SEASONAL CHANGE OF THE MOISTURE TRANSPORT TOWARD EAST ASIA AND THE WESTERN PACIFIC REGION DURING THE ASIAN SUMMER MONSOON

Miki HATTORI, Kazuhisa TSUBOKI (Hydrospheric Atmospheric Research Center, Nagoya University)

East Asia and the western Pacific regions are the northernmost and easternmost parts of the Asian summer monsoon region.East Asian region has a wet climate and has a large amount of precipitation especially in the Baiu/Meiyu season.In order to show how the abundant moisture and the wet climate are maintained, seasonal change of the moisture transport from the Indian Ocean to the western North Pacific and East Asia during the Asian summer monsoon is investigated.Zonal and meridional moisture fluxes which calculated from the 6 hourly data of the NCEP/NCAR reanalysis averaged from 1978 to 1998 were examined from May to September. It is found that there are three typical northward moisture transport areas: the western equatorial Indian Ocean, the Bay of Bengal and the South China Sea.Two typical eastward moisture transport areas were also found: the tropical Indian Ocean and Baiu/Meiyu region in East Asia. Characteristics of seasonal change of these moisture transports are summarized as follows. In May, there are small eastward moisture fluxes around the equatorial Indian ocean and to the south of Japan whereas little northward moisture flux in the Indian ocean and South China Sea.In June, a strong northward moisture flux accompanied with Somali jet are found in the western Indian ocean and it last untill August. It is also found that an intensification and northward spread of the eastward moisture flux in the northern Indian Ocean toward the Arabian sea and the Bay of Bengal around 20N.In the Bay of Bengal, strong northward moisture flux is also found from June to August. In the South China Sea, there are strong eastward and northward moisture fluxes from June to August. They connect to the intense eastward moisture flux area around the eastern China sea and Japan during June and July. In August, the eastward moisture flux increases and reaches to the east of the Philippines, then moisture convergence to the east of the Philippines reaches maximam of the year. On the other hand, northward moisture flux toward the mid-latitude decreases because of the relatively dry southeasterly anticyclonic moisture flux which accompanied by the subtropical Pacific high. In September, the eastward moisture flux in the north Indian ocean shifts southward and weakens. This study indicates that the moisture transport from the tropics and subtropics toward the mid-latitude around Asian summer monsoon regions are closely related to the zonal moisture transport around the northern Indian ocean and the South China Sea and that studying variation and interaction of these moisture transports are needed to understand the water circulation of the East Asian summer monsoon.

THE PRECIPITATION PATTERNS OVER AUSTRALIA AND EAST ASIA DURING THE SEASON OF AUSTRALIAN SUMMER MONSOON

Mong-Ming LU, Ru-Jun MAY (Central Weather Bureau, Taiwan)

The spatial and temporal variability of the precipitation patterns over the vast area from Australia to Northeast Asia (100-150°E, 40°S-40°N) is investigated. Three data sets are used in this study: the surface observed global land precipitation monthly anomalies in 1920-1995 (Dai et al. 1997), CPC Merged Analysis Precipitation (Xie and Arkin 1997) in 1979-2001,and NCEP-NCAR reanalysis monthly data set in 1949-2001. The station data in Taiwan during 1920-2001 is intensively used for verifying the results. Three pronounced precipitation patterns over the area from Australia to East Asia are identified. The patterns are determined based on three key areas, namely, south China and Taiwan, the Philippine Sea and northwestern Australia. Pattern-one has wet anomalies over south China, Taiwan, and Japan but dry anomalies over the Philippine Sea and northwestern Australia. Pattern-two has opposite anomalies to the pattern-one in aforementioned key areas. Pattern-three has wet anomalies over the Philippine Sea but dry anomalies over south China and northwestern Australia. After performing composite, EOF and regression analyses to the data sets, we find that pattern-one is mainly a response to El Niño and the warm SST anomalies over the Indian Ocean. Pattern-two is a response to cold SST anomalies over the equatorial central Pacific, the marginal seas of Asian continent from the South China Sea to the East China Sea, and the subtropical northwestern Pacific. Associated with the cold SSTs, there are compensating warm SSTs over the eastern south Indian Ocean, the Philippine Sea and the subtropical north Pacific. The SST anomalies associated with pattern-three are similar to

pattern-two in the tropics, but distinctly different over the northwestern Pacific, particularly in the subtropics. The contrast in the precipitation patterns and the associated large-scale fields suggests that the subtropical SST anomalies can influence the precipitation patterns in the region of study through a global-scale teleconnection mechanism. When the SSTs are warmer over the Philippine Sea and subtropical northwestern Pacific, the convection is stronger in that area, which subsequently enhance the downstream Rossby wave train that can subsequently enhance the intensity of the Asian winter monsoon. The intensity of the Asian winter monsoon makes directly impact on the phase relationship between the precipitation over south China, the Philippine Sea and the northwestern Australia.

PRINCIPAL COMPONENT ANALYSIS OF PRECIPITATION REGIMES OVER INDIAN SUBCONTINENT

Anu SIMON, Mohankumar K. (Dept. of Atmospheric Sciences, Cochin University of Science and Technology)

In a tropical country like India, the economy essentially depends on agriculture, which in turn depends mostly on the seasonal rains. The amount of rainfall however, undergoes variations from place to place and also from time to time. It will be of great importance to know whether this variability exhibits any identifiable pattern or whether the variation is purely random. As the monsoon is known to be organized spatially on a large scale and is persistent in time for several months, it will be useful to study the rainfall variability on a few optimal scales. However, since the optimal time and space scales of rainfall is not yet defined, the existence of rainfall patterns are to be investigated in a empirical manner. Eventhough, the south-west monsoon (June-September) is the major rainfall season of India, the post-monsoon season or north-east monsoon (October-December) is equally important for the southern peninsula. A study on the spatial patterns of the rainfall distribution is important. The present paper is concerned with both spatial and temporal variation of rainfall by composing the large scale data into empirical orthogonal functions (EOF) in space and principal components (PC) in time. The main emphasis of the study is to explain the spatial structure of rainfall considered and to bring out information about the seasonal, intraseasonal and interannual variability. The similarity between the western and central parts of India appears to be the most dominant feature of the annual precipitation regime. This mode of variability accounts for 50% of the total variance. The well recognized feature of the monsoon rainfall where excessive rainfall over Western Himalayas and deficient rainfall over the plains of north-west India associated with the movement of a western disturbance is brought out as a second component which explains 8% of the total variance. Monthly transitions of rainfall shows that September rainfall is an indicator for the rainfall during the first month of the northeast monsoon.

INTRA-SEASONAL VARIABILITY OF THE INDIAN MONSOON AS EXAMINED FROM THE NCMRWF ANALYSES AND GLOBAL MODEL SIMULATIONS

Sarat Chandra KAR, Shyam Vir SINGH (National Centre for Medium Range Weather Forecasting)

The Indian summer monsoon exhibits considerable intra-seasonal variability (ISV) during the summer monsoon months (June, July, August and September, referred to as JJAS hereafter) over India and its neighborhood. Intra-seasonal variability is not only seen in the spatial and temporal patterns of rainfall, it is also noticeable in observed wind patterns. Most predominant modes of ISV are popularly known as variability in 10-20 days and 30-50 days. There is also significant year-to-year variations of the ISV. At NCMRWF, global analyses are prepared on an operational basis using a global data assimilation forecasting system at T80L18 resolution, since 1994. In the present study, intra-seasonal variability of the Indian monsoon has been studied using these data for the JJAS months along with CMAP rainfall data (pentad). It was noticed that during 1998 monsoon season, considerable intra-seasonal variability existed in the sea surface temperatures (SST) over the Bay of Bengal (from TMI data and Buoy data). The NCMRWF analyses also showed similar trend as far as the atmospheric variables are concerned. In order to examine the air-sea coupling, the NCMRWF global model was run for this season using NCEP monthly SST, weekly SST, and TMI daily SST. The model could simulated observed intra-seasonal variability. This study shows that intra-seasonal variability in the Indian monsoon region could be a strongly coupled air-sea interaction process.

FOUR DIMENSIONAL RAINFALL AND LATENT HEAT RELEASE DISTRIBUTION WITH THE ASIAN SUMMER MONSOON CIRCULATION: THE RELATIONSHIP BETWEEN THE NORTH AND THE SOUTH OF THE PLATEAU

Akiyo YATAGAI (Research Institute for Humanity and Nature)

The Asia monsoon system is, in a sense, characterized with the existence of a huge landmass, namely the Tibetan Plateau, comparing with the other monsoon systems. The southern foot of the Tibetan Plateau (Himalayas), Assam-Bengal and west of Western Ghats are well known as huge-rainfall regions because of orographic rainfall in the summer monsoon season. The latent heat release over these regions is a major energy source of the monsoon circulation. However detailed structure of the heavy rainfall has not clarified yet, and satellite remote sensing data is expected to investigate in such kind of the regions. Therefore, the four-dimensional rainfall pattern over south Asia in summertime is studied, using Precipitation Radar (PR) data acquired by the Tropical Rainfall Measuring Mission (TRMM). We used three years (1998, 1999 and 2000) rain rate and near surface rain products and made composite rainfall pattern for both diurnal and Indian-monsoonal active/break cycles, in order to overcome a weak point of sampling error of TRMM/PR. For comparison latent heat release is computed with ECMWF operational with 0.5 grid resolution dataset for the same period. Since the plateau exerts a significant influence on mid-latitude arid climate as well as very wet climate in the South Asia, we analyze the above mentioned variations with respect to the relationship between the north and the south the Tibetan Plateau. It is well-known that most part of land area shows precipitation maximum in the evening (afternoon hours), however strong convective precipitation along the foot of the Himalayas (Nepal, Bhutan, and Assam region) is seen at around the mid-night (18 UTC, 00 LST) to the morning (00 UTC, 06 LST). Latent heat release by ECMWF data shows roughly corresponding diurnal cycle with 1km order in the altitude and 500 km order in the horizontal scale. The independent upper tropospheric humidity estimated from GMS-5 water vapor channel reveals more moisture in the morning than that in the evening tat around the Tibetan Plateau (over the foot of Himalayas, Taklimakan Desert and west part of Chinese plain region) with a ring structure about 500 km in horizontal scale. So we conclude the strong convective precipitation observed along the foot of Himalayas in the mid-night to the morning, heat the mid-troposphere more than that in the daytime, and vertically transport

moisture to the upper troposphere more than that in the daytime. In the active phase of the Indian monsoon, precipitation mainly occurs over the whole part of India, Bay of Bengal, and west of the Western Ghatz, while in the break phase very strong precipitation is seen in the foot of the Himalayas and over Bangladesh. Although summer precipitation at the Himalayas and at the Western Ghats is almost the same, the averaged storm height is around 5km around the west of Western Ghats in the active phase, while in the south of Himalayas, it reaches almost 10km in altitude in the break phase. Related atmospheric circulation, atmospheric heating, and their interannual variability are also shown at the conference.

MC03/11P/A07-002   1420

SEASONAL AND DIURNAL VARIATION OF SURFACE TEMPERATURE OVER THE TIBETARN PLATEAU USING GMS DATA

Yuichiroh OKU, Hirohiko ISHIKAWA (Disaster Prevention Research Institute, Kyoto University)

In the progress of Asian summer monsoon, the Tibetan Plateau has been thought to play an important role as an elevated heat source/sink protruded into the middle of troposphere. All the thermal effect from the Tibetan Plateau to atmosphere is passing through the near surface and boundary layer to free atmosphere. During the GAME (GEWEX Asian Monsoon Experiment), surface sensible and latent heat fluxes were measured at some sites with eddy covariance technique. From the surface measurements of GAME/Tibet, it has revealed that the boundary layer is characterized by its strong diurnal cycle. Although the land surface atmosphere interaction is experimentally revealed at these sites, they only represents fluxes in a patch scale around the measurement site. Thus, it is necessary to estimate the diurnal change of surface fluxes, and integrate the patch scale knowledge to the regional scale understanding over the plateau. Remote sensing from satellites offers the possibility to derive regional distribution of various surface meteorological elements in combination with sparse field experimental stations. For this purpose it is required to use the continuous data observed by geostationaly satellite. For the Tibetan Plateau the GMS-5 provides continuous measurements from June 1995. The advantage of GMS is to observe the earth from a stationed position to monitor the change of meteorological phenomena at short time intervals. This advance makes it possible to analyze intra-diurnal variation over large area. We develop a methodology to retrieve one of important surface parameters, the land surface temperature, using GMS/VISSR images. The surface temperature retrieval method, infrared sprit-window algorithm, for NOAA/AVHRR measurements is applied with some modifications. The results of comparing estimated surface temperature from GMS data using this algorithm with in-situ surface measurements shows high correlation coefficient, it is nearly 0.8 or over. Almost 7 years, from 1996 to 2002, hourly surface temperature data is prepared. Analysis using this data shows the difference of diurnal variation of surface temperature between the eastern plateau and the western, which caused by the difference of surface condition. In the western plateau, the falling ratio of surface temperature in spring nighttime is about 1 K per hour, which is twice as quick as that in the eastern. In the morning, although it is less of obvious, the heating is faster in western than eastern. This seems to be caused by the difference of surface condition between the western plateau and the eastern. The western part of the Tibetan Plateau is relatively dry, so that the radiative cooling in the nighttime expects to become much stronger than the eastern. Also, the ground surface of the western plateau is easy to be heated and cooled. Thus, diurnal range of surface temperature is about 5 K greater in the western plateau than in the eastern.

MC03/11P/A07-003   1440

ATMOSPHERIC WATER VAPOR AT KOTOTABANGDURING DIFFERENCE PERIODS OF SEASONAL RAINFALL

Yudi Iman TAUHID[1], Manabu D. YAMANAKA[3], Tien SRIBIMAWATI[2], Mori SUICHI[1], Hamada JUN-ICHI[1], Peiming WU[1], Taichi SASAKI[1], Noriko OKAMOTO[3], Fumie MURATA[3], Namiko SAKURAI[3] ([1]FORSGC, JAMSTEC, [2]Agency for the Assessment and Application of Technology (BPPT), Jakarta, Indonesia, [3]Graduate School of Science and Technology, Kobe University, Japan)

Atmospheric water vapor is an important parameter governing various processes of hydrological cycle ranging from global to local. It becomes more crucial in humid tropical region, since this area has the greatest water vapor amount corresponding to the equatorial strong solar radiation and high temperature through the year. In particular, the Indonesian maritime continent area plays a role of the major latent heat source due to high humidity evaporated from Indo-Pacific warm water pool. This paper will describe the temporal and vertical variation of atmospheric water vapor and wind related to the seasonal rainfall amount of this region. Atmospheric water vapor at Kototabang (0.2° S, 100.3° E, 864 MSL), West Sumatra-Indonesia has been observed intensively during different seasons (May-June, August and November 2001), mainly with GPS rawindsondes (508 launches) and GPS water vapor soundings. Concerning seasonal variation of rainfall amount, each period (28 days continuously) has been designed as transition, dry and rainy seasons respectively. Vertical variations of specific humidity (q) in the three periods show values of q are the highest (10-18 g/kg) at below 2 km heights and gradually decrease as increasing the height (at 8 km above surface then q values are less than 2 g/kg). Daily variations of q seem more clearly during transition season than other seasons, especially near surface (below 2 km). Meanwhile, between 3-7 km heights, variations of q are less variablr during rainy season than the other seasons. Estimated precipitable water by GPS rawindsondes (PWR) and by GPS water vapor soundings (PWG) have showed good agreement. Higher values of PWR are related to higher values of PWG as well as higher rainfall amounts. Mean diurnal variations of PWR during transition periods have larger variations (35-42 mm) than dry (33-37 mm) or rainy (37-40 mm) seasons, but each maximum values appear at similar local time, around 19 LT for all seasons. There is a seasonal shifted of diurnal cycle of PWG which is coincided with seasonal variation of diurnal cycle of moisture fluxes in both zonal and meridional. Concerning the seasonal variation of zonal moisture flux in the lower atmosphere (approximately below 6 km), eastward moisture fluxes become stronger, maximum values are increasing from transition (50-60 g/kg.m/s) to rainy (90-100 g/kg.m/s) seasons. Not only the maximum values but also the duration (more longer) and height (more higher) of large fluxes are increasing. On the contrary, in the upper layers (6-10 km heights), westward mosisture fluxes are weaker. It was confirmed that the lower level moisture fluxes come from Indian Ocean (which can bring abundant of water vapor) into the study area (associated with westerly and southerly) dominantly during rainy season.

MC03/11P/A07-004   1520

SURFACE HEAT AND WATER BALANCE TRENDS IN EASTERN ASIA IN THE PERIOD 1971-2000

Jianqing XU[1], Shigenori HAGINOYA[2], Kazuyuki SAITO[1], Ken MOTOYA[1] ([1]Frontier Research System for Global Change, [2]Meteorological Research Institute)

Climatic variations over Eastern Asia, including the Tibetan Plateau, were analyzed using meteorological data for 32 points in the period 1971 to 2000. Changes in heat and water balances were examined using potential evaporation and a wetness index as suggested by Kondo and Xu (1997a, 1997b). Climate zones in Eastern Asia identified by the wetness index matched well with the distribution of vegetation. Average monthly temperatures

increased over the 30 years, with the sharpest increase in February. The data showed that diurnal temperature ranges have decreased, but the range of ground surface temperature increased in recent years. Vapor pressure shows increase trends in most of the stations, this is due to the temperature increase. But the trends of relative humidity are decreased in most of the stations. It is suggested that although the water vapor become abundant in the atmosphere, but it is harder to condense to cloud because of the temperature increase. We also noticed that the cloud amount shown a decrease trend in the most of the stations. From the Tibetan Plateau, through central China, to southern Northeast China, there has been an increase in potential evaporation and pan evaporation, which may be related to higher temperatures and a lack of surface water.

