such relations would be useful for estimating prior covariance for the local Gauss coefficients and, hence, would be helpful in the inverse problem consisting of estimating local Gauss coefficients from a set of data. Setting the problem as a Boundary Value Problem on a domain defined by the intersection of a cone and two spheres, and splitting it up into two sub-problems with simpler boundary conditions, we propose a new set of two bases which solves the difficulties mentioned above. One of them is one of the bases proposed by Haines, but the second one contains so-called conical or Mehler functions, with complex degrees. The decomposition of the initial problem is not unique, but it can be demonstrated that among all possibilities, there are only two which lead to the build up of two mutually orthogonal bases. Beside these theoretical aspects, numerical difficulties had to be solved in order to be able to compute accurately the generalized Legendre functions up to large degrees and order. The algorithm of Over and Smith has been incorporated into our routine for this purpose. The effectiveness of this formalism and numerical implementation may be shown by an accurate reconstruction of the main field on the conical domain, either using the main field as boundary condition or by the computation of the local Gauss coefficients from a set of main field data distributed on a regular three-dimensional grid. We will show also an application to the regional secular variation modelling on a small cap covering the French territory.

POLAR LITHOSPHERIC FIELD FROM MULTIPLE SATELLITE OBSERVATIONS

Benoit LANGLAIS[1], Michael PURUCKER[2], Susanne VENNERSTRØm[3] ([1]NAS/NRC at NASA/GSFC, [2]Raytheon ITSS at NASA/GSFC, [3]Danish Space Research Institute)

Mapping the magnetic field of lithospheric origin is a key to betterunderstanding the properties of the oceanic and/or continentallithosphere. Models are usually based on local, airborne surveys, oron satellite datasets. The first kind of data doesn´t allow largescale anomalies to be well modeled. The second one usually relied onthe scalar measurements of the POGO series, or on the short timemission MAGSAT. The launches of Ørsted (Feb. 1999), CHAMP (Jul. 2000)and SAC-C (Nov. 2000) gave a new opportunity for studying the magneticfield of the Earth from the satellite perspective. Thismini-constellation, which can be considered as a small satelliteobservatory network, provides for the first time multiple,simultaneous field measurements at satellite altitude. Of particularinterest is the data density above the North and South pole areas ofthe Earth. In this study, we use the equivalent dipole source methodto model the lithospheric field over polar (±60°) areas. We use amultiple step approach. First, data are selected globally, withrespect to the local time and external magneticperturbations. Spherical harmonic (SH) models are built, usingshort-time data subsets. The core contributions are then removed fromthe measurements. The computed residuals are carefully selected, inorder to remove as much external perturbations as possible. Becauseonly the total intensity enters the SH model, it is possible to usethe average of the component perpendicular to the main field directionto determine the quiet intervals. The sorted residuals are then usedto infer the susceptibility of field-aligned dipoles located in thelithosphere. The modeled dipoles are finally used to predict themagnetic field of lithospheric origin at a constant altitude. Acomparison with other studies is shown. A discussion with respect tothe season (winter or summer) is presented, as well as a comparisonbetween the North and South pole areas.

IMPROVEMENT OF THE ANTARCTIC GEOMAGNETIC REFERENCE MODEL BY USING NEW SETS OF DATA

Luis R. GAYA-PIQUE[1], Angelo DE SANTIS[2], Joan Miquel TORTA[3] ([1]Istituto Nazionale di Geofisica e Vulcanologia, Rome, Italy / Observatori de l'Ebre, Roquetes, Spain, [2]Istituto Nazionale di Geofisica e Vulcanologia, Rome, Italy / Earth Science Department, G. D'Annunzio University, Chieti, Italy, [3]Observatori de l'Ebre, Roquetes, Spain)

The first Antarctic geomagnetic Reference Model (ARM) was published in 2002. This model was intended as an alternative to global models like IGRF to give account of the geomagnetic main field south of 60° South latitude, with the main practical purpose of reducing magnetic survey data obtained from 1960 onwards to a common epoch. The first version of the model was developed using observatory annual means and a selected but reduced set of Oersted satellite data. In this work we use new sets of data to improve the quality of the model. Data coming from Pogo, Magsat, and Champ satellite missions are used, as well as a larger set of Oersted measurements. A suitable selection of all these data was performed to minimise the effect of external fields. On the other hand, the updating of the observatory database and the inclusion of data coming from a stratospheric balloon platform, contributed to a better representation of the field measured near the Earth's surface.

A NEW THEORY ON THE EARTH'S MAGNETIC FIELD

Eugene D. RICHARD[1] ([1]American Geophysical Union, Sigma Xi, [2]Sigmz Xi)

With the use of basic principals of electricity and magnetism, a new approach to the theory of the earth's magnetic field is given; this approach also lends itself to a new theory on the earth's magnetic reversals. This approach has been tested by the author by construction of a magnetic model which helped in the final approach to the theory presented. A mathematical model was derived from this model that yields six parameters which are described in the paper. A two and a three dimensional computer model are available and can be seen on the web site {www.earthsgeomotor.com or www. earths-magnetic-field-and-how-it-reverses-and-more.com }. For reversals, relativity was introduced and utilized to show that reversals were cyclic and controlled by the interior heat of the earth. In addition, the cycle from normal to reverse shown in the computer models were all equal in time, however in spots where the internal heat of the earth is being altered by volcanoes, hot spots, and oceanic ridges the aborted reversals, short time between reversals, and delayed reversals could be explained. In conclusion, both of the above web sites have a free E-Book available which goes into the theory in detail and shows that the theory described is simple, complete, and has no reference to someone in the past, only well known laws of electricity and magnetism.

NORTH MAGNETIC POLE MOTION: JERK OR REVERSAL?

Vladimir V. KUZNETSOV

The velocity of drift of North magnetic pole has increased about five times through the last 20 - 30 years. What is a reason of this phenomenon: is it a usual cyclic process causing a stop of a pole in 2140, or the effect of Jerk-69, or is it a start of the geomagnetic field reversal? Since 1860 modern magnetic poles, as North, and South, are drifting towards each other along the paths peculiar to the drift of virtual magnetic poles through the reversal. The possible reasons of the phenomenon of poles acceleration are discussed. It is shown, that the measurements of the North magnetic pole location carried out during the nearest 3-5 years, would help to answer this question.

TRACING BACK THE MAGNETIC JERK OF 1991 TO THE CORE-MANTLE BOUNDARYBY NUMERICAL EXPERIMENTS

Ludwig BALLANI[1], Dietrich STROMEYER[2], Ingo WARDINSKI[3], Hans GREINER-MAI[4] ([1]Dept. Geodesy and Remote Sensing, GFZ Potsdam, [2]Dept. Geoengineering, GFZ Potsdam, [3]GFZ Potsdam, Section 2.3)

New global magnetic data (Gauss coefficients up to degree and order 13 from 1980 to 2000) are processed with a recent non-harmonic downwardcontinuation method. It solves the related inverse boundary valueproblem by approximating the solution (e.g. at the core-mantleboundary) of an equivalent Volterra integral equation with afinite-dimensional minimum-norm solution. In an extended version themagnetic field components in the top layer of the fluid outer core canbe determined if fluid velocities of special type are prescribed. Using a weakly conducting mantle and the high conducting fluid in theouter core we investigate the temporal structure of the jerk in 1991calculating different field components in dependency of the depthbeneath the core-mantle boundary (up to 100km) and for some types ofassumed velocities.

MODELLING THE EARTH'S MAGNETIC FIELD USING WAVELETS FRAMES

Aude CHAMBODUT[1], Mioara MANDEA[1], Matthias HOLSCHNEIDER[2] ([1]Laboratoire de Geomagnetisme, Institut de Physique du Globe de Paris, [2]Universtitat Potsdam, Applied and Industrial Mathematics, Potsdam, Germany)

Wavelets analysis has proven to be a powerful tool for numerical studies and signal processing. The use of a frame of wavelets to model the geomagnetic field, allows us to take advantage of the flexibility of frames (as opposed to the rigidity of orthonormal bases) and the localization properties of wavelets. Firstly, we describe a simple technique for constructing wavelets on the sphere with properties which are useful for applications in geomagnetism. Here we discuss how to optimize the choice of the wavelets basis, with special regard to the choice of the evolution of scales, the number of wavelets, etc. To illustrate the completeness of the wavelet frame we show how well the wavelets are able to reproduce the spherical harmonics. Once shown the potential of wavelets, we apply this technique to describe the geomagnetic field at global and regional scale. Finally, we report on some field models obtained when observatories or satellite data are used, and we conclude with discussions and future work.

ANALYSIS OF THE REGIONAL MAGNETIC FIELD AND ITS SECULAR VARIATIONS OVER THE ROMANIAN TERRITORY

Ligia-Narciza E. ATANASIU[1], Mioara MANDEA[2] ([1]INSTITUTE OF GEODYNAMICS, 19-21 Jean-Louis Calderon St., Bucharest-37, Romania R-70201, [2]INSTITUT DE PHYSIQUE DU GLOBE DE PARIS, 4 Place Jussieu, 75252 Paris cedex 05, France)

Many geological features of the Earth's lithosphere create variation in the Earth's magnetic field that can be detected by satellites. The resulting magnetic anomaly maps can provide new insights into the tectonic features and broad structure of the lithosphere. By the combined analysis of data provide by satellite missions (Orsted, Champ), ground data and aeromagnetic data we created a database and we was able to calculate the components of the magnetic field (Declination-D, inclination-I, vertical intensity-Z, horizontal intensity-H, total intensity field-F) over the southeastern European territory (especially over the Romanian territory). We calculated all the components of the magnetic field at different epochs. We thing that is very interesting because the possibility to study the evolution of the magnetic field in time and space. Taking into consideration that the Romanian territory is a very important part of the alpino-carpatho-hymalaian belt we hope that the resulted data set may considerably improve to the knowledge on the tectonics and geodynamics of the southeast European zone and Romanian territory.

REGIONAL MODEL OF THE GEOMAGNETIC ANNUAL CHANGES IN AND AROUND JAPAN ISLAND BASED ON NOC AND SCH ANALYSIS

Mitsuru UTSUGI[1], Hiroki SHIRAI[1], Hideo HAMASAKI[1], Teruaki NISHIKI[1], Satoshi FUJIWARA[2] ([1]First Geodetic Div., Geodetic Dep., Geographical Survey Institute, [2]Ministry of Land, Infrastructure and Transport)

In G.S.I. (Geographical Survey Institute of Japan), continuous geomagnetic observation and repeat survey (we call it as the first class magnetic survey) were conduced from early 1950's. From these data, reference values of intensity and direction of the magnetic field in and around Japan Island was estimated, and these information were published in every 10 years (1980, 1990 and 2000). To extract more accurate information about the magnetic field distribution and annual change from the observed data, we started to consider the construction of the geomagnetic spatial-temporal model for the area of Japan Island and, partially, surrounding seas. Inside the Japan area, there are many geomagnetic stations continuously observing the geomagnetic field. For example, our institute has 2 observatories and 13 magnetic stations which observe the geomagnetic 3 components and total force, or only total force, continuously. So that, we configured the goal of our study to establish the scheme to construct the regional 3 components magnetic models using only the continuously observed magnetic data set which consists of X, Y, Z and F time series. For this purpose, we tried to combine the technique of NOC and SCH (Spherical Cap Harmonic) analysis. This is because, to use the total force data, it might be the very easy way to apply the potential analysis method. To estimate the expressivity and clarify some problems come up with practical use of NOC + SCHA method, we treated the IGRF synthesize time series (period 1990-2001 and time spacing is 0.25 year) as the input data. The magnetic stations that we assumed were 34 points (in 16 points, 4 components (X, Y, Z and F), and in 18 points, only total force data were given). The locations of each station are identical with that of the actual geomagnetic stations. Using NOC + SCHA (colatitudes of half angle of the spherical cap is 45 degree and maximum degree of Gauss coefficients is 4), we can explain the input data with accuracy of 2-3 percent of input data and this accuracy will be suitable for our purpose. Now, we are trying to construct the monthly 3 component model using continuously observed geomagnetic data in the period of 1996 to 2002. In our presentation, we will discuss about the expressivity and accuracy of our model.

RAPID CHANGE OF THE GEOMAGNETIC SECULAR VARIATION FIELD AS REVEALED BY THE FIRST ORDER MAGNETIC SURVEY OF JAPAN

Hideo SAKAI[1], Naokatsu SUZUKI[2], Toru YAMAGUCHI[3], Hiroo MIZUNO[4] ([1]Department of Earth Science, Toyama University, [2]Pasco Co. Ltd., [3]Graduate School of Science and Engineering, Toyama University, [4]Department of Education, Kagawa University, ret.)

Annual change distributions of the geomagnetic three components X, Y and Z have been compiled at discrete two-year epochs on the basis of available results from the first order magnetic survey of Japan, and annual mean values from observatories as well. The annual change distributions and their temporal changes have been examined from various angles in order to offer evidence that they are of internal origin. In the early 1980's, an abrupt change in the annual rate of secular variation in the Y component was observed in western Japan. This event has been associated with a rapid and remarkable change in the trend of isopors. Along with this Y event, the annual rate of change in the Z component showed an appreciable increase over the previous epochs reaching more then 20nT/year. These changes observed in Japan are confirmed by comparing the secular variation fields from IGRF 1980 and 1985. A remarkable difference in the fields between these epochs can be seen in the Far East. The difference in the trend of isopors for the Y component is quite similar to that obtained from the surveys. Every isopor from IGRF 1980 intersects every isopor from IGRF 1985 nearly at right angles. Although the land of Japan is limited, still the progressive change of annual change distribution with time can be investigated by using observations repeated many times at more than fifty magnetic stations. The secular variation field over the entire surface of the earth can be reproduced by a set of changing radial dipoles on the surface of the core. Mizuno(1984) showed that an abrupt changes in Y and Z annual changes observed in Japan in the early 1970's could be attributed to the development of dipoles forming a line which was thought to have rapidly progressed from India through east China to Japan sea. These dipoles are directed radially inwards(positive dipoles). The same method has been applied to the event in the 1980's. Sets of core surface radial dipoles responsible for IGRF 1980 and 1985 secular variation fields have been derived. Comparison of these dipole distributions in and around Japan shows that the dipoles described above increased their strength and extended to the pacific side. This change in the distribution and strength of dipoles provides a possible explanation of the change in the annual change distributions in the 1980's. The time scale of the redistribution of dipoles must be very short. The change in the dipole distribution is episodic. A comparatively stable state with gradual changes continues for years, which is succeeded by an abrupt change. This is the character of the jerk. The jerk has been regarded as a global event. However, the consideration given here strongly suggests that it must be regional. Mizuno, H., rapid and episodic variation of the geomagnetic secular variation field., Bull. Geograph. Surv. Inst., Vol.29, No.1, p1-102, 1984.

NATIONAL RESEARCH INSTITUTE OF ASTRONOMY AND GEOPHYSICS, HELWAN EGYPT

Deebes Hanafy ALY, Ahmed F. M, EL. saed M., Arafa T. (National Research Institute of Astronomy and Geophysics)

A new geomagnetic survey during a period of two years (2000- 2001) was performed to cover Egypt satis factory . Using a proton magnetometer, the total intensity (F) of the Earth´s magnetic field were measured in 2000 sites of third order, along profiles of total length 5 200 K.m. About quarter of those occupied in previous surveys were reoccupied to produce the secular variations . Reduction to epoch 2000.0 was done. The field data was used to produce 4 charts: a) the total intensity (F) chart of the Earth´s magnetic field in n.T. over the sarface of Egypt, b) the isoporic chart using the available old data, c) the Egyptian Geomagnetic Reference Field (EGRF) chart to the epoch 2000.0 .This chart is obtained, using computer, to produce both the observed data and the EGRF2000.0 every 1/4 degrees.

LONG-WAVELENGTH OF GRAVITY AND MAGNETIC FIELDS WHILE THE STUDY OF THE URALS DEEP STRUCTURE

Vsevolod SHAPIRO, Faina NIKONOVA (Institute of Geophysics)

The Ural mountains preserve a late Paleozoic collision that forms a 2500 kmsuture in the world's largest landmass, Eurasia. Several features of the mountain belt are atypical when

A

compared with other Paleozoic orogens such as Appalachians, Caledonides and Variscides. The problem of regional field extraction is of undoubted importance for the interpretation of gravity and magnetic data on long (1000 km and longer) profiles, aimed at the construction of density magnetic sections throughout theentire thickness of the crust. This problem became particularly significant inthe last years when a complex of geophysical data became available from longgeotraverses such as Granit, Rubin, Quarts and others. A special investigationrof potential field in the region was fulfilled for establishing the relationshipbetween the Urals and the East European, Siberian and Kazakhstan Cratons. The regional components of gravity and magnetic field bearing information on deep structure of the orogen were analyzed.The gravitational data was investigated for several sufficiently long (1000 kmand more) E-W profiles crossing the South, Central and North Urals. The new technique was used for the extracting of the regional component of the gravitational field. The main feature of the revealed regional component is theappreciable low over the main Ural structures as compared with the adjacentplatforms. The extent of the negative anomaly in the regional gravity field is of the order of 400-500 km, with the maximum amplitude about -30 mGal. This fact is particularly interesting, if one takes into account that the absolute gravity ximum is confined to the Ural structures. The special survey of long, multi-altitude aeromagnetic traverses across the Urals designed to ensure that the long-wavelength component of the magnetic field was properly sampled. The survey was flown in 1980-1988 in area between 52-680N and 52-720E. Seven E-W traverses, each 1000-1200 km long, and two meridional traverses were flown. After subtraction of the reference field, an anomalous field is left which contains only those wavelengths that are largerthan about 1000 km. The main result of study is revealing the regional negativemagnetic anomaly with the size about 300 km and amplitude about 150-250 nT,which spatially coincides with the negative anomaly in gravity field. Along eachprofile, the inversion results indicate a major depression of the magnetic basement beneath the Uralide orogen. The interpretation is that the contrast inbetween magnetic crystalline basement (of the East European Craton to the westand the Siberian Craton and Kazakhstan microcontinent to the east) and the intervening terranes, which appear to have significantly lower average magnetization. The mentioned gravity maximum is in reasonable agreement with location of number of very intensive local magnetic anomalies produced by well-known Uralian magnetite bodies.It appears that checking in space of negative gravity anomalies with lessmagnetic zone is in part composed of thick sequence of Riphean rocks which mayhave been accreted against the margin of the East European Craton in pre-Uraliantimes.

GEOPHYSICAL SIGNATURE ON THE SUBSURFACE STRUCTURE OF THE AEOLIAN ISLANDS, ITALY

Shigeo OKUMA[1], Tadashi NAKATSUKA[1], Mitsuhiko SUGIHARA[1], Masao KOMAZAWA[1], Shun NAKANO[1], Ryuta FURUKAWA[1], John Joseph ELENJIPARAMPIL[2], Robert SUPPER[3], Massimo CHIAPPINI[4] ([1]Geological Survey of Japan, AIST, [2]Adelaide University, [3]Geological Survey of Austria, [4]Istituto Nazionale di Geofisica e Vulcanologia)

We, under an international cooperation, have conducted various geophysical surveys to better understand the dynamics of volcanic activities of the Aeolian Islands, which are located between the southern tip of the Italian Peninsula and Sicily Island. Supper et al. (2001) conducted an aerogeophysical survey such as magnetics, VLF and gamma ray in 1999, which were supplemented by detailed ground geophysical measurements such as geoelectric and magnetic surveys to investigate the physical structure of Vulcano and Lipari Islands. They compiled a high-resolution aeromagnetic map and conducted a temporal magnetic modeling, suggesting subsurface intrusions beneath the older volcanic outcrops on the west coast of Vulcano. They also compared the data with the older regional data by AGIP (Barberi, 1994) and showed a difference during the 15 years period. Sugihara et al. (2002) conducted gravity measurements of around 400 points on Vulcano in 2000 with a positioning by a differential GPS, particularly along with the profile lines of geoelectric and ground magnetic surveys by Supper et al. (2001) and compiled a detailed gravity map with denser station spacing than previous studies (Bonasia et al, 1973; Iacobucci et al, 1977, Barberi et al., 1994). They discussed a relationship between geothermal activity and gravity anomalies on the island. They also found a local gravity high inside the Fossa crater and modeled a denser rectangular prism beneath the crater, implying the existence of the self-sealed volcanic rocks under which geothermal fluids circulate. Komazawa et al. (2002) added more gravity stations on Vulcano and Lipari in 2001 to recompile a gravity map of the area. The Bouguer anomaly map with an assumed density of 1.8 kg/m³ indicates gravity highs on the southern half of Vulcano called Piano, corresponding to a lava lake suggested by geologic studies. We have had an additional aerogeophysical survey, mainly magnetics this time, in early November 2002 in spite of an eruption of Mt. Etna on Sicily. The survey was flown with a real-time differential GPS on the same line of the 1999 survey for the Vulcano-Lipari area and also extended the survey northeastward up to Stromboli Island, which is continuing periodical eruptions. The comparison between the magnetic anomalies of 1999 and 2002 surveys can be conducted on the common surface, which the anomalies are reduced onto by a mathematical calculation. The geophysical signature on the subsurface structure of the Aeolian Islands and the results of a magnetic comparison by our method will be discussed.

GAV.06/09P/D-002	Poster	1400-155

CONSISTENT GEOMAGNETIC IMAGES OVER THE SW MARGIN OF THE EAST EUROPEAN PLATE

Lucian BESUTIU[1], Mikhail I. ORLYUK[2], Inna K. PASHKEVICH[2], Georgeta BESUTIU[3], Svetlana V.ELISEEVA[2], Vasile NEAGA[4], Andriy A. ROMENETS[2] ([1]Sabba S. Stefanescu Institute of Geodynamics of the Romanian Academy, [2]Institute of Geophysics NAS of Ukraine, [3]Geological Institute of Romania, [4]Institute of Geophysics and Geology NAS of Moldova)

Joining regional geophysical images crossover the state border has became a practice during the last years in an attempt to solve large scale tectonic problems. Eastern Romania, Republic of Moldova and SW Ukraine represent the area where East European Plate (EEP), Scythian Plate, Moesian Plate, Carpathian Alpine Orogene, and North Dobrogea folded zone met each other. The examination and understanding of their junctions is rather difficult to make because the almost part of the bedrock in the area is hidden by the thick Neogene to Quaternary post-tectonic cover. Magnetics represents an appropriate tool for investigating

such areas, but previously obtained geomagnetic information within each national territory has its individual peculiarities: instruments and methodology used for data acquisition and processing, survey epoch, geomagnetic datum, reference field, etc. Therefore, trying to construct common geomagnetic images cross over the borders, large discrepancies were found. UKROMM project represents a joint venture of several scientific organizations from Romania, Ukraine and Republic of Moldova mainly aimed to overcome such difficulties and join airborne magnetic maps of the three countries covering the SW margin of EEP. As a first step, some pilot-maps have been constructed for the low Danube region (MAGLODAN sub-project) in an attempt to solve various problems that occur during such a complex research. After completing the pilot-stage, research extended to the area of the SW margin of EEP. The paper is aimed to the achievement of several crossover the state border consistent geomagnetic images, as a result of UKROMM project. Integrating the national geomagnetic standards was one of the main tasks within the project. Common observations were made at the geomagnetic observatories Surlari (Romania), Stepanovka (Ukraine) in order to compare their datum, and particular studies were devoted to the secular variation (SV) evolution on the national territories of the three countries. A special geomagnetic reference network covering the study area was designed and achieved in order to remove SV effects from the previously achieved data. Additional ground observations were also added in order to fill up some gaps within the former Ukrainian airborne maps. Finally, a computer database for both topography and geomagnetic information on the study area was designed and achieved, and data were brought at the same datum. The accuracy of the joining operation was checked up by constructing a map of the horizontal gradient of the geomagnetic field, which is very sensitive to the presence of any data inconsistency, but no discontinuity was revealed along the state border zones. Based on thus achieved data, several consistent geomagnetic images were constructed for the area by using various reference fields in order to separate regional/local effects and emphasize some tectonic features. Brief preliminary geological considerations are also made.

PRELIMINARY INTERPRETATION OF THE MAGNETIC ANOMALIES OF THE EASTERN VIETNAM SEA AND RECENT REGIONS

Hung Viet LUU, Minh Huy LE (Hanoi Institute of Geophysics, NCST of Vietnam)

In this paper we showed that with appropriate choose of the noise-signal ratio,the reduction to the pole at low latitude based on a Wiener filtering approachof Hassen and Pawlowski could be applied on the magnetic equator. Using this reduced-to-the-pole method, we have found that the geological boudaries determined from the reduced-to-the-pole magnetic anomalies of the Eastern Vietnamsea and recent regions (from the magnetic anomaly map of East Asia publicatedby Geological survey of Japan and Commitee for co-ordination of joint prospectingfor mineral in Asian offshore areas) correlate remarkably well with the majorgeological features, including major faults, seafloor spreading segments, volcanic or intrusive blocks... These results could be considered as very important informations to reconstruct the tectonic history of the region.

GAV.06/09P/D-004	Poster	1400-157

TIME CHANGES OF GEOMAGNETIC TRANSFER FUNCTIONS AT LUNPING, TAIWAN RELATED TO EARTHQUAKE OCCURRENCES

Kuang-Jung CHEN (Department of Earth Sciences, National Taiwan Normal University)

Time change of the transfer functions for short-period geomagnetic variations at Lunping, Taiwan, Geomagnetic Observatory is examined in association with earthquake occurrences near Lunping from 1988 to 2000. Using the geomagnetic data with a sampling interval of one minute, traditional transfer functions for the frequencies from 0.1 to 10 cycles/hour are calculated day by day. The method of analysis is based on the power spectrum analysis as developed by Everett and Hyndman. Monthly means are statistically obtained from these daily values of transfer functions. Small fluctuations are likely to be accounted for by seasonal changes probably originating in the external magnetic disturbance. All the transfer functions show the significant anomalous frequencies at 2, 3, 4, and 6 cycles/hour. Some remarkable changes of transfer function Au, possibly related to the earthquakes which occurred near the Lunping Observatory are found.

COMPREHENSIVE MAPPING THROUGH THE DATABASE OF AEROMAGNETIC ANOMALIES OVER JAPAN

Tadashi NAKATSUKA, Shigeo OKUMA, Rie MORIJIRI, Masahiko MAKINO (Geological Survey of Japan, AIST)

Aeromagnetic survey data have been accumulated over the Japanese islands. Aeromagnetic area survey was initiated in the Geological Survey of Japan (GSJ) by Dr. J. Suyama and colleagues in 1964. The activity of this area survey was mainly aimed at the evaluation of petroleum potential in continental shelf regions. In 1981-1983, the New Energy Development Organization (NEDO), Japan, had a large project of aeromagenic surveys (so-called Curie Point Surveys) of inland parts. The data from two organizations above have enough coverage over the Japanese main land and surrounding sea areas. The data from surveys by GSJ are stored in files with three types of unified formats. Those from NEDO surveys were also recovered from magnetic-tape archives into another two types of formats. There was a problem that the discontinuity exists between IGRF residual maps of adjacent areas surveyed at different epochs. However, it is proven that this discontinuity can be mitigated by adopting the DGRF model, instead of tentative IGRF model, as a reference base, because the tentative model sometimes fails to predict the secular variation of the geomagnetic field. The aeromagnetic anomaly data are attributed to the geographic position, which is based upon a specific geodetic datum. In Japan, regulations on the geodetic system was revised in 2001, and the formal geodetic datum today is same as the global standard WGS (ITRF), while the old datum (Tokyo Datum) is still used widely. The difference between the two amounts to 500m of the apparent dislocation. We should therefore be careful that the data in different geodetic system are not confused. Former work on the compilation of similar data were done by Makino et al. (1992) to publish the ″Magnetic map of the Japanese Islands″, in which the upward continuation filtering was applied, and a linear trend was further removed in each survey area. Now the data manipulations of such filtering are easily realized in the database, and also some kind of inversion softwares are going to be implemented in the system.

DIGITAL COMPILATION OF MAGNETIC ANOMALY MAP OF THE NORTH PACIFIC OCEAN

Takemi ISHIHARA (Geological Survey of Japan, AIST)

A new magnetic anomaly map of the Pacific Ocean east of 140 E of the northern hemisphere

was compiled. Marine magnetic data, which were collected by various research cruises and are available from the U.S. NGDC were utilized in this compilation. Bad navigation data were first edited: if anomalous ship´s velocities were obtained by calculation from neighbouring navigation and date/time data, the navigation and date/time data were checked.Then magnetic anomaly values were recalculated using DGRF reference fields. If absolute values of the obtained anomalies > 5000 nT, they were removed. After these editing procedures, data biases for each tracklines were adjusted to minimize the cross-over errors, and a gridded data set was generated. The data coverage is still scarce except near Hawaiian Islands, Japan, Aleutian Islands, and the west coast of North and Central Americas. However, lineated anomalies due to past seafloor spreading are clearly visible in the compiled map, and the amplitudes of anomalies generally increase northwards.

COMPARATIVE AEROMAGNETIC STUDY OF SEISMIC HAZARDS IN TWO PACIFIC RIM FOREARC BASIN SETTINGS: PUGET SOUND, WASHINGTON, AND COOK INLET, ALASKA

Richard W. SALTUS, Richard J. BLAKELY, Peter J. HAEUSSLER (U.S. Geological Survey)

Puget Sound, Washington, and Cook Inlet, Alaska, both host forearc basins above active subduction zones. In both regions active compressional features are superimposed on the original subsidence strata. Both regions include major population centers---the greater Seattle/Tacoma area in Puget Sound and the much smaller Anchorage/Kenai area in Cook Inlet. In addition to the urban infrastructure, the Cook Inlet region has oil and gas production facilities and pipelines. Detailed, high-resolution aeromagnetic studies have been undertaken to assist in hazard assessment in both regions. Here we compare and contrast the results of separate studies in the two regions. The basins of the Puget Sound and Cook Inlet regions all overlie and are surrounded by volcanic rocks that provide significant magnetic sources. The generally basaltic Crescent Formation is uplifted to relatively shallow levels in fault blocks between the basins of the Puget lowlands and forms magnetic anomalies that trace the bounding faults (e.g., the Seattle fault, Tacoma fault, and south Whidbey Island fault). In the Cook Inlet, basement magnetic sources include the volcanic and volcaniclastic Talkeetna Formation, as well as a number of dioritic to mafic intrusions on the northwestern side of the inlet, and the very magnetic tonalites exposed along the Border Ranges fault on the southeastern side of the inlet. In contrast to the Puget Sound basins, magnetic basement rocks do not come to shallow levels in the Cook Inlet compressional structures. There is significant magnetic material within the shallow sedimentary sections of all these basins. In particular, the Blakely Harbor Formation in the southern Puget Sound contains abundant basalt pebbles shed from the Crescent Formation. Shallow offset of the Blakely Harbor Formation gives rise to magnetic anomalies that can be used to map the active strand of the Seattle fault, which lies beneath Seattle and produced a M7 earthquake 1100 years ago. In the Cook Inlet, Quaternary volcanic detritus shed off the generally magnetic Alaska Range appear to account for significantly magnetic horizons within the shallow Tertiary Sterling Formation and overlying Quaternary rock section. Folds and anticlinal truncations of these shallow magnetic layers result in a series of long, linear, short-wavelength anomalies that trace the likely horizontal extent of deeper blind thrusts. The common occurrence of generally magnetic, volcanic and volcaniclastic rocks and detritus in forearc settings makes it probable that both high angle and thrust faults will have some magnetic signature both at shallow and basement levels. This means that detailed aeromagnetic studies provide an effective way to map potentially hazardous structures in the basins of the Pacific Rim.

IDENTIFICATION OF POSSIBLE DEEP PENETRATIVE FRACTURES ON THE SOUTHWESTERN COLORADO PLATEAU, U.S.A

Mark E. GETTINGS (U. S.Geological Survey)

The Redwall limestone is thought by many to be the principal aquifer feeding the springs and seeps on the south side of the Grand Canyon in Arizona, U.S.A. The Redwall limestone is overlain by several impermeable shale units of the Colorado Plateau, and thus recharge to the aquifer is probably totally by seepage down penetrative fracture systems. The National Park Service has sponsored a two-year study by the U. S. Geological Survey to produce an initial map coverage showing the location of possible deep penetrative fractures that might be important in groundwater recharge of these aquifers. The area of study was the Colorado Plateau south of the Grand Canyon and west of the Black Mesa area. The approach used was to assume that fractures penetrating to the Redwall limestone probably also penetrate into the underlying crystalline basement. A map of a minimal set of deep structures that may be fractures was obtained from analysis of persistent curvilinear features of the gravity and magnetic anomaly datasets. This was correlated with maps of major surficial fractures obtained from geologic, topographic, aerial photographic, and satellite imagery maps. The resulting maps define a sub-set of possible penetrative fractures because 1) not all deep fractures have magnetic or gravity anomalies detectable at the surface, 2) surface fractures may be missed or not identified from the surficial data, and, 3) some areas have very sparse data coverage in one or more of the necessary datasets. Nevertheless, the resulting penetrative fracture distribution maps constitute an objectively obtained, repeatable dataset. These maps constitute a benchmark from which additional studies can begin. The geophysical anomaly data were available at a 500m grid interval, and geologic mapping in large areas was only of reconnaissance nature, so the analysis was carried out at a scale of 1:250,000 over the study area. Most newly defined penetrative fracture locations paralleled known fracture or fold axes, which are dominantly northeast and northwest trending. A less pervasive, and more interrupted, north-south trend was also recognized. This north-south trend appears to be related to an old fabric in the basement rocks defined by north-south trending gradients of many magnetic and gravity anomalies. The analysis was carried out digitally, and the final product was a set of digital map layers suitable for use in a Geographical Information System.

UTILITY OF SATELLITE MAGNETIC OBSERVATIONS FOR ESTIMATING NEAR-SURFACE MAGNETIC ANOMALIES

Hyung Rae KIM[1], Ralph R.B. VON FRESE[1], Patrick T. TAYLOR[2], Jeong Woo KIM[3] ([1]Dept. of Geological Sciences, The Ohio State Univ., [2]Code 921 Geodynamics branch, GSFC, NASA, Maryland, USA, [3]Dept. of Earth Science, Sejong Univ., Republic of Korea.)

Regional to continental scale magnetic anomaly maps are becoming increasingly available from airborne, shipborne, and terrestrial surveys. Satellite data are commonly considered to fill the coverage gaps in regional compilations of these near-surface surveys. For the near-surface Antarctic magnetic anomaly map being produced by the Antarctic Digital Magnetic Anomaly Project (ADMAP), we show that near-surface magnetic anomaly estimation is greatly enhanced by the joint inversion of the near-surface data with the satellite observations relative to conventional minimum curvature Ørsted observations are especially advantageous relative to the Magsat data that have order-of-magnitude greater

measurement errors, albeit at much lower orbital altitudes. CHAMP is observing the geomagnetic field with the same measurement accuracy as the Ørsted mission, but at the lower orbital altitudes covered by Magsat. Hence, additional significant improvement in predicting near-surface magnetic anomalies can result from the CHAMP data. Our analysis also suggests that considerable new insights on the magnetic properties of the lithosphere may be revealed by a further order-of-magnitude improvement in the accuracy of the magnetometer measurements at minimum orbital altitude.

DISPLACEMENT OF THE GEOMAGNETIC EQUATOR STOPS AT THE DEFLEXION OF MACHUPICCHU AS PART OF THE TECTONIC PROCESS IN SOUTH AMERICA

Teodosio Chavez CAMPOS[1], Casaverde RIO[2], Israel Chavez SUMARRIVA[3] ([1]Post-graduate shool of system, University National of Ingenering, [2]Scientific consultant, National Institute of Civil Defense, [3]National University of Ingeneering, Av. Pablo Carriquiry 451, Lima-27, PerAEName1-1=Mateo)

The magnetic field distribution of the earth's surface shows an important temporal variation, named secular variation (SV). The secular variation is one of the important characteristics of the geomagnetic elements. Recently it has been observed an extraordinary high speed variation of the phenomenon, comparedwith geological scale time, when the magnetic equator crosses Brazil towards northeast. The origin of this change could be a consequence of fluid motion in the outer core of the earth. The secular variation of the vertical Z componentand so inclination I component) of geomagnetic field is particularly important. The geomagnetic equator, where the inclination (I) of the magnetic field iszero degrees, when it crosses at South America, stops in its southward motion between the years 1938-1939, at the latitude 13º - 14º S in Peru. This behavior has been calculated with the model of the IGRF (International Geomagnetic Reference Field) and proven with data of the Huancayo Magnetic Observatory (HMO). On the other hand in the zone of Brazil the magnetic equatormove toward the northeast. This stopping of the geomagnetic equator in CentralPeru is given in the zone of the deflexion of Machupicchu (or deflexion of Abancay), and it is due to the tectonic process between the Nazca and south american plates. Which generats a deep structure with characteristics still unknowon. It is originated to beginnings from the derives continental when Sudamerica was separated from Africa, generating a depth structure in the direccion of the large defects transformantes of the Atlantic middle. Besides it is a structural feature, important in South-america because its developmentmorfoestructural, necessarily implies a control of tectonic process of large scales. The deflexion of Machupicchu is an area of seismic calm, to either side of this seismic discontinuity, and the inclination of the Benioff plane is different: weak to the north, strong to the south. The anomalies maps of Bouger (without topographical correction) it registers the deflexión, and thesame thing happens with electric conductivity anomaly. The Nazca ridge is situated front of these anomalies.