MC03/11P/A07-005   1540

MODES, MECHANISMS AND TELECONNECTION OF TROPICAL NORTH AFRICA CLIMATE VARIABILITY

Abebe YESHANEW (National Meteorological Services Agency)

Modes of tropical North African hydroclimate variability are investigated based on rainfall and Nile River stream flow data (1950-1998/7) using continuous wavelet transform (CWT). It is found that Sahelian climate is characterised by ENSO timescale and decadal rhythm. The mountainous and equatorial regions are attributed by high frequency and interannual signals. The mechanisms that control this broad spectral mode of tropical North Africa climate are studied based on NCEP/NCAR ocean-atmospheric reanalysis and is found that large-scale east-west overturning of Atlantic and Pacific drive the hydroclimate swing of the North Africa through the upper-level velocity potential dipole and convection polarity. The ENSO mode determines the pole and the strength of the polarity between North Africa and South America through these zonal circulations. The tropical North Africa climate teleconnection with regional atmospheric circulation corroborates with long record that Pacific Walker Circulation-Atlantic Zonal Circulation are pivotal large-scale circulations that control the tropical North Africa climate variability. Integrated global angular momentum and quasi-biennial oscillation also play a significant role. Locally, the African Easterly Jet associated to Indo-Pacific SST determines the rainfall dipole configuration between Sahel and Guinea Coast.

MC03/11P/A07-006   1600

SOME RECENT STUDIES OF THE CHARACTERISTICS OF WEATHER SYSTEMS (INCLUDING THE MONSOON SYSTEMS) OF WEST AFRICA USING SATELLITE DATA

Simon Oyediran OJO (Department of Geography,University of Lagos)

In most previous writings on West African weather, there have been problems obtaining data for accurately examining the characteristics and consequences of patterns of the weather systems. With the recently available satellite data in Nigeria, it has become a big challenge for meteorologists and climatologists to use this satellite data and information to critically examine the characteristics and patterns of the weather and climate systems and their implications for the characteristics and consequences of environmental change in the region, and for better understanding of the weather systems in general and the monsoon systems in particular. It is the purpose of this paper, therefore, to examine the characteristics and consequences of ocean-atmospheric interactions and their consequences for the weather systems, and with special emphasis on the monsoon systems during the rainy season. Satellite data for 1998 and 1999 rainy seasons were used for detailed illustrations, and with respect to (a) the beginning of the rainy season (b) the middle of the rainy season (c) the little dry season and (d) the end of the rainy season. The paper first discusses the main factors usually associated with the characteristics and consequences of the weather systems, including the intertropical discontinuity (ITD) and the ocean factor, winds, topography, land and sea contrasts, which are especially significant for local scale systems and the characteristics and consequences of the disturbances during the period of study. The paper then discusses the various characteristics and consequences of the weather systems as they relate to meso and micro scale systems in West Africa, and the significance of the dynamic controls, particularly the relative significance of topography and land and sea contrasts as major factors in the potential predictability of the monsoonal systems, and developing prediction models for West Africa. The results of the study show that (a) although the ITD and the ocean factor are significant for inducing significant changes in the characteristics and patterns of change in the air-sea interactions, it is becoming clearer that (a) the influence of topography and micro scale land and sea contrasts are very significant factors influencing and initiating evolution of the weather systems, while the ocean and other factors influence the changes in the patterns of movement of the weather systems and (b) the characteristics of the variations and change in the patterns of movement of the weather systems are also significantly affected by the weather systems in other parts of the world especially by the European weather. The implications of the results for improving forecasting and prediction of weather and climate in West Africa are then discussed, particularly as regards (a) the need for consideration and inclusion of most of the significant factors in developing models for the region (b) the need for adequate considerations of the three scales of operations of weather and climate systems, namely macro, meso, and micro scales, in developing such regional models and (c) the need for continued acquiring of satellite and other data and information for continuous monitoring of the weather systems and their implications.

SEVERAL DAYS VARIATION OF TEMPERATURE INVERSIONS OVER THE PRE-MONSOONINDOCHINA PENINSULA AND THEIR EFFECTS ON THE TRANSITION TO MONSOONONSET

Shin-Ya OGINO[1], Yoshihiro TACHIBANA[2], Masato NODZU[1], Eisho AZUMA[3], Yoshinori KAMATA[3], Yuko KAMIAKITO[3] ([1]Graduate School of Science and Technology, Kobe University, [2]Liberal Arts Education Center, Tokai University, [3]Graduate School of Science, Tokai University)

Characteristics of several days variations of temperature inversionswhich frequently appear over the Indochina Peninsula in the late dryseason were described and physical mechanism of the variations wereexamined based on the thermodynamic equation. We have found that

M

thevertical advection of temperature is one of the important processeswhich cause the several days variations of inversion heights. Thebackground and purposes of this study are described below in detail. The Indochina peninsula is the peculiar region where the rainy seasonstarts earliest among the other Asian monsoon regions. To clarify thereason for this peculiarity is one of the most important issues amongthe Asian monsoon studies. Several factors which control thebeginning of the rainy season over the Indochina peninsula areconsidered: large scale subsidence, temperature inversion, transportedhumid air from the ocean, sensible heat flux, synoptic scaledisturbances propagating from mid-latitude, and so on. For example,the inflow of the humid air may activate convections, while the largescale subsidence may have an effect to suppress convections. Amongthese factors, the role of temperature inversion is of our interest. We noticed that strong temperature inversions appear at 3-4 km heightin the late dry season over Thailand. Our preliminary analysis usingworldwide radiosonde data clearly showed that the region from thenorthern part of Indochina peninsula to the southern part of China isone of the peculiar region where the strong and high-level inversionsappear in the late dry season. We consider a possibility that theseinversions play an important role on the seasonal transition from dryto rainy seasons. The temperature inversion may suppress convections,because the inversion is a quite stable layer. This is an essentialrole due to the inversion. However, the suppression of convectionsmay result in the separation of the air above and below the inversion.As a result, some atmospheric quantities and matters, such as heat,water vapor and aerosols, may be accumulated below the inversion. Theaccumulation of heat and water vapor below the inversion may decreasethe atmospheric stability, which can rather activate convections. Theaccumulation of aerosols below the inversion may affect the radiationbudget and cloud generation process. But, it is not obvious whetherthese effects would activate or suppress convections, because whichstrongly depends on the property of the aerosols. In any case, theessential and accompanying effects of the temperature inversionpossibly modulate or control the seasonal march of the thermodynamicfields and the beginning of the rainy season. Based on the abovementioned preliminary considerations, we have startedto study the temperature inversions over the Indochina peninsula in thedry season. The objectives are (1) to understand the physicalmechanisms of the generation, maintenance and disappearance of thetemperature inversions and (2) to understand the role of the inversionson the seasonal transition over the Indochina peninsula. It is expectedthat this study would provide us physical understanding on thetransition process from dry to rainy seasons over the Indochinapeninsula.

MC03/11P/D-002 Poster 1400-177

FINE VERTICAL STRUCTURE OF THE HORIZONTAL DIVERGENCE OVER THE ASIAN SUMMER MONSOON REGION

Noriyuki NISHI (Graduate School of Science, Kyoto University)

Fine vertical structure of tropical circulation in the middle and upper troposphere was investigated, particularly paying attention to (horizontal) divergence and vertical wind. It is still difficult to make direct observation of large-scale (>1000km) divergence; precise data was limited to several special intensive periods and regions (e.g. TOGA COARE IOP 1992-93). Lack of direct observation results in poor reliability of divergence field in global objective analysis. Data analysis of divergence in some global analyses was conducted to detect meaningful regional fine structure. To get supporting evidence for the reality of patterns detected in global analysis, some indirect physical variables which were observed rather directly and precisely were also analyzed. In most part of the tropics (15S-15N), the sign of climatological divergence at a point is same throughout the upper troposphere (300-150hPa) in global analysis datasets (ECMWF, NCEP Reanalysis and JMA). However, complicated vertical change of sign is detected in some specific regions and seasons; the most remarkable patterns were detected in Asian monsoon region in JJA, south Indian Ocean in JJA and around Philippine in DJF. Sounding data and remote sensing data by satellites were used to confirm the reality of detected patterns. In this presentation, results on the pattern in Asian monsoon region in JJA are presented with using TRMM satellite data and GMS5 data. The most typical case was detected in ECMWF operational analysis during the period of 18-22 June 1998. In this period, clear western edge of cumulus activity was almost fixed at 85E. Westerly with speed of more than 15m/s were dominant in the lower troposphere, whereas easterly with speed of 30-50m/s at 70-100E along 10N at 100-200hPa. Though upward motion in ECMWF analysis dominated from the sea surface to the tropopause height in the east of 85E, the height range of upward motion was gradually confined to the top of upper troposphere as shifting to the west: it confined above 400hPa at 82.5E and only around 200hPa at 80E. In GMS infrared image, each cluster remained several hours; convective part of each cluster was stagnant or moved slowly to the east. In most of the clusters, the high cloud top (less than 210K) in TRMM Virs Channel 4 (IR) image extended 200-500km west of the western edge of near-surface precipitation in TRMM TMI. Observed shallow pattern of divergence with several kilometer scale in the upper troposphere results from horizontally extended upper tropospheric stratiform clouds in the extremely strong wind shear in Asian monsoon region.

MC03/11P/D-003 Poster 1400-178

THE CHARACTERISTICS OF INDIAN OCEAN DIPOLE MODE - PRELIMINARY STUDY OF THE MONSOON VARIABILITY IN THE WESTERN PART OF INDONESIAN REGION -

Eddy HERMAWAN (The Indonesian National Institute of Aeronautics and Space (LAPAN))

Prediction of El-Nino and Southern Oscillation (ENSO) phenomena in Indonesia, generally is corresponded to the Sea Surface Temperature anomaly (SSTa) and Southern Oscillation Index (SOI) along West to East Pacific Ocean between Darwin (Australia) and Tahiti (Hawaii Islands). This phenomena is assumed having a good correlation with the moving average of convective activity, especially in the western part of Indonesia region which always covered by giant clouds like Cumulonimbus (Cb). Since only a few atmospheric and oceanography data in this region, we tried to investigate in this paper the preliminary results of the characteristics of Indian Ocean Dipole (IOD). We used the Sea Surface Temperature (SST), Sea Level Pressure (SLP) and Outgoing Longwave Radiation (OLR) of Dipole Mode Index (DMI) anomaly. By applying the spectrum method, we found that the most predominant peak of these parameters are three months oscillation such as on SST and SLP data analysis. While, for OLR data, the most predominant peak is six months oscillation. We suspect these phenomena are correspond the transition season from dry to rainy season for SST and SLP, and Monson season for OLR.

MC03/11P/D-004 Poster 1400-179

DIURNAL VARIABILITY OF THE PRECIPITABLE WATER OVER THE EAST ASIA DURING GAME-IOP

Nobuhiko ENDO (Frontier Research System for Global Change)

The water cycle of the Asian summer monsoon has many influences on agriculture, economy and human life over the broad Asian region. GAME and SCSMEX were conducted over the Asia in the early summer of 1998. One of the objectives of the both projects is to investigate the water and energy cycle in the Asian summer monsoon system. Diurnal

---

variability of convective activity over the western Pacific, the Southeast Asia and the Tibetan plateau have investigated by several researchers. However the diurnal variability of precipitable water (PW) has not been understood well. In this paper we will describe the seasonal change of the precipitable water (PW) and the diurnal variability of the water vapor over the East Asia using the GAME and SCSMEX data sets.Enhanced upper-air observation was carried out during the GAME and SCSMEX IOPs. The frequency of upper-air soundings is about two to four times per day. However the enhanced observation period is different from region to region. For example the enhanced observation was made from May to June around the South China Sea while the enhanced observations was conducted from May to August over the Tibetan plateau. PW is evaluated by the trapezoidal formula using with the significant level data. We define the daily mean of PW is average of the data at 00 UTC and that at 12 UTC for describing the seasonal change of PW with twice daily routine upper-air observation data, although twice daily sampling of upper-air soundings have some biases (Dai et al., 2002). In May, the daily mean of PW is about 50 mm in southern China and is about 10-20 mm in northern China. Over the Tibetan plateau, PW is less than 10 mm. As the Meiyu frontal zone and/or monsoonal flow advance to the north, PW is increased over central and northern China. Seasonal change of PW is relatively small around the coast of the South China Sea.Diurnal variability of PW is investigated with fourth daily soundings and objectively analyzed data. During the monsoon season the daily maximum of PW was appeared at 18 UTC (about 02 local time) over central and southern China. Although the surface evapotranspiration is vigorous in the daytime, the daily minimum of PW was observed at 06 UTC (about 14 local time). The amplitude of the diurnal variability is about 4-5 mm in central China. The fraction of the diurnal variability is extremely large over the Tibetan plateau, although the diurnal range of PW is less than that at lower altitudes. Diurnal variability of PW and its relationships to the monsoonal flow are discussed.

MC03/11P/D-005 Poster 1400-180

CLIMATOLOGY AND TRENDS OF LOW LEVEL CLOUD IN THE EAST ASIA DURING SUMMER

Nobuhiko ENDO (Frontier Research System for Global Change)

Clouds play important roles in water cycle and have influences on the radiation budgets. Houghton et al. (2001) summarized many aspect of the global change. It is considered that increased surface temperature may induce enhancement of water cycle. Sun and Groisman (2000) and Sun et al. (2001) reported the change of the frequency of low-level cloud in Former USSR and United States. However climatology and trends of low-level cloud in the East Asia are not well understood. In this paper we will present climatology and trends of frequency of low-level cloud appearance for the East Asia.The Extended Edited Cloud Report Archive (EECRA; Hahn and Warren, 1999) for the period of 1971-1996 is main data sets of this study. We selected the stations met following conditions: the stations are in the region from 70E to 135E and from 15N to 55N, and have at least 100 reports for each month of each year. Although the low-level cloud codes have 9 cloud types, we re-categorized cloud codes into four cloud types (St/Sc/Cu/Cb). The frequency was obtained for each month of each year at each station.Climatology of the frequency of the low level cloud was obtained for 26-yrs data. Dominant low level cloud type is cumulus over northwestern, northern and central China in JJA. Cumulonimbus is frequently observed in the Former USSR and over the Tibetan plateau. In Korean peninsula, northeastern China and Thailand, stratocumulus is dominant in low-level cloud during JJA. Dominant low level cloud type in southern China is stratocumulus in May, while Cumulus cloud frequency tends to become predominant in July. Linear regression analysis and the nonparametric Mann-Kendall rank test was employed to detect the trend of frequency of low level cloud. Cumulus cloud frequency has decreasing tends before the monsoon season over the most of China, and the frequency of cumulonimbus also tended to decrease in Thai and the coast of South China Sea in May for the period of 26-years. On the other hand Stratocumulus frequency increased in Thai, the coast of the South China Sea, eastern Tibetan plateau, northeastern China and Mongolia. The trends for the other months also have same features. Trends of surface specific humidity and precipitable water and its relations to the trends of the low-level clouds are also discussed.

THE WITHDRAWAL OF THE BAIU CAUSED BY MID-LATITUDE WAVES

Shin-ichi SUZUKI (Disaster Prevention Research Group, National Research Institute for Earth Science and Disaster Prevention)

The Baiu is a rainy season in early summer around the East Asia. Compared with the onset of the Baiu season, the withdrawal of the Baiu is an abrupt seasonal march in Japan. Usually, the Baiu front, a precipitation belt in the Baiu season, disappears in late July as a high pressure anomaly area appears around Japan. Ueda et al. (1995) explained this high pressure anomaly as a Rossby-wave propagation excited by the convective heating in subtropical western North Pacific. However, such a relationship between the withdrawal of the Baiu and convective activity in subtropical region is not always evident. In our study, the formation mechanism of the high pressure anomaly, which appears around Japan in the process of the withdrawal of the Baiu, is analyzed during the past 23-year from 1980 to 2002,using NCAR/NCEP reanalysis data. Assuming that these high pressure anomalies are formed by propagation of Rossby-waves in our analysis, we calculate wave-activity flux (Takaya and Nakamura, 1997) to analyze the propagation of Rossby-waves. In climatological data, a pair of low pressure anomaly in the subtropical western North Pacific and high pressure anomaly around Japan clearly appears in late July at the lower troposphere, as shown by Ueda et al.(1995). This situation corresponds to the withdrawal of the Baiu in climatological data. However, the results of the analysis of individual cases indicate that such a clear pattern of the wave propagation from subtropical region hardly appear at the withdrawal stage of the Baiu. On the other hand, over half of high pressure anomalies are associated with various kinds of disturbances in midlatitude, such as stationary Rossby-waves, non-stationary Rossby-waves, synoptic disturbances, and so on. There is no withdrawal of the Baiu related to the disturbances in midlatitude in our analysis of climatological data.

INTRASEASONAL RAINFALL VARIATIONS IN A MOUNTAINOUS REGION OF SUMATERA, INDONESIA

Jun-Ichi HAMADA[1], Manabu D. YAMANAKA[2], Shuichi MORI[1], Yudi Iman TAUHID[1], Tien SRIBIMAWATI[3] ([1]Frontier Observational Research System for Global Change / Japan Marine Science and Technology Center, [2]Frontier Observational Research System for Global Change / Japan Marine Science and Technology Center, and Kobe University, [3]Indonesian Agency for the Assessment and Application of Technology)

Localities of intraseasonal variations in a mountainous region of Sumatera, Indonesia are examined by using pentad rainfall data at 46 stations in 1992. The most remarkable characteristic of rainfall variations is the contrast between the coastal and the inland mountainous region. Annual rainfall amounts are more abundant in the coastal region (more

than 3,000 mm/year) than in the inland region (1,000-3,000 mm/year). As for the intraseasonal variations, three types in which rainfall is distributed mainly near the coast, mainly in the inland area and over the whole region are found. Intraseasonal variations are dominant for the occurrence of the coastal / the whole active type rainfall patterns, whereas seasonal variations with southern-hemispheric summer maximum is predominant for the inland type rainfall. From correlation and composite analyses, rainfall variations in the coastal region are well related with large-scale cloud disturbances over the Indian Ocean accompanying with low-level westerly wind. Whereas, inland rainfall variations are related with convection near large islands such as the southern part of Sumatera, Kalimantan and Jawa (in the central part of the maritime continent) mainly during easterly wind period. It may be suggested that coastal rainfall is governed by the large-scale cloud disturbance over Indian Ocean (intraseasonal variations) and inland rainfall is mainly caused by local circulation (diurnal variation). Besides, rainfall variations in a mountainous region of Sumatera may be controlled by the interaction between surface topography and monsoon.

THE CONVECTIVE ACTIVITY IN PRE-MONSOON OVER THE INDOCHINA PENINSULA

Masashi KIGUCHI, Jun MATSUMOTO (Department of Earth & Planetary Science, University of Tokyo)

The convective activity in Pre-monsoon over the Indochina Peninsula was investigated using the daily mean reanalysis data, the OLR data and rainfall data in 1998. In early April, middle April and early May (Pre-monsoon season), the lower OLR region extended southward from the mid-latitude zone to the Indochina Peninsula. The interval of southward extension was about 10-20 days. After the periodic convective activity, the lower OLR region migrated northward from the low-latitude zone in middle May. After that, the major part of the Indochina Peninsula was under the lower OLR area. The spatial scale of the periodic convective activity before the monsoon onset was not local, but synoptic. The southward extension of the cold air at 600hPa occurred periodically in accordance with the periodic convective activity. According to the time series of specific humidity in the inland area of the Indochina Peninsula (12.5-22.5N, 100-110E) and zonal wind along 110E (12.5-22.5N) at 850hPa, peaks of specific humidity from April to early May coincided well with the periodic convective activity over Thailand. During this period, when zonal wind was easterly from the South China Sea specific humidity increased. On the other hand, after the monsoon onset, specific humidity increased when zonal wind was westerly. Furthermore according to the distribution of the specific humidity and wind at 850hPa from 1st to 3rd April in 1998, the moisture inflow from the South China Sea came along the edge of the North Pacific high. We calculated the time-latitude section of lapse rate between at 700hPa and at 600hPa, and between at 850hPa and 700hPa, respectively. Between at 700hPa and at 600hPa, the unstable conditions existed at the periodic convective activity. It was suggested that weakening of strong inversion layer. While between at 850hPa and at 700hPa, it was found that the unstable condition of the lower layer was cyclic in pre-monsoon season. The unstable conditions existed before the periodic convective activity. Then after the rainfall the lower layer became stable. But after the monsoon onset, such unstable conditions did not exist at the lower layer. It was found that the cold air extended southward before the periodic convective activity. Further it was clear that the easterly belong the edge of the North Pacific high from the South China Sea brought in the increase of moisture in the inland area of the Indochina Peninsula. It was suggested that the periodic convective activity in pre-monsoon season was related with the southward extension of cold air from the mid-latitude zone and the increase of moisture in the inland area of Thailand from the South China Sea. Furthermore, according to investigate the unstable condition, the unstable condition of the middle layer (about 3-4km) and of the lower layer (about 1.5-3km) existed at and before the periodic convection, respectively. We suggested that the heating of the surface and the inflow of the cold air produced the lower and the middle unstable condition, respectively.

DIURNAL LAND-SEA RAINFALL PEAK MIGRATION OVER SUMATRA ISLAND, INDONESIAN MARITIME CONTINENT OBSERVED BY TRMM SATELLITE AND INTENSIVE RAWINSONDE SOUNDINGS

Shuichi MORI[1], Jun-Ichi HAMADA[1], Yudi I. TAUHID[1], Manabu D. YAMANAKA[3], Noriko OKAMOTO[2], Fumie MURATA[2], Namiko SAKURAI[2], Tien SRIBIMAWATI[4] ([1]Frontier Observational Research System for Global Change (FORSGC), Japan Marine Science and Technology Center (JAMSTEC), [2]Graduate School of Science and Technology (GSST), Kobe University, Japan, [3]FORSGC, JAMSTEC and GSST, Kobe University, Japan, [4]Agency for the Assessment and Application of Technology (BPPT), Jakarta, Indonesia)

Diurnal cycle of rainfall and its regional variation around Sumatra Island, Indonesian maritime continent are examined mainly using TRMM satellite Precipitation Radar (PR) and intensive rawinsonde observations. Based on the advantages of PR sensor that can detect raindrops directly regardless of the ground and cloud conditions, and distinguish rainfall into stratiform and convective types, following characteristics are found regarding the rainfall variation over this area.1) Convective rainfall in the late evening is predominant over the land region of Sumatra Island, whereas rainfall in the early morning composed of both stratiform and convective types almost evenly is predominant over the surrounding sea region of the island.2) A rainfall peak in the daytime and that in the nighttime migrate with time starting from the southeastern coastline of the island into the inland region and into offshore region, respectively. The total distance of migrations is up to approximately 1,000 km per day that equals to roughly 10 ms-1 of average migration speed.3) Using intensive rawinsonde observation data, it is also found that remarkable diurnal variations appear also in the middle troposphere corresponding to the migrating rainfall peaks over both the inland and coastal sea regions.4) Finally, a mechanism of the rainfall peak migrations is discussed comprehensively using TRMM PR, rawinsonde, Equatorial Atmospheric Radar (EAR), Geostationary Meteorological Satellite (GMS), and ground based observation data.

FORMATION PROCESS OF THE PRECIPITATION SYSTEMS IN THE MEIYU FRONT ON THE CHINA CONTINENT DURING GAME/HUBEX 1998

Takeshi MAESAKA[1], Hiroshi UYEDA[1], Teruyuki KATO[2], Masanori YOSHIZAKI[2] ([1]Hydrospheric Atmospheric Research Center, Nagoya University, [2]Meteorological Research Institute, Japan Meteorological Agency)

The Meiyu front is a part of activities of the East Asian summer monsoon. In this paper,the characteristics and detailed structures ofthe precipitation system in the Huaihe River Basinduring the Intensive Observation Period (IOP) of theGAME (GEWEX Asian Monsoon Experiment)/HUBEX(Huaihe River Basin Experiment) 1998 were investigated with dual Doppler radar, heat and moisture budget analysis, and numerical simulation to clarify the formation process of the precipitation systemsin the Meiyu front on the China Continent. During the IOP, severe precipitation associated with the Meiyu front was brought on 29 June and 2 July 1998.The precipitation event on 29 June was associated with the Meiyu front moving northward in the subtropical air mass(ISA type), while the precipitation event on 2

July was associated with the Meiyu front which located on thepolar front (OPF type) and moved southward. The ISA-type Meiyu front moved northward,and two types of precipitation systems formed in this front.One was the organized pair of the convective precipitation system on the convergence line near the ground, and the stratiform precipitation system formed to the north ofthe convective precipitation system. The other was the linear convective precipitation system to the south ofthe convergence line near the ground.In the former precipitation area, the stratiform precipitation system generated a cold pool nearthe ground. This cold pool intensified the local temperature gradient to maintain the Meiyu front,although there were only weak or reversed thermal gradient in the subtropical air mass.In the latter precipitation area, because the airnear the ground was very moist, weak cold pool was enough to cause the condensation to createa successive linear convective precipitation systemin the leading side. The OPF-type Meiyu front had the temperature and moisture gradient and moved southward, since the polar air mass spread to 30 °N in latitude.This Meiyu front also accompanied with the organized pair of the convective and stratiform precipitation systems to the north of the convergence line on the ground. However, there was not any precipitation system to the south of the convergence line,since the lifting condensation level (LCL)was higher than that in the ISA type; therefore,a new convective precipitation system was generated with the synoptic convergence. The difference of the precipitation processes between two types of Meiyu fronts was caused by the difference of the LCL to the south of the front, and the difference of the LCL associated with the latitudinal front motion.

SIMULATION OF HEAVY RAINFALL EVENTS DURING INDIAN SUMMER MONSOON USING A MESOSCALE MODEL

Sijikumar S[1], Mohankumar K[2], Joseph V. PORATHUR[3] ([1]Research Student, [2]Professor, [3]Visiting Professor)

During south west monsoon season the west coast of India observes heavy rainfall events. One of the reason for these events is the formation of off-shore vortex. Offshore vortices are mesoscale in character with linear dimensions of the order of 100 km or even less and their presence is detected by weak easterly winds at coastal stations. The peculiarity of the rainfall associated with these vortices is that the rainfalls over the coast are heavier than those over hill stations just few kilometers east. Identification is the greatest difficulty in the study of these vortices because of the lack of mesoscale data. They form when the monsoon is normal or strong over the Arabian Sea. They are very small both horizontally and vertically and can be located at present by coastal surface winds only. As part of our study we tried to reproduce a case of intense rainfall more than 40 cm that observed during 1980-1990 using PSU / NCAR mesoscale model MM5. The objective of the study is to find whether a small scale vortex can be simulated using a high resolution mesoscale model. We examined four cases with input data from NCEP / NCAR reanalysis project. The model is run on triple nested domains at 90, 30 and 10 km resolutions. Simulations are done for 48 hours. After 6 hrs of integration there is a trough formed along the coast. The trough intensified into a vortex and is more clear on 950 hPa level. The predicted vorticity at this level are very high and the values can be attributed to the predicted mesoscale vortex. Above 850 hPa level the intensity of vortex becomes less. The vortices first formed over the east Arabian sea and afterwards it moves west northwestwards. The simulations are also done with uniformly flattened terrain to study the role of Western Ghats in the formation of these vortices.

DEVELOPMENT OF A HIGH-RESOLUTION ASSIMILATED DATASET FOR SOUTH AMERICA REGION

Dirceu Luis HERDIES, Jose A. ARAVEQUIA, Rosangela CINTRA, Jose P. BONATTI (Center for Weather Forecasting and Climate Studies, National Institute for Space Research)

This work is concentrated on the period from September 2002 to January 2003, when the DRY-TO-WET/LBA (LBA is one of the regional continental field experiments of the GEWEX-Global Energy and Water Cycle Experiment) campaign took place in southwestern Amazon and VAMOS (Variability of American Monsoon Systems) Experiment , which is sponsored by the International CLIVAR (Climate Variability) Office, EXPERIMENT occurred in Argentina, Bolivia, Brazil, Chile, Unites States, Paraguay, Peru and Uruguay . The experiments measured temperature, moisture and wind profiles from rawinsondes, surface fluxes, soil parameters, precipitation , etc. The Regional ETA/PSAS Data Assimilation System (ETA/RPSAS), implemented at CPTEC in 1999, was used to produce a high resolution reanalysis (40 km) for this pilot period. The circulation over South America obtained with this reanalysis are in good agreement with the observations and shows a more detailed structure.On a longer time scale, this regional system will be the engine for a regional South American Project which will serve the purpose of refining the data products available with recent reanalysis from NCEP, ECMWF and DAO/NASA. These regional data assimilation datasets represent an advancing in our undestanding of the South American climate and synoptic climatology, given its high resolution and utilization of observational data not yet available to the global reanalysis aforementioned. This work will also serve as a iproof of concept for a longer term reanalysis project for the South America.

SUMMERTIME ENSO TELECONNECTIONS OVER THE EURASIA

Eun-Jeong CHA (Center for Climate System Research, University of Tokyo)

 The atmosphere over the extratropical regions thousands of kilometers remote from the equatorial Pacific is sensitive to the warming of those waters during El Nino. It is apparent, however, that not all extratropical regions are sensitive to El Nino, nor is its impact uniform throughout the year. Furthermore, different El Nino events have been accompanied by an assortment of climate anomalies in the extratropics. Within the NH, a distinct annual cycle of ENSO-related teleconnections occurs, with a strong response in boreal winter.Compared to the influence of El Nino on the global climate system in winter time,those in summer has received little attention specially the East Asia, upstream region with respect to the midlatitude westerlies. According to thecorrelation, it is not highly correlated between SST in Nino 3.4 and observed mean surface temperature over Korea both JJA and DJF. Although the correlationcoefficients are low or the marginal value, it is easily recognized by probability density function (PDF). It is obvious that the PDF shifts towardnegative in JJA El Nino and positive in JJA La Nina regimes when the Nino 3.4 SST anomalies are positive and negative, respectively. During El Nino developing summer, the anomalies in the boundary layer are displayed the three noticeable areas with significance. The wide positive temperature anomalies are centered over the equatorial eastern Pacific Ocean in response to the basinwide warming, while the negative temperature anomalies arelocated in the western tropical Pacific. In addition, the other negative anomalies are located over the west part of Tibetan Plateau and the East Asian region. These anomalies have a barotropic structure from the lower to the upper troposphere and zonally elongated from North Africa reached to the East Asia it applies to only El Niño summer. Further interestingly, the anomalies have near zonally uniform symmetric structure about the equator. The distinct anomalies

developing summer of ENSO implies that different teleconnection mechanisms are at work.

SEASONAL CHANGES OF SUB-TROPICAL FRONTAL ZONE OVER EAST ASIA

Hiroaki TAKAHARA, Jun MATSUMOTO (Department of Earth & Planetary Science, University of Tokyo)

Over East Asia, Sub-Tropical Frontal Zone (STFZ), including so-called Baiu (Mei-yu) and Akisame (autumn rain) frontal zone, exists throughout the year and changes its latitudinal position and frontal activity with seasonal march. So, STFZ is one of the most important components of East Asian monsoon system, and characterizes East Asian climate. In this study, we made surface front database by using daily surface weather charts analyzed by the Japan Meteorological Agency (JMA) for 22 years (1979-2000) and examined the seasonal changes of STFZ over East Asia. The surface front database is constructed by recording a latitude (per 1 degree) and kind (stationary, warm, cold, or occluded) of a front at an intersection of each front and each circles of longitude (per 5 degrees, 110E-150E) on JMA surface weather charts at 0900JST every day. Time-latitude sections of 5-day mean frequency of all kinds of front and stationary front are made at each longitude. There is large difference of seasonal changes between in China (115E) and around Japan (140E). In China, the Mei-yu season (from late May to late July) is an only season with very primary frontal frequency, and spring rainy season (from late February to middle May) is also recognized as secondary high frequency. In autumn frontal frequency is not so high as in spring. Around Japan, on the other hand, not only Baiu season (from late May to early August) but also Akisame season (from early September to late October) has very high frontal frequency. In spring, frequency of all kinds of front is rather high, but frequency of stationary front is not so high as in China. A comparison of seasonal changes of latitudinal position and frontal activity of STFZ is made between El Nino (La Nina) years and all 22 years. About latitudinal position, in El Nino (La Nina) years, STFZ shifts southward (northward) in summer and northward (southward) in winter at each longitude. About frontal activity, there are some differences between in China and around Japan. In China, STFZ is intensified in spring rainy season and late Mei-yu (in early Mei-yu and autumn) in El Nino (La Nina) years. Around Japan, on the other hand, STFZ is intensified from late Baiu to Akisame (in early Baiu) in El Nino (La Nina) years. Especially in autumn, frontal activity anomalies of STFZ in El Nino (La Nina) years are quite different between in China and around Japan.

MC03/11P/D-015   Poster   1400-190

DETECTION AND DYNAMICS OF THE PRINCIPAL MODE OF ASIAN SUMMER MONSOON VARIABILITY

Natsuko YASUTOMI, Masahide KIMOTO (Center for Climate System research, University of Tokyo)

Principal modes of Asian summer monsoon variability are identified. To extract principal modes, vertically integrated moisture fluxcomponents are used. The separation of principal modes obtained fromthis analysis is better than those of conventional analyses usingprecipitation and OLR. The mechanism of the formation and maintenance of the most dominant mode is also pointed out. The spatial pattern regressed against the principal component of the first empirical orthogonal function mode ofmoisture flux components shows an anomalous circulation over thePhilippines and northeast-southwest dipole convective anomaly centersover western subtropical Pacific and eastern Indian Ocean.This mode is dominant from intraseasonal to interannual variability. We shall call this anomalous circulation pattern ˝Indo-Pacific dipolepattern˝. The Indo-Pacific dipole pattern is weakly correlated to simultaneousmonthly sea surface temperature. This pattern also represents large proportion of the total variance ofAGCM control run whose lower boundary condition is fixed toclimatological SST. This is the pattern which can be excited without any externalforcings. To understand dynamics of formation and maintenance of the principal mode,linear responses of summer basic state to random thermalforcings given in Asian monsoon region are solved.The most dominant response to those random forcings is extracted.It contains anomalous circulation over the Philippines in the lower level,and its vertical structure corresponds to that of Indo-Pacific patterncalculated from reanalysis dataset.Indo-Pacific dipole pattern is preferred mode of atmosphere in Asian monsoon region in summer. Vorticity and moisture budget analyses indicate that moistureconverges over the western Pacific and diverges over the Indonesia when the cyclonic circulation anomaly over the Philippines is formed.The convection over the western Pacific is activated by verticallyunstable atmosphere and the convection over the eastern Indian Oceanis suppressed. The dipole convection strengthens the cycloniccirculation over the Philippines in turn. It is true of theanticyclonic circulation over the Philippines. This feedback mechanism maintainsIndo-Pacific dipole pattern, preferred mode of basic state in summer.