AEROMAGNETIC ANOMALY EXPLORATION BETWEEN YULE BAY AND MERTZ GLACIER (EAST ANTARCTICA)

Bozzo EMANUELE[1], Detlef DAMASKE[2], Fausto FERRACCIOLI[3] ([1]Dipartimento per lo Studio del Territorio e delle sue Risorse, Univ. di Genova, Viale Benedetto XV,5, 16132 Genova ITALY, [2]BGR, Stilleweg 2, 30655 Hannover GERMANY, [3]British Antarctic Survey, High Cross, Madingley Road, Cambridge, CB3 0ET UK)

The GITARA VI aeromagnetic campaign was performed over George V-, Oates-, and Pennell Coasts during the joint 1999-2000 German-Italian GANOVEX VIII-ITALIANTARTIDE XV Antarctic campaign. The general aim of the survey was to explore crustal structure and tectonics of the northernmost Transantarctic Mountains and its ″backside″ component, which is in major parts unknown. Over northern Victoria Land the aeromagnetic survey provides new coverage of tectonic units involved in the Ross Orogen. These widely debated units are often referred to as accreted terranes, marking an Early Paleozoic active margin of the East Antarctic Craton. Over western Oates Land and George V Land the aeromagnetic survey area extends over the northernmost edge of the Wilkes Subglacial Basin. This basin has been interpreted either as a flexural depression in thick Precambrian crust, or conversely as a more recent rift basin floored by extended crust. We present total field magnetic anomaly maps along the Antarctic coast between Yule Bay and Mertz Glacier and highlight the location and character of the main aeromagnetic anomalies. Where possible, we contrast these anomalies against geology and magnetic susceptibility measurements to interpret their sources. The Lillie Glacier anomaly map reveals contrasting magnetic signatures over the Late Devonian-Early Carboniferous Admiralty Intrusives of the Everett Range and of Yule Bay. Geochemical data indicate that these rocks could indeed differ, since they may have assimilated different proportions of pre-existing continental crust. A near-circular anomaly overlies the enigmatic occurrences of volcanic rocks of Unger Island and Surgeon Island granite. These rocks have been inferred to represent remnants of an accreted terrane or basement to the Robertson Bay metasediments. The Oates Coast map displays a linear magnetic anomaly over the Matusevich Glacier. It reveals mostly buried Cambro-Ordovician(?) Granite Harbour Intrusives and ultramafic rocks. Such rocks are associated with a major fault zone or maybe with a hitherto unrecognised suture within the Wilson Terrane. Just west of the Matusevich Glacier, the highest-amplitude anomaly of the entire survey overlies the Archangel Nunataks gabbro. Magnetic anomalies along the George V Coast indicate that the 180 Ma Ferrar Large Igneous Province may extend along the northernmost edge of the Wilkes Subglacial Basin. Specifically, comparison with similar anomaly patterns detected about 1000 km further south of the present survey suggests that thick Jurassic intrusions may exist along the northeastern flank of the Wilkes Subglacial Basin. Finally, an anomaly break close to the northwestern flank of the Wilkes Subglacial Basin, could mark the unexposed boundary between the Precambrian East Antarctic Craton and the Ross Orogen. The anomaly itself is co-linear with a major fault detected from seismic data offshore Mertz Glacier.

GANOVEX VIII: AN AEROMAGNETIC SURVEY ALONG THE ANTARCTIC COAST BETWEEN COMMONWEALTH BAY AND CAPE ADARE

Detlef J. DAMASKE[1], Heinz-Dieter MOELLER[1], Emanuele BOZZO[2], Fausto FERRACCIOLI[2], Massimo CHIAPPINI[3] ([1]Bundesanstalt fuer Geowissenschaften und Rohstoffe, [2]Dipartimento per lo Studio del Territorio e delle sue Risorse, [3]Istituto Nazionale di Geofisica e Vulcanologia)

Aerogeophysical investigations make it possible to survey extended and inaccesssible areas of mountain and glacier regions. Based on an areal coverage, the structural interpretation of magnetic anomaly patterns allows to recognize rocks or rock types and yields tectonic structures in the earth´s crust. Moving from areas geologically known to the unknown, one can extrapolate results or compare with magnetic patterns of other regions. For two decades BGR has carried out aeromagnetic surveys over large areas of Victoria Land and the western Ross Sea in cooperation with institutions in Italy (DIPTERIS, ING) and in the United States (USGS, INSTAAR, Ohio State University). GANOVEX VIII continued this research by - extending the survey across the western shoulder - the Transantarctic Mountains (TAM) -

A

of the Ross Sea Rift to study the transition to the East Antarctic Craton, - selecting the Oates- and George V Coasts to investigate the apparently high basement area between the subglacial Wilkes Basin (paralleling the TAM) and the continental shelf towards the Pacific / Indian Ocean, - conducting aeromagnetic surveys of the northern (Pennell Coast) TAM for correlation of marine tectonic elements between Australia and the Antarctic with structures in northern Victoria Land. A total of 26575 km of survey lines were acquired over an area of 83800 km². The complete coastal region from the Mertz Glacier to Yule Bay over a length of approximately 1000 km was surveyed for the first time.

PEOPLE AS BIOSENSORS FOR MAGNETIC STORMS AND SOLAR WEATHER DETECTION

Olga Valerievna KHABAROVA, Mary Valerievna RAGULSKAYA, Eugeniy Antonovich RUDENCHIK (Department of Solar-Terrestrial Coupling, IZMIRAN (The Institute of Terrestrial Magnetism))

The results of many biophysical experiments and data of medical statistics confirm that people are susceptible to changes of environment (particularly, to leaps of geomagnetic field strength – magnetic storms) and space weather. In this connection, an experiment for revealing of solar weather - human health linkage from physical point of view is carried out in IZMIRAN, Sector for Helio-Ecological Coupling from 1998(see http://helios.izmiran.rssi.ru/helioecology/index.html). The experiment is based on a method of measurements of acupuncture points electroconductivity; the measurements are led daily; number of tested people - 40. The values of electroconductivity of each point characterize the functional condition of corresponding organs. Statistical checks show that the hypothesis about the casualty of coincidence of human health's sharp changes with atmosphere pressure fluctuations, geomagnetic and solar activity growth can be rejected at the 0.01 level of statistical significance. It means that detected human reaction – change of heath status in the time domain (±2 days) of the magnetic storm commencement is not causality. So, the question about the origin of such phenomenon is emerging. It was found out that the time of registration of human health status changes before the magnetic storms commencement always coincides with the increase of amplitude of magnetospheric oscillations with periods 4-250 min. It was shown that the applying of parametrical resonance theory at biological systems (in our case - living organisms) could explain this fact. In accordance to calculations, the frequencies of 4-250min diapason of periods are resonant with the own frequencies of human brain and endocrine system. It was found out, that bioeffective amplification of geomagnetic oscillations with mentioned periods before magnetic storm commencement can be consequence of simultaneous increasing of solar wind oscillations (see abstract by O.Khabarova, E.Rudenchik "The possibility of magnetic storms prediction due to analysis of solar wind data").

AEROMAGNETIC SURVEY OVER UNZEN VOLCANO

Ayako OKUBO[1], Yoshikazu TANAKA[1], Naoto KITADA[1], Mitsuru UTSUGI[2], Hiroshi SHIMIZU[3], Takeshi MATSUSHIMA[3] ([1]Depart. of Geophysics, Kyoto University, Japan, [2]Geographical Survey Institute, Tsukuba, Japan, [3]Faculty of Science, Kyushu University, Japan)

We conducted helicopter-borne magnetic surveys over Unzen Volcano, southwestern Japan on September 18, 2002 in order to investigate the subsurface structure of Unzen graben and the cooling process of the lava dome formed in the latest eruption spanning between 1991 and 1995. Unzen volcano started a phreatic eruption in November, 1990 at summit craters after a quiescence of 198 years. After intensive ash ejection in February 1991, a lava dome appeared at the eastern neighbor of the previous peak of Mt. Fugen in May, 1991.The lava dome, named Heiseishinzan, gradually grew on the eastern flank of Mt. Fugen and yielded frequent pyroclastic flows until the surface activity ended in 1995. The survey consists of three flights of 1 hour for each. The first flight covers an area over Futsu, Chijiwa, and Kanahama faults, the major normal faults that form Unzen graben system. The second and the third flights cover the summit area of Unzen volcano with spiral trajectories at altitudes of 1000 and 500 ft, respectively. The spacing between the survey lines is about 500 m. Geomagnetic total field was recorded by an optical pumping magnetometer (GEOMETRICS) and an Overhauser proton magnetometer (GEM) installed in and over the sensor bird, which is suspended with a wire of 20 m long under the airframe. The sampling intervals of these magnetometers are 0.1 sec and 0.5 sec, respectively. While real time navigation was achieved by a portable GPS receiver with a PC monitor, precise positioning data of the sensor bird was obtained by the differential GPS technique with a time resolution of 1 sec. Diurnal magnetic variations of extra-terrestrial origin were removed by subtracting the total field data recorded at a temporal station nearby. As a next step, we estimated the effect of surface topography using a statistical correlation method (Grauch, 1987) in order to model a deeper magnetic structure. In the present study, we propose a plausible model of magnetic structure beneath Unzen volcano. Main features of the magnetic map are positive anomalies on the summit area of the volcano (Heiseishinzan lava dome and Mt. Fugen) and a negative anomaly on Unzen hot-spring area.

HIGH-RESOLUTION AEROMAGNETIC DATAFACILITATE MAPPING AND CHARACTERIZATIONOF CASCADIA EARTHQUAKE HAZARDS

Richard J. BLAKELY, Ray E. WELLS (U.S. Geological Survey)

The Puget Lowland-Willamette Valley urban corridor (Washington and Oregon) lies within the Cascadia forearc and above the subducting Juan de Fuca plate. Northward migration and clockwise rotation of the forearc are accommodated in part by crustal faults, some capable of M 7 earthquakes. Crustal faults are known or suspected to underlie the major population centers of the urban corridor, yet the cover of vegetation, young surficial deposits, and urban development hampers study of these structures. Tertiary volcanic rocks of diverse origins, however, underlie the region and produce distinctive magnetic anomalies that facilitate geologic mapping and help identify hazardous structures. During the past

decade the USGS has systematically acquired high-resolution aeromagnetic data over 80,000 km² of the Cascadia forearc, including its highly urbanized areas. These data are useful at many scales: They help define the limits, thickness, and internal structure of the Cascadia forearc as a whole, but also serve to map crustal faults in exceptional detail. Here we present two case studies: The Seattle fault zone in western Washington extends east-west beneath Seattle and was responsible for a M 7 earthquake 1100 years ago. The fault zone accommodates uplift of regions to the south relative to the Seattle basin to the north, with 9 to 10 km of structural relief on the highly magnetic Eocene basement. Much of the fault zone is concealed beneath glacial deposits and water, but the volcanic basement produces distinctive magnetic anomalies that illuminate hanging-wall geology. Miocene conglomerates within the Seattle basin are also magnetic, generate distinctive magnetic anomalies where deformed, and thus constrain mapping of specific strands of the Seattle fault zone within narrow spatial limits. The active strand of the Seattle fault zone is interpreted to extend at least 50 km east-west and lie beneath the neighborhoods of greater Seattle, conclusions now being validated by ongoing paleoseismic investigations. In northwestern Oregon, the Portland Hills and Mount Angel faults form northwest-striking, right-lateral structural zones that in large part lie beneath thick surficial deposits of the northern Willamette basin. Basalt flows of the Miocene Columbia River Basalt Group underlie much of this region and now serve as post-Miocene strain markers that produce characteristic magnetic anomalies. A M 5.6 earthquake occurred in 1993 on the Mount Angel fault about 50 km from downtown Portland. Prior to the earthquake, the location and characteristics of the Mount Angel fault were known primarily through widely spaced wells and seismic-reflection profiles. Models of the fault based on new high-resolution aeromagnetic data provide a three-dimensional view of this structure, indicate how it kinematically links to other elements of the structural zone, and suggest that it extends >60 km and thus may be capable of M 6-7 earthquakes.

AEROGEOPHYSICAL SURVEY OVER IWATE VOLCANO, NORTHEAST JAPAN

Shigeo OKUMA, Tadashi NAKATSUKA, Rie MORIJIRI, Shinichi TAKAKURA (Geological Survey of Japan, AIST)

A helicopter-borne electromagnetic survey (HEM) with simultaneous measurements of the Earthq´s magnetic field was conducted to better understand the subsurface structure of Iwate volcano, northeast Japan with a special reference to an increase of seismic and fumarole activities. The Quaternary volcano is geologically divided into two parts, i.e. an eastern part called the East-Iwate, which is a stratovolcano with a small summit crater and younger than the other in age, and a western part called the West-Iwate, which comes with an east-west elongated caldera of about 2km wide and is overlain by the volcanic products from the East-Iwate at the eastern edge. The HEM system is a modified DIGHEM-V model that is operated at five frequencies ranging from 220 Hz to 137,500 Hz with five-fold frequency increments. The survey was flown in late 2000 at an altitude of 70-100 m above terrain along north-south survey lines and east-west tile lines, spaced 100 m and 1,000 m apart, respectively. A post differential GPS system was employed for flight path recovery.The observed electromagnetic data were processed and apparent resistivity maps for each frequency and cross-sections of apparent resistivity profiles were created. Aeromagnetic anomalies were reduced onto a smoothed observed surface and a reduction to the pole anomaly map with a terrain correction was created. The characteristics of apparent resistivities and magnetic anomalies (reduction to the pole) are obviously different between the East- and West-Iwate volcanoes. In general, apparent resistivity highs ($> 4,000~\Omega \cdot m$) and magnetic highs ($> 2,000$ nT) lie dominantly in the East-Iwate, while apparent resistivity lows ($< 250~\Omega \cdot m$) and magnetic lows (< -200 nT) in the West-Iwate, corresponding to a difference in the geologic age and hydrothermal activities of the volcanoes. Concerning a recent increase of the volcanic activity on the ground in the West-Iwate, an apparent resistivity low of 5 - 15 $\Omega \cdot m$ occupies on the divide on the half way to Mt. Ubakura from Mt. Kurokura, where severe fumarole activity was being observed during the survey. Although a magnetic high lie over the divide, the amplitude of the anomaly is decreasing with getting close to Mt. Kurokura, where the activity was the severest. Lava flows from sub volcanoes around the West-Iwate caldera can be recognized by a coincidence of magnetic and apparent resistivity highs on the northern slopes of Mt. Ubakura and Akakura-dake and southern slopes of Onigajyo and Kamakura-mori. On the contrary, magnetic lows (< -1400 nT) and apparent resistivity lows ($< 30~\Omega \cdot m$) can be seen in geothermal and/or altered areas mainly on the southern flank of the West-Iwate volcano, implying a usefulness of the HEM survey for detecting these parts.

GAV.06/10A/A11-003   **0910**

HELICOPTER BORNE EM STUDIES OVER THE MOUNT USU REGION, JAPAN

John Joseph E.[1], Shigeo OKUMA[2], Tadashi NAKATSUKA[2] ([1]School of Earth and Environmental Sciences, The University of Adelaide, [2]Institute of Geoscience, AIST/GSJ, Tsukuba 305-8567, Japan)

Mount Usu in the northern part of Japan is an active volcano. Latest eruption of this volcano was in the year 2000. An airborne electromagnetic (AEM) survey was conducted in this region to study shallow subsurface electrical conductivity distribution and thereby investigate the geohazards and environmental settings. The reported survey was conducted in October 2000, while the volcanic eruption was still continuing. We used a modified helicopter borne system called DIGHEM-V. It is a multi-frequency system that contained within a 10m bird towed beneath the helicopter. This bird has 5 stand-alone transmitting-receiving coil pairs corresponding to 5 different frequencies such as 137500 Hz, 27500 Hz, 5500 Hz, 1100Hz and 220 Hz. Two coil pairs are oriented in the co-axial directions (i.e. with the axes of the flight direction) and three coil pairs in the horizontal coplanar direction (axes vertical). For obtaining precise positioning of the helicopter and flight altitude we used a combination of DGPS system, a radar altimeter and a Video camera, which were installed on the helicopter. There were 85 survey lines in the North-South direction with line spacing of 100m and 15 survey lines in the East-West direction with line spacing of 1000m. Airborne EM data were processed and data inversion were carried out to estimate the depth-resistivity distribution of the whole survey region. Since the EM signal frequencies used are very high, we could obtain the shallow (~0-150 m) resistivity distribution. Preliminary result shows the presence of a 3-layer resistivity structure with a top layer which is less resistive (<200 Ohm-m) followed by a high resistive layer (500-5000 Ohm.m) which is underlined by a low resistive layer (<500 Ohm.m). Central region of Mount Usu seems to be more resistive (400-2500W-m) than the surrounding region. By examining the resistivity distribution maps of lower frequencies, it is clear that a similar trend in resistivity persists downward. Selected transects of the depth-resistivity profiles clearly show the presence of a highly resistive body at a depth of 60-70m depth beneath the SW slope of the mount summit. This highly resistve body may be indicating the presence of avalanche deposits of the previous summit. A detailed discussion on data collection, processing and comparison with apriori geological and geophysical information will be presented.

GAV.06/10A/A11-004 0930

HIGH RESOLUTION AIRBORNE MAGNETIC SURVEYS TO INVESTIGATE THE STRUCTURE AND SYSTEM CHANGES IN ACTIVE VOLCANIC REGIONS OF SOUTHERN ITALY

Robert SUPPER[1], Shigeo OKUMA[2], Massimo CHIAPPINI[3], Riccardo DERITIS[3], Iacopo NICOLOSI[3], Christian STOTTER[1], Ingrid SCHATTAUER[1] ([1]Geological Survey of Austria, [2]Geological Survey of Japan / AIST, [3]Istituto Nazionale di Geofisica e Vulcanologia)

In the years on from 1999, several high resolution airborne magnetic surveys were carried out by the Geological Survey of Austria in cooperation with different partner in active volcanic regions of southern Italy (Vesuvio, Campi Flegreii, Vulcano,AE. However within this presentation we focus on the airborne surveys conducted at the Eolean Islands (Italy) in a close cooperation with the Geological Survey of Japan and INGV Roma..Southern Italy is characterised by several active volcanic regions like Mt. Vesuvio, Campi Flegrei, Mt. Etna and the Eolian Islands. A few of these are surrounded by some of the most densely populated areas in Europe like Napoli and Catania or are popular tourist destinations, like Vulcano Island. Therefore in view of hazard mitigation it is very important to understand the structural and geological settings of these areas.The purpose of the airborne surveys was to map the geophysical anomaly structures of this area from a regional point of view and to correlate them, including other potential field data, with recent volcanic activities to find significant geophysical anomaly patterns caused by these activities. Moreover these data sets should provide a basis for future research activities including volcanic hazard monitoring.A first survey on Vulcano and Lipari Island was conducted in 1999.Within the 1999 airborne magnetic survey only a restricted area of the Vulcano/Lipari area has been covered. Therefore some of the structural important magnetic anomalies of this region could not be investigated in detail. Therefore, for a second airborne magnetic survey, conducted in 2002, the area under investigation was significantly enlarged, including also the regions of Panarea and Stromboli, which recently have shown a increasing volcanic activity. The detailed results of these surveys are shown, outlining the main structural trends of this region. Some first results of modelling are also given.Additionally, as one might expect that due to the geodynamics of this area, corresponding changes of the magnetic anomaly pattern may occur with time, the same lines measured in the 1999 survey were reflown to get hints for changes in the magnetic field within the last three years. As both surveys were unavoidably conducted at slightly different flight altitudes, delicate field transformation algorithms had to be applied to make the data comparable without loosing much information. The results show a degrease of the magnetic field in western parts of the Vulcano-Lipari complex. This results and limitation of this method to monitor changes in the volcanic system are also discussed.

GAV.06/10A/A11-005 0950

AIRBORNE MAGNETIC ANOMALY IMAGES OVER STROMBOLI (AEOLIAN ISLANDS, ITALY)

Massimo CHIAPPINI[1], Iacopo NICOLOSI[1], Riccardo DE RITIS[1], Shigeo OKUMA[2], Robert SUPPER[3] ([1]Istituto Nazionale di Geofisica e Vulcanologia, [2]Geological Survey of Japan/AIST, [3]Geological Survey of Austria)

The recent volcanic activity at Stromboli Island has threaten the local population. Remotely-sensed data, such as magnetic anomaly data provide an important means for obtaining geological information on the area, helping to delineate tectonic features, and to characterize the area magnetically. Only the apical part of the large Stromboli edifice emerges from the sea, therefore spatial observations need to be extended offshore far enough to cover the whole structure.An international consortium has been established, and a high resolution aeromagnetic survey was conducted. The effort constitutes a considerable step ahead, with respect to the existing magnetic data in the area. In fact, the magnetic anomaly field shows the major known structural features; also it clearly reveals the presence of a high frequency magnetic pattern associated to tectono-volcanic elements.

ANALYSIS AND INTERPRETATION OF AEROMAGNETC DATA OF RUNGWE VOLCANIC PROVINCE, SOUTHWEST TANZANIA

Isaac Muneji MAROBHE (University of Dar es Salam)

The Rungwe volcanic province lies at the triple junction of the East African Rift System in southwest Tanzania. The volcanic province consists of basalts, trachytes, tuffs and volcanic ash erupted along vents that were controlled by basement structures. The youngest eruption of Kiejo is believed to have erupted in 1800 AD. The volcanics overlie basement and sediments that range from Karoo to Neogene. The countrywide aeromagnetic data surveyed in 1976 to 1980 at flight spacing of 1 km and altitude of 120m above the ground has revealed subsurface structures that have not been mapped by conventional methods. The Data has been analysed by enhancing the anomalies using filtering methods in the frequency domain. Two prominent magnetic lineaments NE/SW and NW/SE are revealed from the data. NE/SW lineaments terminate against the Mbozi Block whereas the NW/SE runs parallel to the block. Based on magnetic relief and amplitude, the aeromagnetic data of the area show two distinct provinces. The two provinces coincide with the young and old volcanic provinces. Individual anomalies are dipolar in form and have amplitude ranging from 50 to 300 nT, however there is one anomaly that has an amplitude of 3500 nT. The individual anomalies have been interpreted to get body parameters whereas spectral analysis suggest that depth basement is as high as 9 km in some parts..

MGANETIC ANOMALY ANALYSIS USING 3D SPACING GEOMAGNETIC VECTOR FIELDS

Nobuhiro ISEZAKI (Department of Earth Science, Faculty of Science, Chiba University)

I observed the vector geomagnetic fields at Niniu, Hokkaido,Japan by themagnetometer developed in my laboratory which consists of a flux-gatemagnetometer, a ring laser gyro-scope(RLG), cpus, a GPS receiver andmemory storages. RLG measures attitude with the precision of 0.001-0.005 degrees for yaw,pitch and roll. I used a helicopter and towed amagnetometer 30m behind it. A helicopter flied from 50m to 1000m abovethe ground with the speed of about 80km/h and sampling rate of 5hz.Niniu is located in the Hidaka collision zone and there are outcropsof serpentinites in the eastern part of the surveyed area where strongmagnetic anomalies are observed. I analized 3D spacing vector geomag-netic anomalies to get magnetization structure beneath the area assumingpiles of polygonal prism structure.I adopted 3 different processes,1: X,Y,Z ANOMALIES USED, N SOLUTIONS OBTAINED AT ALL OBSERVATION POINTS2: X,Y,Z COMPOSITE ANOMALIES USED, 1 SOLUTION OBTAINED3: INDIVUDUAL X,Y,Z ANOMALIES, 3 SOLUTIONS OBTAINED FOR X,Y,AND ZIn the process 1, for 1 magnetic structure there are 3 unknowns,namelymx,my and mz(3 components of magnetization) while there are 3

componentmagnetic anomaly data at each observation point, then we have N(numberof data points) solutions which will give us an information for generalfeature of magnetization distribution because each solution will representthe magnetization of small local area just beneath the observation point.I will show the results of 3 processes and most optimum magneticstructure of NINIU.

THE THREE-DIMENSIONAL MAGNETIZATION VECTOR INVERSION

Ryuji KUBOTA, Akinori UCHIYAMA (Kawasaki Geological Engineering Co., Ltd.)

A three-dimensional non-uniform magnetic modeling is proposed to obtain information about the oceanic crust and/or a seamount. Our method is different from the semi-norm method of Parker et al. (1987). The structure of the crust and/or a seamount body was divided into many blocks modeled by layered and rectangular prisms, and parameters were assigned to each block describing magnetic three components. Our data were the magnetic total force on the sea. A set of linear equations for data was formulated in terms of the direction cosines of magnetization for each block. The solution was obtained by using the conjugate gradients method because of its fast and accurate advantages of calculation. The magnetic intensity is inversely proportion to the third power of distance between an observation point and a source, and consequently coefficients for shallower blocks in the linear equations are large values compared with ones for deeper blocks. Therefore the observed sea surface anomalies were continued to several altitudes (upward continuation) in order to suppress effects of differences among those distances depending on the depth of each block, relatively. On the other hand, a common set of the three direction cosines was defined for several blocks to decrease the number of unknown parameters. A computer program has been tested with artificial data and applied to sets of data observed during the first phase of the Kaiko project carried out with the R/V JEAN CHARCOT in 1984.

GAV.06/10A/A11-009 1130

DETERMINATION OF THE PARAMETERS OF COMPACT FERRO-METALLIC OBJECTS WITH TRANSFORMS OF MAGNITUDE MAGNETIC ANOMALIES

Daniela Ivanova GEROVSKA[1], Marcos ARAUZO-BRAVO[2], Petar STAVREV[3] ([1]Department of Earth Resources Engineering, Laboratory of Geothermics, Kyushu University, Fukuoka 812-8581, Japan, [2]Department of Electromechanical Engineering, University of Burgos, Burgos 09006, Spain, [3]Department of Applied Geophysics, University of Mining and Geology)

The transforms based on magnitude magnetic anomaly (MMA), or modulus of total magnetic intensity T, including the MMA itself, the modulus of the full gradient of the MMA, R, the half of the square root of the Laplacian of the square of the MMA, E, and the Laplacian of the MMA, L, are low sensitive to the direction of the source magnetisation vector and show high centricity. The shape of the anomalies of these transforms is ten times less strongly dependent on the magnetisation vector direction than the shape of the anomalies of the measured field. The transforms based on MMA, with only non-negative values, for a dipole source show displacement of the maximum of the anomaly from the epicentre, in respect to the depth of the causative body, of 25%, 20%, 15% and 8% for T, R, E and L, respectively. Their obtaining requires calculation of only first order horizontal derivatives of the component magnetic anomalies X, Y and Z, obtained through transformation of the measured total magnetic anomalies (TMA). We studied the use of the magnetic transforms of the TMA based on the MMA of a dipole source and that of their ratios for determining the geometric and physical parameters of compact environmental ferro-metallic sources. Analytical formula for all the parameters of the magnetic dipole based on calculation of MMAs, their gradients and Laplacian, and their ratios, were obtained. The horizontal position of the dipole source is determined by the maximum of the Laplacian of the MMA, which is the transform with highest centricity. The depth to the source is determined by the maxima of ratios of the transforms based on MMA, producing depths, which are functions only of the depth and a magnetisation inclination factor. The least dependent on the magnetisation inclination factor was found to be the ratio of T and R, which makes it the most suitable ratio for the dipole depth estimation. We applied the approach on model data and on magnetic anomalies over environmental sources, represented by UXO and clutter, from the Badlands Bombing Range, USA. The obtained parameter values were compared with those estimated through Euler deconvolution using unprescribed structural index and linear model of the background. The comparison showed that both methods produce similar depth results for the objects with estimated structural index over and around 2.5, i.e., for the sources, which to a great extent can be approximated with a dipole.

GAV.06/10A/A11-010 1150

A METHOD OF DELINEATING DEEP PENETRATIVE FRACTURES IN THICK SEDIMENTARY ROCK SEQUENCES

Mark E. GETTINGS (U. S.Geological Survey)

In many areas characterized by a thick surficial layer of sedimentary rocks, the mapping of deep penetrative fractures has become an important undertaking. Flat-lying sedimentary sequences often comprise significant portions of basins and plateaus, and if they contain regional aquitards such as shales, mudstones, siltstones, or some limestones, the vertical hydraulic conductivity is essentially zero except where broken by steeply dipping fractures. In these environments, the only significant recharge to deep aquifers is via deep penetrative fractures, and mapping their probable location is thus an important objective for groundwater studies. Here, it is assumed that the geologic environment is a thick section of sedimentary rocks (1-3 km) overlying a heterogeneous crystalline basement of contrasting units of magnetization and density. The sediments are assumed to be flat-lying or only gently deformed, so that bedding plane hydraulic conductivity is not a factor other than possibly providing horizontal conduits to fracture systems where the water can percolate to deep levels. The strategy is to map structures in the basement that are likely to generate fractures, mainly fault and fold axes, and to superimpose this map on a surficial fracture map derived from geologic and other shallow data. Coincidences of deep fracture candidates down-dip from surface fractures define the likely penetrative fractures. Maps of the likely deep fracture, fault, and fold axis locations are prepared by interpretation of curvilinearly persistent features of magnetic and gravity anomaly maps. A primary tool for this interpretation is the location of local analytic signal maxima. Modeling is usually required to resolve ambiguities in location of signal maxima with respect to the location of the actual fault, fracture, or fold axis. If magnetic horizons are present within the sedimentary section and if there is evidence of significant non-vertical dip of racture systems, an intermediate depth layer must be utilized. Maps of surficial fractures are prepared from geologic maps to define known faults and fold axes. Fractures are obtained from aerial photographs, satellite images, topographic maps, and any other remote sensing data available. The deep and surficial fracture maps are then superimposed and candidate penetrative fractures defined from analysis of coincident or nearly coincident features. If there is significant dip to the surficial fractures, this must be taken into account using depth estimates computed from the gravity and magnetic anomaly data. There are several sources of difficulty with the method. For the deep fracture pattern, a lack of sufficiently precise or closely spaced magnetic and

A

gravity anomaly data will mean that not all anomalies will be detected and thus lineaments, especially subtle ones, will be lost. If fracture or fault systems do not juxtapose rocks with contrasting density or magnetization, there will be no anomaly. For the shallow fracture dataset, lack of sufficiently precise data is a limitation, and some anthropogenic factors may lead to false identifications. Shallow burial by surficial deposits may obscure fractures. The net result of these sources of error is that the set of penetrative fractures defined by this method is a lower bound.

GAV.06/10A/A11-011   1210

UTILITY OF COMPREHENSIVE MAGNETIC FIELD MODEL IN STUDYING THE EARTH'S LITHOSPHERE

Dhananjay RAVAT[1], Thomas G. HILDENBRAND[2] ([1]Department of Geology, Southern Illinois University Carbondale, [2]U.S. Geological Survey)

Near surface magnetic surveys are generally reduced using IGRF/DGRF and additional diurnal and regional corrections to meet specific survey needs. In preparing continental scale compilations, which involves surveys acquired at widely different times, the levels of derived magnetic anomalies from adjacent surveys do not often merge properly because of the failure of IGRF/DGRFs in representing correctly the secular variation of the geomagnetic field. Merging of these surveys is generally accomplished by warping individual surveys until discontinuities are minimal at the survey boundaries. The resulting field is often not the correct representation of the intermediate and long wavelength magnetic anomalies and can severely affect the interpretation of regional crustal magnetic sources, the Curie isotherm, and related properties of geodynamic interest. Models of geomagnetic field, continuous in space and time, such as the comprehensive model (CM) (Sabaka et al., 2002), are helpful in avoiding the poorly constrained or ad hoc warping step and preserving the magnetic anomaly signal. Using the CM and various near surface magnetic data sets over North America, we show that near surface magnetic anomalies based on such models can be better defined than those computed using the IGRF/DGRF and therefore they are more useful for exploration and scientific purposes. The CM also is useful in modeling some of the diurnal variations of the magnetic field.

INDIAN TECTONIC STRUCTURE THROUGH AEROMAGNETIC DATA

Mita RAJARAM, Anand SASIDHARAN (Indian Institute of Geomagnetism)

Available degree-sheet aeromagnetic maps, over India (from 8 to 24 degrees North), acquired from the Geological Survey of India, were rigorously reprocessed. These degree sheet maps include surveys carried out by different agencies at different epochs with different survey altitude (5000' / 7000' / 9500') and flight line directions but with a constant flight line spacing of 4 km. The data have not been corrected for the main field. Aeromagnetic surveys have not been conducted over the Deccan trap covered regions. These maps were digitized along contours, corrected for the main field, gridded at 2 km interval, reduced to a common altitude of 5000ft and merged. The crustal anomaly map thus prepared depicts very distinctive structural trends related to the different tectonic blocks of the region. The Southern Granulite Terrain (SGT), the Dharwar, Bastar, Sighbhum cratons, the Eastern Ghat Mobile Belt (EGMB) and the Central Indian Tectonic Zone are distinctly visible on the map. The data has been analysed to throw light on the various tectonic blocks of the region, ranging from the Archean to the present. The changing inclination ($1o < I < 35o$) of the main magnetic field makes it difficult to identify the magnetic sources directly from the anomalies; we therefore calculate the analytical signal. It dramatically maps the charnokites, the iron ore series (Bailadilla, Singhbhum, etc) and is able to delineate the orthopyroxene isograd, the Sileru Shear amongst others. A very striking feature is the long arcuate shaped shear that extends for over 1000 km in Central India across the Peninsula from west to east to mark the edge of the Eastern Ghat block, the Bastar craton and possibly the Dharwar craton. We call this as the Main Peninsular shear. Proposed geotectonic models are based on inadequate data and studies of relatively small regions and it is in this regard that the aeromagetic data could provide very valuable information. From the aeromagnetic anomaly, its analytical signal and Euler solutions we bring out the subsurface structure of the region and redefine the tectonic elements especially in regions with large surface cover. Results of this study will be presented.

GAV.06/10P/A11-002   1420

ANALYSIS OF AEROMAGNETIC DATA OVER SINGHBHUM, INDIA, FOR IDENTIFICATION OF URANIUM DEPOSITS

Anand P. SASHIDHARAN, Mita RAJARAM (Indian Institute of Geomagnetism)

Two distinctive types of Uranium mineralization occur in the Singhbhum Uranium Province (SUP) of the Indian subcontinent,: 1) the early quartz-pebble-conglomerate type and 2) shear controlled hydrothermal type. The country's main Uranium producing mines (second type of mineralaization) are located on the mapped Singhbhum Shear zone. Detailed high resolution aeromagnetic data was collected over SUP under Operation Hard Rock. The aeromagnetic survey was flown at a height of 61–122 m with a flight line spacing of 500m. Aeromagnetic data over a part of SUP covered under Operation Hard Rock has been analysed. The total field anomaly map prepared after applying necessary corrections depicted signatures of several known geological formations viz. the Singhbhum Shear zone (SSZ), the Dalma volcanics, Dhanjori lavas, etc. To identify the magnetic sources, the analytical signal map was prepared. The magnetic sources are clearly concentrated along the arcuate shaped Singhbhum Shear and also on the small part of the Barabhum shear zone that falls within the study area and can be explained as due to the magnetite present in this shear zone as accessory mineral in rocks hosting uranium mineralisation. To throw light on the depth, position and the nature of the magnetic sources, 3D Euler Deconvolution method has been adopted. The Euler solutions confirm that the SSZ turns EW in the southern part under the Tertiary gravels and alluvium. The region covered by Tertiary gravel and alluvium is deepest compared with the other regions. The sources within the Shear zones seem to be shallow, having an average depth of 300 ±45m, but can be as low as 100m. Distinctive magnetic sources have been identified in the Central part of the zone lying between the Dalma volcanics and the Chotanagpur Granitic Gneissic Complex. The sources in this zone are shallow and depict similar magnetic characteristics as the Singhbhum Shear Zone and may be a zone of concealed uranium deposit that can be explored in the future. The entire SUP is studied with respect to the aeromagnetic data of Central India and the results will be presented. The analysis shows the importance of conducting high resolution aeromagnetic surveys and how a proper and systematic analysis of aeromagnetic data can be useful in the identification of concealed mineral deposits.

GAV.06/10P/A11-003   1440

AEROMAGNETIC IMAGING OF THE JUTULSTRAUMEN AREA, WESTERN DRONNING MAUD LAND (EAST ANTARCTICA)

Fausto FERRACCIOLI, Phil JONES, Mike CURTIS, Philip LEAT (Geological Sciences Division, British Antarctic Survey)

During the 2001/02 Antarctic campaign a combined aeromagnetic and aerogravity survey was performed over the Jutulstraumen area in western Dronning Maud Land (East Antarctica). This aerogeophysical survey was part of the MAMOG (Magmatism as a Monitor of Gondwana Break-up) project. This project aims at assessing driving forces of Gondwana break-up as Africa rifted away from East Antarctica, while investigating related Mesozoic magmatic and tectonic events. However, current Mesozoic break-up models are hampered by the lack of robust geophysical constraints on the magmatic and structural context of the Dronning Maud Land margin. Additionally, Dronning Maud Land was situated in the pivotal region, between East and West Gondwana during the transition from fragmentation to Gondwana amalgamation. Hence, new geophysical imaging of the Mid-Proterozoic to Early-Paleozoic tectonic structures of Dronning Maud Land was also required. The aeromagnetic survey over the Jutulstraumen area was flown on a 1 km line spacing grid, with tie line interval of 8-km, at a constant barometric altitude of about 2700 m. An area of about 15300 km2 was covered. This is the first airborne aeromagnetic campaign over Antarctica with such detailed line spacing. Some long profiles were also flown to image longer wavelength features for aerogravity. Aeromagnetic data processing involved standard procedures: quality control, post-processing of GPS data, magnetic compensation, filtering, base station correction, IGRF removal, statistical levelling and microlevelling. The final processed data were gridded with a grid cell size of 250 m (1/4 of the line spacing). A 1: 250,000 scale shaded relief aeromagnetic anomaly map was produced, leading to the identification of the following major aeromagnetic anomaly features. A broad positive anomaly chain with amplitudes of about 250 nT is observed over the H.U. Sverdrupfjella. It likely images the Middle to Late Proterozoic Maudheim Province, though some higher frequency anomalies correlate with more recent granitoids of Pan-African age. Just to the west of the Sverdrupfjella anomaly, two discrete aeromagnetic anomalies reveal the extent of the Jurassic alkaline intrusions of Straumsvola and Tvora. The aeromagnetic image shows that similar intrusions are unlikely beneath the inferred Jutulstraumen rift structure. However, a very high-amplitude (1000 nT) anomaly at Straumsnutane, along the inferred western flank of the rift, may reveal an unexposed mafic intrusion. The Jutulstraumen itself exhibits a pattern of distinct magnetic highs and lows that suggest a hitherto unrecognised complexity of the rift itself. High-frequency magnetic anomalies mark the Borgmassivet and Ahlmannryggen areas; they relate to mid-Proterozoic dolerites and to probable faults displacing them. Finally, by combining the new detailed aeromagnetic data with previous Russian data over adjacent areas, we shall discuss some new implications for Mesozoic and Proterozoic to Early-Paleozoic tectonics and magmatism.

GAV.06/10P/A11-004   1500

AIRBORNE AND GROUND GEOPHYSICS USED FOR REGIONAL TECTONIC ANALYSIS

Sven G. AARO[1], Håkan SJÖSTRÖM[2] ([1]Geological Survey of Sweden, [2]Department of Earth Sciences, Uppsala University)

The magnetic and gravity fields give in many case insights to brittle and ductile shear zones, fractures, folds and rock contacts. By determining the petrophysical properties of the constituent rocks the size, shape and orientation of the formations can be revealed. For Proterozoic and older rocks the best results will be given by integrating magnetic and gravity data with petrophysics, bedrock information, EM and seismic data if available. In Sweden and other countries where most of the bedrock is covered with till and swamps the geophysical information is of crucial importance for a meaningful bedrock mapping and naturally also for exploration. The geophysical databases at the Geological Survey of Sweden (SGU) contain airborne measurements, gravity measurements and petrophysics as well as magnetic observatory data. Since 1960 the airborne measurements have been carried out at low altitude (ground clearance 30 or 60 m) and with 200 m line separation. The systematic gravity measurements started in the 1950's, in the ore-bearing regions in the northernmost part of Sweden, and petrophysical measurements in the 1960's. Today, systematic regional gravity measurements are normally made with a distance between the gravity stations of 1 to 2 km, but in areas with few outcrops and with a special magnetic signature a station distance of 0.5 to 11/2 km is used. The petrophysical data bases contain density, magnetic susceptibility and q-value information from about 60 000 samples, as well as radiometric information from in- situ and laboratory measurements. To illustrate the benefit of the geophysical information the Hassela shear zone (HSZ) in the central part of Sweden is discussed. The HSZ is interpreted as a Paleopoterozoic tectonic domain boundary across the Fennoscandian Shield. This zone is the most prominent of several, c. 1.8 Ga crustal-scale, dextral shear zones in central Sweden. These more or less transpressive zones are components of a structural evolution including the formation of E-W regional folds and variably dipping, E-W stretching lineations.

GAV.06/10P/A11-005   1520

THE OKAVANGO GIANT DYKE SWARM (NORTHERN BOTSWANA): INSIGHTS FROM COMBINED GROUND-LEVEL MAGNETIC AND AEROMAGNETIC DATA

Jérôme DYMENT[1], Gomotsang TSHOSO[2], Charly AUBOURG[3], Bernard LEGALL[2], Jean-Jacques TIERCELIN[2], Fred JOURDAN[4] ([1]CNRS UMR 7097, Institut de Physique du Globe, Paris, FRANCE, [2]CNRS UMR 6538, Institut Universitaire Européen de la Mer, 29280, Plouzane, FRANCE, [3]CNRS UMR 7072, Universite de Cergy Pontoise, 95031 Cergy, FRANCE, [4]CNRS UMR 6526, Universite de Nice-Sophia Antipolis, 06108 Nice, FRANCE)

The Okavango Giant Dyke Swarm (OGDS) is a 100 km wide dyke complex which cut across Northern Botswana on 1000 km along a N110 ° E direction. Although the dykes outcrop locally from the Kahalari sands in the river beds, the OGDS has so far been mapped using the dense aeromagnetic data available in Botswana. To complement such remote-sensing data, field work including a complete transect of the OGDS along the Shashe River (Northeastern Botswana) has provided rock samples, direct geological observation, and geophysical profiling. Rock samples, basalt and dolerite, were dated using Ar-Ar technique, leading to the definition of two families, Karoo dykes (about 85%, 178.3 ± 1.1 to 179.3 ± 1.2 Ma) and Proterozoic dykes (about 15%, 758.2 ± 6.6 to 1223.8 ± 10 Ma), which otherwise are structurally undistinguishable. Rock magnetic measurements have been performed on some samples and show a dominant remanent magnetization of about 1 A/m. As for the direct geological observation, 171 dykes have been charted and described, although a significant amount remained hidden by the Kahalari sands. A typical dyke is vertical, 5 km-long and 20 m-thick, and exhibits a N110 °E direction. In addition, a high resolution magnetic profile, 100 km long, have been recorded along the same section using a portable land magnetometer. The altitude of measurements is 2 m above ground-level (5-10 m above the magnetic sources), and the maximum sampling interval is 10 m. Unlike the aeromagnetic data, the ground-level magnetic profile has a resolution sufficient to distinguish unambiguously the

signature of each dyke. Therefore, it allows the identification of 423 dykes, which compare to the 171 dykes actually seen on the section. The dyke thickness ranges between 5 and 70 m, (average 20 m). This would represent an extension of about 6-10%. The average skewness of the magnetic anomalies associated to dykes is 50 °, in agreement with the location of paleomagnetic poles for Karoo ages. The skewness values show no clear difference between the two families of dyke. The range of magnetization intensity deduced from forward modeling (by adjusting the amplitude of synthetics to the observed anomalies) ranges between 0.35 and 8.82 A/m, with an average of 2.75 A/m in rough agreement with sample measurements. Again, no clear difference is observed in terms of magnetization intensity between the two families of dyke. A striking result is that almost all the dykes exhibit a constant, apparently normal magnetic polarity. Only 12 on a total of 423 dykes show an opposite behavior, all located in a very small area. As the mid-Jurassic was a period of high geomagnetic reversal frequency (about 2.5 reversal / Ma), this observation suggests that the Karoo dykes have formed in a very short time - 0.5 to 1 Ma. Such a rapid occurrence for Karoo volcanism, already suggested from radiochronological dating of Karoo extrusives in South Africa, is comparable to other flood basalt usually associated to the inception of plume head with the continental lithosphere.

GAV.06/10P/A11-006   1600

DEEP-SEA MAGNETIC SURVEY OF RAINBOW HYDROTHERMAL SITE ON THE MID-ATLANTIC RIDGE: MAGNETIC SIGNATURE OF A HYDROTHERMAL SITE IN ULTRAMAFIC ENVIRONMENT

Kaori NAKASE[1], Jérôme DYMENT[2], Kensaku TAMAKI[1], Michiko YAMAMOTO[3], Morgane RAVILLY[4], Mitsuko KITAZAWA[2], Yves FOUQUET[5] ([1]Ocean Research Institute, 1-15-1 Minamidai, Nakano-ku, Tokyo 164-8639, JAPAN, [2]CNRS UMR 7097, Institut de Physique du Globe de Paris, 4 place Jussieu, 75005 Paris, FRANCE, [3]GEOMAR, Wischhofstrasse 1-3, D-24148 Kiel, GERMANY, [4]CNRS UMR 6538, Institut Universitaire Européen de la Mer, 1 place N. Copernic, PlouzanAE FRANCE, [5]IFREMER Centre de Brest, B.P. 70, 29280 PlouzanAE FRANCE)

Most of the hydrothermal vent systems discovered so far on the Mid-Atlantic Ridge (MAR) lie on basaltic substratum. Major exceptions are Sites Logatchev and Rainbow, both located on outcropping ultramafic rocks. Cruise IRIS (Interdisciplinary Research for hydrothermal Interaction during Serpentinisation) of R/V L´Atalante was designed to study the hydrothermal activity in ultramafic environment and its possible role in the early development of life. In May 2001, Site Rainbow (MAR 36 ° 14'N) was investigated through a variety of experiments using IFREMER deep-sea ROV Victor. Among these experiments, one dive was fully devoted to a Deep Sea Three Components Magnetometer (DSTCM) survey of the site area. A total of 22 lines, amounting for more than 16 km, were collected, among which 19 lines, 700-800 km long and 60 m apart, densely covered the whole site area. The magnetic data were acquired about 1 to 10 m above seafloor, providing an ultra-high resolution never achieved so far on a hydrothermal system in ultramafic environment. Both the magnetic effects from the ROV and the main geomagnetic field were evaluated and removed. The absolute magnetization of the seafloor was estimated in the following way: (1) synthetic magnetic anomalies were calculated along the ROV tracks, assuming a local 2D topography (as given by the immersion and altitude of the ROV) and a unit (1A/m) magnetization of the seafloor, (2) observed and synthetic anomalies were compared on sliding windows, and if the coherence between both signals is high, an estimate of the magnetization is given by the ratio between observed and modeled anomalies. Unlike the hydrothermal systems in basaltic environment, generally characterized by a lower magnetization as the result of pervasive alteration of the highly magnetized basalt layer, the Rainbow site exhibits a very strong magnetization (higher than 28 A/m). This observation can be explained by the formation of magnetite during the serpentinisation process. Local significant decreases in magnetization intensity may be associated to later stages of hydrothermal vent evolution, suggesting that the newly formed magnetite is further altered to less magnetized minerals (maghemite, clay minerals) during the continuing hydrothermal weathering.

GAV.06/10P/A11-007   1620

SUBSURFACE STRUCTURE MAPPING OF QUSEIR AREA, NORTHERN RED SEA, EGYPT, USING HIGH-RESOLUTION AEROMAGNETIC DATA

Abuelhoda Mahmoud ELSIRAFI[1], Ahmed Said SALEM[2], Keisuke USHIJIMA[1] ([1]Professor, [2]Doctor)

Exploration in the Egyptian Red Sea has had little success in locating a hydrocarbon accumulation. The complex block faulting and Miocene salt structure are the main problems entailed the oil exploration. The complex basement block structure arises from the different ages of faults and the difficulty of determining the exact age relations. In an attempt to identify the possible subsurface structure framework, we designed and applied high-resolution aeromagnetic survey over Quseir area, Northern Red Sea, Egypt. A sensitive airborne system has been built that includes an airborne magnetometer of 0.001 nT sensitivity. Pdas-1000 data acquisition system with GPS satellite navigation for positioning was used. Geosoft Oasis software was used for all merging, correction, and editing functions. Digital manipulation of aeromagnetic data allowed the development of higher derivatives and analytic signal maps. The end result product was a map where geologic structures with magnetic expression where defined. The surveyed area is affected by sets of fault systems, which are mainly trending in the NNW-SSE, NE-SW to ENE-WSW directions. Moreover, structural interpretation of the surveyed data enabled delineation of promising areas for further oil exploration.

GAV.06/10P/A11-008   1640

MAGNETIC AND SEISMIC STUDIES FOR DELINEATION OF THE SHAPE AND PARAMETERS OF EL HAMRA WATER RESERVOIR BURIED STRUCTURE, WESTERN DESERT, EGYPT

Nasser Mohamed HASSAN[1], Mohamed El-Saead EL-BOHOTY[2], Fathy Mohamed AHMED[2], Taha Taha RABAH[2] ([1]Geophysics Dept., Fac. of Sc., AIN SHAMS Univ., [2]National Research Institute of Astronomy and Geophysics, CAIRO, EGYPT)

An intensive magnetic and seismic field surveys have been performed in EL Hamra area in the Western Desert of Egypt to delineate the subsurface tectonics controlling the occurring subsurface water reservoir and the surface salt lakes. The constructed total intensity magnetic map for the study area was reduced to the pole and the RTP map was subjected to application of linear wavelength, Walter and Mark method (1993) after modifications .Also two dimensional modeling and seismic interpretations were carried out. A comparative analysis was carried for the different filtered magnetic maps. It was found that the main tectonic trends are taking the directions NW-SE and NE-SW. The application of Walter and Mark (1993) method to the RTP magnetic anomaly map showed that there are three faults bounding El Hamra area from the east, west and south directions. The applied two dimensional modeling technique indicated that these faults are making a graben crossing El Hamra area .The seismic interpretations revealed two faults extending from the basement to the overlying sedimentary section. The El Hamra water spring flows along one of these fault lines. The depth of the fault reaches about 30 meters from the ground surface.

CAN WE ESTIMATE TOTAL MAGNETIZATION DIRECTIONS FROM AEROMAGNETIC DATA USING HELBIG´S FORMULAS?

Jeffrey D. PHILLIPS (U.S. Geological Survey)

Helbig (1963, Zeitschrift für Geophysik) published integral equations for estimating the vector components (Mx, My, Mz) of the total magnetization from the vector magnetic field components (ΔX, ΔY, ΔZ). Schmidt and Clark (1997, Preview) have advocated applying these integrals to modern total fieldaeromagnetic survey data by first converting the total field data to vectorcomponent data using linear transformations. According to Helbig, (1) theintegrals over -∞ to +∞ of ΔX, ΔY, ΔZ, yΔX, and xΔY should all vanish, and(2) the integrals over -∞ to +∞ of xΔX, yΔY, xΔZ, and yΔZ should yield Mz,Mz, Mx, and My, respectively. To apply these formulas to gridded magneticdata, a quadrature algorithm using a 2-D trapezoidal rule was implemented ina moving window across the grid. If (1) is not satisfied within each window,the moments (2) will depend on the choice of origin. Therefore, within eachwindow mean values are removed from ΔX, ΔY, and ΔZ to assure that thefirst three integrals of (1) are near zero, and planar surfaces are removed fromΔX, ΔY, and ΔZ to reduce the magnitudes of the remaining two integrals of(1). Continuous grids of magnetization inclination, Im, and declination, Dm,are produced based on quadrature results at the center of each window. Thesegrids must then be sampled at estimated source locations. Any location errortranslates into directional error, because the estimated inclination anddeclination tend to vary rapidly in the vicinity of a source. To locate thesources using a "closeness" algorithm, two different window sizes are used toestimate the magnetization parameters (Im and Dm), then the grid cells wherethe two solutions are in close agreement are taken as the preferred sourcelocations. Schmidt and Clark (1997), using an unspecified algorithm, havedone a Helbig analysis on aeromagnetic data over the Black Hills Norite,South Australia. They report an estimated magnetization direction of Im = -32°, Dm = -151°, which is within 22° of the measured total magnetizationdirection of Im = -20°, Dm = -131° (Rajagopalan and others, 1993,Exploration Geophysics). Results from application of the closeness algorithmyield Im = -9°, Dm = -130°, which is within 11° of the measured result. Ifresults of the closeness method appear unreliable, it is possible to turn themethod around and ask questions such as "Which grid cells correspond tosources that are consistent with induced magnetization?" or "Which grid cellscorrespond to sources that are consistent with magnetization in a givendirection?" This approach worked well on aeromagnetic data nearAlbuquerque, New Mexico, where the volcanic centers and flows are Tertiaryin age, so magnetization directions collinear with the present field could beassumed.

HIGH RESOLUTION DATING OF THE SEAFLOOR 40 YEARS AFTER VINE & MATTHEWS: INSIGHTS FROM MAGNETIC ANOMALIES, ROCK MAGNETIC PROPERTIES, AND PALEOINTENSITY MEASUREMENTS ACROSS THE CENTRAL INDIAN RIDGE, 19°S

Jérôme DYMENT[1], Annick CHAUVIN[2], Helene HOREN[3], Mitsuko KITAZAWA[4], Christophe HÉMOND[5] ([1]CNRS UMR 7097, Institut de Physique du Globe, 4 place Jussieu, 75005 Paris, FRANCE, [2]CNRS UMR 6118, Geosciences Rennes, 35042 Rennes, FRANCE, [3]CNRS UMR 8538, Ecole Normale Superieure, Paris, FRANCE, [4]Ocean Research Institute, University of Tokyo, Tokyo, JAPAN, [5]CNRS UMR 6538, Institut Universitaire Europeen de la Mer, 29280, Plouzane, FRANCE)

For 40 years, thanks to Vine and Matthews, marine geoscientists use magnetic anomalies to date the seafloor and reconstruct the history of oceanic basins. The extraordinary success of this technique relies on the irregular succession of geomagnetic polarity reversals and the ability of the oceanic basalt to record them. This method allows dating with a resolution of about 1 Ma for the recent times, quite sufficient to reconstruct basin history but much too low to properly address modern issues on the oceanic crust formation at mid-ocean ridge axes. Other dating methods, such as radiochronological techniques, are quite difficult to apply, because MORBs are generally depleted in the elements required by these techniques. Fortunately, recent investigations in different oceans show that the oceanic basalt are not only an excellent recorder of the geomagnetic polarity, but also a quite good recorder of the geomagnetic intensity. These results, from the slower Mid-Atlantic Ridge at 21 ° N (20 km/Ma full rate), the slightly faster (45 km/Ma) Central Indian Ridge at 19 ° S, and the ultrafast East Pacific Rise at 17 ° S (150 km/Ma), suggest that high resolution magnetic data can be used to date the seafloor with a much higher resolution, depending the spreading rate and the altitude of the measurements. To investigate this hypothesis, we have collected a large amount of magnetic data on two transects of the axial anomaly (from ridge axis to Brunhes-Matuyama transition on both ridge flanks) on the Central Indian Ridge at 19 ° S. These data include surface (2500 m above seafloor = asf), deep tow (500-1000 m asf), and submersible (1-10 m asf) magnetic anomalies, as well as rock magnetic properties and paleointensity determinations measured on about 150 samples collected by deep-sea submersible Nautile. The submersible anomalies are corrected for the submersible magnetic effects and absolute magnetization of the seafloor are determined by comparing the observed anomalies with synthetics computed for a constant magnetization using the real topography and dive path. Sea surface, deep tow, and submersible anomalies exhibit similar behavior with different resolutions: they compare well to the paleointensity records deduced from the sedimentary cores. The rock magnetic properties show the existence of two types of magnetic carriers: a rather large grain-sized titanomagnetite and a very small grain-sized magnetite. Thermomagnetic analysis (both in high and low magnetic field) indicates that titanomaghemite is present in all rocks samples. The paleointensity was determined by applying the original Thellier double-heating procedure to both the glassy margin and the crystalline part of pillow-lava. Paleointensity results obtained on the crystalline part are systematically higher (10 to 20%) than on glasses, a discrepancy possibly explained by a cooling rate effect on the thermoremanent magnetization intensity. The magnetization estimated from submersible anomalies and from direct measurements are compared to these paleointensity determinations to investigate how well the magnetization reflects the geomagnetic field intensity.

SUBSURFACE STRUCTURE OF THE KITAKAMI PLUTONES, NORTHEAST JAPAN, CONSTRAINED BY PETROPHYSICAL AND GEOPHYSICAL DATA

Shigeo OKUMA, Hiroshi KANAYA (Geological Survey of Japan, AIST)

The Geological Survey of Japan (GSJ), AIST has been measuring rock physical data mainly of granitic rocks in Japan under the same condition in laboratory for more than 30 years and has constructed a petrophysical data base called PB-Rock 21 (Petrophysical Data Base of Basement Rocks in Japan for the 21st Century; http://www.aist.go.jp/RIODB/pb-rock21/). As an example of a use of the petrophysical data to interpret geophysical data, we will show here a case study conducted in the Kitakami Mountains, northeast Japan, where the late-Cretaceous Kitakami granites intruded into Paleozoic and Mesozoic sedimentary rocks, which widely cover the surface. The Kitakami granites are composed of more than 50 named blocks, which are classified into six zones (Zone I ~ VI) based on their mode of occurrence, megascopical features and petrography (Katada, 1974). The database indicates that the Kitakami granites are the most magnetic (> 0.01 SI) on average among pre-Tertiary granites which outcrop in the Japanese Islands, whereas the intensity of Natural Remanent Magnetization (NRM) is relatively low. Consequently, Qn ratio is low (< 0.5) and the effect of NRM can be negligible when interpreting magnetic anomalies caused by the rocks. On the contrary, Paleozoic and Mesozoic sedimentary rocks surrounding the Kitakami granites are almost non-magnetic in contrast to the magnetic granites. This means it is straightforward to estimate the dimensions of the Kitakami granites by interpretations of the magnetic anomalies in the area. As for the density of the Kitakami granites, the rocks are relatively dense (average dry and wet densities > 2.75 kg/m³) and roughly equivalent to that of Paleozoic and Mesozoic sedimentary rocks, suggesting that it is not easy to interpret gravity anomalies caused by the granitic rocks. Petrophysical data vary in some amounts among each block. Generally, the more magnetic, the denser the specimens are. Granitic blocks, which belong to Zone IV and VI, are more magnetic and denser than the others, suggesting to a quantitative difference of mafic minerals. We conducted an interpretation of aeromagnetic anomalies over Mt. Himekami where the Himekami granites, one of the Kitakami granites outcrop, taking account of the rock magnetic data. The granitic block is composed of geologically and magnetically three sub-blocks. Assuming the horizontal dimensions by geologic maps, a three dimensional modeling to estimate the depths of the model was conducted by trial and error. The result suggests the bottom depth of the block is around 1.0 km below sea level, when the bottom surface is flat. Furthermore, we will show the results of other granitic blocks in the area including subsurface ones in our presentation.

RELATION OF MAGNETIC ROCK PROPERTIES TO AEROMAGNETIC CHARACTERISTICS OF AN ARCHEAN TTG-MIGMATITE AND GNEISS AREA, THE NORTHERN FENNOSCANDIAN SHIELD

Meri-Liisa AIRO (Geological Survey of Finland)

Aeromagnetic interpretation of an area comprising Archean TTG-migmatitesand gneisses in eastern Finland is complemented by information on rock properties for more than 14 500 samples. Statistical analysis of the magnetic property data (intensity of induced and remanent magnetizations) and rock densities of such a great number of samples representing diverse rock types, implies to classification and characterization of varied basement blocks and investigation of the structure of the uppermost crust. The magnetic anomaly field of the study area (100 km x 100 km) is decorated by 20-30 km broad regional magnetic anomalies, rising about 100 nT from the generally weakly magnetic surroundings, and local magnetic anomalies representing variation in mineral composition. A 2 km wide belt of N-S striking banded magnetic anomalies, caused by Archean greenstones, divides the area into western and eastern parts. These parts differ in their aeromagnetic character, referring to a change in deformation styles. The whole terrain is structurally fragmented by a network of Palaeoproterozoic mafic dyke swarms. Reasons for the dissimilar aeromagnetic characteristics are examined on the basis of the variation in the magnetic properties and densities for diverse rock types, and compared between the western and eastern parts. For example, the magnetic properties measured from the outcropping TTG-gneisses do not explain the magnetic field intensity in the eastern part. In the same way, there is no such change in the densities, which would explain the 12 mgal increase in Bouguer-anomaly from west to east across the greenstone belt. An explanation is, that denser, more intensively magnetic rocks below the surface, most probably representing a higher metamorphic degree must cause the observed regional effects in magnetic and Bouguer-anomaly fields.

AEROMAGNETICS- A DIRECT TOOL FOR THE DISCOVERY OF CARBONATITE PLUGS IN NORTHEASTERN INDIA

Ram Babu Venkata HARI (NATIONAL GEOPHYSICAL RESEARCH INSTITUTE)

In the northeastern part of India, the Meghalaya plateau and the Mikir hills are occupied by Archean-Proterozoic gneissic complex with acid, basic and alkaline intrusives. The carbonatites are emplaced along a NE trending zone from Mawpyut in Jaintia hills district to Barpung in the Mikir hills of the Karbi Anglong district of Assam, through Sung valley, Jasra, Samchampi, Sam Taran and Tarpung area. The carbonatites of northeastern India are considered to be much younger (about 100 Ma) when compared to those occurring in other parts (except Ambadongar) of India. Due to their association with magnetizable minerals such as pyrite and magnetite, and due to large areal extent, these carbonatite complexes produce strong magnetic anomalies, which can be observed even at a height of 1000 m above ground. The Sung valley carbonatite complex in Meghalaya plateau is associated with an intense (3500 nT) aeromagnetic anomaly produced at a height of 2000 m. The anomaly is a predominant low, which is unusual at this magnetic latitude of 40° N. The change of polarity of the observed anomaly reveals the presence of remanance, which is an important clue to look for similar anomalies in other parts of the map. Similar type of anomalies could be seen near Jasra in the Meghalaya plateau and Tejpur in the Mikir hills region. While the anomaly near Jasra was proved to be due to a carbonatite plug, the other three anomalies are yet to be proved on ground. Based on palaeo-latitude calculations from the magnetic anomalies, the age of emplacement is identified to be Jurassic, which agrees well with the geo-chronological estimates. Thus the aeromagnetic data proved to be a direct tool for the discovery of carbonatite plugs in northeastern India.

GROUND MAGNETIC STUDIES OVER DECCAN VOLCANIC PROVINCE, MAHARASHTRA, INDIA

Vinit C. ERRAM, Mita RAJARAM, Anand P. SASHIDHARAN (Indian Institute of Geomagnetism)

The enormous mass of basaltic rock known as the Deccan Trap is of great importance in the geological structure of the Indian Peninsula. It now covers about 200,000 sq. m., and

formerly extended over a much wider area. The maximum trap thickness is about 6000 ft. They form some of the most striking physical features of the Peninsula with many of the most prominent hill ranges having been carved out of the basaltic flows. The Deccan Volcanic Province (DVP) is one of the most important regions of continental flood basalts in the world, comprising a sequence of basaltic flows extruded through fissures in the crust from a large magma chamber during 65 Ma. The Deccan flood basalts may be major carriers of remanance and this will leave its signatures in the magnetic data. No aeromagnetic data has been collected over this region possibly because of the expected noise due to the trap cover. Ground magnetic studies were initiated over the DVP in Maharashtra, parts of Karnataka and Goa regions for deciphering the magnetic anomalies beneath the Deccan Traps and to study the source depth extent of the entire region. An area of around 25,000 sq.km. was surveyed using PPM and Fluxgate magnetometers for the magnetic total field F, and the vertical component Z. Due to the high topography and lack of road access the data distribution is skewed. The main trend shown in both the F and Z anomaly maps is NW-SE. It is very interesting to see that the NW-SE lineament is a continuation of the lineament seen in the aeromagnetic map in the southeast region from Chennai; this continues up to the coast and merges with a lineament evident in the marine magnetic anomaly. This long linear structure should have major implication on the tectonics of the area. The ground data were analysed to study the source depths and characteristics. Results of this study combined with the adjacent aeromagnetic and marine magnetic data will be presented.

MAGNETIC SURVEYS IN SABZEVAR OPHIOLITIC ZONE, IRAN

Abolghasem KAMKAR-ROUHANI (Department of Mining and Geophysics, Shahrood University of Technology, Shahrood, IRAN)

Sabzevar ophiolitic zone with a long spread pattern of east-west is located in the northeast of Iran. Having a length of 300 km and a narrow width, this ophiolitic zone is famous for its chromite deposits of podiform type. These chromite deposits, which are scattered in the form of chromite lenses in the subsurface, are associated with mafic and ultramafic igneous rocks (e.g. peridotite) containing high amounts of magnetite. The magnetic anomalies over the chromite lenses are, in fact, related to magnetite contents of these kinds of igneous rocks. The results of microscopic studies on the polished sections, prepared from the ore samples taken from the zone, indicate that the magnetite contents of the samples vary in a wide range of 5 to 30 percent of the total volume of the samples. Airborne magnetic and radiometric surveys over the zone were conducted by Iranian Atomic Energy Agency (IAEA) along a regular flight lines pattern having a distance of 1 km between the parallel flight lines. The total field magnetic data, obtained from the airborne magnetic surveys, were processed in two steps: In the primary processing step, at first the raw magnetic data, obtained from the data acquisition stage of the airborne magnetic surveys, were checked, and then, the positioning coordinates corresponding to the magnetic data were exactly determined. A geographic positioning system (GPS) measuring instrument was used in the data acquisition stage to determine the coordinates of the places where the magnetic measurements were made. In the secondary processing step, a number of corrections such as drift, elevation, parallax, international geomagnetic reference field (IGRF), levelling and microlevelling corrections, and also necessary filters or transformations, were applied on the magnetic data. Based on the processed magnetic data, a total field contour map from the Sabzevar ophiolitic zone was provided in which large magnetic anomalies were considerable. Due to ambiguities in the interpretation of the aeromagnetic data or anomalies, locating the chromite lenses appeared to be difficult. The main point, arising an ambiguity in the interpretation stage, was that neither all of the magnetic anomalies, mainly due to high magnetite contents of the rocks, were related to the presence of the chromite lenses in the subsurface, nor all of the chromite lenses were associated with high amounts of magnetite producing considerable magnetic anomalies. As the results of both qualitative and quantitative interpretation steps of the magnetic data from the ophiolitic zone were not completely applicable to locate the chromite lenses, an integration of geological, geochemical and geophysical findings was used to determine the location of these chromite lenses in the subsurface.

RECOGNITION OF MAGNETIC ANOMALIES ASSOCIATED WITH ORE DEPOSITS USING GIS IN MAHNESHAN REGION, IRAN

Abolghasem KAMKAR-ROUHANI (Department of Mining and Geophysics, Shahrood University of Technology, Shahrood, IRAN)

Mahneshan region, with an area of 2472 square kilometres in the northwest of Iran, is geographically located at latitude of 36:30 to 37 degrees north and longitude of 47:30 to 48 degrees east. There are a large variety of igneous, metamorphic and sedimentary rocks in the region. Although sedimentary rocks cover most of the region, the outcrops of igneous and metamorphic rocks are also remarkably seen in the east, south and west of the region. The results of dating tests on the rock samples, taken from the geological units and formations present in the region, also show that the rocks have been formed in a wide range of geologic time from the Precambrian to the Quaternary. Geological reports from the region indicate the presence of various mineralisations of gold, copper, lead, zinc, tin and tungsten associated with plutonic and metamorphic rocks. Based on airborne magnetic surveys carried out in the region, a total magnetic field contour map has been provided by Geological Survey of Iran (GSI). The map indicates higher total field values (magnetic anomalies) in the north, northeast, west and southeast parts of the region. The large magnetic anomalies in the north and northeast parts of the region are attributed to a shallow but thick bed rock or basement of igneous (or metamorphic) type overlain by a thin overburden of sediments covered the ground surface in these parts of the region. The west and southeast parts of the region, however, are covered by igneous and metamorphic rocks, and thus, the magnetic anomalies in these areas may be associated with metallic mineralisations. For reduction of ambiguities in the interpretation of magnetic data, and thus, locating ore bodies, a vertical first derivative transformation has been applied on the total field data. As a result, a first derivative magnetic anomaly map has been obtained in which local magnetic anomalies due to the metallic mineralisations can be recognised. Geographic information system (GIS) has also been used to manage the spatial magnetic data, and as a result, the first derivative magnetic data have been reclassed. Weighting operation has, then, been applied on different classes of the first derivative magnetic map using the weight of evidence feature in GIS. Thus, based on the two groups of contrast values (i.e. contrasts above 1 and below 1), a binary map of first derivative magnetic data from the region has been produced. This binary map indicates the locations of more likely mineralisations (i.e. those with contrast values above 1) with a different colour (e.g. red) from the rest of the map. Therefore, points or places with higher contrast values on the map can represent the locations of more possible ore deposits.

GAV.07/07P/A13-009   1700

USING ROCK PROPERTY MEASUREMENTS TO UNDERSTAND AEROMAGNETIC ANOMALIES RELATED TO INTRABASIN FAULTS: A CASE STUDY FROM THE CENTRAL RIO GRANDE RIFT, USA

V.J.S. GRAUCH, Mark R. HUDSON, Scott A. MINOR, Jonathan S. CAINE (U.S. Geological Survey)

Faults within sedimentary basins are commonly associated with low-amplitude aeromagnetic anomalies, but whether the anomalies are produced by tectonic juxtaposition or as the result of chemical processes along the fault zone has been poorly documented. We used rock-property measurements, geophysical analysis, and geologic information to confirm that the anomaly associated with the San Ysidro Fault near the west side of the central Rio Grande rift is primarily produced by tectonic juxtaposition of sedimentary units with differing magnetic properties. More than 1000 m of sedimentary section is exposed and offset 400-700 m across the northerly-striking, down-to-the-east normal fault, located ~30 km northwest of Albuquerque, New Mexico. A 10- 20 nT aeromagnetic anomaly from a survey flown 150 m above ground closely follows the fault over most of its exposure. Magnetic susceptibility (k) measurements from 254 sites were used to characterize the magnetization of the stratigraphic units. The uppermost formation, consisting of poorly lithified rift-basin sediments, shows highly variable k values, with most in the range of 1-33 x E-04 (SI). k generally increases with increasing sediment grain size. The underlying formation, consisting of older rift-basin sediments, shows less variation in k, with most values in the range of 5-13 x E-04 (SI) and less correlation with grain size. The geometric mean of k sampled from the two lowermost formations, composed of pre-rift clastic sediments and sedimentary rocks, is 1.3 x E-04 (SI). We developed magnetic models along several profiles across the fault by assigning the characteristic k values to the units in geologically constructed cross-sections. Calculated responses from the magnetic models fit the observed curves to first order. Some differences between models in the assignment of k for units in the uppermost formation were required, which is expected based on its measured variability. Comparing the models to magnetic depth estimates from the observed data confirms that magnetic contrasts arise at several different juxtapositions of units along the fault and between the same juxtaposed units along strike. In addition, deviations in the anomaly gradient location from the mapped fault trace can be explained by differences in the depth to the shallowest contrast and by variations in fault dip. Thus, tectonic juxtaposition of different stratigraphic units is the primary cause of the aeromagnetic anomaly associated with the San Ysidro Fault. Further study should lead to a better understanding of the detailed relations between lithology, structure, magnetic properties, and aeromagnetic sources. This understanding will help us use aeromagnetic data to predict which lithologies are juxtaposed across buried faults and their structural configurations in other parts of the basin, which are important for understanding the alluvial basin aquifer system.

MAGNETIZATION OF OCEANIC CRUST SUBDUCTING BENEATH THE JAPAN TRENCH

Yumiko NODA[1], Toshiya FUJIWARA[2], Yukari KIDO[3] ([1]Department of Earth Sciences, Toyama University, [2]Deepsea Research Department, Japan Marine Science and Technology Center, [3]Institute for Frontier Research on Earth Evolution)

We present characteristics of crustal magnetization around the northern Japan Trench, analyzed from magnetic anomalies. The northwestern margin of the Pacific Plate is being subducted beneath the northern Japanese Islands at the Japan Trench. In the northern part of this trench, the Pacific Plate has a series of parallel magnetic anomalies (Japanese Lineations), identified as chron M10-M7 (130-127 Ma). These anomalies are well lineated and have high-amplitudes of ~500-1000 nT, peak-to-trough, in the seaward slope of the trench. The amplitudes of anomalies gradually decay to the landward from the trench axis, associated with the plate subduction. Crustal magnetization was calculated to correct for effects of increasing depth of subducting plate and seafloor topography. We used a three-dimensional inversion method. Upper surface of the magnetic source layer is assumed to be the surface of oceanic crust. In the seaward slope, ocean drillings and seismic reflection profiles indicate that the thickness of sediment layer is ~500 m. Meanwhile, densely distributed seismic refraction and reflection profiles in the study area enable us to constrain the surface of the subducting oceanic crust, in the landward of the trench. Uniform thickness of the magnetic source layer, and constant direction of magnetization within the source layer are assumed in this calculation. As the general trend of magnetization, the magnitude gradually decreases as the plate subduction proceeded. In the study area, temperature in the subducted oceanic crust is supposed to be still lower than 100 °C, deduced from heat-flow measurements, even at depth of 20 km beneath the seafloor. Thus, temperature effects to reduce the magnetization could be insufficient. Otherwise, low temperature chemical demagnetization is possible for reducing the magnetization. The apparent decay in magnetization would reflect some kind of destruction and mechanical disorganization of the topmost part of the subducting oceanic crust by friction along the plate boundary, resulting in progressive randomization of natural remanent magnetization of the magnetic layer. There appeared to be along-lineation variation in magnetization. The wakes of higher magnetization, sub-perpendicular to the strike of lineations, may suggest non-transform discontinuities that originated at a mid-ocean ridge, where the oceanic crust was formed.