THE 2000/2001 SUMMER DROUGHT OVER BRAZIL AND ITS ASSOCIATION WITH SST ANOMALIES

Anita Rodrigues de Moraes DRUMOND, Tercio AMBRIZZI (Department of Atmospheric Sciences; Institute of Astronomy, Geophysics and Atmospheric Sciences; University of Sao Paulo)

Precipitation deficits were observed over the Southeast, Northeast and Center-West Brazilian regions during the austral summer of 2001 and contributed to the worsening of the energy crisis that was occurring in the Country. A low level anomalous anticyclonic circulation observed over eastern of Brazil enhanced the deviation of moisture transport which usually occurs from the Amazon basin to the Southeastern of Brazil and inhibited the occurrence of South Atlantic Convergence Zone (SACZ) events in that period. However, an anomalous low level northerly moisture flux was observed over La Plata Basin and positive precipitation anomalies occurred over Bolivia, Paraguay, northeastern Argentina and southern Brazil. These anomalous features were accompanied by the anomalous activity of the upper-tropospheric cyclonic vortices over Northeast Brazil, the enhanced convection over the Indonesia and the re-intensification of La Niña conditions. Using the ensemble technique a numerical study was carried out to investigate the role of different observed Sea Surface Temperature (SST) forcings over the 2001 January-February-March anomalous South American atmospheric circulation. Reynolds SST monthly means were used as boundary conditions to study the influence of South Atlantic, South Indian, South Pacific and Equatorial Pacific oceans. The simulations were run from September/2000 to April/2001 using the Community Climate Model version 3.6 (CCM3.6/NCAR) General Circulation Model. Ten integrations using different initial conditions (IC) were done to each experiment. These ICs were extracted from a 10 years Control Integration which used the repetition of the climatological SST annual cycle as boundary condition.Numerical experiments suggested that the combined influence of South Pacific and Equatorial Pacific oceans could be responsible for the observed drought. These experiments simulated the low level anticyclonic anomaly observed over eastern Brazil. The positive precipitation anomalies observed in the subtropics were fairly reproduced by the South Pacific experiment. However, both experiments have poorly reproduced the anomalous low level northerly moisture flux observed over La Plata Basin. Therefore, the intensity of the precipitation anomalies over the

subtropical regions was much weaker. For the South Indian experiment no significant signal was observed. The South Atlantic experiment presented a weak precipitation anomaly and opposite signal for some regions when compared to the observational data. It could be that the formation of an anomalous cyclonic circulation over the positive SST anomalies has contributed to this result. This anomalous circulation may have favoured the anomalous low level NW-SE moisture flux over the center of Brazil, enhancing the occurrence of SACZ events.

MC03/11P/D-017   Poster   1400-192

ORGANIZATION MECHANISM AND HEATING EFFECTS OF MESOSCALE CONVECTIVE SYSTEMS RELATED TO THE ACTIVITY OF EQUATRIAL WAVES

Chiharu TAKAHASHI[1], Hiroshi UYEDA[1], Masayuki MAKI[2], Koyuru IWANAMI[2], Ryohei MISUMI[2], Thomas D. KEENAN[3] ([1]Hydrospheric Atmospheric Research Center, Nagoya University, [2]National Research Institute for Earth Science and Disaster Prevention, [3]Bureau of Meteorology Research Centre,Victoria Australia)

The relationship between organization of mesoscale convective systems(MCSs) ,there heating effects to the environment in the Australian region and the activity of the Madden-Julian ocsillation(MJO) and the equatorial Rossby wave(ERW) is investigated.The study mainly uses the observed Dopplar radar data , NCEP-NCAR reanalysis data and outgoing longwave radiation(OLR) . The changes into the ˝active˝ or ˝break˝ monsoon conditions of the atmospheric circulation and convection are primarily associated with eastward propagation of convective anomaly from the Indian Ocean to the western Pacific in the austral summer November through March during the dominant intraseasonal oscillation.However, the daily precipitation and clouds amount observed over the northern Australian region are not necessarily to be consistent with phase and amplitude of seasonal anomaly on the MJO mode extracted by long period bandpass-filtered OLR and wind field.It is indicated that amplitudes of short-periods-filtered convective seasonal anomaly is larger than those of MJO and peak days of those conversely exhibits enhancement of precipitation. Therefore, these precipitation variance occurred by deep convection followed with westward-moving depressions to the around of observation area, which are usually clear over the sea off northeastern coast. That is further suggested that occurrence of the convective gyre is probably due to ERW. In most cases of continental origin MSCs(CMSCs) the isolated squall lines types composed of a leading convective line and trading stratiform region ,which occurred and developed in large low level wind shear, resulting from very strong low-level convergence accompanied with a disturbance like cyclone located over the northern ocean off continent, this is attributed to be the peak of ˝break˝ or transitioning ˝break˝ to ˝active˝ phase in midlevel drysituations as lately and low-level easterly . It was further characterized that convectively generated cold pool that could trigger new cells converged with moisture sea breeze, consequently enhanced rear inflow jet. On the other hand maritime origin MCSs (MMSCs) was usually formed and developed in large wind shear between low-level and upper-level, on the contrary small in low-level, during early ˝break˝ phases in moderate westerly, the consequently peak of ˝active˝ in transitioning easterly to westerly or lately ˝active˝ in strong westerly.It is also indicated that MMCSs is formed on convective moisturizing condition, therefore makes it more favorable for next convection. Indeed some new convective lines evolved during short time interval, where the cool low-midlevel backyard moist outflows from self-produced stratiform region converged with developing strong rear inflow jet with a maximum of wind speed between 2 and 4 km, suggested a positive feedback between water vapor and convection. One of the most important roles of MCSs is the heat and moisture transport.The vertical structures of convective-stratiform heating and vertical wind motions such as maximum height and magnitude were also estimated, which change according to the regimes and stages of MCSs evolution.It is found that the heating rates normalized by rainfall amount is significantly large within MMSCs stratiform rainfall region in the middle-upper troposphere. These findings suggest to the possibility of improving in parameterization of numerical models.

EFFECTS OF AEROSOLS AND GREENHOUSE GASES ON THE SOUTHEAST ASIAN MONSOON SYSTEM

Beate Gertrud LIEPERT[1], Johann FEICHTER[2] ([1]Lamont-Doherty Earth Observatory, [2]Max-Planck Institute for Meteorology)

Air pollution increased drastically during the 1950s to 1980s and decreased slightly at the end of the 1990s in Southeast Asia. At the same time greenhouse gases warmed the surface by about 0.6K globally. We investigate the effects of these changes on the Southeast asian monsoon system with two sets of climate simulations. The atmospheric model is the ECHAM4 general circulation model coupled to a mixed layer ocean of the Max-Planck Institute for Meteorology in Hamburg. One set of experiments simulates the direct and indirect aerosol effect on the energy budget of the surface and the second the set of experiments simulates the effects of both greenhouse gas forcing and direct and indirect aerosol effect. The model responds to these forcings is a change in the surface energy budget of the Indian Ocean and a change in moisture transport to the continent. Results of these simulations will be presented and discussed.

VOLATILE ABUNDANCES, CLOUD STRUCTURE, AND ORIGIN OF JUPITER'S ATMOSPHERE

Sushil K. ATREYA (University of Michigan at Ann Arbor)

Cassini-Huygens spacecraft flew by Jupiter at a distance of 140 RJ (10 million km) on 30 December 2000. Spectral features of ammonia ice were identified at 10 micron [1]. Discrete ammonia ice clouds were also identified in the equatorial region and the GRS turbulent wake using diagnostic wavelengths near 1.6 and 2.74 microns in the Galileo near infrared mapping spectrometer observations [2]. We suggest the discrete clouds of ammonia are transient, and they overlie a near ubiquitous cloud of ammonia ice whose spectral signature may be masked by photochemical haze and micrometeoric dust falling from above.

Thermochemical models predict clouds of ammonium hydrosulfide and water below the ammonia clouds [3]. However, Galileo probe failed to detect a water cloud, and only a tentative association of the tenuous cloud seen at 1.3 bar with ammonium hydrosulfide-ice can be made [3]. The meteorologically anomalous region where the Galileo probe entered, a 5-micron hotspot, is a region of downdraft where the jovian air is dry. Although the near absence of clouds in the Galileo probe entry site is consistent with the depleted condensible volatiles measured by the mass spectrometer [3], the missing information on the abundance of water in deep well mixed atmosphere is critical to the models of the formation of Jupiter and its atmosphere [4,5]. The icy planetesimal hypothesis [4] and the clathrate hydrate hypothesis [6] have been invoked to explain the enrichment of heavy elements in Jupiter´s atmosphere. Continued exploration of Jupiter, especially with multiprobes, is needed to answer unambiguously such fundamental questions as the accretion of Jupiter and the evolution of its atmosphere.References: [1] M.H. NUMERICAL MODELING OF JUPITER'S MOIST CONVECTION LAYER: SENSITIVITY TO DEEP WATER CONTENT

Kensuke NAKAJIMA[1], Shin-ichi TAKEHIRO[1], Masaki ISHIWATARI[3], Yoshi-Yuki HAYASHI[2] ([1]Department of Earth and Planetary Science, Faculty of Sciences, Kyushu University, [2]Division of Earth and Planetary Sciences, Graduate School of Science, Hokkaido University, [3]Graduate School of Environmental Earth Science, Hokkaido University)

´Moist convection´ i.e., convection associated with the phase change and the cloud physics of water, is supposed to occur in Jupiter´s atmosphere.Nakajima et al (2000) examined the structure of the moist convecting layer by runnung a large-domain two-dimensional fluid dynamical model for a long time.Their result shows that the water condensation level acts as a dynamical and compositional boundary. The convection below the condensation level is Benard-like and water mixing ratio is homogeneous.Above the condensation level, transient convective clouds develop and water mixing ratio is highly inhomogeneous.The horizontal average of mixing ratio decreases rapidly with height just above the condensation level, resulting in a distinctive stable layer at 5 bar.These features do not match the observation by the Galileo probe showing dry layer extends down to as deep as 20 bar level, but they did not take the discrepancy seriously because the Galileo probe entered a rather special place where the humidity is considered to be exceptionally low. Nakajima et al (2000) assumed that the mixing ratio of water vapor in deep levels to be the value computed from the oxygen content in the solar atmosphere.However, a recent theory of solar nebula suggests that the water content in Jupiter may be 9 times the amount in the solar atmosphere (Gautier, 2001), which is consistent with the large value implied by the fast propagation speeds of the wavy features observed after the impacts of the nuclei of Comet Shoemaker-Levy in 1994 (Ingersoll and Kanamori, 1995). If the deep water mixing ratio is so large, the water condensation can occur at much lower levels.Then the deep dryness observed by Galileo probe may be global feature of Jupiters atmosphere. Considering the wide uncertainty of the deep water vapor content, we repeat the numerical experiment of Nakajima et al (2000) with different values of deep water mixing ratios assumed.The results shows that, until a certain critical value of deep water mixing ratio, which corresponds to about 5 times the ˝solar˝ value, the convective clouds develop from the water condensation level, which moves to deeper levels with the increase of water vapor. At the same time, the activity of convective clouds becomes more vigorous because larger amount of latent becomes available. However, with still larger amount of water vapor, the clouds around the condensation level becomes stratiform; convective clouds develop from a higher levels. This behavior results from the heavy molecular weight of water compared with ˝dry˝ component of Jupiter´s atmosphere (Guillot, 1995). The present result implies a possibility as well as a limitation of the diagnoses of deep water content from the structure of atmosphere that is remotely observable from space.

MC04/10P/B22-003   1445

NUMERICAL MODELLING OF EQUATORIAL JETS ON JUPITER AND SATURN

Y.H. YAMAZAKI, D.R. SKEET, P.L. READ (Department of Physics, University of Oxford)

Using a new general circulation model of Jupiter and Saturn, we investigate the origin of the super-rotating equatorial jets with off-equatorial ´shoulders´ that are observed at the cloud top level of Jupiter and Saturn. We have recently developed a general circulation model for the stratosphere and troposphere of Jupiter and Saturn. It uses the dynamical core of the Unified Model of the UK Meteorological Office,which has been employed for both operational weather forecasts and climate research in and outside the United Kingdom. The three-dimensional, nonlinear numerical model is an implementation of ageneralized primitive equations set that handles all components of the Coriolis force due to the planetary rotation, and geometrical termsthat are associated with the finite thickness of the atmosphere. The generalization was introduced to the Unified Model to improve the model accuracy in the tropics of the terrestrial atmosphere, but it also provides a significant advantage for investigations of the Jovian and Saturnian troposphere, which are expected to be deep and weakly stratified. The origin of the Jovian jets has been of great interest for centuries,and a debate of deep convection versus shallow weather layer modelshas been active since Busse introduced his cylindrical convection modelin 1976. Recent numerical experiments with deep Boussinesq sphericalshell models have had some success in producing an equatorial jet of reasonable wind speed, but shallow ´weather-layer´ models tend toave difficulty in producing a superrotating jet near the equator.This is not a surprising result because of the conservation of angular momentum in an axisymmetric model. In order to overcome this difficulty within the context of the weather layer model, we investigate the plausibility of the wave-induction model by Maxworthy (1975). Hisidea is that a vertically propagating equatorial Kelvin wave willdeposit a prograde momentum to the mean flow as it travels upward. This will produce a superrotating jet of roughly Gaussian shape along the equator. A further interesting feature of the equatorial jets is the presence of off-equatorial peaks in the westerly winds in both the Jovian and Saturnian atmospheres. However, neither the cylindrical convection model nor the simple wave-induction model can explain these characteristics. We introduce a Hadley-type meridional-verticalcirculation, which by itself produces a pair of narrow jets off theequator primarily because of the conservation of angular momentum.We superimpose a differential heating in the latitudinal direction toforce the Hadley type circulation and successfully generate the off-equatorial jets. When this mechanism is combined with the Kelvin-wave induction, we reproduce the equatorial prograde jets with shoulders for both Jupiter and Saturn. The origin of thisadditional Hadley mechanism will also be discussed.

AEROSOL STRUCTURE IN JUPITER'S POLAR STRATOSPHERE

Robert A. WEST (Jet Propulsion Lab, Caltech)

Images obtained by the Cassini Imaging Sub-System (ISS) duringapproach to Jupiter over a 2.5-month period beginning October 1, 2000show the motion and evolution of stratospheric haze features andcircumpolar Rossby waves. Of particular interest is a large dark ovalseen only in ultraviolet wavelengths (most prominently in filter UV1,effective wavelength 263 nm). This oval is seen to form at thebeginning of the period. After several weeks it appears to be aboutthe same size and shape as Jupiter´s Great Red Spot. It continues toevolve by stretching in longitude and compressing in latitude. Thecontrast which produces this feature is probably caused byauroral-related gas-phase chemistry or/and by very small (radiussmaller than ~ 0.1 micro-meter) particles. It is not seen innear-infrared images which are sensitive to larger aerosol particles.A more superposing the UV images and the 890-nm methane images showsthat the large oval sits on the boundary of the morphologically smoothpolar stratospheric haze seen in the 890-nm methane filter. Thesedata provide interesting clues to the nature of Jupiter´s polar vortexand will help to motivate a quantitativedynamical/chemical/microphysical model. This work was performed bythe Jet Propulsion Laboratory, California Institute of Technology.

MC04/10P/B22-005   1530

THE SYSTEMATIC CALCULATION OF ADIABATIC STRUCTURE OF JOVIAN PLANET ATMOSPHERES

Ko-ichiro SUGIYAMA, Masatsugu ODAKA, Kiyoshi KURAMOTO, Yoshi-Yuki HAYASHI (Division of Earth and Planetary Sciences, Hokkaido Univ.)

We investigate vertical profiles of adiabatic lapse rate, amount of condensed species, and static stability of the Jovian planet atmospheres by using a newly developed calculation method. Our method consists of three procedures as follows: (1) equilibrium composition is calculated by minimizing Gibbs free energy for various temperatures and pressures, (2) entropy is calculated for the equilibrium composition, and (3) adiabatic curve dS = 0 is obtained by seeking the temperature and pressure relationship under which the value of entropy is conserved. In our method, it is not necessary to consider the details of corresponding chemical reactions. Therefore, one of the advantages of our method is that modification of numerical code is almost unnecessary when different elemental compositions and potential temperatures are given. In previous studies, the adiabatic profile of Jovian planet atmospheres has been obtained by direct calculation of entropy conservation for ascending air parcel according to given chemical reactions (Weidenschilling and Lewis, 1973, Icarus, 20, 465-476). We estimate dependency of vertical profiles of adiabatic lapse rate, amount of condensed species, and static stability on elemental composition for each Jovian planet atmosphere. In this series of calculations, the initial abundances of condensable species are taken from the solar abundance to several ten times the solar. The results of these calculations systematically reveal the effect of atmospheric composition on structure of atmosphere, which are useful for consideration not only of vertical distribution of cloud layers, but also of dynamics of cloud convection within the Jovian planet atmospheres.