MARINE MAGNETIC ANOMALIES FOR SHIKOKU BASIN, NANKAI TROUGH

Yukari N. KIDO[1], Toshiya FUJIWARA[2] ([1]IFREE, JAMSTEC, [2]DSR, JAMSTEC)

The Nankai Trough and Shikoku Basin, where the Philippine Sea plate subducts beneath the Eurasia plate, has a series of magnetic lineation patterns demonstrating a seafloor origin aligned NW-SE. They are clearly visible seaward of the trough but gradually disappear to the NW across the axis. The development of the Shikoku basin started in the late Oligocene (~25 Ma), splitting the proto Kyushu-Palau arc into two parts. The spreading direction changed to east-west at 23 Ma. From 23 Ma to the final stage of active eruption at 7Ma, several transform faults, fracture zones, off-ridge volcanism and other tectonic traces were produced. We collected marine magnetic data across Shikoku basin and the Nankai Trough together with MCS and OBS seismic structural data. We also use geomagnetic anomaly data provided by the GSJ´s East Asia magnetic anomaly map, the Hydrographic

Department, and JAMSTEC. In this paper, we present forward and inverse magnetic modeling with slab depth distribution and discuss the decay process of magnetic anomalies from viewpoints of seismic stratigraphy and structure. The objectives of the study are: (1) to reveal the characteristics of the subducting plate with magnetic anomalies; (2) to identify geomagnetic properties with intensity variations and shape of magnetic layers; (3) to build a 3D magnetic crustal structure model in this region. We identify five categories from magnetic intensity distribution in the subducting northern Shikoku basin; the westernmost zone; Kyushu-Palau Ridge, the easternmost zone; Zenisu ridge, the middle; Kinan Seamount chain, the Ashizuri zone, and Kii Peninsula zone. Magnetic inversion analysis with slab depth observes cyclic intensity along the Kyushu-Palau and Zenisu ridge zones. Along the Kinan Seamount Chain and off the Kii Peninsula zone, intensity lineation along traces of segmentation and fracture can be seen. The magnetic lineation for Ashizuri is clear up to the trough axis, with rapid attenuation landward of the axis. The main component of total magnetic force is 300 nT at 50 km south of the trench axis, which can be modeled with a 2 km thick oceanic crust with 8 A/m magnetization. Along the trench axis track line, a 2 km thick crust with 7 to 2 A/m magnetization is required to explain the magnetic profiles. At 50 km north of the trench axis, non magnetic crust is needed. One potential mechanism for reducing the magnetic amplitude is low temperature chemical demagnetization. The other possibility is horizontal dislocation of oceanic crust along active faults; such as splay faults, heterogeneous structure and interaction between the decollemont.

MAGNETIC SIGNATURES OVER FOUR SEDIMENTARY BASINS OF EASTERN CONTINENTAL MARGIN OF INDIA

Vinit C. ERRAM, Mita RAJARAM, Anand P. SASHIDHARAN (Indian Institute of Geomagnetism, Plot No. 5, Sector-18, Near Victoria Petrol Pump, Kalamboli (Highway), New Panvel (W), Navi Mumbai- 410206.)

The Eastern Continental Margin of India (ECMI) is important from the point of view of oil exploration. Four petroliferous sedimentary basins were chosen from ECMI to the study long wavelength features: the Mahanadi basin of Orrisa, Krishna-Godavari basin of Andhra Pradesh, Palar basin and the Cauvery basin of Tamilnadu. Ground magnetic data were collected over these four basins with a station spacing of 5 to 10 km and dictated by road access. The anomaly maps contain combination of trends and comparison with the marine magnetic data shows that the anomalies continue into the offshore region. The trends in the ground magnetic anomalies corroborates very well with the aeromagnetic maps and signatures of the Sileru shear, Nallamalai shear, contacts between the crystalline and the sedimentary basins etc are evident on the maps. To identify magnetic sources related to different depths, various transformations have been applied on the total field anomaly map of all the four basins. The second vertical derivative and downward continued map showed NE-SW and E-W trends related to ridges and depressions of all the four coastal basin implying that these are shallow features. The deeper features evidenced from upward continuation showed NW-SE trends only in Mahanadi and Krishna-Godavari basins. Thus these two basins are composed of two structural units associated with different tectonic events. The Palar basin, which separates the Cauvery basin towards south from the Krishna-Godavari basin and Mahanadi basins towards north, marks the transition region with two structural domains in the north and with single domain in the Cauvery basin south of Palar basin. The Orthopyroxene isograd separates the Southern Granulite Terrain (SGT) from the northern Dharwar craton and Eastern Ghat Mobile Belt (EGMB). The Palar basin lies within this transition zone and also brings out the two structural domains to the north with a single domain to the south. The Palar river fault appears to control the tectonic activity of the region. The analytical signal identifies the Charnockites as the main magnetic source of the area. The data were also filtered and euler depths calculated. Results of the analysis will be presented. A comparison with the magnetic data from Antartica and Australia should help to build a tectonic model of the Gondwanaland separation.

MAGNETIC AND ELECTRICAL STUDY IN ARCHEOLOGICAL SURVEY: THE FOX-AMPHOUX SITE (FRANCE)

Daniel HERMITTE, Pierre-Etienne MATHE, Andre REVIL, Ginette SARACCO (CNRS-UMR 6635, CEREGE, Department of Geophysics, Aix-en-Pce)

A total magnetic field survey of the archeological site of Fox-Amphoux (Southern France) was performed by a G858 cesium vapor probe combined to electrical resistivity profiles in order to localize and characterize the archeological structures. Magnetic mapping was obtained using the kriging extrapolation method on a 1x2.5m grid step. A Wenner protocol (64 electrodes of 1m spacing) combined with classical RES2DINV software, was performed to obtain resistivity data as inversion results from potential measurements. This site is potentially constituted of several buried ovens, as suggested by the numerous decimetric fragments of artefacts lying on the field. These structures are embedded in a clayey soil on a carbonated substrate, outcropping at site boundaries. Both resistivity and magnetic method point out anomalies of two different wavelenghts, above and below ten meters, which characterize respectively the main geological and archeological structures. Spatial distribution of resistivity and magnetic anomalies are in a good agreement. These methods appear complementary to localize and determine the nature of sources. Magnetic mapping allows an horizontal determination of archeological structure, while the resistivity method gives a better constrain on the burial depth. Similarly, the higher the resistivity (e.g. carbonates) contrasts the lower the susceptibility contrast is, and reverse. So archeological artefacts of various nature can be detected either by one or both of these methods. Further work will consist in an automatic characterization of archeological structure by position scale method (wavelet transform). The validity of the choice of the analyzing wavelet will be check by using the petrophysical parameters obtained in this study.

GAV.07/07P/D-005   Poster   1400-146

MAGNETIC PROPERTIES OF OIL-GAS-BEARING ROCKS OF THE CENTRAL PART OF DNIPER-DONETSK TROUGH

Roman KUDERAVETS, Valentyn MAKSYMCHUK, Jurij GORODISKY (Carpathian Branch of the Subbotin Institute of the NAS of Ukraine)

Small amplitude positive local delta T anomalies were revealed by the results of high-accuracy magnetic prospecting in the Dniper-Donets trought over a series of oil-gas-bearing structures. Their nature can be explained by lithofacial and epigenetic rock magnetic variations in the oxidized-reduced zones of carbon deposits. Though, there is no trustable experimental data on magnetic properties of rocks in these zones. To study peculiarities of lateral and vertical magnetic perceptability, mineral rock composition distribution within oil-gas-bearing areas in Dniper-Donetsk trough a series of investigations of these characteristics have been conducted for productive and unproductive holes. In general, the magnetic perceptability of core from 19 holes, near oil-gas deposits and far from theirs as well were determined. A statistic analysis of the obfained cappa values was done, rock mineral composition in some holes was determined. The results make it possible to

conclude:1. The cut is composed mainly of terrigenous rocks and is characterized by a slight differentiation by the magnetic perceptability (0-150x10E-5Si)2. Small values of rock magnetic perceptability (1-3x10E-5Si) and dispersion for low Visean substage of low carbon with which oil-gas-bearing of the region under study is closely connected were determined.3. Statistic analysis proved the existence of some types of cappa distribution within the hole in particular it differs within productive and unproductive formations.4. Larger values of cappa and their dispersion in comparison with analogical deposits in productive formations, were revealed.5. A series of secondary epigenic minerals: quartz, kaolinite, aragonite, ankerite, dolomite, pirite, hematite, siderite was determined in the deposit zone and out of it. The largest amount of ironminerals (ankerite, pirite, hematite, siderite) was found in terrigeneous rocks (argillite) located over and under carbon deposits. The analysis of the outcomes testifies to the significant influence of carbon on magnetic perceptability distribution and mineral composition in the zones of oil-gas-bearing.

EROSION PREDICTION OF UNGAUGED BASINS (PUBS): INTEGRATING METHODS AND TECHNIQUES (ICCE, ICRS AND ALL IAHS COMMISSIONS)

MATHEMATICAL MODEL FOR PREDICTING SOIL EROSION THROUGH RUN-OFF FROM UNGAUGED WATERSHEDS

Uttam C. SHARMA (Indian Council of Agricultural Research)

The northeastern region of India , having an area of 255090 sq km, is predominantly hilly. Though the region is endowed with rich natural resources of soil, water and vegetation , it has remained economically backward due to gross misuse and mismanagement of these resources. Prevalence of shifting cultivation , land ownership pattern , heavy precipitation ,low accessibility due to hilly terrain , lack of proper infrastructural and marketing facilities are the major socio-economic constraints hindering judicious management of natural resources . Shifting cultivation alone results in deforestation and an annual loss of 88.3 million tonnes of soil and 10620, 370 and 6050 tonnes of N, P_2O_5 and K_2O. The practice was alright when the shifting cycle used to be 25 to 30 years and the land was rejuvenated with vegetation but with reduction in shifting cycle to 2 to 10 years , the surface soil gets washed away with rain water due to constant human interference on hill slopes. With increase in population from 10.5 million in 1951 to 40.0 million in 2001, there is tremendous pressure on land, water and forests. Heavy annual rainfall of 250 cm has caused unabated soil erosion in the hills and silting of river beds and floods in the plains . A soil erosion model was developed for describing the loss of soil in order to estimate the overall soil loss from ungauged watersheds with known parameters . The data used to develop the model was collected from long term study on eight gauged watersheds ,undertaken at ICAR Research Complex , Barapani and Byrnihat , Meghalaya , India as well as also from some other gauged watersheds under different agro-climatic conditions and slopes. Four parameters viz slope of the land , rainfall, soil clay content and vegetation cover were taken as independent variables and soil loss through run-off as dependent variable, for developing the model. These parameters are mainly responsible for controlling the soil loss through run-off from the watersheds. The gauged watershed comprise only a minute fraction of the total ungauged area of the region which require soil erosion estimation on spatial and temporal basis. The vegetative cover was considered in the scale of 1 to 5, 1 being bare soil surface and 5, being the extremely dense forests with trees, bushes and grasses. The mathematical model is: Soil loss through run-off (tha^{-1}) = 41.73 + 0.181 x slope (%) + 0.046 x rainfall (cm) - 0.387 x clay (%) - 8.125 x vegetation cover (1 to 5 scale).The model was applied to the data obtained from gauged watersheds during subsequent years for validity and was found quite effective in estimating soil loss through run-off from watersheds. However, further investigations are required for refinement of the model.

A DISTRIBUTED HYDROSEDIMENTOLOGICAL MODEL FOR ESTIMATING SEDIMENT EROSION AND DEPOSITION IN YELLOW RIVER BASIN

Zongxue XU, Kuniyoshi TAKEUCHI, Hiroshi ISHIDAIRA, Changming LIU (Institute of Materials & Environmental Technology, Graduate School of Engineering, Yamanashi Universiy)

Although great achievements have been made on hydrological research in the past several decades, the problem of how to predict reliably the sediment erosion and deposition in ungauged river basins has being still a great challenge for hydrologists. The objective to obtain available information on hydrological variables such as precipitation, streamflow, especially sediment erosion and transport is also a great challenge and a key issue for the integrated water resources management in the Yellow River basin, where streamflow and sediment erosion rate are not monitored in most part of the catchment, and it is therefore quite difficult to identify where and how much erosion or deposition of sediment has occurred in the study area. The simulation for the erosion, transport and deposition of sediment involves complex interactions among precipitation, surface and subsurface hydrologic processes, soil properties, land cover and topography. For this kind of complex spatial process, conventional conceptual rainfall-runoff model has its limits on the simulation ability. On the contrary, GIS and spatially distributed models provide great potential for improving humankind´s capability to understand hydrological processes, especially those in ungauged basins. In this paper, a spatially distributed hydrosedimentological model for the simulation of water budget and estimation of the sediment erosion is proposed and applied to Wei River basin, one subbasin of the Yellow River in China. The total area of the basin is 139,000 km² and is subdivided into 48,146 grid cells with a horizontal spacing of approximately 2kmx2km. The unique characteristics of the strongly variable land use, soil, and geography are schematically represented through those square cells. The hydrological processes are simulated at the grid scale. DEM data is taken from GTOPO30 database. Daily precipitation, temperature, wind speed, and other climatologic data are taken from National Climatic Data Center (NCDC). A catchment digital elevation model is created through an automatic processing of the elevation data, streamlines, and soil and vegetation cover data by using Arc/View GIS software. Routing of the water and sediment to the catchment outlet is performed by simplified equations of continuity and motion for both water and sediment. The governing equations are integrated and calibrated on a daily time scale by using available field data on precipitation, climatological observations, and sediment data in the study area. The numerical simulations show that the proposed mathematical model is able to adequately simulate the water and sediment budgets in the catchment on a daily time scale. It also shows that the GIS and spatially distributed modeling have indeed greatly improved the capability for characterization of streamflow, erosion and transport of sediment at the basin scale.

APPLICATION OF A RAINFALL-SEDIMENT-RUNOFF MODEL TO THE UPPER BRANTAS RIVER BASIN, INDONESIA

Takahiro SAYAMA[1], Kaoru TAKARA[2], Yasuto TACHIKAWA[2] ([1]Graduate School of Civil Engineering, Kyoto University, [2]DPRI, Kyoto University & CREST, JST)

The circulation of water and substances is important to deal with environmental problems in river basins. Sediment is one of the significant substances that have a potential to change the environment of basins. Being covered with very fine volcanic ash, the Brantas river basin, East Java, Indonesia yields a lot of sediment, which will be deposited at dam

reservoirs and riverbeds, and these sediment movements increase flood risk and shorten the lifespan of dams. There are some measures to protect erosion and to decrease sediment deposits at dam reservoirs, such as forestation and Sabo dams. Accurate prediction of sediment movement in river basins and relevant evaluation of these measures are very important for integrated water and sediment management. Distributed hydrological models have been applied to investigate sediment movement in basins considering geographical conditions, meteorological information, and human activities. However, we often face to the problem that there are not many reliable data, especially related to sediment. Remote sensing and simple in-situ measurements for hydrological analyses could be useful tools for the compensation. This research constructs a distributed sheet erosion process model for sediment runoff prediction in a catchment scale. The model deals with spatial information such as flow direction, slope and land cover. GIS has generated a DEM from digitized contour map, and classified land cover based on ADEOS/AVNIR images acquired on June 4, 1997. Constructed here is a grid-cell based distributed rainfall-sediment runoff model. Surface and subsurface flows on each grid-cell are simulated by the Kinematic Wave model, and the transportation capacity of overland flow is calculated based on the unit stream power theory for modeling sediment yield and deposit processes physically. Sediment yielded in slope cells moves in the flow direction derived from the DEM to river grid-cells. For realistic simulation of riverbeds, bed load and suspended load in the channel are calculated in river grid-cells by incorporating elevation change caused by sediment movement. The model is applied to the Lesti River basin (625 km²) located in the upper Brantas River basin. The performance has been verified with historical hydrological data (hourly rainfall and discharge sequences during a rainy season from November 1995 to April 1996). The verification indicates that the model can reproduce the sedimentation record at the Sengguruh dam located at the junction of the Lesti River and the Brantas main reach. Further, the volume of eroded material at the cultivated hill slope of Mt. Semeru is found larger than other parts of the basin, which is analogous phenomenon to the natural physical process of sediment erosion. The model simulation gives us information to predict the risk of changing the circulation of substances in basins.

PHYSICALLY-BASED MATHEMATICAL FORMULATION FOR HILLSLOPE SCALE PREDICTION OF EROSION AT UNGAUGED BASINS

Hafzullah AKSOY[1], M. Levent KAVVAS[2], Jaeyoung YOON[3] ([1]Istanbul Technical University, [2]University of California, [3]University of California)

An explicit finite difference scheme for erosion and sediment transport on upland areas of a watershed is derived. The derivation is based on the unsteady state one-dimensional sediment continuity equation and the momentum equation simplified with the kinematic wave approximation. The derivation is ended up with a linear partial differential equation to be explicitly solved by a finite difference scheme. Hydrological part of the model uses a simplified scheme for which a linearized partial differential equation was developed. Outputs of the hydrological simulations are given as inputs to the erosion and sediment transport routine. Upland erosion is thought of as sheet erosion. Erosion due to rainfall and that due to runoff are considered. Rainfall erosion and runoff erosion include non-physical calibration parameters. Calibration of those parameters is of great importance for ungauged basins where data do not exist. In this study, at the end, a backward finite difference scheme is chosen to solve the resulting equation together with appropriate boundary and initial conditions. Hypothetical data sets are used in evaluating the applicability of the model developed in the study.

CALIBRATING SEDD MODEL FOR SICILIAN UNGAUGED BASINS

Vito FERRO[1], Costanza DI STEFANO[1], Mario MINACAPILLI[1], Mario SANTORO[2] ([1]Dipartimento di Ingegneria e Tecnologie Agro-Forestali, University of Palermo, Italy, [2]Dipartimento di Ingegneria Idraulica ed Applicazioni Ambientali, University of Palermo)

Identifying areas of the landscape that are most sensitive or susceptible to erosion stimulated the study of within-basin variability of the sediment delivery processes and the use of spatially distributed models coupled with Geographical Information Systems. At first in this paper, for a basin divided into morphological units, a Sediment Delivery Distributed (SEDD) model based on the Revised Universal Soil Loss Equation (RUSLE), with different expressions of the topographic factors, and on the sediment delivery ratio SDR_i of each morphological unit is briefly reviewed. In particular, the within-basin variability of the hillslope sediment delivery is modelled by a sequential approach. This approach follows the sediment mass in a Lagrangian scheme and applies appropriate delivery factors SDR_i to each sequential modelling morphological unit. The sediment delivery factor SDR_i is calculated by the relationship proposed by Ferro and Minacapilli (1995) in which a only parameter b appears. The model was applied using as morphological units the square cells (square size equal to 50 m) of a Digital Elevation Model realized by ARC-INFO software and using a topographic map on scale 1:25,000. The application of SEDD model was developed for five Sicilian basins having a reservoir at the basin outlet and an area ranging from 20 to 70 km². All basic information for applying the model (rainfall erosivity, soil erodibility, topographic factors, travel time, etc.) were stored into the information layers of a GIS managed by ARC-INFO software. The application of the model at mean annual temporal scale allowed to calculate both the spatial distribution of the sediment yield (raster cover) and the sediment yield Y_b at basin outlet, which is equal to the sum of the sediment yields Y_i produced by all morphological units into which the basin is divided. For the five investigated Sicilian basin the sediment balance equation at the basin outlet, which equates the sediment yield measured Y_m by reservoir sedimentation to the basin sediment yield Y_b calculated by SEDD model, allowed to estimate the values of the only parameter b of the model. Finally, the b values obtained for the five monitored basins were used to establish an estimate relationship useful for applying the SEDD model to Sicilian ungauged basins.

HYDROLOGICAL MODELING OF IMPERFECT GAUGED BASINS: A NEW CHALLENGE

Jun XIA (Insititute of Geographical Science & natural Resources Research, Chinese Academy of Science)

Many countries of the world have been facing increasing problems in managing their water resources. The imperative of the sustainable development puts several tasks on water management. China is an example of a country where water related problems are multifold and range from water shortage, eco-environment degradation to food safety, such as the courses drying up of low reaches of the Yellow River which almost became an annual events since 1972, and water crisis of the three river's alluvial plain in last two decades in terms of shallow groundwater depletion. In order to manage water resources in a sustainable manner, it was emphasized to study hydrological processes associated with water problems to understand causes of existing vulnerability of water resources and provide more information of water resources change in basin/regional scale to try to increase water safety. This paper address following problems:(1) Analysis of the time-space variation of the basin hydrological

cycle: To identify the fundamental characteristics of hydrological changes by using the basic information obtained from the hydrological processes and the analysis data from the multiple features of the time-space field. (2) Remote sensing information identification and parameterization of land-water interactions: To provide useful information for the construction of the hydrological model by making use of remote sensing data obtained from MODIS/TM combined with DEM and other GIS data layers, the mathematical model to be developed is required to capture the changes of types and coverage of vegetation, temperature in canopy layer and land surface, rate of reflection, soil water wetness, evapotranspiration capacity, and urbanization impact. Furthermore, through downscaling research, we aim to obtain the characteristic pattern of parameter variations of the basin-scale hydro-ecological model.(3) Modeling and verification of the time-space variation of the basin hydrological cycle: This covers the study on how the information obtained from unit dynamic processes of water cycle can be used to extract required information at basin scale by using nonlinear parametric regression techniques in statistics. We aim to build a hydrological cycle model based on the specific characteristics of the land and environmental conditions of Northern China. This model will help us understand the interrelationship between the information obtained from the experimental site and the entire study region. It will integrate the physical processes of and interactions between surface water and ground water, the changes in land use/cover and the remote sensing information obtained. Simulation studies will be performed to examine the effectiveness of the model, and to evaluate the impact of human activities on the water carbon cycle. Problem is " Can we do hydrological modeling & prediction in the imperfect gauged basin? How we can reduce uncertainty of hydrological modeling in large basin? ". Hydrologists will have to face new challenges and opportunities that will be discussed in the Workshop.

THE APPLICATION OF AGRICULTURAL NON-POINT SOURCE POLLUTION (AGNPS) MODEL FOR THE SEDIMENT YIELD AND NUTRIENT LOSS PREDICTION IN DUMPUL SUBWATERSHED, CENTRAL OF JAVA, INDONESIA

Sutopo Purwo NUGROHO (The Agency for the Assessment and Application of Technology)

Soil erosion in Indonesia is one of that nation's most serious environmental degradation problems. However, reliable measurement of erosion remains limited, and estimates of soil productivity are even rarer. Assessing the extent and seriousness of erosion, therefore, remains a difficult task. Nevertheless, identification and assessment of erosion problems could have an important role in influencing better land use and conversation practices. Watershed management plan should used be done with use them AGNPS model. The model was used to identify critical areas within the watershed where land treatment should be focused to optimize result. Furthermore, the land and water conservation could establish on the critical areas according to bio geophysics of conditions from the watershed. The application of the AGNPS model in the Dumpul subwatershed , Central Java, resulted in a coefficient determination between AWLR and AGNPS of 0.94 when the latter model was for measuring sedimentation rates. Further analysis of the relationship between model versus measurement nutrient loss, phosphorous loss, and chemical oxygen demand loss has 0.98. Sediment yield, calculated by AGNPS model respectively nutrient loss, phosphorous loss, and chemical oxygen demand loss have 420.82 kg/ha, 6.83 kg/ha, 4.26 kg/ha, and 0.1 kg/ha respectively. The result of the model simulation at Dumpul subwatershed was get that land use change with farmstead would increase for peak runoff volume, peak runoff flow rate, sediment yield, nitrogen loss, phosphorous loss, and chemical oxygen demand concentration of about 36,5%, 39,8%, 118,1%, 87,4%, 90,6%, and 110% respectively. But, by the land and water conservation as crop contoured on all of watershed would decrease of about 33,3%, 29,8%, 57,2%, 45,9%, 46,6% and 41% respectively. At the same methods, crop contoured with combine terrace would decrease of about 52,1%, 51,4%, 77,4%, 68,2%, 68,5% and 72%.

EVALUATION OF CREAMS MODEL IN PREDICTING EROSION FROM AGRICULTURAL PLOTS IN BIRJAND, IRAN

Nasser TALEBBEYDOKHTI (Department of Civil Engineering, University of Shiraz)

Agricultural soil considered being one of the most important natural resources for each country. Nowadays, erosion from agricultural land is a serious threat to human welfare and even a limiting factor in shaping human life.Erosion from agricultural land not only deteriorates top soil for which thousand of years are required for their creation, but also their accumulation in reservoir and transmission line may interfere with usual functioning of such hydraulic structures.This research is undertaken to further our understanding of erosion processes and delineate factors affecting erosion rate. To achieve the objectives cited in the study, four experimental plots with dimension 1.4´2.0m and different physiographic settings were separated from adjacent land in Birjand region. After designing a field rainfall simulator, synthetic rainfall was applied to each plot and a set of rainfall-runoff and corresponding sediment load were gathered for further processing.Simulation of observed behavior was achieved via a continuous-based, distributed and physically based rainfall-runoff model so called CREAMS. After splitting the data set into two pieces, the first piece was used for model calibration, while the second piece was used for model verification.Results obtained from this research showed that (1) CREAMS hydrologic module is quite capable in replicating system response, while the erosion module was not successful partly because of uncertainty involved in data collection procedure and partly due to lack of calibrating this module. (2) Both sensitivity analysis and calibration of model is very sensitive to the selected state variable. Runoff calibration will trigger hydraulic conductivity and suction head while calibration for evapotranspiration will trigger some other calibrating parameters.

PROBLEMS OF MODEL SELECTION IN SEDIMENT YIELD PREDICTION

Shou-shan FAN (Clarkson University)

Sediment yield from a watershed can be defined as the sum of all soil erosion less all sediment deposition within the entire watershed Computer models have long been used by scientists and engineers in analyzing sediment yield from a watershed Today in the United States, many computer models are available for use in predicting sediment yield. Unfortunately, all models are only approximations of the real world and are embedded with certain degrees of uncertainty. Therefore, the proper selection of models that would best fit a particular circumstance is always a critical and difficult task. While models are highly useful tools they can also be a source of misinformation for users and project managers who do not understand all the assumptions, capabilities, and limitations of a particular model. Unfortunately, this has been case in regulatory analysis. This paper is based on the author´s experience working with a major Federal regulatory agency and an interagency sedimentation model evaluation group which consists of ten major agencies It analyzes

several sediment yield approaches that have been used in the United States.

PARSIMONIOUS STATISTICAL MODELS FOR FAST ESTIMATION OF THE SUSPENDED SEDIMENTS DISCHARGES IN UNGAUGED BASINS

Ionel HAIDU, Gavril PANDI (Dept.of Geography, Univ.of Cluj-Napoca)

In many parts of the world the hydrometrical network for suspended sediments measurements is still poor, but the need of information as regarding the erosion and the sedimentation rises continuously. In the other parts, because some economical reasons, the tendency is to reduce the existing network. In both cases the consequence is the necessity to explore much more the existing limited data. There are hydrological basins or regions having observations only on discharges or precipitations, and only a few stations having data on solid discharges, too. Therefore it is impossible to apply a deterministic model, or may be, it is too expensive to do it. This is the case when, for simple and fast estimation purpose, the statistical single input-output methodology could be applied. In Romania, at the beginning of the seasons there is a need for the information about the suspended alluvial in ungauged basins, in order to plan the erosion protection works, to assess the sedimentations rates in channels and in man made lakes and in order to plan the water resources managements. The 25 basins' monthly discharges and suspended alluvial discharges observed in the period 1960-2000 in Northwestern Romania (Tisza-Somes basin) were considered in order to check some statistical parsimonious models for simulation and forecasting. In order to get forecast or synthetic sequences of solid discharges in ungeuged basins, we need a physical support capable to transfer the model on the length of the river or from a river to another. The physical support could be a mathematical relationship between the parameters of the model and any physiographical characteristic of the basin. Three models were tested: PARMA, Simplified Thomas-Fiering (STF) and the regression R=f(Q) model. In order to transfer the models from the gauged to the ungauged basins, GIS procedures were used, the results being parameters maps. Model tests on simulation as well as on forecasting were made according to the ˝split sample˝ principle. The simulation and the forecast performance of these models are compared using various measures of accuracy (RMSE, Cc, R2 etc). The stochastically models PARMA and STF give unexpected errors. The most valuable seems to be the R=f(Q) model which is a third order polynomial. The inferred law shows that the shape of regression curve (explained by the model parameters) is depending on the basin's size. There is possible to determine a coefficient of distortion of the curve on the length of the river. Therefore, the problem is reduced to the liquid discharge forecasting in the ungeauged basins. In this paper is used the monthly rainfall-runoff model of Vrije Universiteit Brussels. Also, on the base of upstream and downstream curves shapes of R=f(Q) a similar curve for the ungauged basin has been estimated. This model gives good results on the length of the river but satisfactory results for the comparable rivers in the same region. Better results were obtained for the maximal season (power curve) and for the minimal season (modified exponential).

DEVELOPMENT OF AN INTERACTIVE EMBEDDABLE GEOGRAPHIC INFORMATION SYSTEM (E-GIS) PROGRAM FOR SOIL EROSION PREDICTION

Ahmad MUNIR[1], Muhammad Nurdin ABDULLAH[2] ([1]Faculty of Agriculture and Forestry Hasanuddin University,, [2]The Ministry of State for Research and Technology of the Republic of Indonesia,)

Erosion is a critical aspect in the overall water resources project and its properties are a dynamical phenomenon. A computer model was developed for simulating such dynamical phenomenon. The computer model is named E-GIS (Embeddable Geographic Information System) which is specially designed for soil erosion prediction. The model was programmed using Borland Delphi and MapObject component. It consists of five sub models. The first sub model is DATABASE, it is used for managing data for the model. The second sub modelis AKUISISI deals with data acquisition. The third sub model is RAMAL deals with forecasting simulation of erodibility and crop factor coefficients. The fourth sub model is SIMULASI, its main function is erosion simulation, this is the core of the model. The fifth sub model is E-GIS, deals with spatial erosion simulation. The sixth sub model is LAPORAN deals with spatial presentation of erosion variable. The model was tested and validated using recorded data at the Jeneberang Watershed, South Sulawesi, Indonesia.

HS01/08P/C29-006   **1600**

SPACEBORNE RADAR INTERFEROMETRY: A PROMISING TOOL FOR EROSION ASSESSMENT IN UNGAUGED BASINS

Filippo CATANI[1], Paolo FARINA[1], Sandro MORETTI[1], Giovanni NICO[2] ([1]Department of Earth Sciences, University of Firenze, Via La Pira,4 50121 Firenze - Italy, [2]National Research Council, Institute of Radioastronomy, c/o ASI/CGS, 75100 Matera - Italy)

Population growth and urban development, with the consequent requirementof improved supplies and development of new potential water resources,have increased the need of an accurate knowledge of hydrological phenomenaat basin scale, such as runoff, erosion-sedimentation and mass movements,in order to assess the possible consequences of their future evolution onhuman activities. However, the prediction of these evolutionary trends isoften difficult due to the lack of data concerning hydrological parameters.This problem can be mainly connected to the difficulties in the measurementof such data. In particular, mass transfer rates are generally measured atfew chosen points along the main channels of the watershed. This approachusually leads to unsatisfactory results since sediment transfer is mainlycontrolled by scale invariant pulse processes which are spatially andtemporally scattered everywhere within the watershed. Local pointmeasurements unavoidably involve the loss of information on spatialvariability generating averaged or lumped values. In this contextthe extraction of such information could benefit from the use of a remotesensing technique, characterized by large scale and low cost. SpaceborneSAR interferometry in the last few years has been successfully applied toreconstruct the topography of the observed scene and to measure with amillimeter accuracy changes on the earth surface induced by differentgeophysical phenomena. The aim of the present work is to investigatethe possible contribution of the interferometric technique in the retrievalof hydrologically-related geomorphic parameters. In particular the attentionhas been focused on the possibility to obtain two different types of data:i) continuously updatable DEMs of basins with a suitable vertical accuracyand ii) quantitative spatially distributed estimates of sediment transferamong hillslopes and between hillslopes and channels. These information canbe extremely valuable for the calibration of hydrological models as well asfor a better understanding of the spatial and temporal distribution of thelandscape sculpting processes in a wide range of scales within the basin.The method has been applied by using SAR data acquired by the ERS satelliteson different test-sites located in the Italian Alps and Apennines.

ASSESSING THE EFFECT OF LAND USE CHANGES ON RUNOFF IN THE TA-CHOU BASIN

Pao Shan YU, Yu Chi WANG, Chun Chao KUO (Department of Hydraulics & Ocean Engineering, National Cheng Kung University)

Land development and urbanization is significantly increasing these two decades because of population and economy development in Taiwan. The change of land use has caused the effect on hydrological processes. Unfortunately, almost areas arenot suitably monitored such changes. Therefore, to investigate the influences of urbanizing on runoff hydrograph much depends on a distributed rainfall-runoffmodel, which can simulate the spatial hydrological processes. The Ta-Chou basin,in which there has a significant change on land use recently, is chosen as the study area. Both the Remote Sensing and GIS techniques are combined with a grid-based distributed Rainfall-Runoff model to assess the impact of land use change on runoff. As there are no any observed runoff data for model calibration, the calibrated model parameters from neighbor watershed are used inthe studied area for runoff simulating. The 1972 LANDSAT MSS and 2000 SPOT satellite imageries are applied by using both traditional supervised and unsupervised classification methods to identify the land use types, and assess the land use changes from 1972 to 2000. It is found that impervious area is significantly increased and woodland is decreased in this period, the quantity is about 147% and 81% respectively. Finally, the land use, soil type, and basin characteristics obtained by using GIS and RS are input to the distributed rainfall-runoff model to simulate the influences of land use change on runoff. The results reveal that peak flow and runoff volume of 10 years return period is increased around 10% and 25%.

HS01/08P/C29-008   1640

RUNOFF, SEDIMENT YIELD AND NUTRIENTS LOSS MODELING USING REMOTE SENSING AND ARCVIEW SWAT2000 ON AGRICULTURAL WATERSHED OF EASTERN INDIA

Vinay Kumar PANDEY[1], Sudhindra Nath PANDA, Narendra Singh RAGHUWANSHI, S. Sudhakar SUDHAKAR ([1]Department of Agricultural and Food Engineering, Indian Institute of Technology, [2]National Remote sensing Agency, Department of Space, Hyderabad, India)

The accurate prediction of runoff and sediment yield is necessary for the design of conservation structures and to select the priority watersheds for implementing conservation and management programs. The potential change in agricultural management practices can have notable effects on hydrological processes at regional scale. To assess the current resource management system,a small agricultural watershed was selected in Jharkhand state of EasternIndia with objective to evaluate the use of physically based, continuoushydrological model SWAT2000 for simulation of hydrological system and to investigate the potential of nutrient losses through runoff and sediment. Indian Remote Sensing Satellite (IRS-1D LISS-III) was used for landuse/landcoverclassification. Initially the model was calibrated and then validated with different land use. The results revealed that the time to peak of simulated runoff matched consistently well with the measured values during the calibration period. The coefficient of determination (r2) of 0.92 and 0.96 for runoff and sediment yield, respectively, indicated a close relationship between measured and predicted runoff and sediment yield. Nash-Sutcliffe simulation efficiency (ENS) of 0.89 and 0.89 for runoff and sediment yield, respectively, also resulted the same trend. Overall percent deviation for runoff and sediment yield, respectively, indicated that the model waspredicting satisfactorily results. Magnitude and temporal variation ofsimulated runoff matched closely with the observed runoff (r2=0.94) forthe entire validation period. Nash-Sutcliffe simulation efficiency (ENS)of 0.941 and 0.927 and Dv of -8.369 and 0.927 % indicated that the modelwas accurately validated for predicting runoff and sediment yield fromthe watershed. A high value of r2 of 0.99, overall deviation of -9.25 % indicated that in general, the simulated monthly surface runoff and sediment yield compared well with measured monthly values. The observed and simulatedmean of NO3-N, organic nitrogen, soluble phosphorous, and organic phosphorous were not significantly different at 95 % level of confidence. The values of %deviation (Dv) were found to be -11.45, 14.16, -16.36, 7.38 (in 2000) and -17.06, -11.702, 12.12, 16.39 (in 2001) respectively for NO3-N, organic nitrogen, soluble phosphorous, and organic phosphorous indicating that the model was predicting nutrient losses satisfactorily. The value of coefficient of determination (r2) of 0.82, 0.84, 0.81, 0.82 (in 2000) and 0.83, 0.82, 0.81,0.82 (in 2001) respectively for NO3-N, organic nitrogen, soluble phosphorous, and organic phosphorous indicated close agreement between the observed and simulated values of nutrient losses. Thus, ArcView SWAT2000 can successfully be applied for accurate prediction of runoff, sediment yields and nutrient losses and thereby provide necessary database for developing suitable managementplans with sound scientific basis.

LAND USE SCENARIO BASED GIS-MODEL FOR REDUCING SEDIMENTATION RATE AT BILI-BILI DAM INDONESIA

Muhammad Nurdin ABDULLAH, Ahmad MUNIR, Syamsul Arifin ILYAS (Faculty of Agriculture Hasanuddin University Makassar)

This research deals with finding land use scenarios in order to reduce sedimentation at a watershed. This research was conducted at Bili-Bili Dam, South Sulawesi Indonesia. The land use scenario was formulated by using Erosion Model bases Embeddable Geographic Information System. Input data for the model were collected from aerial photograph, satellite imagery and direct observation. Seven land use scenarios were developed for evaluating the most suitable land use at the Watershed. The land use simulation scenario shows that the land without conservation generates 2121.24 m3/km2/year. The fourth scenario (with conservation) can reduce sediment become 1472.76 m3/km2/year which is lower than the Dead Storage Sediment (DSS) of Bili-Bili dam. This value should be maintained in order to maintain the function of dam within 50 years. It was found also that, the existing framework of the land use declared by the local government (Gowa Regency) generates erosion rate is higher than tolerable soil loss erosion (TSL). Therefore the existing land use should be changed in term of following the developed scenario.

USE OF RECONNAISSANCE MEASUREMENTS TO ESTABLISH CATCHMENT SEDIMENT BUDGETS: A ZAMBIAN EXAMPLE

Desmond Eric WALLING[1], Adrian Loric COLLINS[1], Henry M. SICHINGABULA[2], Graham J. LEEKS[3] ([1]Department of Geography, University of Exeter, [2]Department of Geography, University of Zambia, [3]Centre for Ecology and Hydrology, Wallingford)

A sediment budget is increasingly accepted as a key tool for understanding the sediment response of a drainage basin and thus for designing and developing catchment management and sediment control strategies. However, even where they exist, sediment measurement programmes are unlikely to provide the information necessary to construct a meaningful sediment budget for a catchment.There is a need to develop new approaches to assembling this information, avoiding the need for long-term, labour-intensive monitoring programmes. The authors have attempted to develop and test such approaches in the small (63 km2)Upper Kaleya catchment in southern Zambia. Sediment source fingerprinting techniques were used to provide information on the primary sources of the sediment exported from the study catchment. The potential sources identified were the surface soils of areas under the three main land use types, namely, communal cultivation, bush grazing and commercial cultivation, and erosion of channel banks and gullies. Measurements of caesium-137 and excess lead-210 activities in soil and sediment cores collected from the catchment were also used to estimate soil redistribution rates at representative locations within the study catchment under the three different land use types. These data were extrapolated to the entire catchment, in order to estimate rates of soil loss from the catchment slopes and the associated sediment delivery ratios. Cores were also collected from the floodplain areas bordering the stream in the lower portions of the catchment and caesium-137 measurements on these cores were used to estimate rates of overbank deposition on the floodplains and the associated conveyances losses. Integration of the data provided by the sediment source fingerprinting study, the information on rates of erosion and soil redistribution and associated sediment delivery ratios provided by the caesium-137 and excess lead-210 measurements and the available measurements of sediment yield afforded a basis for establishing a tentative sediment budget for the catchment. This indicated that the sediment delivery ratio for the catchment was relatively low, with only ca. 9% of the sediment mobilised within the catchment by erosion reaching the catchment outlet. Erosion of areas under bush grazing provided the major source of the sediment load of the river (63.7%), but erosion of areas under bush grazing (17.1%) and channel and gully erosion (17.2%) were also important sediment sources. The approach developed and successfully applied in the Upper Kaleya catchment should afford a viable mean of establishing sediment budgets in other study areas with limited sediment monitoring programmes.

HS01/09A/C29-002   0920

SOIL EROSION ASSESSMENT FOR WATER RESOURCES MANAGEMENT IN SELECTED SOUHTERN AFRICAN RIVER BASINS USING THE EOSION RESPONSE UNITS APPROACH

Michael MAERKER[1], Wolfgang Albert FLUEGEL[2], Aleksey SIDORCHUK[3] ([1]Center of Environmental Systems Research, University of Kassel, Germany, [2]Geographical Institut, Friedrich-Schiller-University Jena, Germany, [3]Geographical Faculty, Moscow State University, Russia)

Soil erosion is one of the major environmental problems in southern Africa and is likely to become even more severe due to population growth and climatic changes. In situ land degradation caused by soil erosion includes the loss of fertile top soil, reduction of soil productivity as a result of lowered soil fertility, which may indirectly be perceived through decreased harvests. In addition the eroded soil material, viz. sediments, reduce the water quality in a river network. Apart from direct impacts such as reservoir sedimentation, such sediments are a carrier for chemical, physical and biological pollutants, which are stored by adhesion on their active surfaces. Consequently, such reduction in water quality must be viewed as being indirect impacts of soil erosion. Furthermore, progressive land degradation by erosion aggravate water management problems in semi arid regions of Southern Africa where water scarcity is frequent. This interactive dynamics generate the need for the evaluation of suitable methods of land use management that can lead to a reduction of soil erosion and, subsequent sediment yield in runoff. However, before remediation and prevention of excessive soil erosion can be undertaken, the spatial extent of the problem has to be established. An Integrated Water Resources Management in semiarid catchments of Southern Africa should enable managers and decision makers to improve the regional strategic planning of catchment water resources by optimising water use, thus satisfying the demands of competing stakeholders while protecting water and land resources. An innovative approach characterizing erosion processes caused by water and their integrated dynamics was introduced by Maerker et al. (1999, 2001) and Fluegel et al. (1999) with the concept of Erosion Response Units (ERU). The ERUs are used to identify areas subject to different erosion processes and as modelling entities for erosion simulations. Furthermore the ERU concept allows the regionalisation of erosion process dynamics. For the delineation of the ERU as well as for the modelling procedures remote sensing techniques provide spatial information, which is normally difficult to obtain, especially in developing countries of Southern Africa. Here remote sensing techniques were applied to get information about the distributed physiographic and anthropogenic catchment characteristics (land use, soil surface, digital elevation models, etc.). Furthermore the concept of Erosion Response Units (ERU) provides a fully distributed modelling structure. Thus, because the ERU contain detailed information concerning the erosion processes and intensities as well as the relative distribution of erosion processes and consequently allows the application as modelling entities. As already stated by several authors (see also Poesen et al. 1998, Bull & Kirkby 2000) especially the sediments derived from gully erosion cannot be simulated by RUSLE-type models. This was the reason for the development of a differentiated modelling approach to be able to simulate the specific erosion processes and dynamics.

HS01/09A/C29-003   0940

THE USE OF GAVRILOVIC METHOD IN PREDICTION OF EROSION IN UNGAGEDCATCHMENTS: ITS APPLICABILITY AND POSSIBLE DEVELOPMENT WITH NEW SPATIAL DATAMANIPULATION TECHNIQUES

Lidija GLOBEVNIK, Danko HOLJEV, Josip RUBINIČ, Gregor PETKOVŠEK (WATER MANAGEMENT INSTITUTE)

For the prediction of surface, deep and side erosion and sediment yield onthe catchment scale, the Gavrilovic formula has been widely used in Sloveniaand Croatia in the last 30 years. The formula has been developed formanagent practices in erosion protection, mainly in forest management andtorrent control. The model, based on Gavrilovic formula is parametricdistributed model, used for prediction of yearly quantities of erodedmaterial and yearly sediment yield. It uses empirical coefficients(erodibility coefficient, protection coefficient, erosion coefficient) and amatrix of physical characteristrics of catchment subunits. To analyse itsapplicability, we analyse erosion processes and river morphological changesbetween 1970 to 2000 on a 92 km2 large catchment. GIS techniques can be usedfor preparing data from DTM and areal photos, so we are developingGavrilovic based model for erosion prediction.

PREDICTION OF ANNUAL SEDIMENT TRANSPORT IN A SMALL UNGAUGED TORRENTIAL BASINS IN SERBIA

Stanimir C. KOSTADINOV (Department of Erosion and Torrent Control, Forestry Faculty of Belgrade University)

Torrents are two-phase watercourses that occur as the consequence of intensive processes of soil erosion in the watershed. They transport a large quantity of sediment. Previous engineering practice and experience shouws that in the design of all structures on the streams loaded with sediment sediment regime must be seriously studied. A very significant parameter of the sediment regime is the average annual sediment transport. The measurement of sediment transport in the torrents is very difficult and very expensive , and because of this practically all torrents in Serbia are ungauged. This is the reason that for the prediction of average annual sediment transport in ungauged torrential basins, in the watershed management practice of Serbia, the methods by Gavrilović and Polyakov were used. The new method used in latest years is the Modified Polyakov̕s method (method Polyakov- Kostadinov). The research of sediment transport in the experimental torrential watersheds in Serbia shows that the above methods, particularly that by Polyakov, deviate significantly from the results of field measurements. On the other hand, the results of the calculation by the modified Polyakov- Kostadinov method are quite close to measured data. The modification of Polyakov̕s method consists of the calculation of average annual turbidity of water based on the newly introduced parameter of pluvial-erosion index. This method is of regional character and it should be further tested for other regions in order to obtain the corresponding regional analytical correlation.

ESTIMATION OF SEDIMENT- AND DISSOLVED LOAD FROM GREENLAND

Bent HASHOLT (Institute of Geography, University of Copenhagen)

Greenland, with an area of 2 million sq.km., has very few gauging stations determining the load into the sea. However, the influence on the neighbouring arctic seas is obviously strong. In order to estimate this load, no single method can provide a solution. The paper discuss the application of different types of methods of estimations. Estimation results are compared with results from the few existing gauging stations in order to find calibration procedures.

HS01/09A/C29-006 — 1040

EROSION PREDICTION IN UNGAUGED GLACIERIZED BASINS

Jim BOGEN, Truls Erik BØNSNES (Norwegian Water Resources and Energy Directorate)

The meltwater from glaciers often carries large amounts of sediment. Planning for hydropower development in glacierized areas thus needs sediment data as a basic input for the design and location of sand traps, sedimentation chambers or settling basins to prevent damage to waterways and machinery. Changes in sediment delivery may also affect the ecology of downstream reaches of regulated rivers, so sediment data is also needed to assess possible environmental impacts. Techniques for estimating sediment transport in ungauged glacier meltwater rivers may, however, be different from those employed in unglacierized basins. In this paper, methods are discussed for estimating sediment yields in ungauged glacierized areas; the sediment load within ungauged parts of the Svartisen hydropower scheme in Northern Norway is estimated as a worked example. Long term measurements of sediment yields of various glaciers in Norway have revealed that erosion rates to a large extent are controlled by bedrock geology, glacial variables and the large scale morphology of each individual glacier. Measurements of bed load Gb and suspended load Gs of two glaciers gave a relation Gb = k Gs. Values of the constant k were found to be 0.5 at Nigardsbreen and 0.42 at Engabreen, an outlet glacier of the Svartisen ice cap. This relationship is due to the fact that suspended load is derived from abrasion and crushing of the coarser material supplied by subglacial quarrying processes. In the Svartisen power plant, water is collected through 45 intakes in a complex tunnel system totalling 100 km. Water is then transferred from the reservoir, or directly from the tunnels, to the power station. It was desirable to have estimates of both suspended load and bed load for all the intakes. The supply of bed load to each intake was computed employing an assessed value of k for each glacier. Direct measurements of sediment fluxes were carried out in a monitoring programme covering selected locations. The sediment yields of the remaining ungauged catchments were then estimated from a characterisation of each individual glacier and the underlying bedrock. The results indicate a total of 17,300 t/yr for the Southern tunnel complex and 11,000 t/yr for the Eastern one. The amount of sediment delivered by the glaciers draining directly into the reservoir was calculated to be 103,000 t/yr, applying sedimentation rates from dated sediment cores from the reservoir bed. The validity of measurements obtained from Norwegian glaciers is then discussed together with the applicability of the methods to other glacierized mountain areas.

HS01/09A/C29-007 — 1120

FIRST-ORDER ESTIMATE OF OVERLAND FLOW BUFFERING IN A FRAGMENTED TROPICAL UPLAND BASIN

Alan D. ZIEGLER[1], Thomas W. GIAMBELLUCA[2] ([1]Water Resources, Princeton University, [2]Geography, University of Hawaii)

We determine, for a fragmented upland watershed in northern Vietnam, the degree to which the current juxtaposition of land-cover mitigates the hydrological/geomorphological impact of accelerated surface runoff by the process of buffering (on down-slope patches) overland flow generated on upslope source areas. Our methodology replies on the following data and analyses techniques: (1) field measurements of infiltration-related soil properties, including saturated hydraulic conductivity (Ks), porosity, and soil texture; (2) one-minute rainfall data; (3) GIS analyses (at 30m x 30x resolution) of land-cover distribution, patch-related phenomena, and flow-transitions among the various land covers; and (4) diagnostic simulations of Horton overland flow (HOF) generation using the KINEROS2 runoff model. Using the above-mentioned data and simulation outputs, we develop an objective function to estimate basin-wide overland flow (BWOF) for the 10 largest observed storms. We then compare the BWOF values for the current land-cover arrangement with those of other fragmentation scenarios, including maximum/minimum fragmentation and random distribution of land cover. The comparisons show that the current land-cover distribution provides more buffering of erosion-producing HOF than the case where small land-cover patches are distributed at random (i.e., a higher degree of fragmentation). However, HOF-related impacts (including surface erosion, delivery of sediments to the stream system, change in the nature of storm response) could be further mitigated if land covers having relatively high Ks were intentionally positioned between swidden fields and the stream system.

CONSTRUCTION OF A SEDIMENT BUDGET FOR THE UPPER INDUS RIVER BASIN

Khawaja Faran ALI, Dirk H. DE BOER (Department of Geography, University of Saskatchewan)

The rate of soil loss is ever increasing owing to natural and anthropogenic factors. This requires efficient monitoring and quantification methodologies so that effective land management strategies can be applied for controlling soil erosion. Construction of sediment budgets can be a useful technique since it provides a comprehensive accounting of the sources and disposition of sediments in the drainage basin. Sediment budget studies have mostly dealt with smaller catchments whereas larger basins pose challenges like the identification and contribution of different sediment sources. Sediment budgets studies are usually hampered by the inadequacy of data in quantity and quality. Not only the collection of such data is expensive and labour intensive, but also the data is collected only at a few points, which raises the question of representativeness. Remote sensing is emerging as a useful tool for larger areas in environmental applications. Soil erosion causes physical and visible changes in the surface properties of soil that can be measured in qualitative and quantitative terms, both spatially and temporally, using remote sensing techniques. GIS tools can be utilized further for combining spectral, spatial and temporal characteristics of remotely sensed data along with other available auxiliary data in erosion models for quantifying rates and patterns of soil erosion. The available historic hydrologic records can serve as control data for evaluating the contribution of sub-basins and balance calculation. A multidata type analysis approach, therefore, seems practicable for constructing sediment budgets for poorly-gauged large river basins. The Upper Indus is a unique, large river basin located in high Himalayan mountain areas exhibiting one of the highest rates of sediments transport. The greater Himalaya are a supreme example of young and rising mountain ranges where topography dominates the sediment dynamics. Sediment is contributed to the headwaters by the melt-water issuing from glaciers; by processes such as mass movement; by debris torrents; and by channel erosion during outburst floods from land-slide-, moraine-, and glacier-dammed lakes. The process is further accelerated by tectonic instability, high relief, steep slopes, heavy monsoon rainfall and runoff from glaciers in heavily ice-covered area. The Upper Indus is a poorly-gauged, data-sparse river basin. Since several water resources development schemes including high dams are planned, it is now important to conduct sediment studies in the region. This will help in understanding the characteristics of high sediment yield areas under natural environment and contribute for the better implementation of planned projects. For such a river basin, determining spatially distributed soil erosion using the classical techniques will be difficult, time consuming and expensive. It is, therefore, expected that a multidata type analysis approach of integrating remotely sensed data in a GIS framework supported by hydrologic and other auxiliary data will prove to be useful.

THE IMPORTANCE OF INSTITUTIONAL ARRANGEMENTS SHOWN BY EROSION EXAMPLES IN THE REPUBLIC OF MOLDOVA

Wolfgang SUMMER[1], Wolfgang DIERNHOFER[2] ([1]International Commission on Continental Erosion, [2]IAHS - Hydrology 2020)

Due to the breakdown of the former Soviet Union, the centrally organised economic network collapsed, and the large-scale agricultural structures became obsolete as markets for agricultural products disappeared overnight. The Republic of Moldova was left with an energy- and cost-intensive agricultural infrastructure of single field sizes of several square kilometres. It was impossible to adopt the existing infrastructure to the regional needs of the country within a short period of time.After a decade of inappropriate agricultural management combined with naturalprocesses such as drought, soil losses due to extensive landslides, wind erosion, degradation of soil fertility and many other negative erosion-relatedimpacts, the country's economy is stressed. Agricultural productivity of the soils is threatened as well as agricultural economy and the wealth of the ruralpopulation. It is estimated that soil erosion in Moldova results in a financialloss of 45-55 million Euro annually.Institutional arrangements focusing on land management, the environment, hydrology and other related aspects are in a transition process. At the present,these arrangements are transformed from the previous Soviet system into a new national framework, following the legal rules and regulation of the Republic of Moldova. However, the lack of available information and data on natural processes as well as the lack of legal and strategic guidance to farmers duringthis transition period can be seen as the cause of the devastating situation of the country, thus, shows the environmental as well as socio-economic importance of properly based data aquisition as well as data and information management.

HS01/09A/C29-010 — 1220

EVALUATION OF AN EROSION SIMULATION MODEL IN A SEMIARID REGION OF BRAZIL

Vajapeyam S. SRINIVASAN[1], Ricardo de ARAGÃO[2] ([1]Department of Civil Engineering, Universidade Federal de Campina Grande, [2]Dept.of Civil and Environmental Engineering, Ehime University)

The northeastern region of Brazil is predominantly semiarid and agriculture is the principal vocation of subsistence.The large spatial and temporal variations of the precipitation in the region provoke considerable land erosion. In order to evaluate the soil loss in these basins without any data on erosion, a predictive model that could be used needs to be calibrated and tested . This paper deals with this objective of testing an erosion simulation model for the region along with an analysis of the possible estimation of the calibrated parameters of the model. In order to evaluate the sediment production rates, several experimental plots of 100 m² with varying surface conditions and four micro-basins of about 0.5 ha were installed in an experimental basin located in a typically semiarid region in the northeast of Brazil. The erosion plots were equipped with two collector tanks of 1000 liter capacity that would permit the determination of the total runoff and sediment erosion. In the case of the micro-basins, two of them were cleared bare and the other two were maintained with undisturbed native vegetation. In all the cases, the runoff and eroded sediments were directed to a collector tank equipped with automatic water level recorders, and a triangular weir. Cumulative samples of sediment-water mixture overflowing the weir were collected during each event along with the samples of the mixture in the tank. The collected data enabled the calculation of the total runoff and the sediment yield. Measurements of runoff and erosion were carried out between 1982 and 1991. A hydrodynamic model denominated as WESP was chosen for calibration and simulation of the processes of runoff and erosion involving essentially three parameters: the soil moisture tension parameter, the soil erodibility parameter and the channel erosion parameter. The calibration was carried out on an event by event basis. A large variation in the values of the parameters was noted due to the variation of the soil moisture condition at the beginning of each event. In order to obtain a better estimate of these parameters, they were related to an antecedent precipitation index. While the moisture tension parameter showed a reasonable relationship with the index, the other two parameters showed no such clear trend, but showed some dependency on the soil moisture parameter. These relationships were also used to estimate the values of the erosion parameters for each of the events. The validity of the calibrated model was tested by

comparing the results obtained from using the individually calibrated and estimated parameters in an adjacent micro-basin. The results show that the model simulated the runoff values well, but the calculated erosion values showed larger variations, underlining the complexity of the erosion process. However, the model could be considered a reasonable tool for obtaining the first estimates of erosion from basins without adequate data, but with similar characteristics.

APPLICATION OF A PROCESS-BASED MODEL AS A PREDICTIVE TOOL FOR EROSION LOSS IN UNGAUGED BASINS

Celso A.G. SANTOS[1], Vajapeyam S. SRINIVASAN[2], Carlos O. GALVAO[2] ([1]Department of Technology for Civil Engineering Constructions, Federal University of Paraiba, [2]Department of Civil Engineering, Federal University of Campina Grande)

Erosion of soil and its transport out of a hydrologic basin is a complex process that depends on several factors that can be divided into two groups. The first would be the climatic regime and the characteristics of individual precipitation events. The second would be the basin characteristics that include topography, soil characteristics and the vegetal cover. In order to produce a reliable predictive tool to estimate the soil loss from the basin due to erosion, a long and accurate data not only of the real amount of soil eroded and transported out of the basin, but also of the diverse variables of the afore mentioned groups will be necessary. In developing countries, in particular, such data are scarce and more often than not, must use the available data of a few basins for estimating the erosion loss from ungaued basins. Experimental basins specially installed and equipped for such purposes seem to be a highly practical and economic proposition. The data from these basins could be used to calibrate a suitable hydro-sedimentological model that can be used as a predictive tool either by a direct transposition of the parameters for basins of similar characteristics or for generating even empirical regional relationships for specific types of surface covers. In the semiarid northeast of Brazil, small and medium sized river basins have no monitoring devices that can help evaluate the erosion loss and the Experimental Basin of Sume was installed in early 80s with 4 micro-basins and 9 erosion plots to help understand the processes involved. The data collected till early 90s represent a unique and valuable field data about runoff and erosion in this region. A process-based event-oriented model - WESP, developed by Lopes (1987), has been successfully calibrated utilizing the data collected in the experimental basin. The calibrated model and data from erosion plots of the experimental basin were used to obtain an empirical regional soil loss equation of the type proposed by Musgrave. The results seem quite promising and the proposed method has the potential of being a reliable predictive tool for basins without data in the region.

HS01/09P/C29-002   1420

IDENTIFICATION OF SOURCES OF SEDIMENT TO LAKE SAMSONVALE (NORTH PINE DAM) SOUTH-EAST QUEENSLAND, AUSTRALIA

Grant Brian DOUGLAS[1], Mark PALMER[2] ([1]CSIRO Land and Water, [2]CSIRO Mathematical and Information Sciences)

Lake Samsonvale (North Pine Dam – NPD) is a major dam of approximately $22km^2$ with a capacity of 215000ML which supplies drinking water to Brisbane, the capital city of Queensland in eastern Australia. The catchment area of NPD is approximately $347 km^2$. The catchment of NPD is dominated by four major rock types: the Rocksberg greenstone (19%), Bunya Phyllite (39%), Neranleigh-Fernvale Beds (34%) and granitic rocks (the Mount Samson Granodiorite and the Dayboro Tonalite - 8%). Recent alluvium associated with major drainage networks constitutes approximately 5% of the catchment area. An important problem in the management of water supplies such as NPD is identifying the sources of sediment where there is little information on the composition or relative sediment loads of sub-catchments. This paper develops a Bayesian approach utilising end-member models to model the proportion of various sources in samples taken from NPD. This approach not only allows for the incorporation of prior knowledge about the geochemical signature (composition) of the sources (or end-members) but also allows for correlation between spatially contiguous samples and the prediction of the sediments composition at unsampled locations. Sediments sampled from the NPD in south-east Queensland are analysed to illustrate the approach. Results of the Bayesian end-member model suggest that the majority of sediment is derived from the Bunya Phyllite with important local contributions from the Rocksberg Greenstone and granitic rocks. Overprinting the primary geochemical signature of the catchment sediment sources, particularly in deeper sections of NPD, are enrichments of a number of elements including phosphorus which is strongly correlated with biogenic silica and iron and suggesting a combination of sediment diagenesis during transient periods of bottom water anoxia and the accumulation of algal detritus from the water column.

HS01/09P/C29-003   1440

CHRONOLOGY OF ALLUVIAL SEDIMENT USING DATE OF PRODUCTION OF BURIED REFUSE: CASE STUDY IN AN UNGAUGED RIVER IN CENTRAL JAPAN

Yoshimasa KURASHIGE[1], Hajime KIBAYASHI[2], Goro NAKAJIMA[3] ([1]School of Environmental Science, The University of Shiga Prefecture, [2]Biwako Broadcasting Co. LTD., [3]Nikken Technical Consulting Co. LTD.)

Alluvial terrace have been formed between embankments of the Inukami River which is one of the ungaued rivers in Central Japan. The date of sedimentation of each stratum of the terrace was determined in yearly resolution using date of manufacture of buried refuses combined with dendrochronological technique in 2000. A clear terrace with three layers (Layers 1, 2 and 3 from bottom to top) was found at 1.6 km upstream from the river mouth where alluvial meandering channel is formed. The border between two strata could be found by a humus-mixed layer. Many refuses (more than 100) were found from each stratum, whereas date of manufacture could be read only from two and six refuges in Layers 3 and 2, respectively. In contrast, from Layer 1, no refuse with its readable date of manufacture was found. From Layer 3, a beer bottle (made in 1990) and a beer can (June 1989) were found, showing that this layer was deposited in and after 1990. In contrast, two soft drink cans and four food packages (potato chips, chocolate, sweetmeat and noodle) were found from Layer 2, and the date of manufacture ranged from November 1984 to February 1987. This indicates that Layer 2 was deposited in and after 1987. On the other hand, some *salix* trees were found on the terrace surface. The trees which had age of 18 to 20 years slant to the river-flow direction, whereas the trees with age between 9 to 13 years stood straight. A tree with age of 20 years had germinated from the upper horizon of Layer 1, and trees with age of 13 years and 12 years from the upper Layer 2. In contrast, a tree germinated from upper Layer 3 had age of 9 years. These show that Layers 1, 2 and 3 were deposited in and before 1980, 1987 and 1991, respectively. The comparison between these two chronological results and meteorological data determined that Layers 1, 2 and 3 were deposited in 1980, 1987 and 1990. A clear terrace was also found at 2.0 km upstream from the

river mouth. Some refuses made before 1990 were found from its top layer, indicating that the top layer was deposited in 1990. In contrast, at a site 3.5 km upstream of the river mouth (i.e., on alluvial fan), many refuses could be found, but the date of manufacture could be read only from one food package (made in 1978). The composition of refuses at this site was significantly different from those at downstream sites. The top layer was thus determined to be deposited in late 1970s.

HS01/09P/C29-004   1500

SEDIMENT YIELD ESTIMATION AND CHECK DAMS IN A SEMIARID AREA (SOUTH EDGE OF SIERRA DE GADOR, SOUTHERN SPAIN)

Wenceslao Martin- ROSALES[1], A. Pulido BOSCH[2], J. GISBERT[2], A. VALLEJOS[2] ([1]Department of Geodynamics, University of Granada, Avda., [2]Department of Hydrogeology. University of Almeria, Spain)

Southeast of Spain has semi-arid climatic conditions. Rainfall has a high spatial and temporal variability, from less than 200 mm/year and 750 mm/year. This fact and the intensive human land use for centuries (mining, forestry uses, and fires) and a high topographic gradient, have induced an torrential hydrological behaviour. In the region of Almerú} (southern Spain), the carbonatic massif of Sierra de Gador constitute the natural recharge area of the Campo de Dalias aquifer system. The Campo de Dalias is a typical semi-arid sector with 200 mm/year average rainfall covered by some 20.000 ha of greenhouses of high economical interest. The uncontrolled development of this agricultural activity has produced an increasing in the flood risk, favorised by the location of several greenhouses on the dry stream beds. During intensive rainfall events run-off could reach high values. In 1977 the Spanish authorities carried out a soil and vegetation recovery program including 110 check-dams build up on 17 basins. They have an altitude between 3 and 14 m, with a drainage basin always less than 50 km². The most obvious property of the drainage network is that flow is ephemeral, and the lack of observed data provides the major problem for runoff and sediment concentration modelling. Nevertheless a study has been carried out in order to evaluate the effectiveness of the check dams in trapping sediment. At the present, all the check-dam network has a global reservoir capacity of some 400.000 m³, 88% of it original capacity. From the volume of reservoir fill and the age of the check-dams we have estimate the annual sediment yield in the hole edge, using a coefficient of sediment retention of 35 %, deduced from a suspension sampling campaign in several check-dams during a run-off event. The sediment yield calculated is 59 m³/km-²/year-¹, although in some basins values of near 2100 m³/km-²/year-¹ have been estimated, evidence of a high erodibility in the edge nowadays. With the study carried out we evidence the usefulness of this kind of infrastructure -so frequent and numerous in the Mediterranean area-, as a tool to reconstruct sediment yield histories and to estimate water erosion in small ungauged basins.

HS01/09P/C29-005   1520

RECONSTRUCTING UPLAND SEDIMENT BUDGETS IN UNGAUGED CATCHMENTS FROM RESERVOIR SEDIMENTATION AND RAINFALL RECORDS CALIBRATED USING SHORT-TERM STREAMFLOW MONITORING

David Laurence HIGGITT[1], Victoria Jane HOLLIDAY[1], Jeff WARBURTON[1], Sue WHITE[2] ([1]Department of Geography, University of Durham, [2]Institute of Water and Environment, Cranfield University)

The estimation of sediment yield in upland environments is a difficult task, compounded by the scarcity of long-term monitoring. This is a significant problem when assessing sedimentation in upland reservoirs where there is a need to evaluate sediment budgets from limited information. Sediment is supplied differentially from variable sources within the catchment and the transfer of sediment is not related to rainfall or runoff characteristics in a simple linear fashion. Extreme events are likely to have a disproportionately large influence on sediment transfer. Furthermore, concerns about climate change and the likelihood of more frequent extreme events emphasise the need for predictive capability without reliance on gauging records. The results reported in this paper form part of a EU-funded programme (WARMICE) investigating the potential impact of sedimentation on water resource management in upland environments. Evaluation of the sediment transfer system of a representative reservoir catchment in the North Pennines, United Kingdom, has used reservoir core records to reconstruct sediment accumulation rates and changes in sediment supply. Short term monitoring of contemporary sediment transfer demonstrates that this is a supply-limited system where the majority of sediment is transported during storm events. Daily and seasonal rainfall records and synthetic discharge series can be correlated with the reservoir sedimentary archive and with field evidence of activity from the catchment. The paper examines how geomorphological evidence preserved within upland catchments can be related by extrapolating or constructing discharge series from other sources. It also demonstrates how recent climatic variations identified in the region have impacted on the sediment transfer system.

ESTIMATION OF EROSION AND SEDIMENT OUTFLOW IN OLD DAYS

Takahisa MIZUYAMA[1], Akitsu KIMOTO[1], Yuji YASUDA[2], Masaru TOUHEI[3], Masaharu FUJITA[4] ([1]Division of Forest Sience, Graduate School of Agriculture, Kyoto University, [2]Sabo Technical Center, [3]Kinki Regional Bureau, Ministry of Land, Infrastructure and, [4]Disaster Prevention Research Institute, Kyoto University)

Mountains surrounding Kyoto and its vicinity had been completelydevastated about 100 years ago because of over logging for firewood. The areas are weathered Granite and there were no trees at that time. The mountains were white as covered with snow. A lot of sediment flowed out, to rise riverbed and to cause flood frequently. Intense hillside sabo works; terracing and plantation have been carried out for last 100 years. The areas are covered green almost completely these days. Erosion rate have been observed last30 years in the area. The data are analyzed and an erosion prediction method was made out. The method contains rainfall, topography of slopes andbasins and the condition of vegetation as parameters. The method is applied tothe areas to estimate the erosion and sediment outflow 100 years ago. Riverbed elevation change is also estimated by a sediment routing method based onthe estimated erosion as a boundary condition.

PREDICTING EROSION RATES IN SELECTIVELY LOGGED TROPICAL RAIN FORESTS

Ian DOUGLAS (SCHOOL OF GEOGRAPHY, UNIVERSITY OF MANCHESTER)

The main damage to tropical rain forests under selective logging occurs from the construction of access roads and the opening up of log haulage lines from individual trees to log-loading points. These road building process create linear sediment sources that all too often are connected to stream channels or natural drainage lines. Once these tracks and roads become an effective extension of the drainage network they deliver large quantities of

sediment to channels and may, if unchecked, develop into gullies that continue to erode long after logging has ceased. Additional problems can arise several years after logging when hollow log culverts fail during exceptional storms and landsliding along cut and fill roads sends surges of sediment into the drainage system. Predicting the impact of such disturbance in ungauged catchments involves deriving suitable rates of erosion per unit length and width of road, estimating total road length within the catchment area, making allowances for road gradient and substrate, and calculating the potential sediment yield. Remote sensing can assist in these tasks, but identification of all roads and tracks, and their true widths, under a regenerating forest canopy requires considerable ground-truthing. Estimates derived for disturbed catchments can compare reasonably well with measured small catchment sediment yields determined by continuous flow and turbidity measurements calibrated against regular suspended sediment determinations on water samples. However, episodic mass movements that cause sudden slugs of sediment to move down small streams are often partially due to biotic phenomena, such as the collapse of trees or the decay of hollow log culverts, that are difficult to predict.

ESTIMATION OF HYDROGEOMORPHOLOGICAL PARAMETERS OF A WATERSHED USING GIS

Umamahesh Venkata NANDURI, Ramakrishna K. (Department of Civil Engineering, Regional Engineering College, Warangal)

Water is a primary source of life and sustains all human activities such as domestic needs, agriculture, industries etc. The allocation and management of water resources is becoming a difficult task due to increasing demands, decreasing supply & diminishing quality. This calls for judicious use of water resources. The geomorphology describes the environment in which the hydrological processes operate. A strong mutual correlation exists between geomorphological variables and hydrological characteristics. Such relationship can be applied to both surface and groundwater regime. Thus the linking of geomorphological parameters with hydrological characteristics of the basin provides a simple way to understand the hydrological behaviour of different basins and particularly of ungauged basins.During the last few years the Geographic Information System (GIS) technology has emerged as an extensively effective tool for analysing and prioritizing natural resource management alternatives. Because natural resource management problems are spatial in nature the GIS technology provides a tool for defining the extent of the problem, and facilitates the design and implementation of alternative management strategies. The flexible design of a GIS gives resource managers and planners the tools to effectively manage natural resources and to assess the implementation of regulatory policies before they are implemented.The present study describes the effective use of GIS in carrying out hydrogeomorphological study of a watershed in Warangal District of the state of Andhra Pradesh in India. The GIS is used to estimate the hydrogeomorphological parameters of the watershed, which can be used in watershed planning and management at micro and macro levels. The results of the study are used to infer the hydrological features like runoff potential, infiltration and groundwater recharge of the region. The PC ARC/INFO GIS software is used for the analysis.

SUSCEPTIBLITY OF ROCKS AND FORMATIONS TO EROSION AND SEDIMENT YIELD, LATIAN DRAINAGE BASIN, IRAN

Sadat FEIZNIA[1], Maryam ZARE-KHOSH EGHBAL[1] ([1]Professor,College of Natural Resources,University of Tehran,Karaj,Iran, [2]Watershed Management Office, Ministry of Agriculture, Tehran, Iran)

Susceptibility of formations to erosion is important in conservation of watersheds.Iran is one of the worlds countries that has high erosion and sediment yield production.There are different methods for investigation of susceptibility of formations to erosion,each having advantages and disadvantages.In this reserch, Selby method and factor K inUSLE model were used to investigate sensitivity qualitatively and then by using sedimentyield data, this mather was studied quantitatively. The studied area is Latian Drainage Basin, northeast of Tehran,located in 51,23 to 51,49East longitude and 35,46 to 36,03 north latitude. This basin has eight subcatchments and six hydrometric stations with more than 20 years of water and sediment yield data. The main river is Jujrood River which originates from southern Alborz ranges. At the beginning, it was found that among all effective factors on erosion, geology,slope, land use and climate are the most effective ones in the studied area. Then the maps of four mentioned factors were prepared and were overlain to obtain the mapof land units of the area.Then in each land unit, sensitivity of formations and rocks to erosion was obtained.To do so, in each land unit for pre-Quaternary formations,parameters of Rock Mass Strength Classification of Selby (1980) and in each Quaternary formation parameters of K factor in USLE method were obtained in the field and laboratory. In this way differentformations and rocks of the drainage basin were ranked qualitatively according to susceptbility to erosion. For quantifying sensitivity of formations to erosion, first sediment yield data of fourhydrometric stations were investigated. Then two variable regression analyses were performedbetween sediment yield data of each hydrometric station as dependent variable and four effective factors as independent variables. Then the regression analyses were added together and were classified and according to this classification, sensitivity map of formations to erosion wasprepared. Then multi-variable regression analyses were performed between sediment yield dataand qualitative coeffiecient of sensitivity, slope and climate and sediment yield of each landunit was calculated from these regressions.

THE MECHANISM OF WATER AND SEDIMENT DISCHARGES FROM GULKANA GLACIER, ALASKA: APPLICATION OF FILTER-SEPARATION AR MODEL

Kazuhisa A. CHIKITA[1], Kenta HIRAYAMA[1], Rod S. MARCH[2], Dennis TRABANT[2], Daisaku KIDO[1] ([1]Graduate School of Science, Hokkaido University, [2]U. S. Geological Survey)

The dynamics of englacial and subglacial drainage systems in Gulkana Glacier, Alaska was examined by analyzing the continuous data of water and sediment discharges obtained in a

proglacial river in the glacier-melt season of 2001. The plots of the data on a semi-log paper indicate that each of water discharge and sediment discharge can be separated into˝fast˝ and ˝slow˝ components. The fast component corresponds to an englacial and subglacial, ˝channelized˝ drainage system downstream of snow line in the ablation area, while the slow component is related to a subglacial, ˝distributed˝ drainage system upstream of snow line. The hydrological and meteorological observations revealed that suspended sediment (SSC) and water discharge both increased abruptly in ca. 2 days after the maximum air temperature was recorded. This suggests that a subglacial drainage system then changed drastically from the ˝distributed˝ to ˝channelized˝ drainage system toward the upglacier: This event is probably due to the great erosion of subglacial till under high waterpressure in the distributed system. Flow separation by the AR model, using a numerical filter, was performed to the data sets of water and sediment discharges. As a result, for the slow component, there existed the highlinearity between SSC (mg/l) and water discharge (m³/s). The contributions of fast and slowcomponents over the observation period were calculated at 48.2% and 51.8% for water discharge, and at 89.1% and 10.9% for sediment discharge, respectively.