NEW RESULTS ON TITAN FROM GROUND-BASED OBSERVATIONS

Athena COUSTENIS[1], Mathieu HIRTZIG[1], Eric GENDRON[1], Olivier LAI[2], Michel COMBES[1], Emmanuel LELLOUCH[1], Pascal RANNOU[3], Pierre DROSSART[1] ([1]LESIA, Observatoire de Paris-Meudon, [2]CFHT, Hawaii, [3]Serv. Aéronomie, Univ. de Versailles, France)

I will present new insights on Titan´s atmosphere and surface composition derived from recent observations using large telescopes (such as the CFHT or the VLT) both in spectroscopy (ISAAC) and imaging (PUEO, NAOS, OASIS). Our 2001 atmospheric images show some interestingphenomena: besides the well-known Titan ˝smile˝ observed atwavelengths between 1 and 1.3 micron, we find the situation to becurrently changing, with a clear reversion of the asymmetry found inour FeII (1.64 micron) and Kcont (2.26 micron) filters, sounding higheratmospheric levels (in the stratosphere). We believe this is aseasonal phenomenon, following the previously reported ˝loss of thesmile˝ (Lorenz, 2001). This inversion is progressing and we arefounding its signature in our new images of 2002 at wavelengths of :2.16 (BrGamma), 1.64 (FeII), 2.06 (J2). Another atmospheric phenomenon, the limb brightening reported in our1998 images - interpreted as a firstdetection of possible diurnal effects in Titan´s atmosphere :something like a morning fog, observed after condensation processeshave enhanced in condensates the atmospheric levels between 70 and100 km (Coustenis et al., 2001) -, could not be firmly confirmed in our new data (although there is some indication for it) because the 2001 images wereacquired in mediocre conditions (seeing of 0.5-1 arcsec). A third new feature is observed at wavelengths probing the atmospherearound 2 micron: a bright feature spanning about 2 by 4 pixels in latitude and longitude respectively (0.07x0.14 arcsec or roughly 9x18% of the projected disk) is seen attached to the Southern Pole of Titan and appears stable. This feature could be indicative of an atmospheric (cloud or more likely a vortex) phenomenon or a surface feature (polar cap?). After subtracting the atmosphere from the images sounding the CH4windows, we recover information on the surface of Titan. We find theequatorial spot to be bright again in all the filters investigatedfrom 1 to 2 micron and at the position expected with respect to theorbital phase. A preliminary study of the 2002 images already show pieces of evidencethat the asymmetry inversion is still at work, furthermore at deeperaltitudes than detected in 2001. Since we have observed at consequentnights around the GEE and the GWE, we expect to be able to trace thelocation (and the displacement) of the features observed and to checkthe bright zones found in the trailing hemisphere images of Titan(Combes et al., 1997). I shall also discuss recent findings in Titan´s 5 micron spectrum.References: Combes et al (1997), Icarus 129, 482; Coustenis et al. (2001) Icarus 154, 501; Lorenz et al (2001), Geoph. Res. Letters 28, 4453.; Lellouch et al. (2003), Icarus, in press.

MC04/10P/B22-007   1645

MODELS OF COMET 19P/BBORRELLY DURING THE DEEP SPACE 1 ENCOUNTER

Daniel C. BOICE[1], R. WEGMANN[2] ([1]Space Science Division, Southwest Research Institute, [2]Max-Planck-Institute fur Astropshik)

The Deep Space 1 Mission (DS1) successfully encountered comet 19P/Borrelly on 22 September 2001, returning a wealth of images and in situ plasma measurements. A coma model for 19P/Borrelly is presented that consistently represents the cometary environment from the nucleus surface to the solar wind interaction region. Neutral gas and plasma dynamics and spatial distributions of various cometary species are presented for interpreting in situ plasma measurements obtained during the encounter. The major findings can be summarized as follows: (1) Using estimates of the solar wind conditions and the gas production rate at the time of encounter, a bow shock is expected at a distance of about

M

60,000 to 80,000 km along DS1's trajectory, however, DS1 will not penetrate the contact surface, (2) At closest approach, the plasma speed steadily decreases to about 2 km/s, with an ion temperature of about 200,000 K and electron temperature of about 20,000 K (dominated by photoelectrons), and an ion number density of about 100/cm3, and (3) model abundances of water-related ions, O+, OH+, H2O+, and H3O+, are 1%, 7%, 82%, and 10% of the total water-related fraction, respectively, at the time of closest approach. An initial analysis of the DS1 measurements will be presented within the context of the model results.

PHYSICAL AND CHEMICAL PROCESSES IN COMETARY COMAE

Daniel C. BOICE (Space Science Division, Southwest Research Institute)

The quantity and quality of high-resolution spectra and images of recent comets provide a unique opportunity to advance our knowledge of cometary parent molecules and thereby gain clues to understand the origin of the solar system. In order to successfully interpret the extensive observations in the UV, visible, IR, and microwave regions, the relevant physico-chemical processes must be identified to provide the framework within which comets can be understood and inferences about their composition can be made. Analyses of observations of recent comets (e.g., Kudo-Fujikawa, Borrelly, LINEAR WM1, Hale-Bopp, Hyakutake) have provided valuable insights into the intrinsic properties of their nuclei (e.g., composition, active surface fraction, surface properties, temperature) and the important physical and chemical processes that occur in their comae. The latest results are discussed detailing these processes, concentrating on the collision-dominated inner coma. i.e., thermodynamics (e.g., temperature and velocity structure), photo- and gas-phase chemistry (e.g., composition, gas and electron energetics), interactions between gaseous species and dust (composition in distributed sources, gas-grain reactions, mass-loading and energy balance of both gas phase and dust particles), role of electrons in the coma (e.g., inelastic collisions with primarily neutrals, distribution function and its moments for energy spectrum), optical depth effects and issues related to radiative transfer within the coma, and other topics (e.g., water clusters, near-nucleus boundary layer, transition to free molecular flow). Special consideration is given to the determination of ˝parent˝ species from the plethora of molecules and atoms seen in cometary comae, concentrating on observations of S2, CH, CN, CS, C2, C3, NS, and HCN/HNC, to gain clues for understanding the origins of the solar system and possibly life.

THE EFFECTS OF ION-DRAG ON GRAVITY WAVE HEATING AND COOLING IN JUPITER'S THERMOSPHERE

Michael P. HICKEY[1], Gerald SCHUBERT[2], Richard L. WALTERSCHEID[3] ([1]Department of Physical Sciences, Embry-Riddle Areonautical University, [2]Department of Earth and Space Sciences, Institute of Geophysics and Planetary Physics, University of California, Los Angeles, CA 90095-1567, USA, [3]Space Science Applications Laboratory, The Aerospace Corporation, Los Angeles, CA 90009, USA)

We use a full-wave numerical model to study the propagation and dissipation of two gravity waves in Jupiter's thermosphere. The present treatment differs from our previous study of these two waves by the addition of ion-neutral collisions (ion-drag dissipation) in the model. A Chapman profile is used to model the electron density profile with parameters adjusted to provide a fit to observations. We determine that one of the modeled waves is not significantly affected by the inclusion of ion-neutral collisions because it is viscously damped at low altitudes where electron and ion densities are small. At higher altitudes where significant ion densities occur this wave has a small amplitude. The inclusion of ion-neutral collisions is found to have a significant effect on the dissipation of the second gravity wave (wave 2) because it is viscously damped in the same region where maximum electron and ion densities occur. The Joule dissipation of the currents driven by this gravity wave provides a heating that, in addition to the viscous heating, dominates over the cooling associated with the divergence of the sensible heat flux and leads to a net heating of the thermosphere. We now find that with the inclusion of ion-drag dissipation the contribution of gravity waves like wave 2 can make a significant contribution to the heating required to explain the high thermospheric temperatures.

LEADING ATMOSPHERES EVOLUTION

Therese SCHNECK (Ph.D.1977)

The synchronous rotation of the Moon around the Earth is caused by an unsymetrical distribution of mass in the Moon. Interaction on the Moon slows the Earth rotation about two milliseconds per century.The dust oscuration, the plasma that filled the early universe during its first years was opaque to electromagnetic radiation. The solar system rotates every two hundred forty two million years in the Milky Way at one thousand two hundreds kilometers per second relative to the Microwave Background Radiation(1). Actually, atomic clocks on board GPS satellites are stable within one second in thirty two thousands kilometers at speed of ligthas the effect of the Earth´spassage on plasma(2). Since the Cretaceous-Tertiaryboundary sixty five million years ago, the error on the position of the Earth in space around the sun is more than one earth diameter. Mars had a magnetosphere at the Noachian between 4.4 and 3.8 billion years ago, related to oceans and high carbon dioxide content. A titanium rich-layer was produced by cristallisation of a huge ocean of magma that surrounded the Moon when it formed(3). Oceans, atmospheres and continents where in place by 4.3 billion years on Earth. Meteorites accumulated during early Ordovician at a rate two orders of magnitude higher than today. The carbonate chondrite Tagish Lake meteorite reflect infrared lightbetter than visible light(4). The study of the evolution of the partial pressure of atmospheric oxygen over phanerozoic time supports the hypothesis of high atmospheric content during the Carboniferous. The fluctuations in primary fluid inclusions in marine halites are in phase with oscillations in sea floor spreading rates,volcanism and global sea level. Location of strewnfields associated with tektites crossing the athmosphere and major asteroid impact is aeolian and arid related to sunspots cycle(5) or to interactions between the athmosphere and deep ocean circulation. Maunder minimum refers to a period of particularly low number of sunspots at little ice age from 1645 to 1745.Lidar observations revealed than metals are deposited by meteor ablation at heigh of one hundred kilometers in Earth athmosphere.The upper strastopheric maximum temperatures increase with ozone depletion. Ionospheric parameters change in sixnight hours when a solar flare triggers a geomagnetic storm(6). The cyclone average of 1.5 per year was exceeded in 1995 for the first time since 1964 andreached 3.8 between 1995 and 2000(7).Laser cooled clock Parcs(8) are going to beinstalled on the ISS, where gravity is weaker than at Earth´s surface, in late 2005 and would keep time within one second every 300 million years, apparently nearer to the accretion time of matter. The Earth´s atmosphere dynamic filters out natural hazards as meteorites and cyclones below critical conditions. Earth climate and athmosphere seems more at the new clocks atomic times.GPS are operational since fifty years in a pre-evolving Milky Way. Ref:(1)Penzias and Wilson. PRESENT STATUS OF JAPANESE VENUS ORBITER

Masato NAKAMURA, Takeshi IMAMURA, Takumi ABE, Nobuaki ISHII, Hiroshi YAMAKAWA, Ichiro NAKATANI, Koichiro OYAMA (Institute of Space and Astronautical Sciences)

We have proposed a Venus orbiter which will arrive at Venus in 2009 to the Institute of Space and Astronautical Sciences (ISAS). This mission is now go and we will start the internal Phase B study at ISAS in the fiscal year of 2003. The main purpose of this mission is to reveal the details of the atmospheric motion on Venus and approach the dynamics of the Venusian climate. The angular position of the spacecraft on its orbit (300km x 13Rv with 172 degrees inclination and 30 hours orbital period) is synchronized for 20 hours at its apoapsis with the global atmospheric circulation at the altitude of 50km, thus the snap shots taken every 2 hours will be the images of the same side of the atmosphere. We have 4 cameras to take such snap shots of the planets in different wave lengths. In addition to these 4 cameras, we have a Lightning and Airglow camera (LAC) in visible range. This will be operated when the orbiter is close to the planet. Several other instruments to measure the plasma environment are seriously considered. They are 1)extreme ultraviolet imager, 2)nonthermal ion mass/spectrum analyzer and electron spectrum analyzer, 3)thermal plasma analyzer, 4)plasma wave analyzer and sounder, and 5)magnetometer We expect that the orbiter will survive after the next solar maximum in 2011 and the comparison of plasma environments around Venus before and after the solar maximum should be quite exciting.

METEOROLOGICAL OBSERVATION BY JAPANESE VENUS ORBITER

Takeshi IMAMURA, Masato NAKAMURA, Venus Exploration Working Group (Institute of Space and Astronautical Science, Japan)

The PLANET-C Venus orbiter will be launched in 2008 by the Institute of Space and Astronautical Science, Japan, to explore the Venus atmosphere, with emphasis on the study of the general circulation. Atmospheric circulation is one of the key issues in the study of the Venus climate, and moreover, understanding the Venusian wind system which differs largely from the terrestrial one is a long-lasting issue in planetary meteorology. Although the rotation of Venus is slow with the period of 243 days, the stratosphere near the cloud top circles around the planet with the period of 4.7 days. The mechanism of this wind system, called the super-rotation, is unknown. The delay of the Venusian meteorological research is attributed to the lack of meteorological data within and below the clouds. The Venus mission will bring about a breakthrough by utilizing the near-infrared windows (1.0, 1.7, 2.3, 2.4 micron) at which we can view the sub-cloud atmosphere from space. Successive high-resolution global images of the atmosphere and clouds at such near-infrared wavelengths will enable us to trace atmospheric motions at several discrete altitude levels. Cloud images at long-infrared (10 micron) and ultraviolet (280, 350 nm) wavelengths are also used for this purpose. Radio occultation will yield vertical temperature profiles which are complementary to the optical observations. The detection of lightning discharges by a high-speed detector will give clues to the convective activity in the cloud layer. With these comprehensive meteorological data, we will construct a three-dimensional view of the atmospheric dynamics and investigate the outstanding issues, such as the mechanism of super-rotation, the structure of meridional circulation, meso-scale meteorology, and cloud physics.

| MC04/11A/B22-003 | | 0915 |

VENUSIAN EQUATORIAL KELVIN WAVE IN MERIDIONAL CIRCULATION

Takeshi IMAMURA (Institute of Space and Astronautical Science, Japan)

The influence of the Hadley-like meridional circulation on the Venusian Kelvin wave, which propagates in the super-rotating stratosphere, is investigated, using an equatorial beta-plane primitive equation model. The Kelvin wave has been observed in ultraviolet cloud images as a planetary-scale albedo feature. The meridional circulation has also been observed in cloud images: clouds drift poleward at a speed of 1-10 m/s in the mid-latitude in both hemispheres. Such a fast meridional circulation should influence the Kelvin wave, since the wave has a deformation radius of 2000 kmand extends to the mid-latitude. The model result shows that the wave is modified to have a non-zero meridional wind disturbance, which is absent when the background atmosphere is at rest. The combination of the meridional and zonal winds induces a meridional flux of zonal momentum in the upstream direction of the background north-south flow. In the upper branch of the Hadley circulation, the wave transports zonal momentum equatorward. The theoretical background is reported in another session (MC05 Middle Atmosphere Science). The predicted momentum redistribution should contribute to the maintenance ofthe super-rotation, since a direct cell transports angular momentum upward whenever equatorial regions of the atmosphere have an angular momentum surplus relative to high-latitude regions. It is also suggested that the deformation of the Kelvin wave in the meridional circulation may explain the shape of the albedo feature which is called the ˝dark horizontal Y˝.

CHALLENGE TO DETECT VENUS LIGHTNING BY LAC ONBOARD PLANET-C

Yukihiro TAKAHASHI[1], Jun YOSHIDA[1], Masaki TSUTSUMI[2], Tomoo USHIO[3] ([1]Department of Geophysics, Tohoku University, [2]Arctic Environment Research Center, National Institute of Polar Research, [3]Department of Aerospace Engineering, Osaka Prefecture University)

Whether lightning is occurring in Venus or not is still under controversy, although extensive studies have been made using data obtained by optical and wave instruments onboard spacecrafts and from ground for almost 20 years. In order to conclude the discussion, we plan to install a lightning and airglow camera (LAC) at the Venus orbiter, PLANET-C, which will be arrived in 2009. Lightning discharge is a phenomenon that reflects the dynamics and material characteristics in the planetary atmosphere. Charge separation in the thundercloud is considered to be caused mainly by frictions between ice crystal and hail, which are closely related to atmospheric motion especially for vertical convection. Therefore, the lightning activity is an excellent quantitative indicator for the activity of atmospheric convection. In the Earth it is pointed out that the lightning activity is very sensitive to the global atmospheric temperature and H2O density at high altitude, one of the significant molecules causing the green house effect. It can be inferred that also in Venus the lightning are generated mainly by the vertical convection and the global observation of lightning is a good method to get information on the atmospheric activities and characteristics of cloud particle in the planet with a good time resolution. The lightning in Venus may be similar to sprites or elves observed in the Earth's middle and upper atmosphere. Since the distance between the cloud deck and the ground in Venus is considerably large (about 45 km) and the atmospheric pressure is quite high, the discharge from cloud top to the ionosphere may be more likely

than cloud to ground discharge. Development of LAC is now under design of a proto model (PM). A multi-channel photo-multiplier tube or an avalanche photodiode (APD) with 8 by 8 matrix pixels is adopted as a detector of LAC, which enables us to detect lightning flash at high time resolution of 20 microsecond. The sensitivity shall be determined in order to sense lightning flashes with an optical intensity of 1/100 of average in the earth´s lightning. The data will be stored with time interval of 0.1 second for each flash event using pre-triggering data acquisition. Wavelength of OI 777 nm is chosen for the lightning detection based on the laboratory experiment. To reduce the stray lights from the sun and scattered sunlight in Venus dayside, Optical unit is placed on the surface of spacecraft body and an isolated vane unit will be used. To cross-check the existence of Venus lightning, simultaneous wave measurements are planned in a frequency range from DC to several MHz. Especially, the recording of waveform around 100 Hz, being triggered by optical emissions, might be essential.