THE RELATIONS BETWEEN SEDIMENT DISCHARGE AND FOREST COVERIN A WEATHERED GRANITE MOUNTAIN AREA

Kazuhiro YABE (Department of Forest Science, Tokyo University of Agriculture)

In this study, the author applied the theory of sediment discharge to a mountain stream and examined its applicability for determining the sedimentyield resulting from showers as well as the long-term applicability of the results for mountainous watersheds. Furthermore, using hydrological data obtained in the past 60 years and data of sediment yields, the author analyzed the influence of the process of forest recovery on sediment yield. Soil transportation by flowing stream can be expressed by the sediment discharge formula. Although such formula is generally applicable only for bedload, this study adopted one such formula, the Brown formula is consideredapplicable for bed material load (bedload and suspended load). As a result, the following expression was obtained at Shirasaka watershed (the weathered granite zone). $Q_B = 0.38\ Q_w^{1.40}$ Q_B: Sediment discharge, Q_w: Runoff To verify this result, the author analyzed the relationship between the sediment yields and the runoffs to the 1.40th power measured at 10-minute intervals for a significant period at Shirasaka watershed, and the two sets of data are observed to be well proportional. $Q_B = 1.07\ Q_w^{1.40}$ It became clear that sediment yield in Shirasaka watershed is proportional to runoff to the 1.40th power. However, coefficient values obtained by observation and by calculation are different. This fact suggests that other factors, for example washload, may have a significant impact on sediment yield. Next, in order to test whether the Brown's formula is applicable for the same method was used at Ohora watershed (the new tertiary zone). As a result, the following expression was obtained $Q_B = 0.17\ Q_w^{1.31}$ $Q_B = 0.16\ Q_w^{1.31}$ The result of the experiment was in beautiful agreement with the value that had been obtained by theoretical calculation. Because an outflow of washload is not recognized in the Ohora watershed, this fact suggests that Brown´s formula may express equilibrium of sediment discharge. Next, using sediment data recorded in the past 60 years for Aichi forest and the result obtained from the sediment discharge theory, the author analyzed the relationship between sediment yield and the forest. Sediment yield has a tendency to decrease gradually. Although sediment yield is considerably influenced by precipitation, its tendency to decrease can be observed just as the changing size of the bare lands can be observed by aerial photos. Here, variations in the Erosion Index (E) was studied thoroughly, where ˝E_i˝ is the quotient when sediment yield is divided by runoff to the 1.40th power. Changes in the ˝E_i˝ align well with the changes in the bare-land ratio (L_a). Thus as a result of having analyzed relation of ˝E_i˝ and ˝$L_{a\ i}$˝, it was expressed in an exponential function. It became clear that the Sediment yield could be expressed as a function of bare-land ratio.

VARIATION OF SEDIMENT YIELD RATE AFTER FOREST FIRE IN A STEEP HEADWATER CATCHMENT

Tomohiro NARUOKA[1], Shin'ichi ONODERA[2] ([1]Graduate School of Biosphere Sciences, Hiroshima University, [2]Faculty of Integrated Arts and Sciences, Hiroshima University)

A mountainous area of 63 ha was burned by forest fire in August 2000 in southeast part of Setoda Island, Hiroshima Prefecture, Japan. The area caught fire from a superhighway construction site beside the area. To clarify the influence of forest fire on the variation of sediment yield rate, we investigated profiles of sediment accumulation at a sand guard dam at a steep headwater catchment in this area and monitored sediment discharge by a sediment trap at upper part of the dam. The sediment accumulation reached 160 cm in thickness beside the dam, and the profile could be classified into four layers. Surface layer, that was 20 cm in thickness, was composed of sands and coarse gravels. Second layer with 40 cm thick was composed of sands and gravels with ash. Black colored sandy silt layer, that was 20 cm thick, was accumulated as a third layer. And bottom layer with 80 cm thick was composed of sands and fine gravels. The black layer supposed to be derived from ash immediately after the forest fire. The dam was built in 1992 so the bottom layer had been accumulated for 8 years before the forest fire. The sediment accumulation of the bottom layer was 12m3 and the sediment discharge rate was 1.5m3/yr. One year after the forest fire sediment accumulation reached 56m3 and the rate of sediment yield became 44.0m3/yr. Sediment discharge rates were about 0.05 to 0.20 m3/month in 2001. The rates of sediment discharge became bigger during heavy rain events. Most of sediments were derived from rill and gully erosions on the side slope of the catchment. Denudation rates were 0.075mm/yr before the forest fire and 2.2mm/yr after the forest fire. After the forest fire the rate was about 30 times higher than that of before the fire. Results of this study determine the drastic acceleration of rill-gully erosion and sediment yield by forest fire at steep headwater catchments.

AN EXPERIMENT ON THE INFILTRATION RATE OF TEPHRA DEPOSIT FROM MT.USU, SOUTHWESTERN HOKKAIDO, IN 2000

Yuki ICHIOKA[1], Yuichi ONDA[2] ([1]Graduate School of Life and Environmental Sciences, University of Tsukuba, [2]Institute of Geoscience, University of Tsukuba)

The overlandflow and debrisflow were found to occur frequently in hillslopes covered by the volcanic ash in the Usu eruption in 1977 and the Unzen eruption in 1990-95. After the eruption at Mt.Usu in 2000, nevertheless more rain fell than the 1977-eruption, little debris flow and gully erosion had occurred. The purpose of this study is to examine the mechanism of infiltration rate of the volcanic ash from Mt.Usu erupted in 2000. The large-scale sprinkling experiment and the permeability tests applying varying electrolyte concentration were conducted by using three kinds of ashes at Mt.Usu (total mass of about 2000 kg). The sprinkling experiment had two sizes of raindrops; misty raindrop (mean diameter of 0.24 mm) and larger raindrop (that of 0.80 mm). The experimental flume, 180-cm long, 48-cm wide was prepared, and the gradient of this experimental slope was 5 degrees. The volcanic ash

was air-falled through a 2-mm sieve until a thickness of 5 cm, overlain by coarse sand layers (10 cm). The rainfall was applied 30 minutes in each day for three days. We observed particle structures in several thin sections from the surface on an experimental slope (5-10 mm). When raindrop size is large, the infiltration rate decreases rapidly to 15 mm/h in the first run. In the second and third run, the infiltration rate lowered to 6-7 mm/h. The soil pores are observed to be clogged by the effect of physical crusts. In the case of misty raindrop, the infiltrate decreases very slowly or remains high; the final infiltration rate varies from 9.81 to 29.35 mm/h after the third run. The pores are observed to be not clogged and no evidence of physical crusting. The effect of chemical crusts was examined by the permeability tests applying varying electrolyte concentration (0.5 N, 0.05 N, 0.005 N and distilled water). No well-defined tendency from electrolyte concentration was found, comparing the previous results of Unzen Volcano. Therefore, the effect of the chemical crust at the Usu eruption in 2000 is expected to be negligible. In addition, X-ray diffraction analysis shows the presence of clay mineral such as ´smectite´. This fact indicates the volcanic ash is originated from the mountain body and tends to swell with water. These indicate that if raindrop impact is strong, the impress of raindrop impacts to swollen soil produces clogged pores, but if the raindrop impact is week, swollen soil disperse to vertical direction due to low raindrop compression. Above discussions suggest that after the Usu eruption in 2000, because the raindrop impact was not strong enough for clogging pores and the chemical crust effect was low, the infiltration rate of the volcanic ash from 2000-eruption remained high, so that no debrisflow occurs.

HS01/09P/D-007   Poster   1400-174

ESTIMATION OF SEDIMENT LOAD VARIATION CONTROLLED BY RAINFALL AFTER FOREST FIRE DISTURBANCE IN SMALL MOUNTAINOUS CATCHMENTS, WESTERN JAPAN

Naoyuki NISHIMUNE[1], Shin-ichi ONODERA[2], Tomohiro NARUOKA[1], Tsutomu TAKEI[1], Mitsuyo SAITO[2] ([1]Graduate School of Biosphere Sciences, Hiroshima University, [2]2. Faculty of Integrated Arts and Sciences, Hiroshima University)

Disturbance by forest fire in small mountainous catchments causes greatly increasing of sediment yield. Forest fire often occurs around Seto Inland Sea region, western part of Honshu Island, Japan, because of dry and hot climate in summer. But it is difficult to measure sediment load from all of the catchments around there. In order to estimate the sediment load to Seto Inland Sea, it is important to clarify the long-term variation in sediment yield process as well as sediment load. So, our objective is to confirm sediment yield during rainfall events at the disturbed catchments by the forest fire. Observed three catchments, IK, TB and TY, which were disturbed by forest fire in 2000, 1994, and 1978, respectively, are under different conditions of vegetation. These three catchments have non-vegetation, grasses and secondary forest, respectively. The other conditions such as annual precipitation, drainage area and mean gradient of slope are much the same, 1100mm, 2ha and 30 degrees, respectively. Thickness of sediment on the bottom of the upper stream is 2m in IK, 0.5m in TB, and 0.2m in TY, respectively. Firstly, we confirmed rainfall-runoff pattern in three catchments. In the IK, runoff had the high peak flow and base flow, as compared with that at TB. On the other hand, runoff characteristics changed to low peak flow and high base flow at TY. This result suggested that overland flow generated by strong water repellency on hillslope but a part of rainfall is stored in thick soil layer and valley bottom sediment at IK, as compared with that at TB and TY. Secondary, the annual sediment yield at IK was about ten times higher than the others. It means that sediment yield occurred by surface erosion on steep slope with much erodible soil. Meanwhile, at the other two catchments, sediment yield dominated more than 90% of annual amount during one rainfall event with daily rainfall of more than 100mm. This suggests that sediment yield at the heavy rainfall event determines annual sediment load at the catchment progressed for several years after the fire. Thirdly, we get clear relationships between daily rainfall and sediment yield at three catchments for estimation for sediment load with various conditions after forest fire. At IK, a remarkable increase of sediment yield was observed corresponding to daily rainfall, and it is suggested that sediment yield is active in the catchment immediately after a fire. Sediment yield at TB was larger than that at TY during the event with precipitation of less than 100mm, whereas they were inverted during the heavy rainfall. This suggests that fire disturbance kept high sediment yield from valley bottom sediment without soil erosion on hillslope for more than 5 years after the fire, despite the thin soil layer at TB with a little recovering of vegetation on a slope. When several decades passed after a fire, soil layer was recovered by growth of vegetation, the sediment yield process became active only during a heavy rainfall event.

SEDIMENTATION IN THE RIVER GANGA: STATE-OF-THE-ART

Ajai SRIVASTAVA[1], Ajit K. SRIVASTAVA[2] ([1]Deptt. of Geology, Banaras Hindu University. Vanarasi. Pin-221 005, India, [2]Ecology Laboratory, Deptt of Botany, Banaras Hindu University. Vanarasi. Pin-221 005, India)

´Ganga´, ´Gange´,´Gangeya´ or ´Ganges´, a symbol of purity has served as the cradle of Indian civilization. The river from time immemorial has been India´s river of faith, devotion and worship and revered as a ´Goddess´ and ´Mother´ by millions of Indian .The river in the present time shrieking for her own liberation from the polyhedral monster of pollution due to industrial effluents, harmful and obnoxious chemicals, and domestic wastes generated from the 692 towns situated in its basin. Apart from this, sedimentation in the river channel is an equally serious matter for an environmentalists and sedimentologists. In the upper reaches of the river i.e.,source region weathering and erosion are prominent. As a result of chemical and mechanical weathering, the pre-existing rocks are disintegrated and decomposed. As far as sediment tansport is concerned the river is placed as the third largest sediment transporting river of the world; considering the sediment transport at Farakhka(744 million tonnes/year) as measures,after the Yellow and Amazon rivers. The sediment load of the river often rises to a level of 2 gm/litre of water i.e 2000 ppm,about 2.4 billion metric tonnes/annum. The problem of siltation in the river has caused lateral migration of river channel, cutoffs of meander bends, the evolution of new channels and bars and several morphological changes. Silt deposited in the river raises the river bed which in its turn leads to floods. In 1970,the river carried a large amount of sediment/silt and thus resulted in exessive mortality of the fish at Har ki Pauri-Hardwar, where the fish population is normally high. Sedimentation has reduced navigability in several tracts, creates turbidity, degrades water needed for consumptive or other use. Some remedial measures have been given by ecologists. The role of vegetation in the upper reaches of the floodplain has been emphasized by most of the wetland specialists. Studies have been made on quantifying the degree of effectiveness of population and communities dominated by different herbaceous plants in conserving the soil against erosion. It was found that the fibrous roots of Cynodondactylon, Saccharum benghalensis and Cyperus rotundus conserved between 91 to 96% soil against simulated rainfall erosion. Through shoot clipping experiment, it was found that the relative role of roots is more than of shoots in preventing soil erosion. Besides, prevention of overgrazing in the upper reaches of the river is considered to be a prime factor in the reduction of silt load in the auatic milieu of the river.It was observed in a study conducted to preserve the eco-system that species like polygonum amphibium helps in absorbing toxic load of the heavy metals from the polluted river water and sediments.

Keeping in view of the above, it is the high time that the problem of siltation in the river channel be given due significance in order to maitain an ecological balance.

PRELIMINARY STUDY ON THE PREDICTION OF THE DEBRIS-FLOW PULSATION

Hiroshi SUWA (Disaster prevention Research Institute, Kyoto University)

The 25-30 July 1997 debris flow attacked Kande, a small village on the fan of the Aa River, on sunny days and brought about significant disaster. The Aa River is one of upstream tributaries of Indus River. The author visited the village in the end of July 2000 to make field surveys, and unexpectedly encountered debris flows there. The debris flows were unpredictable there. The 27-30 July 2000 debris flow attacked the village and brought about significant disaster again. Debris flows at the Aa River occurred on sunny days, while debris flows usually occur under heavy rainfalls in temperate countries and tropical countries. We know that breaches of glacial moraine lakes in Himalayan Nepal would generate flash floods and debris flows. Some of the local residents believe in such glacial-lake breach at the Aa River. But we cannot find any lake in the Aa River basin. Debris flows may be generated by rapid melting of glacial ice due to the succession of hot sunny days. Exact processes of such features of debris flows are not known. The July 1997 debris flow consisted more than 20 surges over 6 days and the July 2000 debris flow more than10 surges over 4 days. The phenomena consist of a series of debris-flow pulsation. Debris flows generally occur as an intermittent series of multiple surges with time interval of a few minutes. They are also the series of debris-flow pulsation. The time interval of debris flows at the Aa River is several hours which is much longer than general cases. This remarkable difference in the time interval may be caused by the difference in the mechanism of debris-flow initiation.

LANDSLIDE DETECTION USING SATELLITE REMOTE SENSING IMAGERY

Kwong Fai Andrew LO[1], Hui-Chung YEH[1], Ju-Chen HOU[2] ([1]Dept. of Natural Resources, Chinese Culture University, [2]Digital Earth Research Center, Chinese Culture University)

Landslide detection using satellite remote sensing images has been widely studied. This type of applications often involves either change detection or multi-spectral image classification methodologies. If there is only one set of satellite image, the change detection method has limited use. Collecting and analyzing training area data for image classification are costly and time consuming. This study, therefore, utilize only one SPOT satellite image data for estimating the normalized difference vegetation index (NDVI), and to segregate vegetated and non-vegetated areas of the Ta-An River Basin in Central Taiwan. The haze correction technique is applied to remove the effect of atmosphere. Slope factor and texture feature are then used to identify the landslide area. This study successfully demonstrates the capability of using one set of remote sensing image to map landslide area in a large river basin.

HS01/09P/D-011   Poster   1400-178

USE OF ADVANCED REMOTE SENSING TECHNIQUES FOR RISK EVALUATION OF DEBRIS FLOW HAZARD AT TORRENTS AFTER VOLCANIC DISTURBANCES

Takao YAMAKOSHI, Masaaki NAKANO, Masaaki WATARI (Erosion and Sediment Control Research Group, Public Works Research Institute)

Once a volcano erupts, hydrologic characteristics of the slope of the volcano might be completely altered. Usually, at torrents that originate from the erupted volcano, debris flows can be easily triggered even by a small rainfall. Therefore, it is difficult to evaluate risk of debris flow hazard at the torrents because the complete alteration of the hydrologic characteristics means that accumulation of debris flow occurrence data at the torrents before the eruption becomes almost useless. To re-evaluate the risk of debris flow hazard at the torrents after the eruption, damage of the basins of the torrents should be investigated quickly. However, rapid grasp of the damage by field surveys is almost impossible because of the danger of an erupting volcano and the widespreadness of the affected area. Consequently, remote sensing technique is highly expected to be applied because it enables us to investigate an erupting volcano safely and quickly. Authors tried to utilize recent remote sensing techniques, that is, satellite-borne hyperspectral sensor, air-borne laser scanner, and unmanned autonomous helicopter to know degree of the damage at the time of the 2000 eruption of Usu Volcano. As a result, the following were clarified. 1) Satellite-borne hyperspectral sensor could detect area of ash fall deposition by the eruption as an area where a vegetation index lowers. In the same way, thickness of the volcanic ash could be relatively evaluated through degree of lowering of the vegetation index. 2) Repeated measurements before and after the onset of the eruption by an air-borne laser scanner could show the thickness of mudflow deposit very precisely. However, the thickness of the volcanic ash deposit could not be detected because the significant crustal deformation occurred during the eruption and masked the subtle change of the ground elevation by the volcanic ash deposition. 3) Unmanned autonomous helicopter could give us information in detail even around the center of the volcanic activity, such as thickness of the volcanic ash deposit near the erupting vents. However, it took much time and effort to operate the helicopter, so that it should be utilized with the other remote sensing technique complementarily.

COMPARING TWO INTERPOLATORS DETERMINING SPATIAL WATER BALANCES FOR UNGAUGED LOCATIONS ON SHIKOKU ISLAND

Huaxia YAO[1], Irena CREED[2], Michio HASHINO[3] ([1]Shield EcoRegion, Environment and Resource Management, [2]Department of Biology, The University of Western Ontario, London, Ontario, Canada N6A 5B7, [3]Department of Civil Engineering, The University of Tokushima, Toushima 770-8506, Japan)

Simple methods for generating the spatial distribution of water balance components and discharges are required for water resources management of ungauged basins. This study evaluated statistical methods for interpolating the spatial distribution of precipitation (P), evapotranspiration (ET), and discharge (Q) from gauged data points to ungauged points on the Shikoku Island, Japan. Two methods were examined: a local spline interpolator where for a given point the function was fitted exactly to nearby gauged data points; and a global multivariate regression interpolator where the function was fitted to all gauged data points based on their topographic position (i.e., latitude, longitude, altitude). Local and global interpolators did not generate similar results for P and T (where T was used to calculate ET). The local interpolator produced good estimations of P and T, with high coefficient of determinations between observed and estimated (0.982 for P and 0.991 for T). In contrast, the global interpolator produced a less accurate estimation of precipitation P with coefficient of determination of 0.892, and an accurate estimation of temperature T with a coefficient of 0.998. Distributions of annual evapotranspiration and discharge were derived from interpolated precipitation and temperature, and they showed different accuracy against the

observed ones between the two interpolators. Discharges derived by spline interpolator were more agreeable to observed than that derived by regression interpolator. The number of gauged data points used in the interpolation affected the performance of the interpolators. For P, when the number of gauged data points included in the interpolation dropped from n=118 to 8, both the local and global interpolators maintained a high coefficient of determination r (0.9) until n=37, after which r dropped rapidly. At any given number of gauged data points included in the interpolation, the local interpolator outperformed the global interpolator. Our findings indicate that local interpolators are more appropriate for predicting the spatial distribution of water balance components in mountainous regions similar to Shikoku Island.

A TERRAIN BASED PARAMETERIZATION OF DRAINAGE BASIN RESPONSE: A CASE OF YEWA BASIN

Olusegun Adebayo ADEAGA (Department of Geography, University of Lagos)

Uneven distribution of water resources over space and time within the environment constitutes concern in water resources management. The concern can be enlightened from varied degree of water resources uncertainty, most especially its distribution, potential and development among others.An in-depth study on basin system response provides the basic requirement needed for an effective water management and strategic plan options. Such plan is essential in order to make adequate mitigation plans towards administering severe hydrological extreme consequences which is paramount in most developing countries of the world. This is partly due to ill-defined water planning that characterizes developing countries' developmental processes. Also of importance is the need to balance disparity between water supply and water demand of the ever increasing population.A thorough study of water resources requires a timely, accurate and suitable data on various hydrological components in order to attain an effective and efficient operational hydrology plan. Such studies are being hampered by insufficient data set and numerous ungauged stations as well as poor river network scheme.In the developing world, ill-defined and erroneous information of basins' water resources potential and usage as a result of limited riverflow data set in relation to basin complexities, inconsistency and unrepresented data set as well as insufficiency of good quality data remains the major problem towards attaining a sound water resources assessment.In this study, geomophological and hydrological parameters derived from Digital Elevation Model (DEM) morphological analysis formed the basis of transfer function generating within Yewa basin. Space discretization and Morphological transfer function techniques were used for the flow simulation estimation. Transfer time function is based on a pseudo-time while morphological indices like slope, drainage surface, basin cross sectional shape and roughness, channel width in respect of basin size and local slope and conventional flow lengths among others were used to evaluate resultant erosional processes within Yewa drainage surface and Instantaneous Geomorphologic Hydrograph (IGH) generation. IGH provides better understanding of the volume of water being generated and water resources system sensitivity to impulse rain. Yewa basin lies within Ogun river basin; it is oval shape with a total catchment area of about 4000Km2 with numerous ungauged stations and rich in surface water with flooding being one of the major hydrological hazards hampering socio-economic advancement of the basin.The above analysis were integrated into a GIS framework toward a sound flow estimation and profitable decision making processes for ungauged basin using different rain impulse towards a sustainable water resources management and environmental conservation measures.

WATER EROSION IN A SMALL GRAZED SAHELIAN CATCHMENT: IDENTIFICATION OF SEDIMENT SOURCES

Harouna KARAMBIRI[1], Olivier RIBOLZI[2], Anne COUDRAIN-RIBSTEIN[3] ([1]UMR SISYPHE, Laboratory of Applied Geology, University Pierre & Marie CURIE, [2]UR ECU 049, Institut de Recherche pour le Développement (IRD), [3]UMR Hydrosciences CNRS-UMII-IRD, Universite Montpellier II)

The Sahelian part of Burkina Faso is nowadays undergoing serious problems of natural resources degradations, especially soil erosion, due to the aggressiveness of climatic factors and anthropogenic impacts. This study aims to quantify total soil losses at the outlet of a catchment and estimate the contribution of different sediment sources. To do this, surface water flow and associated solid matters were monitored during three years (1998-2000) on a small grazed catchment (1.4 ha) which is about 64% covered by permeable eolian sandy deposits (DRY soil surface type) supporting most of the vegetation, and about 34% by impermeable bare soils (ERO soil surface type). The annual rainfall amount was 518 mm in 1998, 486 mm in 1999 and 419 mm in 2000 with runoff coefficients of 34%, 23% and 38% respectively. The annual solid-matter export was more than 90% suspended sediment, varying between 4.0 and 8.4 t.ha[-1]. The bedload represented less than 10% of soil losses. The sediment yield reached 4.2 t.ha[-1] in one flood event (10-year return period). During the studied period, a small proportion (20 to 32%) of the floods was thus responsible for a large proportion (80%) of the solid transport. Seasonal variation of the suspended-matter content was also observed: high mean values (9 g.l[-1]) in June, decreasing in July and stabilizing in August (between 2 and 4 g.l[-1]). The changes in suspended-matter content at the outlet were analysed during a typical annual frequency event and the results showed high values (23 g.l[-1]) at the rising stage, followed by a strong and rapid decrease during the first fifteen minutes, and a stabilization around 2.5 g.l[-1] until the end of the rainstorm. To highlight the role and quantify the contribution of the two soil surface types in the sediment flow observed at the outlet, we used different techniques: sediment particle-size distribution, clay fraction mineralogy (kaolinite/quartz ratio) and physical-based modelling. The results indicated that the ERO surface type appeared to be the main source of sediment within the catchment.

METHODOLOGY AND METHODS FOR ASSESSMENT OF HYDROLOGICAL CHARACTERISTICS IN UNGAUGED BASINS

Lobanov Alexeevich LOBANOV (IAHS member, Leading Scientist)

Numbers of sites of hydrological observations are limited in space and time. As usual, the regular observations of hydrological characteristics needed for water projects and other aims are absent in such places. There are three main ways for a simulation and prediction of hydrological characteristics in these conditions: short-term field measurements (an unit measure, a season of observations, several years of record), site-analogies and regional models. In modern changing period the additional problem connects with an assessment of stability of all model´s parameters over the time. It has been proved theoretically that the using of several methods and approaches for a determination of the same hydrological characteristic is better than only one but the best approach, because the random errors become less. Some empirical examples confirm this conclusion. One of them has been realized for using of several regional formulas for computation of design floods and the best decision has been obtained in the case of joint use of two methods. In any case when several methods and approaches are used for ungauged site the first step connects with a

determination of homogeneous region. Main criterion, which can be suggested, is the same climate change tendencies or their absent in time series of hydrological characteristics. Methods for an extraction of climate changes in hydrological time series, determination of their statistical efficiency, directions and contributions have been developed too. In selected homogeneous regions the main three approaches are applied and the particular methods have been developed for their realization. In the case of short-term field measurements, the regional relationships are created which connect the years with short-term data and other years of regular observations in the region. The problems of an averaging of simulated data are discussed as well as the estimation of random errors. In the case of regionalization, the methodology and methods for a development of models on the basis of empirical data have been developed which includes the following main parts: assessment of the kind of one-factor relationships, choice of effective structure of the models and computation of their parameters, analysis of remainders and assessment of stability of coefficients of the models and efficiency of simulated values taking into account a dynamic properties (time factor). Practical application of joint use of regional model and short-term data have been shown for maximum 1% design snowmelt discharge for the one of region in the Central part of Russia. The next question is connected with development of Territorial Construction Norms (TCN), which will be the main practical documents for hydrological computations in Federal regional units of Russia. These TCN will use all records of hydrological characteristics in the particular region and regional models, which will be developed on their basis. The particular GIS with data base of observed and extended time series, software for hydrological computations and regional models will be developed for a realization of TCN and their correction in modern changing conditions (monitoring). Block-scheme of such GIS is presented and discussed.

ESTIMATING EROSION USING GIS FROM SMALL WATERSHED WITH PERENNIAL SPRING IN LOWER SHIWALIKS, PUNJAB, INDIA

Amanjot SINGH (Dept.of Soil and Water Engineering)

The lower Shiwaliks, locally called KANDI area, used to be forest belt of Punjab, India. With the growing population, the forest lands are being brought under agriculture, which ultimately is changing the ecological system of the region. The Kandi area comprises of small watersheds (40-70 ha) and the agriculture mainly is dependent upon monsoon rains. Some of the watersheds have perennial springs flowing through them. The source of these streams has not yet been established but these are thought to be fed by base flow from the upper reaches of the Himalayas. The soil of these watersheds is medium to light in texture and is highly erodable. The groundwater is available in two strata. The upper is shallow perched aquifer of about 2-3 m depth and the lower is confined aquifer available at depth more than 75 m and is difficult to tap because of presence of hard clay layers. Since the monsoon has erratic behavior both in time and space and groundwater cannot be economically explored, it was thought to harvest perennial spring with check dam structure and use the stored water for life saving irrigation to the crops sown at the down stream end. The gullies in the catchments have been established to check the silt load. Now with the implementation of the conservation structure, it is required to monitor and assess the hydroecological changes in the region viz. changing surface flow and subsurface water conditions, and sediment redistribution. To meet the objectives, area has been sub-divided into three micro watersheds, i) the upstream of the check dam, ii) the middle area between upstream and cultivable down stream used for conveyance of water, and iii) the down stream agricultural land irrigated by harvested water. The watershed has been mapped and digitized in Geomedia Professional GIS package and different layers for each effecting parameters are being used for the estimation and redistribution of sediments in the catchment.

RAINFALL CHARACTERISTICS AND SOME OF THEIR MANAGEMENT OPTIONS FOR IMPROVING SOIL PRODUCTIVITY IN NORTH -WESTERN TRACT OF INDIA

Sanjay ARORA, M.S. HADDA (Department of Soils, Punjab Agricultural University)

The North-Western tract receives about 4.2×10^5 ha-m of rainwater which is sole natural water resource with deep to very deep underground water table. Some observations at 3-4 sites in the tract show that runoff varies from 35 to 45 per cent of rainfall and soil loss varies from 25-225 t/ha/yr on a small to large watersheds in the tract mostly in the summer monsoon months. It impairs the productivity of land which is not only physically based but more complex in nature. In order to improve the productivity of the land in the area, large scale development works are being proposed for water harvesting and erosion control. It was observed that a minimum rainfall depth of 10 mm is sufficient to cause runoff and overland flow in the area. These runoff producing rainstorms occur in 15-20 number and their duration varied from 1 to 16 hours. Their maximum fifteen minutes intensity and rainfall erosion index ranges from 4.25 to 240 mm h[-1] and 203.6 to 1523.5 m tons/ha cm/h, respectively. The mean rainfall aggressiveness for ten years (1990- 2000) at Ballowal saunkhri, District Nawashahar was 224.8 thereby yielding an annual soil loss of 112.8 t/ha/yr. This placed it into a category that suffers from high erosion risk. Keeping these points in view, some of the proposed management options of rainwater at on-site and off-site are based in reducing the erosivity of rainfall by manipulating the soil surface, pre-monsoon ploughing, haloding, use of crop residues @ 6-8 t/ha through vertical mulching (band placement), timely and deep tillage operations and adoption of land modifying measures and provision of structures and vegetative barriers for safe disposal of excess runoff water at a non-erosive velocity. Also collecting harvested runoff water in suitable inverted, truncated and pyramid type of tanks or small tributaries in the vicinity of cultivated area. In this connection, a recent study conducted on farmers field showed an increase in yield of maize with the application of 50 % NPK+ 150 % FYM was at par with sowing of maize in raised bunds (15-20 cms). This suggests that sowing of maize in raised bunds could be practiced to economize on the use of chemical fertilizers and manures in the area.

QUANTITATIVE ESTIMATION OF ALIAKMON BASIN DEGRADATION THROUGH THE USE OF G.I.S

Dimitrios A. EMMANOULOUDIS[1], Odysseas P. CHRISTOU[2], Evangelos I. FILIPPIDIS[1] ([1]Department of Forestry, Technological Educational Institute of Drama, [2]GEOINFO, Applied Studies and Research, Gr. Lampraki 133)

The study of the three-fold phenomenon of erosion-transportation-deposition of sediment materials in the broader inner and outer basin area of the effusion basins of rivers and torrents is a scientific issue, which has been researched and analyzed in a great number of papers. Such studies and analyzes usually focus on both qualitative and quantitative estimations, via empirical methods or comparison models, which can be locally or universally applied. This paper deals with the definition of the annual potential degradation of Aliakmon riverbasin (the largest river in Greece). This degradation is the result of erosiveprocesses that take place in the watershed subbasins. The products of this degradation, which are sediment materials, are transferred through the hydrographic system network and part of

them reaches the river exit in the plains, while another part remains in the mountain beds in the form of within-basin depositions. For the quantitative estimation of Aliakmon river basin degradation a new model was used. The stochastic model of Gavrilovic served as a starting point, which was further extended by initiating appropriate adjustments through the use of the G.I.S. In the case of the Aliakmon river basin, the average annual degradation has been calculated with a remarkably high precision. Using this new improved model, which for the first time was applied in an area of several thousand kilometres, a lot of maps were constructed and especially a total map of potential erosion.What is more important, is that this improved model of estimation may be applied to any basin, even extremely small mountainous watersheds up to very large river basins.

PEAK DISCHARGE PREDICTION FROM REGIONAL CATCHMENT CHARACTERISTICS FOR EROSION MODELLING

Andras BARDOSSY[1], Istvan KONTUR[2] ([1]Institute for Hydraulic Engineering, University of Stuttgart, [2]Technical University of Budapest)

Erosion and the solute transport is an important factor of water resources and the engineering planning. Erosion is a complicated process, which is seldom measured directly. Empirical formulae based on selected case studies are generalized and used for catchments with hydrological observations only. It is well known that erosion intensity, the volume of the eroded material is connected with the runoff especially of the peak discharges of the runoff.The purpose of this paper is to predict the frequency and magnitude of discharges which might cause erosion. For this purpose parameters of the stochastic process of discharges is related to the parameters of the precipitation process and the catchment characteristics. The Transfer of the parameters is based on an implicit assumption of the continuty supposing that simmilar catchments have simmilar runoff processes. The methodology is demonstrated on selected catchments in South-West Germany.

PHOSPHORUS BEHAVIOUR IN A GRASSLAND CATCHMENT IN NORTHERN IRELAND DURING AND BETWEEN STORM EVENTS

Wayne MENARY, Phil JORDAN, Richard DOUGLAS, Brian RIPPEY (University of Ulster)

Nutrient-suspended sediment interactions are complex and vary between and within storm events, according to the nutrient component (inorganic/organic) concerned and from one catchment to another depending on local mineralogy and upstream characteristics. Previous studies in Northern Ireland suggest that the process of phosphorus (P) loss to water from soils is via dissolution and desorption. There is evidence, however, to suggest that in some circumstances,the particulate P fraction may be the most mobile form during storm events. This project focused on the nature and controls of storm and non-storm period sediment-associated behaviour of P concentration fractions through detailed investigation on the Oona Water catchment, Co Tyrone, Northern Ireland. The research involved automatic storm-triggered hydrochemical monitoring at 3 different scales, ranging from 0.15km² to 88km², in conjuncture with a weekly discrete sampling monitoring programme at 6 different scales. Total and dissolved P were analysed in order to quantify the role of sediment-associated transport in the overall nutrient budget of the rivers. The study location is characterised by the homogenous nature of soil type (heavy clay over drumlins) within the catchment. This facilitates an examination of the effects of time, scale and season on hydrochemical fluctuations. The research has helped to clarify the behaviour of non-conservative P in the stream network by quantifying the magnitude of P losses and P transformations across different scales and time. It has also facilitated an interpretation of the relative contribution of P fractions from grassland soils to waters in the Oona Water catchment. The methodology employed and data obtained helped to fillknowledge gaps in the behaviour of non-conservative P from the micro to meso scale Results show a dominant particulate P fraction across all 6 scales with total P to soluble reactive P ratios ranging from 1:0.14 to 1:0.24 whilst soil desorption experiments indicate a limited role for this theory of P loss. Despite typically low rainfall intensities for Northern Ireland on a global scale, erosion has to be considered an important factor explaining P loss to water from soils in the Oona Water catchment, given results revealing a dominantparticulate P fraction across various scales, from the micro-scale through themeso-scale.

MODERN CONDITION AND PROSPECTS OF DEVELOPMENT OF TOPOGRAPHICAL AND GEODETIC WORKS AT REALIZATION OF EROSION-PREVENTIVE MEASURES

David Dato GUBELADZE[1], Konstantine Kote BZIAVA[2] ([1]Department of Agricultural Land Reclamation, [2]Department of Agricultural Land Reclamation)

Georgia is one of strong erosive areas among the countries of former Soviet Union. Ravine erosion of soils is widely distributed in all soil and climatic zones. The natural conditions of the country (strongly dismembered relief of district, significant length and steepness of slopes, storm character of deposits, high percentage of tilled plots and small percentage of forest land) create danger formation of the new and active growth already of existing ravines. Unfortunately at present detailed survey of ravine-joist elements of a network are not completely stipulated, and to this day they are represented on a topographical basis with the large generalization. The scheduled network of a condensation is created by polygonometry in 2 categories. The high-altitude network is created by continuation of courses of technical geodesic leveling survey with application of geodetic level instruments of a modern type. The survey is made by a method of tachometry. The stationing register on all length of the ravine is made also. With occurrence of new devices such technology of works grows old. Today it is necessary to carry out construction of geodetic networks of a condensation in territories, which are subject to ravine erosion, on the basis of application of electromagnetic distance-meter allowing quickly, it is reliable and with high accuracy to measure significant distances. Use of such devices will enable to reduce terms of performance of works at the expense of automation of process of linear measurements and owing to application new, perfect circuit of construction of a geodetic substantiation, and also considerably will raise accuracy of definition of coordinates of items. The survey of ravine should be carried out by a tachometric way with application of the same devices. The reconnaissance should be carried out together with rodmen with simultaneous drawing up of an outline in duplicate, on which to render a sequence of points of a reflector that will allow to exclude lying of theodolite courses between basic marks and to reduce amounts of works. It is necessary to note, that with the help of these basic marks it is possible to carry out and number of research works, in particular - study of dynamics of growth of ravines and development new or perfection of existing settlement methods of the forecast of separate kinds of erosive processes. In result the made topographical plan will ensure with necessary accuracy of the following data general and private inclinations of slopes; an arrangement of places of concentration and direction of a drain in various parts of a slope; the detailed image of a relief with the instruction of a degree of its destruction by erosive processes; the area of the water collection; parameters of the ravine (length and width of the ravine in the certain intervals and depth of the ravine in characteristic points of cross section). All this will allow

---

increasing quality of designing of Erosion-preventive measures that in turn will enable to improve a condition of grounds usage in agriculture.

CHARACTERISTICS AND TEMPORAL VARIABILITY OF LARGE WOODY DEBRIS TRAPPED IN A RESERVOIR ON THE RIVER RHONE (FRANCE) : IMPLICATIONS FOR RIVER BASIN MANAGEMENT

Bertrand MOULIN, Herv PIÉGAY (CNRS UMR 5600)

Woody debris is a structural element of river system which provides habitats foraquatic communities but may enhance flooding frequency and damage infrastructure.An abundant scientific literature highlights the role of the wood, particularlyin the fields of ecology and geomorphology. In order to find a balance betweenwoody debris preservation and reintroduced for ecological purposes and the need of channel clearing for risk management objective, more research is now needed tounderstand woody debris entrance, residence time and transport dynamic inregulated rivers.This work use reservoirs which trap woody debris to determine its geographical origin and temporal variability in relation to the flow regime. This approach is illustrated by data collected on the Genissiat dam on the upper Rhêne river (France) which trap all the woody debris even during high floods.The results show that the wood input increase with the flood frequency but also depend on the position of the flood event in the hydrological series. The wood load is significantly high and removed from the dam reservoir when the flood recurrence attains one for 1.5 years. Qualitative description of the wood extracted from reservoir indicates that 83 % of the pieces whatever the size have a natural origin (broken, cut by beaver) when 17 % have been cut by humans. The large pieces of wood (diameter > 12.5 cm) have a more frequently human origin (40 %). Large pieces with roots are unfrequent (10 %) underlining the low contribution of bank erosion. Most of the pieces are strongly smoothed, without any branches, roots and bark confirming the effect of physical breakage of high energy rivers. Amongst 503 samples, 45 % have a riparian origin (Populus, Fraxinus, Alnus).

SOIL EROSION ESTIMATION WITH ARCVIEW GIS

Guobin FU[1], Shullin CHEN[2], Donald MCCOOL[3] ([1]Department of Hydrology and Water Resources, Institute of Geographical Sciences and Natural Resources Research, Chinese Academy of Sciences, [2]Washington State University, [3]USDA-ARS-PWA)

ArcView GIS with the Revised Universal Soil Loss Equation (RUSLE) was used to estimate soil erosion in Pataha Watershed, a typical dryland agricultural watershed in southeastern Washington. With the aid of GIS, the L and S factors can be easily obtained from DEM, R factor from precipitation map, K factor from national SSURGO database, and C factor from crop rotation and land use map. Soil erosion in each piece of land then can be obtained with these available factors. In addition, the Sediment Delivery Distributed (SEDD) Model integrated with GIS was employed to transfer the soil erosion to sediment yield at the watershed scale. The coupling of GIS and soil erosion/ sediment yield models can supply the soil erosion/sediment yield spatial distribution and make procedure faster and more efficient.

HS01/09P/D-024   Poster   1400-191

SEDIMENT YEILD MODEL FOR BHAKRA NANGAL DAM USING SATELLITE REMOTE SENSING DATA

siddharth YADAV[1], Ramesh P. SINGH[2] ([1]department of civil engineering, indian institue of technology ,kanpur , india 280016, [2]professor,department of civil engineering, indian institue of technology ,kanpur , india 280016)

Excessive siltation leading to drastic decrease in the water holding capacity and even damage to concrete hydraulic structures is a common problem in reservoirs. Erosion of top soil in the catchment area is influenced by natural and man-made factor that leads to increase sediment load. Bhakra Nangal dam, 255 m high, straight gravity dam (31.25N and 76.25E) is situated along the river Sutlej. The river Sutlej, originating from Mansarovar Lake on the Tibetan plateau at an elevation of 4572 m, flows in a southwest direction, cutting 915 m deep through the plateau and later entering India after traversing a distance of 320 km in Tibet. Gobind sagar reservoir covers 16867 ha at the FRL of 514 m above MSL and 5063 ha at the minimum water level. The reservoir has been designed to hold 9621 million m3 of water, when full, and 2431 million m3 at DSL. However, due to silt accumulation, the capacity has declined to 7118 and 1973 million m3 respectively. The dam was designed for sediment load of 4.29 ha m 100 km-2 yr-1 but actual sediment load coming is 6.00 ha m 100 km-2 yr-1.In the present study, an attempt has been made to find locations using remote sensing data in Satluj river basin that are contributing more sediment to the river. Sediment yield in any basin depends upon parameters like soil moisture, extent of vegetation cover, surface temperature, soil type, snow thickness (if area is bounded by snow), surface precipitation rate, mean precipitation rate, drainage density, lineament density, lithology, slope of the area. For deducing these parameters optical as well as microwave remote sensing data have been used. Snow thickness has been calculated using SSM/I, for vegetation cover change detection using NOAA AVHRR and IRS -1D LISS –III, soil moisture using MSMR data, The mean precipitation and surface precipitation have been calculated using AVHRR NOAA data, evapotranspiration has been calculated using SSM/I and NOAA data and drainage and lineament density from IRS-1D LISS-III data. The basin area has been divided into different small zones and all the above numerous parameters responsible have been calculated and the locations contributing more sediment have been identified.

IMPACTS OF ENVIRONMENTAL CHANGE AND POPULATION GROWTH ON THE WATER QUALITY AND WATER AVAILABILITY IN INDIA

Shadananan K. NAIR (Department of Physical Oceanography, Cochin University of Science & Technology)

Global environmental changes and demands of increasing population make water resources management a difficult issue in many parts of the world. This is especially true for a developing country like India with an exploding population, a weak economy that is related to agriculture and where there are disputes over sharing of water. Life of majority of the population in India depends on agriculture or related industries. Though India is rich in water resources and water resources development projects have helped attaining self-sufficiency in food, the fast increasing population and associated needs pose serious threat to water availability. Overuse, pollution and improper management have been seriously affecting the quantity and quality of water. Global climate models predict a possible change in the rainfall pattern and hence in the water resources of India in the coming decades. In this study, water balances of different States of India have been computed, incorporating the methods of Penman and Thornthwaite, to estimate the water deficiencies, surpluses and the per capita availability. Considering the rate of growth of population and predicted changes in temperature and rainfall patterns, the situation after two decades has been assessed. Study reveals that the present national per capita water availability of 2150m3 will be drastically reduced to 972m3 in few years. Even today, some states have no surplus water from precipitation annually, after meeting the requirements for evapotranspiration and soil moisture recharge. In almost all parts of India, water deficiencies show an increasing trend and surpluses show a decreasing trend. Though some climate models predict an increase in rainfall, it may not be able to compensate for the reduction in soil moisture due to rise in temperature. This will reduce the water level and runoff in rivers. This situation will surely add to the economic crisis. More investment will be needed in domestic supplies, irrigation, national waterways and for finding alternatives for cheap hydroelectric power. If the present population growth and urbanization continues, the country will find it hard to meet the requirements in domestic and industrial sector and after all in the agricultural sector that may need additional 200MCM water to feed more than 1.5Million population. Guidelines for better management have been provided, considering socio-economic conditions and natural and man made environmental changes on water.

ESTIMATION OF POTENTIAL WATER RESOURCES IN THE LOWER MEKONG RIVER BASIN

NMNS Bandara NAWARATHNA, So KAZAMA, Masaki SAWAMOTO (Department of Civil Engineering, Tohoku University)

Availability of GIS data sets of watershed physical properties and the advancements gained in obtaining distributed meteorological variables with the help of GIS have stimulated the development of physically based hydrological models. The introduction of block wise approach to the TOPMODEL with Muskingum-Cunge flow routing methods (BTOPMC) has enhanced the applicability of TOPMODEL from hundreds of square kilometers to several ten thousands square kilometers. In this research work, BTOPMC is used to simulate hydrological processes in the effective watershed of 277,000 square kilometers from Luang Prabang to Pakse in Loa PDR along the Mekong River. It has becomenecessary to construct reservoirs to meet increasing water demand especially in agriculture and power supply in the lower Mekong river basin. However, with the ongoing debate on environmental aspects of dam constructions, a thorough study from a sound hydrological model is needed to ensure sustainable development. The watershed is divided into four rectangular blocks (250 km*300 km) and the block wise average saturation deficit, which controls the depth to the saturation zone in each grid (1 km*1 km), is calculated in each time step. Upstream observed runoff is used as a boundary condition of the model and four parameters namely, lateral transmissivity under saturated conditions, decay factor, maximum root zone storage, and flood plain Manning coefficient n , are estimated as a function of land use extracted from USGS (United States Geological Survey) global land cover characteristics database. Model parameters were calibrated based on the results at different gauging stations. Reservoir operations are taken into account using simplified ruling curves depending on the purposes of the reservoir. Storages and releases from irrigated crop fields are taken into account by introducing required water level function to the relevant grids. Initially the most sensitive n values for different river reaches were estimated using the shape of simulated hydrographs without any rainfall input. The Mekong River, tributaries and flood plains were differentiated by introducing threshold values for the effective watershed area. Minimum value for the Mekong river basin at Pakse is identified as 0.0015. Annual evapotranspiration was estimated based on a pixel wise methodology related to potential evapotranspiration. The sub basins values ranges from 470 mm to 620 mm. Nash-Sutcliffe coefficient formula was used to evaluate the simulation efficiency. Lowest efficiency value for the year 1993 is 93.5%. Finally, potential water resources distributions at 100 square kilometer grid size were estimated. It has been found that there are sufficient water resources in mountainous area in Laos whereas flat irrigated fields in Thailand need to get water from nearest potential locations for a sustainable development.

HS02/07A/C24-003OP Oral-Poster 0908

CLIMATE CHANGE AND WATER RESOURCES VULNERABILITY IN HEAD AREA OF CHANGJIANG AND HUANGHE

Shao-feng JIA[1], Hua-yun YAN[2], Run-jie LI[3] ([1]Department of Hydrology and Water Resources, Institute of Geographical Sciences and Natural Resource, [2]Bureau of Hydrology and Water Resources Survey of QInghai Province, [3]Institute of Water Resources of Qinghai Province)

The head areas of Changjiang and Huanghe are called as Water Tower of China and have very important significance for water conservation and ecological integrity in Changjiang and Huanghe basins. Although the head area of Changjiang and that of Huanghe are connected together, runoff in two rivers showed different change patterns in recent 50 years. While runoff in head area of Changjiang didn't change evidently   (only decreased by 1% compared to 1950's), runoff in head area of Huanghe had decreased by 10% in the same period. It's surprising that the annual precipitation in the head area of Huanghe didn't change obviously. Detail analysis indicated that the main reason of runoff decrease in the head area of Huanghe was the change of time distribution of precipitation i.e. the decrease of precipitation in summer. Perhaps the rising of temperature which may result in the increase of evaporation and transpiration was another reason. But an interesting phenomenon is that the recorded water surface evaporation in head areas of Changjing and Huanghe decreased while temperature rose and sunlight time increased. In fact, this phenomenon occurred in Northwest China universally and so it worth being paid attention to. Because the main two factors influencing fresh water evaporation are temperature and wind, when temperature

rising, the sole factor inducing the decrease of water surface evaporation must be slowing of wind. Metrological records in those areas proved this deduction and showed obvious decline of annual average wind speed. So the rising of temperature will not certainly induce evaporation increase while wind speed descending. This make the relation between temperature and evaporation, further the relation between climate change and water resources, more complicated. Two phenomena in the head area of Changjiang and Huanghe—The dissimilar runoff change pattern (Changjiang's vs Huanghe's) in the same region when water and energy balance factors such as precipitation, sunlight time, temperature, wind speed and water surface evaporation are similar, and the complex relationship between temperature and evaporation— make it very clear that there is still much uncertainty in the prediction of water resources change in the future in a global changing environment.

HS02/07A/C24-004OP Oral-Poster 0912

AN ESTIMATION OF AVAILABLE WATER RESOURCES

Boris BERAKOVIC[1], Marija BERAKOVIC[2], Ksenija CESAREC[3] ([1]Water Research Department, Faculty of Civil Engineering, Univ of Zagreb, [2]Cratian Waters, [3]Meteorological and Hydrological Service)

Water menagement is a very complex activity and its successfulness depends on many factors and their reliability. In the paper the basic and most influential factors are described. A special attention is given to the estimation of available water resources as one of the basic elements influencing the effectiveness of water management. From the very beginning of water management activities information on water quantity and quality were its basic elements. Today, water balances are made routinely especialy for larger areas, and the results obtained so are not sufficient for efficient water management planing. In the paper approvement possibilities of estimation of available water resources i Croatia are suggested. Successfulness of water management could be improved by simultaneously improving some other influential factors, which are just mentioned in the paper.

CHANGEMENTS CLIMATIQUES, RESSOURCES EN EAU ET SECHERESSES AU MAROC

Mohammed-Said KARROUK (University Hassan II, Centre de Recherche de Climatologie)

En raison du changement climatique, l'environnement climatique actuel au Maroc subi une perturbation due au réchauffement du climat terrestre, qui peut violemment perturber presque tous les systèmes écologiques naturels et de nombreuses structures et institutions dont les marocains ont appris dépendre. Si les climats ne se sont que peu modifiés jusqu'ici, le pays est confront dans les décennies venir, la perspective d'une accélération très forte du changement climatique.Les latitudes marocaines représentent les endroits les plus vulnérables aux effets négatifs de ce bouleversement climatique. Le secteur le plus touch par cette situation au Maroc est l'EAU d'aux sécheresses prolongées et répétitives. Et ce en raison de la nouvelle distribution géographique du cycle de l'eau qui s'installe nos latitudes.Les ressources en eau au Maroc, dépendent principalement du retour des précipitations de la saison humide o il pourrait pleuvoir. Cette précipitation qui connaû' dans notre pays une instabilit accrue nous laisse en permanence inquiétude vis-vis de la disponibilit de cette denrée rare sur laquelle se base l'agriculture et la sécurit alimentaire au Maroc.La circulation atmosphérique est le principal mécanisme l'origine des changements dans les variables climatiques dont l'influence se fait sentir l'échelle régionale. Les fluctuations qui affectent nombre de ces facteurs sont fortement interdépendantes, cause des caractéristiques d'ensemble de la circulation atmosphérique et des interactions qui se produisent entre les surfaces terrestres et océaniques.Les précipitations et les températures ont chang au cours des 100 dernières années au Maroc. Au cours de cette période, les précipitations ont connu des variations substantielles et les fluctuations des tendances ont également ét relativement importantes.Ces variations ont accompagn les grandes fluctuations des événements extrêmes observés dans la zone intertropicale « ENSO », qui se sont répercutés sur les températures et surtout les précipitations au Maroc travers la circulation atmosphérique dominée par les transferts énergétiques. Un événement négatif « El Niño » se manifeste au Maroc par des sécheresses, et un événement positif « La Niña » par des précipitations. Ces fluctuations extrêmes au Pacifique sont devenues ces dernières décennies plus fréquentes et se manifestent par une violence « exceptionnelle ». Les sécheresses récentes au Maroc ont ét très pesantes et catastrophiques (1983, 1995, 1998), et leur brève interruption s'est manifestée par des inondations (1986, 1996, 1997, 2000 et 2001). Cette instabilit accrue des événements océano-atmosphériques met en péril les ressources en eau au Maroc, l'agriculture et la sécurit alimentaire.Le Maroc, déj sensible une variabilit climatique instable, est soumis aux effets du changement climatique dans plusieurs secteurs, savoir: • Le stress hydrique impos divers systèmes biologiques et secteurs socio-économiques, en raison de l'augmentation de la température et de l'évapotranspiration, entraû<erait un bouleversement du cycle hydrologique.• Les perturbations de l'écoulement de surface qui pourrait être excédentaire en cas de précipitations hivernales, et déficitaire dans les autres saisons.• La rentabilit agricole pourrait être altérée en raison des perturbations du cycle hydrique, ce qui poserait une sérieuse menace pour la sécurit Ealimentaire du pays.Des mesures draconiennes nécessaires devraient être entreprises pour s'adapter des éventuels bouleversements, lesquels représentent des facteurs limites pour la continuit en équilibre des écosystèmes et des systèmes socio-économiques.

HS02/07A/C24-006OP Oral-Poster 0920

WORLD MAP OF HYDROGEOLOGICAL CONDITIONS AND GROUNDWATER FLOW

Roald Gamidovich DZHAMALOV, Igor Semenovich ZEKTSER (Water Problems Institute, Russian Academy of Sciences)

The Map was compiled in accordance with special UNESCO Project and printed in the USA in 1999. The methods of groundwater flow assessment and mapping, legend of the map and its main contents were elaborated by Russian scientists (Principal editors Dr. R.Dzhamalov and Dr. I. Zektser). The Map was edited by a special International Editorial Board that included representatives from the Australia, Argentina, Brazil, China, Germany, USA, India, France, Indonesia and numerous other countries.World Map of Hydrogeological Conditions and Groundwater Flow (scale 1:10 mln.) is designed to provide specific and quantitative information for the following practical problems: a) to determine groundwater flow and natural groundwater resources in individual regions of the Earth to characterize water availability and to plan the use and protection of water resources; b) to determine groundwater recharge amounts to establish the regional water balance and existing water resources; c) to determine groundwater contribution to river runoff as it is the most stable portion of total river runoff, as well as to predict changes in river discharges under the effect of large scale groundwater withdrawal; and d) to determine the value of direct groundwater discharge to seas and oceans to establish groundwater contribution to water and salt balances of the seas.The World Map is a special, thematic hydrogeological map whose main content is information on the distribution of several quantitative characteristics of groundwater runoff as

well as geological and hydrogeological conditions of groundwater generation. In small-scale mapping of hydrogeological conditions selection of aquifer systems is a severe problem. It is necessary to distinguish principal groundwater flow media - types (subtypes) of rocks with common conditions of generation and spatial distribution of water-conducting properties. Besides of lithological composition of groundwater flow media on the Map the specific values of groundwater flow characteristics (modulus and coefficients) are presented. This combined representation of two quantitative characteristics appreciable improves the informativeness of the Map. Different colors are connected with groundwater flow media types, intensity of each color reflects modulus of groundwater flow or annual specific groundwater discharge values (from less than 0,1 to 10-20 l/s km2), and brown isolines represent coefficients of groundwater flow or ratios groundwater runoff to annual precipitation. The Map gives also information about special conditions of groundwater flow generation connected with human activities, intensive karstification, river channels with surface runoff losing, and rift zones and regional faults, and so on. Firstly in the hydrogeological mapping, the Map presents conditions of direct groundwater discharge to seas together with quantitative characteristics of this global process expressed in specific values.The results of quantitative estimation and mapping of groundwater flow make it possible to solve several problems of groundwater generation under different natural conditions on a completely new basis by introducing quantitative data into the analysis. The carried out research found the principle global and regional regularities and relation between groundwater recharge and the natural and climatic zonality.

HS02/07A/C24-007OP   Oral-Poster   0924

ASSESSING THE SUSTAINABILITY OF URBAN WATER RESOURCES

Matthias EISWIRTH (Department of Applied Geology, University of Karlsruhe)

With over 40% of the water supply of Western & Eastern Europe and the Mediterranean region coming from urban aquifers, efficient and cost effective management tools for this resource are essential to maintain the quality of life. Traditional water planning regularly concludes that future water demands will inexorably rise and eventually exceed water supplies available in any given location. However, the increasing concerns about the environmental impacts of water projects and their increasing economic costs mean that traditional planning concepts, which assume unlimited supplies of potable water, must be questioned. This includes the source of the water supplies and its appropriate use. With population densities increasing in urban areas and constraints on funding, it is becoming increasingly evident that the present management of urban water resources and systems will not be suitable models for service provision into the 21st century and that increased emphasis will be placed upon the use of groundwater reserves. Without an adequate knowledge base of the current status of urban water resources, and an understanding of the processes involved, the health and safety of the people who depend on urban groundwater as drinking water can not be assured. In spite of strong efforts initiated by the European Union and other international organisations in the past 20 years, groundwater pollution from industry, traffic, sewers and agriculture is still very high. The complex transport processes of groundwater flow are responsible for the wide distribution of recharged water and contaminants. There is evidence that urban downstream aquifers are contaminated by inorganic, organic and microbial pollution. With population densities increasing particularly in urban areas and the corresponding constraints on funding, it is becoming increasingly evident that present urban water systems will not be suitable models for service provision into the 21st century. The overall objective of a new European Commission funded initiative, called AISUWRS (Assessing and Improving Sustainability of Urban Water Resources and Systems), is to develop an innovative system to quantify and manage the problems from unsustainable urban water systems and assess the impact of pollution on the underlying groundwater resources. The overall scope of the AISUWRS initiative is to assess and improve the sustainability of selected urban water systems and resources with the help of computer tools and thus minimise the impact of pollution on the underlying urban groundwater resources. Parts of these model tools have been already developed to estimate the water flows and contaminant loads within the urban water system. This model represents water and contaminant flows through the existing water, wastewater and stormwater systems, from source to discharge point and have already been applied successfully in selected areas in Australia and Germany.

HS02/07A/C24-008OP   Oral-Poster   0928

ASSESSING VULNERABILITY OF WATER RESOURCES TO CLIMATE CHANGE IN MIDWEST

Hua XIE, Wayland J. EHEART (Department of Civil and Environmental Engineering, University of Illinois at Urbana-Champaign)

There exists much scientific evidence showing that our planet is undergoing a global climate change and that the climate change will threaten the status quo of regional water resources that support ecosystem and human society. An assessment was conducted to evaluate the vulnerability of water resources to climate change in the Mackinaw watershed in central Illinios, USA. In this study, the SWAT (Soil and Water Assessment Tool) model was used to predict stream flow and crop yields in a watershed under different future climate scenarios that represent possible climate outcomes predicted by well-known global circulation models. The potential effects of climate change and irrigation incurred by the change, if any, on low-streamflow and profitability of crop growing operations were investigated, for currently customary crops for the region and alternative crops.

HS02/07A/C24-009OP   Oral-Poster   0932

THE BASIC FEATURES OF TRANSFORMATION OF A REGIONAL CLIMATIC FIELD OF PRECIPITATION ON UKRAINE UNDER INFLUENCE OF GLOBAL WARMING

Volodymyr M. VOLOSHCHUK, Svetlana G. BOYCHENKO (Department of meteorology and climatology, Kyiv Taras Shevshenko University)

The main aim of this research is to obtain quantitative estimations of the basic tendencies of changes of the monthly sums of precipitation on Ukraine as a result of global warming and to work out scenarios of transformation of a climatic field of precipitation on Ukraine in first half of 21-th century on their basis.In this research were used the following methods:• Specific statistical analysis of empirical meteorological data which was worked out by authors specially for revealing very small climatic signal on a background of very large meteorological noise with use mainly of a space-time coordination and connectivity of climatic fields;• The climatic theory of similarity of processes of formation of an atmospheric precipitation which was worked out by authors for construction of necessary semi-empirical models;• Comparison with known materials of regional climatic paleoreconstructions of warm epochs of the past.The following main features of transformation of climatic field of the monthly sums of precipitation on Ukraine under influence of global warming up to 2-3 K are established: •Increase of the monthly sums of precipitation for those regions and months of Ukraine for which meteorological norms of precipitation are below 50 mm per month;• Increase of the monthly sums of precipitation for those regions and months of Ukraine for which meteorological norms of precipitation are over 75 mm per month;• Decrease of the

monthly sums of precipitation for those regions and months of Ukraine for which meteorological norms of precipitation are over 50 mm but below 75 mm per month;• Space alignment of a climatic field of the annual sums of precipitation, but averaged on all territory of Ukraine the annual sum of precipitation does not practically change.The important methodological conclusion follows from the obtained results concerning dynamics of a climatic field of precipitation on Ukraine: incorrect averaging on various space-time scales of climatic field of precipitation can result in essential distortion concerning influence of global warming on intensity of regional precipitation. At construction of scenarios of transformation of a climatic field of precipitation on Ukraine two types semi-empirical models are used:• Variability and trends of precipitation as functions of meteorological norms;• Meteorological norms, variability and trends of precipitation as functions of seasons, geographical coordinates of a place and its height above the sea level.The scenarios constructed on the basis of such type of semi-empirical models are convenient for using at assessments of influence of global warming in various branches of economy of Ukraine, which are formulated as stochastic space-time functionals from meteorological parameters.

FEATURES OF WATER RESOURCES SYSTEMS IN GEORGIA

Konstantine Kote BZIAVA[1], David Dato GUBELADZE[2] ([1]. Department of Land Reclamation and Engineering Ecology, [2]Department of Land Reclamation and Engineering Ecology)

The physical-geographical and climatic conditions promoted the large variety of hydrological features both as a whole in all Georgia, and in its separate areas. In Georgia the greatest drain of water (in comparison with the countries of former USSR), exceeding 3000 mm of water per year, however amplitude of fluctuations of this drain depending on territory and river pools is very high. Resources of fresh water of a region are composed from a superficial and underground component of a river drain; underground waters not participating in a river drains and getting directly in the sea; and also water of glaciers, lakes and bogs. The features of water resources of the country are defined by relief and climatic conditions, aridity of territory, mode and geography of a drain of the rivers, and also geographical isolation of Transcaucasia. All variety of natural resources depending on reproduction can be referred to two groups: renewed and not renewed. Now situation essentially has changed, as water has become scarce, and the former resources do not provide needs for it; besides it its quality considerably has worsened. In this connection there was a necessity besides the operational charges to carry out expenses for production of water accessible to use and on improvement of its quality. For example, at regulation of the river drain in reservoir water resources "sharply grow", and the clearing of water source from pollutants improves its quality, also increasing "water resources" etc. Proceeding from above told, it is possible to note, that in a long-term section "the water resources" as against "of water stocks" are variable size varying as quantitatively, and is qualitatively depending on the requirements showed to water. Now volumes of water used in industrial activity of the man and in a life, continuously grows. As a result of it the necessity of involving in activity of the man of all new and new water sources, i.e. transference "water stocks" in a category "of water resources" has appeared. The present stage of development of a human society is characterized by the tendency of increasing water requirement, and consequently, increasing of water resources. Though in absolute sizes, the specific parameters of water resources of East Georgia are not low in comparison with arid zones of other countries, but the conditions of their use are specific and difficult, since they play a main role in water requirement of neighboring Azerbaijan laying below on current of the river Mtkvari and using a transmitted drain from Georgia. This situation is aggravated also by that as East Georgia, and below laying grounds of Azerbaijan by the climatic conditions are sharply require irrigation up. Proceeding from above mentioned, the problem of water in East Georgia carries not only technical and economic character, but also social, as the development of a national economy of Azerbaijan and indirectly of Armenia depends on its decision, as the growing water consumption by Armenia also increases deficiencies in East Transcaucasia.

STREAMFLOW VARIATION OF FOREST COVERED CATCHMENTS

Zoltán GRIBOVSZKI, Mihály KUCSARA, Péter KALICZ (Department of Forest Opening Up and Hydrology, University of West Hungary)

Rainfall concentration and runoff, otherwise rainfall-runoff processes, which cause river water discharge fluctuation, is one of the basic question ofhydrology. Looking for the answer is important because several social-economy demands have a strong connection with small or bigger rivers fromthe point of view both quantity and quality of the water. Gratification or consideration of these demands is complicated substantially that we have stillpoor knowledge about our stream-flow regime. Water resources mainly stem from upper watersheds. Rivers transported water discharge, which is potential usable, is an integral of streams takeits rise in these small small-watersheds. These upper watersheds are the basis of the water concentration process, therefore we have to improve ourknowledge about hydrological processes coming up in these territories. In this article we present runoff regime of three small catchments on the basis of one year data. Two catchments have a similar magnitude 0,6and 0,9 km², and one is bigger about 6 km², which has a part other two above mentioned. We have been analyzed indetail from hydrological elements only features of rainfall, discharge, rainfall induced flooding waves, and basic discharge in rainless periods.Variances of these parameters have been analyzed in relation to catchments surface, vegetation coverage and forest management. Result data set well enforce our knowledge about *small catchments hydrological processes*. On the basis of these fundamentals we can plan moreestablished the management of these lands (forest practices, civil engineering works, usage of natural water resources). Global change could change hydrological regime. These results can also utilize on the long term planning ofland use and water demands gratification.

HS02/07A/C24-012OP   Oral-Poster   0944

FINGERPRINTING CLIMATE CHANGE DRIVEN DROUGHTS IN WESTERN CANADA

Lawrence Chima NKEMDIRIM (Geography and Earth Sciences, University of Calgary)

Some climate models forecast a higher frequency of drought events in western Canada due to an atmospheric greenhouse gas driven climate change. Because droughts are not uncommon there, it is necessary to differentiate events that are either wholly driven or intensified by climate change from 'normal˝ events. Two trends currently identified with century-scale climate change appear to adequately fingerprint climate change inspired droughts in the region. They are (a) statistically highly significant increase in surface air temperature and (b) an equally significant decrease in sea level pressure. Fingerprint One (winter droughts- precipitation poor): Based on homogenized data from 114 stations, mean annual temperature rose at a rate of 2.7˚C/century between 1953 and 1997. This trend was dominated by increases of about 5 and 6oC in the winter and spring respectively. Paralleling the trend was a highly significant reducing trend in surface air temperature especially during the two seasons. Observation and analysis showed that the Polar High Pressure, which dominates the region's winter climate had weakened and the temperature contrast between the Arctic and polar airmasses had declined. The resulting 'softening' of the polar front

correlated well with negative winter precipitation anomalies. Precipitation more than 2 standard deviations below normal were 20 percent more frequent in post 1975 winters than in pre-1975 ones and the difference was statistically significant at 95% confidence level. Additionally, the post-1975 two standard deviation events correlated well with both pressure anomalies and change in mean surface temperature. Fingerprint Two (summer droughts-precipitation rich): The Canada Climate Center model predicted increases in precipitation for the region ranging from 15mm/year to 45mm. An energy balance model, in which all sources of energy including a strong advective component due to the Chinook (a mountain wind, which significantly impacts the temperature regime in the region) were fully specified, enabled a realistic assessment of the region's water balance under the present warmer regime. Water deficit ranging from 250mm above normal in the driest areas to 45 mm in the wettest parts was indicated for the post-1975 period. The Palmer Drought Index was used to identify recent drought events that were severer than they would have been under similar summer and rainfall and antecedent moisture. The frequency of such events increased 35% in the post-1975 period.

THE CONCEPT OF MODERN ARID ZONES OF HYDROGEOLOGY OF CENTRAL ASIA AND ITS PROBLEM

Nasirdjan -TAKHIROV, Shukhrat Saifullaevich RADJABOV (Department of hidrogeology, National University of Uzbekistan)

The hydrogeology as a science intensively developed within last century and its fundamental positions are already formulated.Especially, after 60th of the last century, the accomplishing of any type of hydro-geological researches was accompanied with the decision of a problem to manage the dynamics (changes) and chemical compound of underground waters within the limits of concrete borders.The requirement to a hydro-geological science after 70th has got rather complex character. These requirements follow from an ecological problematic of the regions. The underground hydrosphere is considered (examined) as the mainframe of the geoecological environment and is one of the components for eco-system. So, it occurred the new situation connected to an intensification of technogenesis and gradually, the concept of a hydro-geological science has got the new maintenance (contents), providing an ultimate goal – management of underground hydrosphere within the framework of ecological requirements. The decision of hydro-geological problems in volume of its new concept demands the preliminary system analysis of hydro-geological situation. This work is feasible only in development of the further researches on a new scientific direction – technogenetic evolution of hydro-geological conditions of arid zones, rational use and resource management of underground waters: an ecological policy, balance, preservation, protection and the forecast.The object of research is underground water of hyper genesis zones, that is on a part of lytosphere where the active and slowed down water exchange is observed. Thus, the purpose of maintenance of the uniform concept, system, methodology and methods of management and operation of underground waters for needs of a national economy is pursued within the framework of ecological requirements.On the faculty of hydrogeology of National University of Uzbekistan, researches on the mentioned above new direction on Arid zones – Ustyurt, Aral Sea Region, Kyzilkum, Amu-Darya and Fergana artesian pools - are conducted.Researches on the given direction provide the following:- Revealing of scientific bases for development of underground waters under difficult ecological conditions in the arid zones of Uzbekistan and definition of their role in development of geo-ecological processes;- Identification of water problems and problems of social and economic development- Development of criteria for estimation of opportunities to use the resources of underground waters for social - ecological and technical needs- Development of long-term program to develop the water supply for drink, animal industries, technical needs and for infrastructures- Scheduling of the work on protection, management and rational use of underground waters according to the ecological requirements.

THE GLOBAL WATER SYSTEM PROJECT OF IGBP*, IHDP*, WCRP*, DIVERSITAS

Holger H. HOFF[1], Holger HOFF[1], Carlo JAEGER[1], Denis LETTENMAIER[2], Christian LEVEQUE[3], Harry LINS[4], Michel MEYBECK[5], Madiodio NIASSE[6], Charles VOROSMARTY[7] ([1]PIK, [2]University of Washington, Seattle, USA, [3]Programme Environnement, Vie et Sociétés, Meudon Cedex, France, [4]U.S. Geological Survey, Reston, Virginia, USA, [5]Université de Paris 6, France, [6]IUCN-BRAO, Ouagadougou, Burkina Faso, [7]University of New Hampshire, Durham, USA)

The Global Water System (GWS) plays a central and integrative role in the dynamics of the Earth system. It is a regulator of biogeophysical and biogeochemical processes, and it is also is essential for sustenance of human societies. The GWS is increasingly modified by humans and through climate effects (facets of it have moved well outside the range of natural variability) , without adequate understanding of how the system works. For understanding the changes, feedbacks and potentially critical thresholds within the Earth system, and eventually for better managing the GWS, new synthetic knowledge is required. The Global Water System Project (GWSP) is a new activity being undertaken jointly by the World Climate Research Programme (WCRP), International Geophshere-Biosphere Program (IGBP), International Human Dimensions Program (IHP), and Diversitas. It will address the GWS in a comprehensive fashion at the global scale, building upon the emerging new consolidated Earth systems data sets, global monitoring tools, and predictive and coupled modeling capabilities. The central scientific question that motivates the GWSP is: ″How are humans changing the global water cycle, the associated biogeochemical cycles, and the biological components of the GWS, and what are the social feedbacks arising from these changes?″ GWSP will be structured around three ″framing questions″: a) What are the relative magnitudes of global-scale changes in the global water system that are attributable to changing human activities, and to environmental factors such as climate variability and change?; b) What are the main mechanisms by which human activities are affecting the global water system; and c) To what extent is the global water system resilient to global change? Examples of issues that might be addressed under each of these questions are provided.

HS02/07A/C24-015OP   Oral-Poster   0956

MODELLING OF WATER AVAILABILITY IN GRASSLAND ECOSYSTEMS OF ARID ZONE DELTA PLAINS

Natalia V. PENKOVA[1], V.P. SINGH[2], V.A. KHAYDAROVA[3], N.M. NOVIKOVA[4] ([1]State Hydrological Institute, [2]Louisiana State University, [3]Water Problems Institute, Academy of Sciences of Uzbekistan, [4]Water Problems Institute, Russian Academy of Sciences)

For successful long-term planning and ecosystem management in river deltas of drought-prone regions, it is desirable to develop sufficiently rigorous but not very complex and data-extensive models which are easy to understand and can be used by a wide range of specialists and experts, not sophisticated in purely hydrological, ecological or biological scientific knowledge, for real decision-making. In the contribution, the most simple version of conductance-type combination equation (Budyko´s combined method) is used to calculate within-the-year and long-term variations and trends in water availability (evapotranspiration

and soil water content) for grassland ecosystems in Syrdarya and Amudarya river deltas (Aral Sea basin), Volga and Terek river deltas (Caspian Sea basin) and Mississippi delta plain. The biological response to environmental conditions (atmospheric demand, precipitation intensity, ground water table, soil water properties), and to agrotechnology (fertilization, irrigation) by using non-linear multi-dimentional cubic splines approximations for ″biological″ parameter of the Budyko´s equation is estimated for annual grass crops and perennial herbs, with particular emphasis on the vegetation condition (closed and sparse canopy, high and low productivity, etc.) (Khaydarova, Kucherova and Penkova, 1998). A comparison is made of the results with ones obtained by applying mechanistic volume type models (Singh, 1989), and resistance-type combination techniques (Penman-Monteith equation). The advantages and shortcomings of the models under analysis are highlighted. An application of the models for historical formation of water availability patterns and for possible climatic and economic conditions in the future is presented. The ecosystems of the deltas represent different natural self-development and man-induced stages - from the stage of drying, increasing of soil salinization and decreasing of meadowlands productivity (Aral basin) to the stage of humid-meadow lands restoration conditioned by rising the Caspian sea-level. Vegetation changes in the territories are of long-term cyclic nature, depending on climatic fluctuations and superimposed anthropogenic influences (Novikova, 1997). The superimpositions are investigated for different periods of economic development of states.

CLIMATIC VARIABILITY AND LAND RESOURECS VULNERABILITY IN THE FORCADOS RIVER ESTUARY

Mayowa FASONA (University of Lagos)

The current climatic fluctuations and shift from global climatic normals is causing apprehensions across the blue planet. Data on global climatic indicators show that there has been a net increase in global surface temperature by between 0.30c and 0.50c over pre-industrial periods. Evidences of global warming have already been noted in glacial margin retreat, a rise in snowline, a rise in sea level, northward recession of the tundra margin in the arctic and the ferocious southward march of the Sahara in the tropics. It has also been estimated that an increase of between 10c and 4.50c over the current global temperatures is expected to trigger off accelerated sea level rise of between 0.2m and 1.4m, which have lots of catastrophic implications especially for the coastal ecologies and other low-lying areas of the world. This paper utilizes Remote Sensing and GIS techniques to assess likely implications of accelerated sea level rise on water and land resources of the areas around the estuary of the Forcados River. Current ecological and land resources data on the study area was generated from remotely sensed satellite imagery. This was overlayed with spatial data on elevation, soil, geology and water resources to generate floodable areas sensitivity map for this coastal environment. The implication of this for food security, sustainable water resources management and coastal resources management is also discussed.