MC04/11A/B22-005   0945
POWER SPECTRUM ANALYSIS OF VENUSIAN CLOUD IMAGES

Manabu SHIMOYAMA, Takeshi IMAMURA (The Institute of Space and Astronautical Science, Japan)

A Venus exploration project (Planet-C) is in progress for the purpose of elucidating the Venusian meteorology. In this project, the distribution of clouds and minor gases at different heights are continuously measured by using several cameras which differ from each other in observation wavelength. As a preparation, we have analyzed the cloud images of Venus which were taken by previous missions in order to examine methods for analysis and demands for observations. The cloud images used are the ones taken by the SSI onboard GALILEO at the time of Venus flyby. Observation wavelengths are violet and near-infrared. According to the past examinations, it is thought that the pattern of violet images indicates the distribution of the violet absorption matter, which exist at cloud top height, and near-infrared images reflect the structure of lower cloud at the height of about 50 km. In the beginning we have calculated spatial power spectra for equatorial and mid-latitude regions of those images to investigate the dependence of turbulent structure on latitude and height. Although this kind of analyses has been carried out for the data sets obtained by Pioneer Venus and Mariner, it has not been done for the data sets of Galileo. Moreover the data obtained by Galileo has higher spatial resolution and therefore covers smaller spatial scale which we have never seen. The results are as follows. 1) The power of violet images for equatorial region is bigger than that for mid-latitude region regardless of spatial scale, whereas that of near-infrared images have no dependence on latitude. 2) The slope of the power spectra for near-infrared images is smaller than that of violet images. These results indicate that the production and loss processes of turbulence and the mechanism which connect various scale phenomena vary with height. In this report, the slopes of the power spectra are also compared with the case of the Earth.

MC04/11A/B22-006   1000
SUPERROTATION IN A VENUS-LIKE AGCM

Masaru YAMAMOTO[1], Masaaki TAKAHASHI[2] ([1]Faculty of Education, Wakayama University, [2]Center for Climate System Research, University of Tokyo)

A maintenance mechanism of Veunsian superrotation is investigated by using a CCSR/NIES Venus-like atmospheric general circulation model. For a T10L50 experiment, a zonally uniform solar heating is used. The superrotation with velocities faster than 100 m/s is formed near 60 km altitude and a maximum of total angular momentum density is located at 21 km. The strong poleward flow over 10 m/s is seen above the cloud top (> 70 km) where the zonal flow steeply decreases with height. The upward flow of about 1 cm/s at the equator and the downward flow at the poles are seen near the cloud top (65-70 km). The vertical flow is formed continuously in the height range from the surface to the middle atmosphere. The meridional circulation of a single cell is predominant in the model atmosphere and effectively pumps up angular momentum from the lower to the middle atmosphere. The angular momentum is transported poleward by the meridional circulation, and a part of the transported momentum is returned back to low-latitudinal regions by vortical and divergent flows of various waves. Rossby, mixed Rossby-gravity, and gravity waves transport the angular momentum equatorward. Vertically propagating gravity waves predominantly transport the angular momentum downward. The zonal-flow deceleration by the gravity waves enhances the meridional circulation above the cloud top. The results support the Gierasch mechanism (Gierasch 1975; Matsuda 1980; 1982), as was simulated in previous Venus-like AGCMs (e.g., Del Genio and Zhou 1996). Although barotropic waves are emphasized in the previous AGCM studies supporting the Gierasch-Rossow-Williams scenario (Gierasch 1975; Rossow and Williams 1979), various waves play important roles in formation and maintenance of the superrotation in the present study. Large horizontal eddy diffusion required in the Gierasch mechanism corresponds to the equatorward momentum flux caused by not only barotropic waves but also other various waves. The eddy downward angular momentum flux, which corresponds to the small vertical eddy diffusion in the Gierasch mechanism, is caused by vertically propagating gravity waves. The dynamical process simulated by our Venus-like AGCM is one of possible mechanisms of Venusian superrotation. For a T21L50 experiment, fast equatorial waves of c $> U$ (c: phase velocity, U: longitudinally averaged zonal flow) also contribute to upward eddy transport of angular momentum. Since the upward vertical momentum fluxes by the fast equatorial waves of c $>$ U cancel the downward fluxes by vertically propagating gravity waves of c $<$ U in low latitudes, the downward angular momentum transport by waves is ineffective in the equatorial region. Thus the cloud-top superrotation is enhanced in the T21 model.

THE MYSTERIOUS ATMOSPHERE OF VENUS, AND THE EUROPEAN VENUS EXPRESS MISSION

Fred W. TAYLOR (Oxford University)

In November 2002, the European Space Agency approved a new mission to the planet Venus that will launch in November 2005. The spacecraft is a polar orbiter, which uses a slightly modified version of the bus developed for the Mars Express mission, which launches in May 2003. The scientific payload includes sophisticated infrared spectroscopic and imaging instruments that can operate in the near-ir ´windows´ and sound the atmosphere down to the surface.This paper will describe the scientific objectives of the project, which include the investigation of the composition, chemistry, cloud structure and dynamics of Venus´ atmosphere. Specific questions posed by our current knowledge and limited understanding of the Venus environment will be described, and the key measurements to help resolve them discussed.

MC04/11A/B22-008   1100
THE INCEPTION OF THE OCEANS AND THE MISSING CO2 ATMOSPHERE OF THE EARTH

Lin-gun LIU (Institute of Earth Sciences, Academia Sinica)

The oceans started to grow when the surface temperature of the Earth cooled to below about 450 oC, if the terrestrial planets were covered by ″magma ocean″ after accretion. As envisaged and supported by earlier studies, a CO2-dominatedatmosphere probably existed in the early history of the Earth. Carbon dioxide was removed away from the air mainly by dissolving into water during condensation (or the growing ocean), and then forming carbonate rocks in early geological history. The role of the green organisms in removing CO2 from the air is probably minor, though all sedimentary rocks contain a very large amount of reduced carbon of biogenic origin. A large-scale hydrosphere probably never existed on Venus, and not for long on Mars. Thus, the atmospheres of these latter planets are composed mainly of carbon dioxide.

MC04/11A/B22-009   1115
STABILITY OF MEAN ZONAL FLOW IN CYCLOSTROPHIC BALANCE

Masahiro TAKAGI, Yoshihisa MATSUDA (Department of Earth and Planetary Science, University of Tokyo)

In the mean zonal flow in cyclostrophic balance (e.g. the superrotating zonal flow in the Venus atmosphere), there is a possibility that the baroclinic instability arises (Matsuda, 1984; Young et al., 1984). Since the cyclostrophic balance with the hydrostatic approximationis equivalent to the balance between the buoyancy due to themeridional temperature difference and the centrifugal forcedue to the mean zonal flow with vertical shear, there exists available potential energy, which may be convertedto kinetic energy of disturbances. Young et al. (1984) shows that the so-called baroclinic instabilityoccurs at the cloud level in the Venus atmosphere. It should be noted, however, that the disturbance generated inthe cyclostrophic flow is not necessarily similarto the baroclinic wave in the terrestrial atmosphere, because the local Coriolis parameter (Coriolis parameter definedin the coordinate rotating with the mean zonal flow at a certainaltitude) is highly dependent on the altitude.To investigate stability of the mean zonal flow in cyclostrophicbalance in the wider parameter range than those of the previousstudies, 2D and 3D models are developed.In the result of the 2D model, it is found that the unstable modes are similar to those of theusual baroclinic instability when the Rossby number (Ro) is small. When Ro is large and the vertical shear (the centrifugal force)is small, the baroclinic wave cannot spread over the whole vertical region,and separates into two modes propagating in the east and westdirections to the mean flow at the mid-altitude. When the vertical shear is large,the unstable mode similar to the usual baroclinic instabilityappears again even if Ro is large. Applying the 3D model on the sphere to the middle Venus atmosphereincluding the cloud layer, the result of Young et al. (1984) can be confirmed.In the case of the lower Venus atmosphere (from the ground to 40 km), the unstable mode whose phase velocity is in the direction ofthe mean flow appears. This mode has the amplitude in the lower latitudes, and may have some role in the vertical transport of zonalmomentum (Yamamoto and Tanaka, 1997).

MC04/11A/B22-010   Invited   1130
SUBMM DETECTABILITY OF MOLECULAR SPECIES IN PLANETARY ATMOSPHERES WITH GREAT AND HIFI

Paul HARTOGH, Christopher JARCHOW (Max-Planck-Institut fuer Aeronomie)

In the near future two new instruments will help to improve our knowledge about the structure and composition of planetary atmospheres. The German REceiver for Astronomy at THz frequencies (GREAT, from 2004) on the Stratospheric Observatory For Infrared Astronomy (SOFIA) and the Heterodyne Instrument for the Far Infrared (HIFI, from 2007) on the Herschel Space Observatory will sound planetary atmospheres in ranges of the sub-millimeter- wave spectrum not accessible from ground. Since the sensitivity of these instruments is very high, a large number of new species may be detected during so-called deep line surveys. In case of good signal-to-noise ratios, altitude profiles of the detected molecules can be retrieved using the information of the pressure broadening and the optical thickness of the lines. Among others the vertical profiles of water vapor and its isotopes in the lower and middle atmosphere of Mars and the upper atmosphere of the giant planets are of great interest. In this talk we will present simulations of molecular spectra as they may be detected by GREAT and HIFI, taking into account the absorption of the Earth middle and upper atmosphere (GREAT only), nadir and limb emissions and absorptions of the planets, the instrument specific parameters including telescope size, sensitivity of the heterodyne receivers, efficiency of the observations modes, calibration and finally the frequency resolution of the spectrometers. We define a detection of a line, if the line amplitude is larger than 3 times the measurement noise (RMS). This detection can provide information about the column density of the species. In case the lines are much stronger they may contain information about the vertical distribution of the molecule in the planetary atmosphere. We will present a number of inversion calculations of our radiative transfer model. These retrievals will show which altitude resolution of a vertical profile can be expected as a function of the signal-to-noise-ratio of the simulated lines.

APPLICATION OF NONLINEAR OPTIMAL PERTURBATION TO THE STUDY OF THE INSTABILITY AND ASSOCIATED PREDICTABILITY OF PLANETARY ATMOSPHERIC MOTIONS

Mu MU, Zhiyue ZHANG (LASG,Institute of Atmospheric Physics,Chinese Academy of Sciences)

Instability problems and associated predictability problems are central ones in the study and numerical prediction of planetary atmospheric motions. Linear singular vector (LSV) and linear singular value (LSVA) has been adopted to study these problemsfor the atmosphere of the earth. In this approach it is assumed thatthe initial perturbation is small enough such that its evolutioncan be governed by the tangent linear equations of the original nonlinearequations.This essential assumption limits the applicability of the method to study the effects of nonlinearity on the instability and predictabilityof atmospheric motions. Mu (2000), Mu et al (2001), Mu et al (2002) proposed new conceptsof nonlinear singular vector (NSV) and conditional nonlinear optimalperturbation (CNOP), which are the natural generalizations to LSV. Results of both theoretical and numerical analysis demonstrated the nonlinear effects can be better treated by NSV and CNOP. In this study, we first apply LSV,NSV and CNOP to the study of stability and instability of barotropic motions of Jupiter´s atmosphere. Particular attention is paid to the stability of Great RedSpot .Then the associated predictability is investigated by LSV,NSV and CNOP too. The importance of using nonlinear approach rather than linear oneis clearly demonstrated . The results also show that NSV and CNOP areuseful tools to the investigation of instability and related predictability of planetary atmospheric motions.

TEN YEARS OF THE 'EUROMARS' CLIMATE MODEL

Peter Leonard READ[1], Stephen LEWIS[1], Claire NEWMAN[1], Luca MONTABONE[1], Henning BÖTTGER[1], Francois FORGET[2], Frédéric HOURDIN[2], Monika ANGELATS I COLL[2], Miguel LOPEZ-VALVERDE[3], Jean-Paul HUOT[4], Marie-Christine DESJEAN[5] ([1]Department of Physics, University of Oxford, [2]LMD-CNRS, Paris, [3]Instituto de Astrofisica de Andalucia, Spain, [4]ESA-ESTEC, [5]CNES)

2003 marks the tenth anniversary of a collaboration between Oxford University and Laboratoire de Météorologie Dynamique du CNRS in Paris, whose objective has been to develop a comprehensive and detailed numerical circulation model for the atmosphere of Mars. Despite an inauspicious start, following the loss of the Mars Observer spacecraft in 1993, and thanks to consistent support from PPARC in the UK and CNRS in France (and more recently from ESA and CNES), this project has gone from strength to strength, culminating in the present suite of models which are capable of capturing many aspects of the observed meteorology and climate of Mars in considerable detail. In the present talk, we will review the current status of development of the 'Euromars' model, now involving an additional collaboration with the Instituto de Astrofisica de Andalucia in Spain. In the present configuration, Oxford and LMD run their own dynamical solvers (pseudo-spectral and finite-difference in the horizontal, respectively), whilst sharing a common library of physical parametrizations of all of the main physical processes which cannot be resolved by the model grids. These are now of comparable sophistication to those in use for long-term climate modelling studies of the Earth, and results generally compare very well with the increasingly extensive range of observations becoming available from missions such as NASA's Mars Pathfinder lander, Mars Global Surveyor (MGS) etc. Recent developments include a reasonably full representation of the transport cycles of dust and water in the Martian climate system, including an emerging ability to simulate the autonomous and spontaneous initiation of regional dust storms at appropriate phases of the seasonal cycle. Some examples of recent achievements will be presented, and compared with available observations. In new developments, the LMD version of the model is being extended into the thermosphere. In the latest efforts, a full meteorological data assimilation scheme has been implemented and interfaced with the Oxford version of the Euromars GCM. Results indicate that Mars's atmosphere is highly amenable to assimilated analyses of asynoptic mapping observations e.g. from the TES instrument on MGS. To date, a first pass of the entire MGS/TES dataset has been completed, allowing the recovery of a detailed synoptic, day by day determination of the fully three-dimensional state of the Martian atmosphere for nearly two Mars years. The talk will conclude with an overview of this dataset, some highlights from the MGS mapping period, and an outlook for the future.

MC04/11P/B22-002   1430

A NUMERICAL STUDY OF VERTICAL EDDY MIXING DUE TO GRAVITY WAVESGENERATED BY THERMAL CONVECTION IN THE MARTIAN ATMOSPHERE

Masatsugu ODAKA[1], Kiyoshi KURAMOTO[1], Kensuke NAKAJIMA[2], Yoshi-Yuki HAYASHI[1] ([1]Division of Earth and Planetary Sciences, Graduate School of Science, Hokkaido University, [2]Department of Earth and Planetary Sciences, Faculty of Sciences, Kyushu University)

CO_2, the major constituent of the Martian atmosphere, isdissociated into CO and O by ultraviolet radiation in the Martianmiddle atmosphere. However, the observed concentrations of CO and Oin the Martian middle atmosphere are much smaller than those predictedby simple photochemical equilibrium. In a one dimensionalphotochemical model, the observed concentrations are explained by thecontribution of vertical mixing process (McElroy and Donahue, 1972);the HO_x catalytic chemical reaction which promotesrecombination of CO and O is enhanced by the vertical eddy transportof its source, H_2O, from the lower to the upperatmospheres. The intense eddy diffusion coefficient assumed in the one dimensionalphotochemical model may be explained by a strong mixing due to wavebreaking. One of the candidates for the waves is the verticallytraveling internal gravity waves generated by the thermal convectionin the lower atmosphere. In order to estimate the efficiency ofpossible mixing due to gravity wave breaking, we have performed adirect numerical simulation of generation, vertical propagation andbreaking of internal gravity waves caused by the thermal convectionunder dust-free condition. The numerical model utilized is the two-dimensional anelastic modeldeveloped by Odaka et al. (2001). The computational domain extends to51.2 km horizontally and 50 km vertically. The horizontal boundarycondition is cyclic. Both horizontal and vertical grid intervals are200 m except for the lowermost 200 m layer where the verticalresolution is enhanced. The solar flux at the top of the modelatmosphere changes diurnally with the condition of Ls = 100 at 20N. The initial condition is a motionless atmosphere with horizontallyuniform temperature. The numerical integration is started at LT =6:00, and is performed for 24 hours. The numerical results show that the horizontal and verticalwavelengths of the internal gravity waves in the stratosphere are from15 to 20 km and about 10 km, respectively. The temperature deviationassociated with the waves is about 10 K around 40 km height. Theeffective vertical diffusion coefficient, Ke, can be diagnosed as thevertical heat flux associated with the wave motion divided by thevertical gradient of the horizontal mean potential temperature. Thehorizontal mean values of Ke above 25 km hight have the same order ofmagnitude as that used by the one dimensional photochemical model ofNair et al. (1994). This suggests that the internal gravity wavesgenerated by thermal convection in the Martian lower atmospherecontribute greatly to the vertical mixing in the Martian middleatmosphere.