SMALL HYDROLOGICAL BASINS IN DELTA REGIONS AND THEIR VULNARIBILITY TO CLIMATIC CHANGE: THE CASE OF THE MARK-VLIET BASIN

Victor Jan WITTER (Water Authority)

The paper gives an overview of changes in population, land use and economy, affecting the hydrology of the Dutch/Netherlands basin of the Mark and the Vliet. This is a relatively small hydrological basin (ca 140.000 has) situated in the Delta of the rivers Rhine, Meuse and Scheldt. The basin is of recent origin. Around the year 1000 the sea starts to penetrate what is now the Mark-Vliet basin and at that time was part of the vast peat-covered Delta of Rhine, Meuse and Scheldt.Consequently, the basin was shaped into its present form in the last 1000 years. The period of study starts in 1820, when sluices were built in the mouth of the rivers draining the basin, the Mark and the Vliet. Three periods can be discerned since then: 1820-1900, 1900-1960 and 1960-2000. Around the year 1900 radical changes land use took place in the southern part of the Mark-Vliet basin, because of large-scale colonization by farmers and forestation of fallow land. Around the year 1960 extensive land consolidation schemes and reconstruction works of water systems took place in the basin, with the objective to modernize agriculture. The changes in rural land-use and water management were accompanied by a rapid urbanization of the region. The period of study extends into the future period till 2050. Provisioned changes in climate and changes in population, land use and economy are analyzed with respect to their effect on water demand and supply and the region 's hydrology. Changes are analyzed with respect to extremes of water levels and discharges, in mean conditions and in high flood and low flood conditions. The paper demonstrates (1) the profound changes that took place in the hydrology of small basins like the Mark-Vliet basin, changes that in large river basins are flattened out; (2) the magnitude of future changes in the hydrology of the region which will be needed to cope with autonomous developments and with the effects of climatic change; and (3) that the magnitude of future changes considerably exceeds that of changes in the past and possibly readjustment is needed of both magnitude of the changes as well as their direction.The results for the Mark-Vliet basin are generalized to small hydrological basins in Delta regions. It is argued that these basins are particularly vulnerable to climatic change.

HS02/07A/C24-002   1100

WATER PROBLEMS & SUSTAINABILITY IN THE NORTH CHINA

Jun XIA (Insititute of Geographical Science & natural Resources Research, Chinese Academy of Science)

Located in the semi-humid and semi-arid regions of eastern China, the North China Plain (NCP) is the largest alluvial plain in China with an area of $32{\times}104km2$. The city such as Beijing, capital of China, is located in this area. Thanks to social-economic development and population growth, water shortage problem has become one of the most important issues in social & economic development. This paper focuses on water resources

sustainability in the Northern of China. Two key issues are presented, namely water cycle to environmental change, and carrying capacity of water resources in this area. The backgrounds will be introduced to show the causes from natural change and human activity impact. From these practical water issues, several interested mathematic problems are proposed. Some of methods were presented to quantify water resources sustainability. It will be indicated that water is a highly precious resource and has become a key-limiting factor that plays a critical role in socio-economic development in the Northern of China. Besides necessary water diversion project from South to North, saving water will be a basic measurement. How to trade off conflicts of water supply and demand in the principle of environmental protection will be the big challenge in the 21st Century in this region.

HS02/07A/C24-003   1115

UTILIZATION OF WATER RESOURCES AND ITS EFFECTS ON HYDROLOGICAL ENVIRONMENT OF TARIM RIVER BASIN IN XINJIANG, CHINA

Changyuan TANG[1], Shizuo SHINDO[1], Xin LI[2], Jianyao CHEN[1] ([1]Graduate School of Science and Technology, [2]Suzhou College of Urban Construction and Environmental Protection, Suzhou, China)

This paper describes the characteristics of water resources utilization in Tarim River basin in terms of both its quality and quantity. It is found that water cycle and water qualities have changed greatly because of human activities in last forty years. Many canals have been built to transfer almost all stream waters for irrigation and farmland salt-washed. For example, irrigation land has increased more than 4.0×105 ha at upstream of the Tarim River, which use almost 40% of the stream water for agriculture. According to the flow statistics of Tarim River in last forty years, the stream flows in middle stream and downstream decreased about 50% and 85%, respectively. As a result, water in downstream of the Tarim River decreased sharply and many lakes disappeared from the desert. Near half of farmlands had been abandoned.According to 52 sampling points of streams that flow from the south part of Tianshan Mountain, it was found that about 37% of streamwaters were $Ca2+-HCO3-$ type and more than 40% either $Na+-Cl-$ type or $Na+-SO42-$type. The water of the former type was the stream water in natural hydrologic conditions, while the water of the later type was stream water affected by agriculture activities.Water use in Tarim river basin has two effects: one is the expansion of irrigated farmland, the improvement of land productivity; the other is the distruction of water balance, salt balance and ecological balance with desertification expanded rapidly in the lower reaches. From 1957 to 1996, annual runoff at Qiala reduced from 1.46 km3 to 0.194 km3. Stream has run out till Alagan in 1972, and moved sand dune increased 20% there. Sand area has expanded 116km2 since 1959, and desertification became seriouslyThe relationships among the water use, desertification and salinazation were also discussed in the study region. It was found that desertification and salinity are twin problems that must be dealt with at the same time with respect to water balance. Desertification is closely related to water distribution along the river. However, when runoff in the tributaries of Tarim River reduced, water consumption in the upper reaches and middle reaches of Tarim River had increased. For instance, water consumption in the upper reaches was 14.77% of total flow in 1960's, and increased to 23.0% in 1994; in the middle reaches it was 61.54%, and 72.56% respectively; in the lower reaches, it was only 4.44% in 1994.

WATER RESOURCES IN BULGARIA UNDER CLIMATE VARIABILITYAND CHANGE

Vesselin A. ALEXANDROV, Marin GENEV (National Institute of Meteorology and Hydrology)

The question of global climate variability and change is a major and important environmental issue facing the world at the beginning of the 21st century. Variability of water resources (e.g. precipitation, river runoff, groundwater) during the 20th century in Bulgaria were investigated. A special attention was paid on the drought period during the last two decades, where soil water content was also considered. Several GCM (global circulation model) climate change scenarios were created for the country. For example, some of the used GCM simulation outputs include the models from the Max-Planck Institute for Meteorology, UK Hadley Center for Climate Prediction and Research, Canadian Climatic Center Australian CSIRO model, Geophysical Fluid Dynamics Laboratory. According to the GCMs used in the study air temperature is expected to increase between 2 to 5°C till the end of the 21st century. In general, precipitation is expected to increase during the winter and to decrease during the warm half-year. It is obviously that there would be some changes in the water resources. Possible scenarios for air temperature, precipitation and annual runoff in Bulgaria assuming the current trends and also the last severe drought period were created, as well. Annual river runoff is expected to decrease up to 14% in 50 years and to be 0% at the end of the 21st century in respect to the current climate. In case that a severe drought period is also assumed within the study, the expected decrease of annual runoff in Bulgaria is between 39 and 45%. On the first hand total precipitation during the potential crop-growing season will increase due to projected increase of the duration of the potential crop-growing season caused by warming. On the second hand however, the total precipitation amount during the actual crop-growing season is projected to decrease due to the GCM simulated decrease of precipitation and because of shortening the actual crop-growing season caused also by expected warming. The Decision Support System for Agrotechnology Transfer DSSAT was used to simulate the impact of climate change scenarios on maize growth, development and yield formation and the parameters of the water balance during the maize growing season. The parameters of the water balance such as seasonal evapotranspiration, runoff, drainage and soil moisture at maturity were included within the analysis. Adaptation options and strategies in respect to irrigation under climate change are also discussed. The national program of the Bulgarian government on the adaptation measures under the current and expected drought tendencies in the country is also described.

IMPLICATIONS OF CLIMATIC VARIABILITY AND CLIMATE CHANGE ON WATER RESOURCES AVAILABILITY AND WATER RESOURCES MANAGEMENT IN WEST AFRICA

Simon Oyediran OJO, Feyi ONI, Olatunde OGUNKUNLE (DEPARTMENT OF GEOGRAPHY, UNIVERSITY OF LAGOS)

This paper begins by examining trends in climatic variations and variability especially during the past three or four decades and their implications for water resources systems and water resources availability in West Africa. It then examines the impacts of the trends in climatic variability on the characteristics of climatic events (including floods and droughts), and the implications of these events on the characteristics of the hydrology and water supply systems. It emphasizes rainfall as a major factor of water resources availability, and the significance for surface and groundwater characteristics in the West African region. It also examines the impacts of climatic variability on the spatial and temporal characteristics of the water balance components with some detailed illustrations using locations and different ecological zones in West Africa. The results show that there were a lot of spatial and temporal variations in the characteristics of rainfall and the water balance components, and their implications for water availability and climatic events (including droughts and floods).

The results also show that the impacts of the trends in climatic variations and climate change on water resources availability have generally been more adverse and especially resulted in water stress in most parts of West Africa. In particular, most years within the study period have been characterized by water deficits and droughts, although flood events, which also have impacted adversely in many parts of the region, have been witnessed because of the general characteristics of climatic variations and variability especially as influenced man. Such human influences have for example, caused increased rates of deforestation and desertification processes, which have in turn resulted in rapid surface runoff and in many cases reduced water quality, and which in turn have affected potable water availability. Using the present knowledge of the characteristics of water supply-demand systems, the paper makes projection into the future of urban and rural water supplies for Nigeria, which is an epitome of West Africa, and using the projected population for the country. It also discusses the problems of acute shortage of freshwater and the prevalence of water stress currently experienced in most parts of West Africa, and whose characteristics would be worsened with the projected climate change, and which points towards the need to plan water resources development strategies and for coherent and effective policies and programmes of development and management of water resources. The paper then examines the two main categories of adaptation measures needed to improve water management and the extent to which they have been applied.The paper finally discusses the need to address a number of mechanisms for implementation of the various adaptation measures. In particular, the paper discusses the urgent need for (a) building capacity and manpower as part of the development of water institutions in the region (b) promoting education and public awareness on the various measures to be used (c) public participation and the involvement of stakeholders (d) the establishment of both national and regional co-operation and (e) the need for climate and other environmental data collection and monitoring.

HS02/07A/C24-006   1200

STRUCTURE OF ECOLOGICAL INDICATORS AND INDEXES FOR GROUNDWATER SUSTAINABLE DEVELOPMENT

Anna P. BELOUSOVA (Water Problems Institute of RAS)

A problem of preserving natural environment being of the same class as national security in many countries, is an important aspect of the global sustainable development problem. The main postulates of the problem have been first formulated at a top level in the Rio-de-Janeiro Meeting in 1992. In many developed countries the basic features of sustainable development are social and economic factors and the environment, that are characterized by special indicators and indexes series. By the present the underground part of hydrosphere (groundwater) as an environment component has undergone under intensive anthropogenic impact considerable qualitative transformations, that is dangerous for human health and environment. It is caused by the fact that due to the surface water pollution by industrial, agricultural and domestic waste water in many countries of the world, groundwater use for potable water supply has essentially increased. Qualitative characteristics for groundwater must be more deep and rich in content, i.e. they should specify processes of groundwater chemical composition changes under natural and anthropogenic factors impact in historical and contemporary time scale. As the groundwater being an environmental component is in a constant contact with its other components (atmosphere, lithosphere, biosphere and a sphere of anthropogenic activities), then its quality directly depends on complex physical-chemical processes, being a result of these contact. Thus, a complex assessment of groundwater quality is needed, using indicators and indexes of sustainability. **Indicator** - is an attributive characteristic of the environment state (in our case it is hydrosphere underground part), fixing an impact on it and its response to this impact. **Index** - is a quantitative characteristic of indicator describing a degree of the environment sustainability to negative impact of natural and anthropogenic factors.   The author has preliminarily elaborated a system of indicators and indexes of groundwater quality sustainability. A system of indicators (Pressure - State - Response) worked out by European Organization for Economic Co-operation and Development was taken as a basis, that was widened due to adding a new indicator of **foresight** and also subdividing all the indicators by time of their manifestation (present and future). Indicator of response is of a more complex structure, it indicates a level of accepted decisions (international, national, regional) and rate of response, planning (operation, perspective). Classification of groundwater sustainability **indexes** has been worked out for authropogenic conditions. These indexes characterizing indicators of Pressure and State are subdivided by their content into the following groups: indexes of damage, indexes of pollution (chemical indexes), static indexes (hydrogeochemical indexes), dynamic indexes and indexes of interaction. Their assessing and compiling maps of groundwater sustainability using indicators and indexes has an advantage as to other methods due to its complexness and the fact that it is also a stage in a general structure of assessing sustainable development of the studied regions.

HS02/07A/C24-007   1215

ASSESSMENT OF THE VULNERABILITY OF WATER RESOURCES SYSTEM IN CHINA

Lihua XIONG, Shenglian GUO (Department of Hydrology and Water Resources, Wuhan University)

With the water resources becoming more and more vital to human´ existenceon the earth, the reliability (or vulnerability) assessments of water resources system are increasingly recognized as the essential component of the integratedwater resources management. These assessments should evaluate the combined effects of climate change and human activities on water resources at all scales from global to regional, with emphasis on the river basin scales. It is the strength of these effects and the watershed´s hydro-climatological characteristics that ultimately determine the vulnerability of water resources system to any adverse impact. This paper is focused on one important question, i.e. how sensitive the watershed long-term runoff is to climate change. Based on the relationship of the watershed long-term runoff change rate with both the long-term precipitation and potential evaporation change rates, which is proposed by Dooge et al., the expressions of the sensitivity factor of watershed runoff to climate change are derived for the watersheds in China. The value of sensitivity factor depends on the long-term hydro-climatological conditions and the land surface properties of watershed. It is inferred that the larger the value of the sensitivity factor, the more vulnerable is the water resources system of watershed to climate change. According to the information of the average annual precipitation, potential evaporation, discharge and the information of the land surface properties of watershed, the sensitivity factors of runoff to precipitation for the nine major hydrological regions, eighty-two hydrological sub-regions of China have been calculated and ranked. It is found that the sensitivity factor of runoff to precipitation in the humid watersheds such as the southwest China is much smaller than that in the regions in need of water resources such as the Yellow river region. The vulnerability ranking of water resources system of all regions in China, which is based on the sensitivity factor of runoff, is very consistent with what the people have recognized in reality. It is hoped that this method of assessing the vulnerability of water resources system by the sensitivity factor of runoff will be useful in reasonably setting up the social and economic development plan in China.

INFLUENCE OF CLIMATE WARMING ON ASIAN LAKES FROM VIEW POINTS OF WATER RESOURCES

Hiroji FUSHIMI (The University of Shiga Prefecture)

Due to the climate warming, glaciers are rapidly melting and lakes are extremely expanding in the Nepal Himalayas, and the region faces further natural disasters including the glacial lake outburst flood and the related landslide phenomena. The water level of Lake Hovsgol in Mongolia has risen 60cm for the recent 20 years, so that the surrounding forests, pastures and the lakeshore town have been inundating year by year. Three causes of the water level rise could be noticed as follows: 1) the formation of a natural dam at the end of the lake caused by the sedimentation of sand and gravel which were transported from the tributary river at the time of heavy rain; 2) the thaw of permafrost around the lake where the ground temperature becomes higher with increases of the incoming radiation due to deforestation owing to the anthropogenic expansion of pasture and fired forest; 3) the thaw of permafrost caused by the global warming. When the average air temperature rises by 3.5 degrees Celsius in Lake Biwa basin in Japan, the amount of snow cover would significantly decrease to 60% of the average (1 billion tons) even if the precipitation exceeds by 20%. When the amount of snow cover is more than the average, the lowest dissolved oxygen concentration in the deep layer of Lake Biwa increases due to the density current of the oxygen-rich snowmelt. However, the dissolved oxygen concentration rapidly decreases, when the amount of snow cover is less than 1 billion tons. The climate warming will significantly decrease the amount of snow cover in Lake Biwa basin and the dissolved oxygen concentration in the deep layer of the lake, leading to further enhancement of eutrophication in the 21st century. There are numerous lakes in the inland mountainous regions and the coastal lowlands of Asia where the mighty rivers, such as Rivers Yellow, Yangtze, Mekong, Ganges and Indus, originate from and flow down to the megalopolises with the rapid population growth in the river mouth areas. At the first stage of the global warming, glaciers and permafrost layers melt, and the lake water increases. However, there comes the shortage period of water resources in the later stage of the global warming due to the shrinkage of glaciers and permafrost layers and this may lead to the serious environmental issues in Asia, when the water resources become scarce especially in the dry seasons. So, there is a need to create a new management system for the rational use of water resources taking into account the recent changes in glacial as well as limnological phenomena due to the climate warming.

HS02/07P/C24-018OP   Oral-Poster   **1404**

APPLICATION OF WATER BALANCE MODEL FOR REVEALING OF HIDDEN CYCLES IN THE CHANGES OF CHARACTERISTICS OF ENCLOSED LAKES (CASPIAN SEA AS A CASE STUDY)

Alexey Vladimirovich BABKIN (Lab. of Hydroecological Research of Inland Water Bodies, State Hydrological Institute)

The specific inter-year variations of level, area and water balance components of large closed lakes are caused by quasi-periodical dynamics of global and regional natural processes. The global factors are directly or through Earth climatic system affect the water regime of the lakes and their catchment areas. The revealing of hidden cycles in the variation of lake's characteristics is acute for exploration of their relationships with global factors and for forecast of their possible changes in the future. {BR} The solution of differential equation of lake water balance permitted to elaborate a mathematical model, where dynamics of the mutually related Caspian Sea characteristics (level, water surface area, evaporation and flow of water to Kara-Bogaz-Gol gulf) are the response of inflow (river run off, precipitation and ground-water run off) oscillation. The oscillation of water inflow causes the variation of sea level, area and water balance components. The extremes of sea characteristics have a time lag, if compared with impact extremes. {BR} The amplitudes of variations of sea characteristics and the time of their delay from inflow were calculated for different values of inflow and for the large number of periods. The dependencies of amplitudes of sea characteristics and the time of their delay to inflow from period of variations are exposed on the special nomographs.{BR} The observation data on water inflow and sea level were approximated by periodic functions. The least sums of quadrates of differences of approximating sinuses and the values of time series of level and water inflow were computed in dependence with the length of period. The cyclic qualities in variation of lake's characteristics are revealed near the periods where there are the minimums of sums of quadrates of differences of approximating sinuses and values of time series of level and water inflow, and where the time delay of level to inflow and relation of their amplitudes of approximating functions are close two the model results. The application of water balance model for analysis of cyclic qualities in dynamics of lake's characteristics make its results more reliable and physically based then the use of statistical approaches only.{BR} The resemble research and modeling of dynamics of lake characteristics may be fulfilled for another large enclosed water bodies of the Earth.

INDUSTRIAL WASTE WATER IMPACT ON WATER QUALITY OF ZARAVSHAN RIVER, UZBEKISTAN

Marina Stanislavovna MOLODOVSKAYA[1], Raisa V. TORYANNIKOVA[1], Nariman M. UMAROV[2] ([1]Central Asian Res. Hydrometeorological Inst., Dept. of Res. and Forecasts of Environmental Pollution, [2]State Spec. Inspection of Analytical Control of the State Com. for Nature Prot. of Uzbekistan)

Zaravshan River valley is one from the most important economical areas of Uzbekistan. The catchment area of Zaravshan River includes territories of several industrially developed areas of republic with the number of largest cities - Samarkand, Navoi, Bukhara, etc. In past, Zaravshan had been the confluent of Amu-Darya River (which is currently the main tributary of Aral Sea) but along with irrigation network development later it became the separated river system. Zaravshan belongs to rivers with the snow-glacial type of feeding. The Height of Flow Formation Zone is 2829 m.a.s.l; Total Length is 2342 km; Total Catchment Area is 12,300 km². In its low stream Zaravshan River is intensively withdrawn by channels network.

The Average Annual Discharge is 169 m³/s. About 96% of Total Runoff is used for agricultural irrigation. There are also 93 Industrial Enterprises, 52 Sewage Disposal Plants at the territory of river basin; 46 Water Intake and 46 Water Release points along the middle stream of Zaravshan River. Specific Human Water Demand in this region has increased in 1.5 times since 1975. Industrial and Domestic Wastes Inflows into Zaravshan River pose a serious threat for Water Quality and Public Health especially in urban zones with high population density. The ecological situation in region has been considerably deteriorating for recent years due to increasing fresh water demands for industrial and agricultural needs. In turn, it has led to the large-scale contamination of surface and ground water of Zaravshan River basin. The Water Quality Assessment after exposure by Waste Water is carried out using the comparison of hydrochemical data obtained from different points of Zaravshan River body with the Admissible Limits. The choice of Representative Hydrochemical Indexes was done with considering wastes composition and pollutants transformation. The main principles were formulated as following: • Representative Compounds(RC) must be specific about prevalent wastes composition;• RC must have Maximum Admissible Concentration (MAC) exceeding maximal over the other compounds;• Velocity of RC transformation after coming into water flow must be minimal. For Zaravshan there were chosen two groups of the RC. The first group is common for any type of water system:.1)BOD; 2)COD; 3)Dissolved Oxygen;4)TDS; 5)Ammonium Ions; 6)Surface Active Substances (SAS); 7)Phenols. The second group is specific one and caused by the character of wastes: 1)Oil Products; 2)Fluorides; 3)Phosphates; 4)Nitrates; 5)Nitrites; 6)Copper; 7)Chromium; 8)Lead; 9)Cyanides; 10)Arsenic, etc. The Hydrological Indexes of Average Contamination and Total Loading of River Flow were calculated with using the average concentration of pollutants in river flow at the point lower than waste water release had been done. The duration of periods of Contaminated and Pure Runoff and their volumes (in shares of Annual Average Runoff or directly in m3/year) also were calculated using Representative Indexes. This methodology can be applied either to single observing point, or river section, or water subject as a whole.

HS02/07P/C24-020OP   Oral-Poster   **1412**

STATUS, TENDENCY AND PROBLEMS OF TRANSBOUNDARY WATER QUALITY MANAGEMENT IN ARAL SEA BASIN

Raisa V. TARYANNIKOVA, Marina S. MOLODOVSKAYA (Central Asian Res. Hydrometeorological Inst., Dept. of Res. and Forecasts of Environmental Pollution)

The system of water use exploited in Aral Sea Basin for the last decades, had led to water deficiency, deterioration of surface and ground Water Quality (WQ) along with corresponding social and ecological disasters. It became one of constraining factors of region stable development. Moreover, many water subjects have lost their ecological and biotic functions as environment of aquatic flora and fauna; landscape-aesthetic shape and recreation abilities. The situation is typical one not only for Zones of Intensive Water Consumption (ZIWC) with the highest antropogenic stress on reservoirs, but also for Water Formation Zone (WFZ) where Surface Water Quality (SWQ) has been always considered satisfactory. The analysis of long-term WQ information has shown the dangerous tendency of intensification of biological productivity, i.e. there is eutrophication and, as a result, deterioration of WQ in WFZ reservoirs. The tendencies of Surface Water Quality for the last ten years are indicated. The antropogenic changing of surface runoff, disregarding the buffering water ecosystems and necessary ecological minimum of river water discharge negatively influence on their social and ecological features. Decreasing water discharges lower than Ecological Allowable Level infringes ecological equilibrium and WQ. The water warming-up increases and contents of Dissolved Oxygen reduces. The pollution density grows up even without their additional coming from outside and ˝hydrological˝ eutrophication and secondary contamination take place. In Central Asian region practically all large and numerous small-sized rivers are transboundary, i.e. they coincide with or intersect the boundaries between two or more States. Currently, the WQ management in region is represented as Complex Regional Program of interacting political, economic, technical and legal operations. That ensures the fulfillment of rules regulating and limiting harmful effect on water environment. The solution of such complicated and actual problems is possible only with coordination efforts of all Regional States, with mutual obligations on realization adequate both of water economic and water-security policies and responsibility of States for Transboundary Waters (TW) Quality state. However, nowadays in region there is not any regulating system of TW Resources Quality. Measures on protection and rehabilitation of Water Resources should be based on ecosystem approach with new understanding WQ problems. All water basins should be considered as single whole ecosystem, concerning which water economic activity is carried out. Just on the base of ecosystem approach it is possible to resolve the primary and challenge task of TW management – definition of quotas of dumping pollutants in TW for each State, appropriate agreements and responsibility for their fulfillment. In future, along with further population growth, urbanization of landscapes, social-economic development of region, antropogenic influence on WQ will be increasing, especially within low-water years. It makes us fall to thinking about the preventive measures just now, not putting off until ˝afterwards˝, and to direct efforts for restoring and preservation of Natural Water Resources.

STUDY ON THE MODELING METHOD OF LAND WATER QUANTITY AND QUALITY AND ECOLOGY COUPLING SYSTEM

Ge TAN[1], Qiting ZUO[2], Jun XIA[1] ([1]Hydrology Studio, Institute of Geographical Sciences and Natural Resources Research, CAS, [2]College of Water Resources and Environment, Zhengzhou University)

As the basic content of quantitative study on Management of Sustainable Water Resources, it is necessary, and difficult as well, to build water quantity and quality and ecology coupling system model. On the basis of application study, this paper puts forward a new method called "Multi-Box Modeling". This method's clue is definitude, calculation is simple, and model is reliable. It is confirmed by the authors that the built model can stand for "land water resources system construction connection" and can be used in quantitative study on Management of Sustainable Water Resources.

SOIL DEGRADATION OF JAVA ISLAND

Seno ADI (BPP Teknologi)

AbstractThe rapid population growth in Java island has caused the pressure to natural resources through intensive agriculture activity. Especially in the upstream region, this situation caused the soil degradation by heavily erosion lead to sediment deposition in the lower region as indicated by the sediment carried of over 10 million ton/year in one river basin in central Java. The land degradation in Java island is not only cause unproductive soil for agriculture development but also cause the disaster such as flooding as well as water crisis. The soil and water conservation activities have been introducing to carry out the land degradation. The Indonesian government under Forestry Departement has such a program called reforestation and regreening, however the farmers have their own interest for land management in relation to the farming commodity that may not take care the soil and water

conservation. The research institute has an important role to link and correspond the farmercommodity interest with the government program in such away the soil and water conservation could be implemented by conducting the appropriate technology thatfacilitate economic development for the farmers.

ASSESSMENT OF THE IMPACT OF INDUSTRIAL EFFLUENTS ON WATER QUALITY IN KORBA AND ENVIRONS, CHHATISGARH, INDIA

L.P. CHOURASIA (Department of Applied Geology,Dr. H.S. Gour Univ)

The effects of multiple industrial pollution sources on the groundwater system were evaluated in the industrial complex at Korbe of Chhatisgarh State of India. The quality of groundwater in the region has been affected negatively due to the discharge of effluents on open and land into ponds, tanks and streams. Water samples from surface water bodies and dug wells were analyzed for their major ion concentrations. The high values of electrical (EC) and concentrations of Na^+, Ca^{2+}, Cl^- and HCO_3^- indicate the impact of industrial effects on water quality. Based on the hydro chemistry, the groundwater is classified into various types such as sodium chloride, sodium-bicarbonate calcium chloride, and magnesium-chloride etc. Its suitability for drinking and irrigation purpose has been assessed. The groundwater quality in around Korba has became hazardous. Some possible remedial measure are suggested.

WATER QUALITY IN NORTHERN KARNATAKA, INDIA - A CASE STUDY

Ramaraju Hanumanahalli KAMBADARANGAPPA[1], Rajkamal[2], Prasanna Kumar N. S.[2], Ranganna G.[1] ([1]Dept. of Civil/ Environmental Engineering, Bangalore Univ., [2]Karnataka Rural Water Supply & Sanitation Agency, Rural Development & Panchayat Raj Dept.)

Of all kinds of pollution that are steadily degrading man's physical, environment. Probably the least recognised is the hidden deterioration in the quality of ground water. Diseases related to the use of contaminated ground water may be divided into those, which are caused by microorganisms, a biological agent (a pathogen), and those, which are caused by chemical substances those that are caused by chemical substances. However, these latter diseases are over shadowed in developing countries by the former, which are the main causes of disease and death. As a part of the preparatory work for the **JAL NIRMAL** Project, a Water Quality Analysis study was undertaken. The objective of this study was to access the nature, extent and severity of Water Quality problems in the project area and the underlying causes thereof. The study was under taken in three pilot districts viz. Belgaum, Dharwad, Gulbarga (and Gadag district as a special case study due to fluoride problem) and the primary data was generated on water quality. There are 281 existing water sources in the 24 villages (10 GP's), out of which 212 sources are in use. Some are not in use due to inadequate quantity and some due to meager quality. 204 samples were collected from all the sources in use and additional 26 samples were collected for analysis of pesticides. The results reveals 174 samples (85%) were found to be non potable. The full-length paper presents the Water Quality status and mitigative measures.

INTEGRATING HIGH RESOLUTION SATELLITE IMAGERY AND WATER QUALITY STATISTICS FOR WATER RESOURCE MANAGEMENT

Nandani Dhammika Kumari DAYAWANSA (Department of Agricultural Engineering, University of Peradeniya)

Water is an important natural resource and is a vital component of plant and animal life with two thirds of the earth being covered with water. Proper management of water resources is of paramount importance as the water quantity and quality deterioration is being widely reported all over the world. Scarcity and the low quality of water are serious problems that are faced by the disadvantageous communities in the less developed countries. With the above background, this study focussed on the use of multidisciplinary approach to handle the water-related issues in a cost effective and sustainable manner. The seasonal variations of the water availability in the reservoirs in a part of the dry zone of Sri Lanka are predicted with high-resolution (IRS LISS III) satellite imagery. At the same time the command areas of the reservoirs/ tanks are identified with the help of the same imagery. The water samples from the water bodies are selected to monitor the water quality status and the crop management information are gathered to be coupled with the water quantity data during different seasons of the year. The extracted information from remote sensing sources and field sampling is used to quantify the extent of water pollution and the contribution of agricultural and other anthropogenic activities on water quality deterioration. The output of the study can be used for policy formulation and determining guidelines for fertiliser and agrochemical use with a proper understanding of the uncertainty coupled with the information. The synoptic viewing capability and the quickness of gathering spatial information in remote sensing approach compared to the field surveying will be economically and technically feasible in sustainable water resource management in a rapidly changing environment.

SEASONAL VARIATION IN WATER QUALITY IN ORLE RIVER BASIN, S.W. NIGERIA 2 CHEMICAL HYDROLOGY

Catherine Imhangulaya IKHILE[1], Stella Maris AKHIONBARE[2] ([1]Department of Geography and Regional Planning, [2]New Grass Technologies)

An investigation of the chemical conditions of water bodies in the Orle River Basin in Edo State, Nigeria was carried out in 1987 and 1997. The quality of the water in the drainage basin was compared between this ten years period for any possible variation due to global changes in climate and population pressure. The results reveal that in 1987, chloride, sodium, biochemical oxygen demand (BOD5) and dissolved oxygen (DO) varied significantly with the seasons. While chloride, DO, BOD5 and COD show increase in the wet season, sodium, potassium, calcium, magnesium, iron, aluminium, silica, nitrate, sulphate and total hardness increased in the dry season and decreased in the wet season. In 1997, while total hardness, silica, nitrate iron and COD increased in the wet season, chloride, calcium, magnesium, DO and BOD5 increased in the wet season and decreased in the dry season. The values of some of the parameters are beyond tolerable limits. The degree of pollution observed in the rivers constituting Orle River Basin is sufficiently significant to necessitate pre-treatment of the basin water prior to domestic and industrial uses. Presently, the natives treat the water with alum before use, but this practice is not sufficient chemical treatment required to make the water safe for consumption.

HS02/07P/C24-027OP   Oral-Poster   1440

CONCENTRATONS OF URANIUM IN SURFACE WATER IN QINGHAI-TIBET PLATEAU

Yuefang LI, Tandong YAO, Lide TIAN, Wusheng YU, Jianchen PU (Key laboratory of Ice Core and Cold Regions Environmental Research, CAREERI, CAS)

U is not also a natural radioactive element but a heavy metal. It has radio-activity and also do harmful to human health just like lead. So many studies pay attention to this element in recent years. Study showed that human mainly intake uranium from water. So it is important to know the content of uranium in natural water. In other hand, the distribution of uranium in water has signifi-cance in geochemistry exploration of uranium and water quality assessment. The Qinghai –Tibet plateau is affluent in water resources and some big rivers are the headwaters of some world rivers such as the Changjiang River and the Brahmaputra river etc. So it is important to know the distribution of U concen-trations in waters in the plateau. We present here data on the dissolved U in surface waters as well as some ground waters in the plateau for the first time in most sites of Qinghai-Tibet plateau. The primary objective of our study is to identify the spatial distribu-tion of U concentrations and establish the background value of uranium concen-tration in the water in the plateau. This study contributes new data on the U content in waters in China. Sampling equipment were pre-cleaned in clean room and concentrations of U were determined by the ultrasensitive inductively coupled plasma sector filed mass spectrometry (ICP-SFMS) technique in clean room conditions. The data show that the concentrations of dissolved U in surface waters are in the range of 0.17 to 6.53µg/L, with a mean value of 2.56µg/L. That is higher than that of World Rivers. The concentrations of U are changeable not only in the same water system but in the different water system and show an obvious spatial variations.The highest concentration was observed in a glacial melt water comes from Xixiabangma mountain located in Himalayan region,the southern part of the plateau.The lowest concentration was found in the west-middle part of the plateau.

HS02/07P/C24-028OP   Oral-Poster   1444

ISOTOPIC EVALUATION OF GROUNDWATER SYSTEMS FOR RISK ASSESSMENT AND MANAGEMENT DURING EXTREME EVENTS

Partha Sarathi DATTA, Sunil Kumar TYAGI (Nuclear Research Laboratory, India Agricultural Research Institute)

In different parts of the world, increasing population, urbanization, and competition for economic development induced indiscriminate exploitation of groundwater and its contamination hamper groundwater management programs. Management strategies require scientific evaluation of groundwater vulnerability to depletion and pollution, and risk assessment, in relation to changes in landuse and other environmental conditions. In this context, the groundwater system in Delhi region has been described, using stable isotopes (^2H, ^{18}O) distributions in groundwater and rainfall. The isotope signatures of Delhi rainfall (^{18}O: -15.3 to +8.0‰ and ^2H : -120 to +55.0‰) generally fall along the world meteoric line, depleted ^{18}O is generally associated with heavy rainfall, and the rainfall deficient years are generally associated with relatively enriched ^{18}O in monthly rainfall. Changes in landuse result in variation in recharge from location to location, both in space and time, with a wide range of ^{18}O signatures in groundwater (^{18}O: -2.8 to-8.6‰), both laterally and vertically, suggesting occurrence of an inhomogeneous stratified system. Groundwater renewal has a selection effect in favor of isotopically depleted rainfall, with most parts receiving less than 5% recharge. Imbalance in recharge with withdrawal resulted in decline in groundwater levels by 8-10m during the last decade. Distribution of ^{18}O and Cl in groundwater suggest occurrence of two main flow systems vertically: (i) Uppermost local flow, rapidly circulating, low salinity, more vulnerable to overexploitation, and (ii) Relatively slow circulating intermediate zone and more vulnerable to salinisation and depletion. The groundwater in different parts has also become considerably vulnerable to pollution, with a wide range of nitrate (30-1600 mg/l), fluoride F (1-16.0 mg/l), Zn (3-41 Mg/l), Cu (5-182 Mg/l), Fe (279-1067 Mg/l), Pb (31-622 Mg/l), Ni ($<$1-105 Mg/l), Cd ($<$1-202 Mg/l). Increase in groundwater contaminants levels, associated with enriched ^{18}O isotope, clearly suggests increasing risk of groundwater to pollution from localized infiltration of isotopically enriched (^{18}O: -3 to -5‰) and highly contaminated agricultural and urban surface run-off water, through stagnant water pools. Governed by the zonal disparity in water supply and groundwater abstraction, many flowpaths of inter-mixing of contaminated water with fresh water bodies can be visualized from ^{18}O and Cl relationships. Risk of groundwater depletion and contamination are governed by rainfall pattern, recharge, withdrawal, and surface run-off characteristics, groundwater-surface water interactions, and sorption/desorption processes in the soil. For comprehensive assessment of risk associated with extreme events, more field research and scientific knowledge is needed on isotopic responses and dynamics of pollutants in the groundwater flow, aquifer´s attenuation capacity for contaminants, under natural and exploited conditions, in relation to land use, wastes disposal and other environmental changes. Risk can be partly minimized or controlled by restricting migration of population from surrounding states, unplanned groundwater abstraction, and eliminating wastes disposal within the protection zones, through strict enforcement of regulatory measures.

GROUNDWATER ISSUES IN PONDICHERRY COASTAL ZONE , INDIA

S.S.SUNDARVEL RAGASAKTHI (IAHS)

The intense use of ground water has caused major water-level declines and significantly decreased the saturated thickness of aquifers in some areas. In many semi-arid to arid regions, ground water has been withdrawn at rates far in excess of recharge, leading to ground-water "mining." This is often accompanied by detrimental environmental side effects, such as reduced ground-water discharge to springs, streams, and wetlands, and land subsidence. Land drainage is a source of ground-water depletion, as the construction of drainage ditches and canals in surficial systems can lead to regional lowering of the water table. A significant component of the total depletion may come from low-permeability confining layers, but they are rarely monitored and usually overlooked. The magnitude of worldwide depletion of ground water in storage may be so large as to constitute a measurable contributor to sea-level rise. But the magnitude of depletion is poorly documented worldwide, particularly in developing countries. The management concept of "sustainable development" may offer a viable approach to dealing with overexploitation of ground-water resources, but its implementation has been largely subjective and sometimes arbitrary. The purpose of this paper is to document methods and examples that would help define the magnitude of the problem in Pondicherry Coastal Zone,India and explore local and regional management approaches to mitigate the problem or assure sustainable development.