DEVELOPMENT OF A GENERAL CIRCULATION MODEL FOR THE EARTH TYPEPLANETARY ATMOSPHERES: THE GFD DENNOU CLUB ATMOSPHERIC GENERALCIRCULATION MODEL VERSION 6

Masatsugu ODAKA[1], Masaki ISHIWATARI[2], Shin-ichi TAKEHIRO[3], Keiichi ISHIOKA[4], Eizi TOYODA[5], Yoshi-Yuki HAYASHI[1] ([1]Division of Earth and Planetary Sciences, Graduate School of Science, Hokkaido University, [2]Graduate School of Environmental Earth Science, Hokkaido University, [3]Department of Earth and Planetary Sciences, Faculty of Sciences, Kyushu University, [4]Graduate School of Mathmatical Sciences, University of Tokyo, [5]Japan Meteorological Agency)

The GFD Dennou Club Atmospheric General Circulation Model version 6(AGCM6) is now being designed and developed as a tool that helps us toconstruct an understanding of dynamics and perform a comparative studyof the planetary atmospheres. The major target of AGCM6 is to developa software structure which enables us to change the model geometry andto build in or remove physical and/or dynamical processes with ease.This means that AGCM6 will be actually a series of virtual modelswhich cover the dynamical hierarchy from a simple geophysical fluiddynamical model to a full GCM and also cover the planetary parametersranging from Venus, Earth to Mars. Also aimed are 1) to incorporate anetwork transparent and self-descriptive data structure, and 2) keepportability which guarantees execution on various types of computers. In these days, GCMs of the Martian and Venus

atmospheres have beendeveloped by various groups to simulate, to a certain extent, thecharacteristic features observed in each atmosphere, respectively.However, from the viewpoint of understanding the simulation resultsand making a comparative study of the planetary atmospheres, currentGCMs, to say nothing about GCMs of the terrestrial atmosphere, arebecoming too complicated and/or specialized in each planet. Now, we have developed a spectral primitive equation model which is aprototype model of AGCM6 dynamical core. The source code is written byFortran 90 and follows the Japan Meteorological Agency Fortran 90coding rule (Muroi et al., 2002). For spectral transformation in themodel, we use ISPACK library (Ishioka, 2002) and SPMODEL library(Takehiro et al., 2002). ISPACK is a toolkit library for developingspectral numerical model, and SPMODEL enables us to improvereadability of the source code. We are proceeding to develop the AGCM6 dynamical core which isincorporated with the network transparent and self-descriptive datastructure. The data format follows the gtool4 netCDF convention(Toyoda et al. 2000), and gtool4 Fortran 90 library (Toyoda etal. 2002) is used for constructing data input/output subroutines. Weare performing Held-Suarez test with AGCM6 dynamical core andconsidering a suitable program structure which makes it easy to applyfor the planetary atmospheres and to generate reduced system models. MERIDIONAL CIRCULATIONS IN THE PLANETARY ATMOSPHERES

Manabu D. YAMANAKA (Graduate School of Science and Technology, Kobe University, Japan / Frontier Observational Research System for Global Change, Japan)

Meridional circulations in the planetary atmospheres are overviewed theoretically. In the steady axi-symmetric linear problem, the meridional flow is given by the external forcing (including effects of nonlinear terms) which is approximated by a Rayleigh-friction-like term proportional to the zonal flow. The vertical flow is given by the external (diabatic) heating/cooling which is approximated by a Newtonian-cooling-like term proportional to the temperature anomaly from a radiatively-equilibriated temperature field. Subsitutions of these formulas into the (two-dimensional) continuity equation in the meridional plane give a first-order differential equation in terms of the zonal flow and the temperature anomaly. This equation and the so-called thermal-wind relationship are essentially equivalent to the Cauchy-Riemann equations for the analytical functions. Using this set of equations, the meridional circulations and their balanced zonal-flow and temperature fields are disscussed generally. Comparisons with the actual atmospheres in Venus, Earth, Mars and Jupiter and expectations for planets outside our solar system are also discussed.

MC04/11P/B22-005   Invited   1515

SOME REMARKS ON THE THEORY OF MULTIPLE EQUILIBRIA IN THE ATMOSPHERE

Jianping LI[1], Shouhong WANG[2] ([1]National Key Laboratory of Numerical Modelling for Atmospheric Sciences and Geophysical Fluid Dynamics (LASG), Institute of Atmospheric Physics, Chinese Academy of Sciences, [2]Department of Mathematics, Indiana University, Bloomington, IN 47405, USA)

The phenomenon of multiple flow equilibria in the atmosphere is a basic characteristic of the atmospheric circulation. However, the necessary conditions of multiple equilibria in the atmosphere are an important and still unsolved problem. Theoretically, this problem is equivalent to find the conditions of multi-solution existed in stationary equations of the atmosphere. Based on the full primitive equations of stationary atmospheric motion the problem is discussed in this paper. Through studying three simplified equations of the atmospheric stationary equations, the linearized equations, adiabatic dissipative equations and forced non-dissipative equations, we prove that for the stationary equations of the atmosphere their stationary solution is either unique or non-existential in the absence of any one of nonlinearity, dissipation and external forcing. Therefore, the joint action of nonlinearity, dissipation and external forcing is the source of multiple equilibria in the atmosphere.

MC04/11P/B22-006   1615

HYDRODYNAMIC WAVES IN THE MARTIAN TOPSIDE IONOSPHERE: THEORY, SIMULATION AND EVIDENCE

Jing-Song WANG[1], Erling NIELSEN[2] ([1]Department of Geophysics, Peking University, [2]Max-Planck-Institut fuer Aeronomie)

The dispersion relation for hydrodynamic waves in an ionosphere with atmost a weak magnetic field shows, that acoustic-gravity wave (AGW) aswell as hydrodynamic hybrid waves may be excited in the topsideionosphere of Mars and Venus owing to fluctuations in the solar windpressure. The hybrid waves result from coupling between two differenthydrodynamic wave modes. One of these modes is the AGW mode, and theother is excited independent of gravity, but dependents on the presenceof horizontal gradients in the background plasma pressure and density.The latter mode propagates horizontally but can also propagatevertically if there is a vertical gradient in the horizontal velocity.This new mode is therefore called Background Gradient Wave (=BGW). Thehybrid waves will cause fluctuations with a wavelength of tens ofkilometers in the vertical plasma altitude profiles when they propagatevertically. The period of the waves will be of the order of 10^4 s. Further properties of possible AGW-BGW waves in Mars and Venusionospheres are given. A one-dimensional simulation of the amplitude and phase of these waves reveals that disturbances induced inthe topside ionosphere can penetrate the ionosphere downward and excitewaves propagating vertically in the ionosphere. Although thecharacteristics of the waves depend on the strength of the initialdisturbance, some critical parameters of the waves do not dependsignificantly on the excitation force and are also found to be quiteindependent of solar zenith angle. The frequency of the excited waves isabout $10^{-3}{\sim}10^{-4}$Hz and the vertical wavelength of about 60km isprevailing. Both agree well with and provide numericalsupport to the theoretical predictions. Spectrum analysis is applied to MGS observations, and structures verysimliar to the waves described above are found in the electron densityaltitude profiles, suggests that these structures are very likely thepredicted waves.

MC04/11P/B22-007   1630

THE EFFECT OF OBLIQUITY AND SURFACE CONDITION ON THE WATER CIRCULATION AND FREEZING CONDITION OF A PLANET: IMPLICATIONS ON HABITABILITY AND PALEO-MARS ENVIRONMENT

Yutaka ABE[1], Ayako ABE-OUCHI[2] ([1]Department of Earth and Planetary Science, University of Tokyo, [2]Centre for Climate System Research, University of Tokyo)

To discuss habitability on extrasolar planets we investigated the water circulation and the condition for the occurrence of a completely frozen state (a ″snow-ball″ state) with a general circulation model for both a land planet case (a wet planet without fixed ocean) and an aqua planet (a planet entirely covered by an ocean). We particularly concerned about the effect of obliquity, because a chaotic change of planetary obliquity is suggeted from dynamics. Since availability of liquid water is a necessary condition for life, water circulation is an important comtrolling factor of habitability. The complete freezing gives severe restrictions on the types of life, even though it may not sterilize the planet. Effects of obliquity and the surface condition are also important issues for understanding the environment of paleo-Mars, which likely experienced active hydrological cycle and large obliquity change. In addition, it has good chance to fall in a frozen state owing to the faint radiation of the young Sun and the large orbital radius. The results are summarized as follows. **1.** There are different regimes of hydrological cycle depending on obliquity. We call them as ″Upright″ and ″Oblique″ regimes. **2.** A land planet shows stronger resistance to the complete freezing than an aqua planet. **3.** Both land and aqua planets in the oblique regime show stronger resistance to the complete freezing than those in the upright regime. **4.** There is a good chance of low-latitude-only freezing (freezing of low latitude without freezing the entire planet) of a land planet with high obliquity. On the other hand, low-latitude-only freezing is unlikely on an aqua planet. From these results, following implications are obtained for habitability on an extrasolar planet and climate of paleo-Mars: **1.** A land planet with some water may be a better place for life than an aqua planet, because an aqua planet easily falls in a frozen state. **2.** It is a difficult question whether high or low obliquity planet is preferable for life, becouse former is resistive to the complete freezing, but the latter shows mild seasonal change. **3.** To keep a wet ground at the low latitude area of paleo-Mars, it must be in the oblique regime, or with oceans. Under such conditions, however, the low latitude is relatively easily covered by permanent snow. Thus, unfrozen wet surface on low latitude requires larger greenhouse gas than that required for unfrozen condition at the present obliquity. **4.** If the obliquity changed significantly while the average temperature was decreasing steadily, there must have been a period while only the low latitude area is covered by permanent snow. It is an interesting question whether we can find such evidence from geological records.

MC04/11P/B22-008   1645
ROLE OF CO2 CONDENSATION IN THE SURFACE ENVIRONMENTAL EVOLUTION ON MARS:PART I. CLIMATE TRANSITION BY ATMOSPHERE-ICE CAP MASS EXCHANGE

Tokuta YOKOHATA, Masatsugu ODAKA, Kiyoshi KURAMOTO (Division of Earth and Planetary Sciences, Graduate School of Science, Hokkaido University)

A significant process in forming the Martian surface environment is the condensation of CO_2, the main component of the atmosphere. In this study, we investigate the climate transition by the atmosphere-ice cap CO_2 exchange. Mars is a cold planet at present. However, several lines of evidence suggest that climate warming and cooling have repeated during its history. In order to study the stability and evolution of Martian climate, we constructed a 2-dimensional (horizontal-vertical) energy balance climate model. The long-term CO_2 mass exchange process between the atmosphere and CO_2 ice caps is investigated with particular attention to the effect of planetary ice distribution on the climate stability. Based on the analysis of the climate stability, we made numerical simulations of the climate transition between warm and cold climate taking into account the evolution of CO_2 ice cap topography (areal extent and altitude). Our model calculation suggests that high atmospheric pressure presumed for past Mars would be unstabilized if H_2 ice was widely prevailed. As a result, cold climate state might have been achieved by the condensation of atmospheric CO_2 onto ice caps. We call this process "collapse condensation". On the other hand, the low atmospheric pressure, which is buffered by CO_2 ice cap near the present pressure, would be unstabilized if the CO_2 ice albedo decreases. This might have led the climate into a warm state with high atmospheric pressure owing to complete evaporation of CO_2 ice cap. We call this process "runaway evaporation". The time scale for the completion of collapse condensation and runaway evaporation is about 10^3 year, which is geologically very short. The pressure drop in the collapse condensation is larger for the larger H_2 ice coverage and lower solar luminosity. The pressure would decrease from 10^5 Pa to 10^3 Pa due to collapse condensation at 3.8 Gyr ago. Areal extent of CO_2 ice cap formed by the collapse condensation would be larger (toward the latitude of 70-80 degree) than the present one (about 85 degree). On the other hand, runaway evaporation could occur if the albedo of CO_2 ice cap decreases enough. Through albedo feedback mechanisms of H_2 and CO_2 ices in the atmosphere-ice cap system, Mars might have experienced warm and cold climates episodically in its history.The glaciated terrains observed in the middle latitude might be a signature of the past extension in H_2 ice coverage. Polar layer deposits around the present ice cap might be traces of the past CO_2 ice cap formed by the collapse condensation.

MC04/11P/B22-009   1700
ROLE OF CO2 CONDENSATION IN THE SURFACE ENVIRONMENTAL EVOLUTION ON MARS: PART II. STABILITY AND GREENHOUSE EFFECT OF THE ICE CLOUD

Tokuta YOKOHATA[1], Yoshiyuki KOSUGITA[2], Masatsugu ODAKA[1], Kiyoshi KURAMOTO[1] ([1]Division of Earth and Planetary Sciences, Graduate School of Science, Hokkaido University, [2]Hitachi Software Engineering Co.,Ltd)

Geomorphological evidence suggests that Martian climate was warm enough for liquid water to be stable about 3.8 Gyr ago. However, the solar luminosity at that time may be too weak to allow the existence of liquid water even if several bars of CO_2 existed in the atmosphere, because the temperature lapse rate is decreased by the CO_2 condensation at the upper region of the atmosphere. Recently, it is widely accepted that the radiative effect of CO_2 ice clouds may resolve this enigma. This theory suggests that CO_2 ice clouds have a strong warming effect because the backward scattering of infrared radiation by the cloudswould be more effective than that of the solar radiation. However, studies on the scattering greenhouse effect of CO_2 ice cloud so far have several problems. The effects of the radiative absorption by the clouds remain poorly investigated, even though the scattering effects of the cloud layer are well studied. In this study, therefore, we construct a one\--dimensional atmospheric radiation model to investigate the stability and greenhouse effect of CO_2 ice clouds on early Mars. We particularly pay attention to the effect of radiative absorption by the cloud. Our numerical results suggest that the cloud particles are condensable in the cloud layer even though they receive the radiative warming. The column density of the cloud layer can be estimated on the basis of the mass balance between the CO_2 condensation and the particle loss due to gravitational settling. In addition, we can also calculate the cloud particle radius from the condensation mass flux and residence time, assumed for the particle number density. Our estimates yield that the cloud particle radius is about 10 micron and the column density is about 1 kg per square meter for the cloud number density same as that of the terrestrial cirrus cloud. Cloud layers most adequate for the greenhouse effect have particle radius of 10--20 micron, because backward scattering of infrared radiation is most effective at these particle size. The cloud layers with these particle sizes can also cause anti-greenhouse effect when the column density is larger than about 1 kg per square meter. This is because the effect of infrared absorption lowers the infrared backward scattering. Our estimate of the particle radius satisfies a necessary condition for the greenhouse effect, but that of the column density suggests that the cloud might have anti--greenhouse effect. However, the column density may not be so large enough to cause an anti-greenhouse effect, since our estimate of the column density corresponds to the highest one by neglecting the effect of the surface infrared radiation.

MC04/11P/B22-010   1715
EVOLUTION OF RESIDUAL CO2 ICE CAP AND CLIMATE CHANGES ON MARS

Kaoru TAKAYAMA, Tokuta YOKOHATA, Masatsugu ODAKA, Kiyoshi KURAMOTO (Division of Earth and Planetary Sciences, Graduate School of Science, Hokkaido University)

Abundant geological evidence including the outflow-channels and polar deposits strongly suggests that Mars has experienced significantclimate changes through its history. Partitioning of CO_2among the atmosphere, polar-caps and regolith plays an important rolein controlling the state of martian climate. Such climate changeswould be caused by the variability of CO_2 partitioning,which may be triggered by changes of boundary conditions such as thesolar flux, obliquity and total CO_2 mass on Mars. In thepast studies, residual CO_2 ice cap has been treated as areservoir with infinite capacity or constant thickness withoutconsidering the formation processes, having inhibited the quantitativetreatment of CO_2 partitioning. In this study, weconstruct a new climate model which can calculate the ice captopography consistently. We apply this model to the partitioning of CO_2 on Mars, and discuss the past climate change andevolution of polar topography. CO_2 is assumed to be partitioned among the atmosphere, icecaps and regolith, which is dependent on the latitudinal surfacetemperature profile. Atmospheric bottom temperature and surfacetemperature are calculated as a function of latitude and theatmospheric pressure using a two dimensional energy balance model. The topography of ice cap is calculated by solving the equation ofmass conservation taking into account CO_2 condensation,evaporation and ice flow. Let us examine first the responses of ice cap extent for variousatmospheric pressures. The CO_2 ice caps extend to lowestlatitude of 40 degrees when the atmospheric pressure is about 10^4 Pa. The lower the latitude of ice cap extent, the larger the ice capelevation at poles (about 15 km for maximum height). CO_2 partitioning is dependent on the total CO_2mass on the martian surface. When the total CO_2 mass islarge enough, most of CO_2 is partitioned into theatmosphere. As the total CO_2 mass decreases, theatmospheric pressure and surface temperature alsodecrease. Subsequently the growth of ice caps becomes possible due tothe condensation of atmospheric CO_2. Once the ice caps areallowed to form, its growth is rapid due to acceleration by the effectof ice albedo and ice flow, eventually massive CO_2 ice capsare formed. The mass and topography of such ice caps are estimated tohave iceline latitude of about 80 degrees and polar elevation of about1.5 km. This extent is similar to that of the observed polar deposits.

MC05   Monday, July 7 - Friday, July 11

MIDDLE ATMOSPHERE SCIENCE (ICMA)
Location: Site A, Room 9

STRUCTURE OF THE POLAR VORTEX AS REVEALED BY ILAS OBSERVATIONS OF MINOR-CONSTITUENTS AND METEOROLOGICAL DATA

Hiroshi KANZAWA (National Institute for Environmental Studies)

The structure of the stratospheric polar vortex is investigated using minor-constituents data (O3, HNO3, NO2, N2O, CH4, H2O, aerosol) for November 1996 - June 1997 of ILAS (Improved Limb Atmospheric Spectrometer), a solar occultation sensor aboard ADEOS (renamed ″Midori″ after the launch), and meteorological analysis data of UKMO and ECMWF. A main advantage of ILAS is to provide longitude - height cross-sections of trace species at a latitude per day in both polar regions: it covers the stratosphere with altitude resolution of 1 km (see the details in the ILAS Special Section papers of J. Geophys. Res.-Atmospheres, Vol. 107, D24, 2002). The 1996/1997 Arctic winter is a characteristic winter because the polar vortex was maintained until the beginning of May 1997, that is, the polar vortex was stable and maintained abnormally long. This brought about abnormally low total ozone in March 1997 (e.g., Newman et al., 1997). The ILAS measurement latitude in the Arctic changed around 65 degrees North in December 1996 to around 70 degrees North in March 1997. ILAS measured the inside, the edge, and the outside of the polar vortex because the polar vortex developed in winter is not symmetric with respect to longitude. ILAS thus gives basic information on the structure of the polar vortex that is one of the main factors determining ozone distribution. The speed of downward motion in the polar vortex is regarded as an index of degree of isolation of the polar vortex. Using long-lived tracer (CH4, HF, and H2O) data of HALOE (Halogen Occultation Experiment) aboard UARS (Upper Atmosphere Research Satellite), several authors have carried out estimates of downward motion for the Antarctic polar vortex (Russell et al, 1993; Schoeberl et al., 1995; Kawamoto and Shiotani, 2000). No work of the kind has been carried out for the Arctic polar vortex because it is not so much stable as the Antarctic one and because frequency of HALOE measurements in high latitudes is low. Using long-lived tracer data of ILAS, we try to make an estimate of downward motion speed in the stable polar vortex of 1996/1997 Arctic. The mixing of the polar vortex air in the ″horizontal″ direction is also estimated to evaluate the degree of isolation of the polar vortex. For the evaluation, plots of ILAS data in cross-sections of potential temperature - potential vorticity based equivalent latitude are carried put. Moreover, a new method named time threshold diagnostics (TTD), having been developed by Sugata (2000) for estimating effective flux of air parcels across given boundaries, was applied with use of ECMWF data. The Antarctic vortex is also investigated using data from ILAS and possibly ILAS-II now in orbit on ADEOS-II which was launched on 14 December 2002.

MC05/07A/A09-002   Invited   0930
FINE SCALE STRUCTURES IN THE DYNAMICS AND THE CHEMISTRY OF THE POLARVORTEX: SIMULATIONS WITH THE CHEMICAL LAGRANGIAN MODEL OF THESTRATOSPHERE (CLAMS)

Rolf MUELLER[1], Paul KONOPKA[1], Jens-Uwe GROOSS[1], Gebhard GUENTHER[1], Baerbel VOGEL[1], Hildegard STEINHORST[1], Daniel S. MCKENNA[2] ([1]ICG-I, Research centre Juelich, 52425 Juelich, Germany, [2]NCAR, ACD, Boulder Colorado, USA)

The chemical Lagrangian model of the stratosphere (CLaMS) is achemical transport model that simulates the full stratospheric chemistry including heterogeneous reactions and represents transport employing an Lagrangian scheme. That is advection is represented through trajectory calculations and mixing is implemented via a novelscheme that allows control over both the intensity and the location where mixing occurs depending on the

properties of the atmosphericflow. Through this design, CLaMS is particularly useful to representsmaller scale features in the atmosphere and thus useful to be applied to the interpretation of observations. Here, we focus on observations in the polar and midlatitude region ofthe Northern hemisphere in 1999-2000 (when the SOLVE-THESEO 2000experiment was conducted). CLaMS calculations in conjunction with balloon-borne and aircraft measurements show that the chlorinechemistry and ozone loss in late winter 2000 is in general welldescribed by the model calculations. Some exceptions will bediscussed. Furthermore, fields of long-lived tracers are wellreproduced by the model calculations, including filamentary structures observed by in-situ aircraft measurements. An assessment of the relative role of chemistry and mixing in of outside vortex air onchlorine deactivation in winter 2000 was possible through modelcalculations. These show that deactivation is almost exclusively dueto chemistry, the mixing effect not exceeding a few percent. Finallyfirst model results on the dynamics and chemistry of the split vortexin Antarctica in September 2002 will be shown.

MC05/07A/A09-003 Invited 1000

SEASONAL VARIATIONS IN CHEMICAL TRACERS IN THE UPPER TROPOSPHERE/LOWER STRATOSPHERE BASED ON HALOE OBSERVATIONS AND MODEL SIMULATIONS

Mijeong PARK[1], William J. RANDEL[2], Douglas E. KINNISON[2], Rolando R. GARCIA[2], Wookap CHOI[1] ([1]School of Earth and Environmental Sciences, Seoul National University, [2]National Center for Atmospheric Research, Boulder, Colorado)

The seasonal variations of methane, water vapor, ozone, and nitrogen oxides(NO_x) are examined in the upper troposphere/lower stratosphere (UTLS)based on 10 years measurements by the Halogen Occultation Experiment (HALOE). The observed variations are compared with the output of the Model for OZone And Related chemical Tracers (MOZART). Tropical methane at the 136 hPa level shows maxima in the Northern Hemisphere (NH) summer in both HALOE and MOZART, which implies enhanced stratosphere-troposphere exchange (STE) and mass transport into the stratosphere, especially in the Asian monsoon region. Another, weaker maximum in methane is observed in NH winter in HALOE but not in MOZART. The tropical seasonal cycles of water vapor derived from HALOE and MOZART are in good agreement except during the 'wet' phase of the 'tropical tape recorder' which is somewhat moister in MOZART. The annual cycle of water vapor correlates well with the tropical tropopause temperature and the summer monsoon circulation. Moist monsoon air entering the lower stratosphere becomes a direct source of moisture and contributes to the moist phase of the 'tape recorderAEsignal over the equator, especially in MOZART. In the annual cycle of ozone both HALOE and MOZART show strong tropical upwelling in NH winter. The seasonal cycle of NOX in the tropics observed by HALOE shows a maximum in NH winter, whereas a minimum is calculated with MOZART. This minimum seems to be due to inadequacies in the parameterizations for convection and lighting, which are responsible for transport and chemical generation of NO, respectively. The seasonal variations of methane, water vapor, and ozone point to the importance of the NH summer monsoon region for transport of these constituents into the lowermost stratosphere.

MC05/07A/A09-004 Invited 1100

THE REANALYSIS FOR STRATOSPHERIC TRACE GAS STUDIES (RESTS) PROJECT

Steven PAWSON (UMBC GEST Center)

The ˝Reanalysis for Stratospheric Trace Gas Studies˝ (ReSTS) project intends to provide a state-of-the-art meteorological dataset for use in chemistry-transport models (CTMs). The initial focus is on the period from May 1991 until April 1995, which encompasses the initial few years of observations from NASA´s Upper Atmosphere Research Satellite (UARS) as well as the abrupt increase and slow decay of volcanic aerosol loading from Mount Pinatubo. The reanalysis is being performed using NASA´s operational ˝GEOS-4˝ data assimilation system. The results presented in this paper will begin with an overview of the meteorology of the ReSTS period, validating the ReSTS data against independent analyses, followed by an evaluation of the system statistics (the ˝Observation minus Forecast˝ for different input data types). Some sensitivities to the assumptions made in the assimilation process will be presented, including aspects of the forecast model and the statistical model used in the observation-forecast merging. Aspects of trace-gas transport will be discussed, focussing on the on-line water vapor distribution (which is a quasi-inert trace gas in the stratosphere), off-line transport studies of ozone and selected long-lived species, as well as assimilated ozone. The results will be discussed in the context of transport studies and our ability to use reanalyzed datasets to examine long-term variations in the meteorology and composition of the middle atmosphere.

MC05/07A/A09-005 1130

A COMPARISON OF ISENTROPIC TRANSPORT INTHE STRATOSPHERE

Diane PENDLEBURY, Timothy J. DUNKERTON (NorthWest Research Associates)

Two-dimensional chemical transport models can be very useful in studying trends in climate and long-lived chemical species. However, it is important in these models to properly characterize the transport of tracers and other chemical constituents, since the full three-dimensional winds are not used to transport the chemical species in these models. Previous work has shown that it is sufficient to use the residual circulation in regions where the flow is linear and steady, and the waves are non-breaking. However, this relationship quickly breaks down in regions of even weak nonlinearity. Vertical transport in most of the stratosphere is naturally described by cross-isentropic motion, since potential temperature is conserved (expect for diabatic heating/cooling of air which indicates an actual change in the particle position), and isentropic surfaces are monotonically increasing with height. A similar coordinate for describing meridional transport is potential vorticity (PV), since it is also conserved following the motion. However, potential vorticity surfaces are not monotonic in latitude, particularly in theregion of the surf zone. PV equivalent latitude solves this problem by grouping air parcels by PV value, however, in doing so it ignores the spatial distribution of distinct air masses. This may be important if polar vortex air is entrained into the surf zone. By the PV equivalent latitude label, this air still belongs to the polar vortex, but it is now photochemically distinct from the polar vortex. Particle advection is used to analyse transport off PV contours on an isentropic surface. Particular attention is paid to motion within the surf zone, where PV gradients are very weak, and to motion across transport barriers (the edges of the surf zone), where PV gradients are relatively strong. Particles are initialized along constant PV surfaces in an already developed surf zone so that instantaneous velocities may be computed. The residual velocity, Lagrangian mean velocity, the particle transport velocity and the modified Lagrangian mean velocity will be calculated and compared. All quantities agree reasonably well in regions of linear waves, but not within the surf zone where PV contours overturn and are highly distorted. Discrepancies between these quantities and the meaning of each in different regions will be discussed. The possibility of labelling distinct air masses while making use of the PV equivalent latitude will be discussed.

MC05/07A/A09-006 1150

STRATOSPHERIC CHEMISTRY MODELLING USING ERA-40 METEOROLOGICAL FIELDS

Pascal SIMON[1], Franck LEFEVRE[2], Vincent-Henri PEUCH[1], Hubert TEYSSEDRE[1] ([1]Météo-France, [2]CNRS-SA)

The MOCAGE model is a Chemistry-Transport Model (CTM) that has recently been developped by Meteo-France on the basis of the REPROBUS stratospheric CTM (Lefevre et al, 1994). The main innovations of this new model are 1) the possibility to run the model with several nested grids and 2) its high degree of flexibility, with several options for the chemistry, physics and dynamics. It is thus possible to use the MOCAGE CTM for a large range of scientific applications, from studies of regional tropospheric pollution to studies of the stratospheric ozone hole phenomenon. The version of the model we will present here is the ˝climate˝ version, that has been developped specifically for long-term integrations and chemistry-climate interaction studies; it includes a parametrisation of the important tropospheric dynamical and physical processes, such as convective transport, dry and wet deposition, and an explicit representation of tropospheric and stratospheric chemistries using about 80 species and 200 reactions. In this presentation, we will show results from a validation experiment with this version of the MOCAGE CTM, in which it is forced by the ERA-40 meteorological fields over the 1990-2000 period. ERA-40 is the reanalysis project of the European Center for Medium-range Weather Forecast (ECMWF) of the 1958-2001 period, that is about to be completed; compared with earlier reanalysis made at ECMWF (ERA-15, for the 1978-1993 period), one specificity of the ERA-40 experiment is that the model top level has been placed in the mesosphere, so that ERA-40 also provides an analysis of the stratosphere in addition to the more conventional tropospheric analysis. The first part of the talk will be devoted to a presentation of the climatology of ERA-40 in the stratosphere and its comparison with operational analysis and ERA-15 climatologies. Focus will be put on the temperature field and on the Stratosphere-Troposphere Exchange, as both features are important factors influencing the representation of stratospheric chemistry. In the second part of the talk, we shall present MOCAGE results, with emphasis put on the ozone field, that will be compared with several observation datasets available for the 1990-2000 period: satellite data (TOMS, MLS, ...), ground-based (WOUDC) and in-situ (MOZAIC) measurements.

TESTING MIDDLE-ATMOSPHERIC OZONE PHOTOCHEMISTRY WITH TIMED SATELLITE OBSERVATIONS

Daniel R. MARSH, Anne K. SMITH (National Center for Atmospheric Research)

Factors that affect the distribution of ozone in the mesosphere andlower-thermosphere (MLT) include solar ultra-violet fluxes,transport processes on scales from molecular to planetary, the distributionof water vapor and other hydrogen species, and the temperature dependenceof key reaction rates. Theoretically, these factors can be incorporatedinto global models that allow prediction ozone concentrations throughout the MLT. The paucity of ozone observations, in particularextended observations during both day and nighttime, has made testing ofthese models problematic. With the launch of the Thermosphere, Ionosphere,Mesosphere, Energetics and Dynamics (TIMED) satellite, we now are able torigorously test our understanding of ozone photochemistry. We presentcomparisons of TIMED observations of composition, airglow and dynamicalfields with simulations from ROSE, a 3-dimensional mechanisticchemical transport model. The ability of this model to simulate a varietyof MLT observations on diurnal and seasonal timescales is evaluated.

MC05/07P/A09-002 1430

OZONE PERTURBATIONS IN THE ARCTIC SUMMER LOWER STRATOSPHERE AS A REFLECTION OF NOX CHEMISTRY AND PLANETARY-SCALE WAVE ACTIVITY

Hideharu AKIYOSHI[1], Takafumi SUGITA[1], Hiroshi KANZAWA[1], Nozomi KAWAMOTO[2] ([1]National Institute for Environmental Studies, Tsukuba, 305-8506 JAPAN, [2]National Space Development Agency/Earth Observation Research Center, Tokyo, 105-8060 JAPAN)

Ozone concentration perturbations in the high latitude lower stratosphere were observed by Improved Limb Atmospheric Spectrometer (ILAS) after the polar vortex breakdown at the beginning of May 1997 and until the end of June of that same year. Simulations and a passive tracer experiment using the CCSR/NIES nudging CTM show that the low-ozone perturbations observed in May were caused by the Arctic polar vortex debris, while those after the end of May resulted from a dynamical elongation of the polar low-ozone air mass developed by NOx chemistry in the summer polar stratosphere. These low-O3 air masses of different origin were advected or extended from the polar region to the ILAS measurement points. An episodic event of a dynamical O3 perturbation in June 1997 on a chemically induced meridional O3 gradient is presented. These results show that a timing of the polar vortex breakdown may affect the O3 background gradient in the summer lower stratosphere at mid and high latitudes. The O3 distribution will be discussed comparing with N2O distribution, which shows the polar vortex debris with the low concentration for a few months after the polar vortex breakdown in 1997.

MC05/07P/A09-003 1450

ANALYSIS OF YEAR-TO-YEAR OZONE VARIATION OVER THE SUBTROPICAL WESTERN PACIFIC REGION USING EP_TOMS DATA AND CCSR/NIES NUDGING CTM

Libo ZHOU[1], Hideharu AKIYOSHI[1], Kohji KAWAHIRA[2] ([1]National Institutes for Environmental Studies, [2]Fukui Prefectural University, Kenjojima, Yoshida-Matsuoka Fukui 910-1195)

Most recently, Kawahira et al. [2002] found that the total ozone less than 225 DU was located around (20oN, 130oE) over the subtropical western Pacific by EP-TOMS observation in December 2001. They also showed that a total ozone less than 200 DU was observed by the ground based measurement at Hongkong (22.22oN, 114o19´E), China and Naha (26.12oN, 127o40´E), Japan in the subtropical western Pacific for a few days in December, and with the lowest value below 190 DU. Such a local low ozone value stimulates us to study the ozone variation and its mechanism over the subtropical western Pacific. The year-to-year ozone variation over the subtropical western Pacific region is studied, especially the ozone lows in the 1996/97, 1998/99, and 2001/02 winters, using the Earth Probe Total Ozone Mapping Spectrometer (EP_TOMS) ozone data from August 1996 to July 2002. Using the regression methods developed by Ziemke et al. [1997], the signals included in the total ozone over the subtropical western Pacific region were analyzed. The results show that (1) the total ozone includes the seasonal variability, solar, QBO, ENSO signals, and MSU temperature variation; (2) the seasonal variability is dominant among them; and (3) the QBO-

associated regression fit contributed greatly to the unusual ozone lows in the winters of 1996/97, 1998/99, and 2001/02. A nudging chemical transport model (CTM) is used to simulate the year-to-year ozone variation and explain the mechanism for ozone lows from a 3-D ozone field. The CTM was developed using the Center for Climate System Research/National Institute for Environmental Studies Atmospheric General Circulation Model (CCSR/NIES AGCM) and introducing a nudging process for temperature and horizontal wind velocity. The ozone lows over the subtropical western Pacific are well simulated. The year-to-year variation in the total ozone is closely related to the position of ozone minimum, which is largely controlled by the QBO cycle. However, the discrepancies between the calculated ozone and observation show that the heterogeneous reaction processes may have some influence on the ozone variation over the subtropical western Pacific. Further comparison of two models with and without considering the NAT and ice formation shows a heterogeneous loss of about 3 DU of total ozone. Since the calculated loss may be overestimated, results show that the heterogeneous reaction processes may have smaller influence on the total ozone compared to the influence by the dynamical processes.

MC05/07P/A09-004	Invited	1510

DYNAMICAL INFLUENCES ON OZONE CHANGES

Theodore G. SHEPHERD (Department of Physics, University of Toronto)

The stratospheric ozone distribution represents a balance between dynamics and chemistry, with processes of both kinds playing a first-order role. Thus, while the stratosphere hasbeen chemically perturbed over the last few decades by increased halogen loading as well as long-term changes in other trace species, the effects of these perturbations need to be considered together with dynamical influences, whichact together with chemical processes in a coupled manner.Dynamical changes over decadal time scales may arise from the ozone changes themselves, from long-term climate change, orfrom natural variability. This talk will assess our current understanding of dynamical influences on ozone changes, both in midlatitudes and in polar regions, with an emphasis on the northern hemisphere.

MC05/07P/A09-005	Invited	1610

CHEMICAL SPECIES MAPPING ON TRAJECTORIES (CSMT): A NEW SCHEME OF CHEMICAL OZONE LOSS ANALYSIS USING A BOX MODEL ALONG TRAJECTORIES

Sachiko HAYASHIDA[1], Akiko KAGAWA[1], Sachiko KAWASE[2], Nao IKEDA[2] ([1]Faculty of Science, Nara Women's University, [2]Graduate School of Human and Culture, Nara Women's University)

We propose a new scheme to create synoptic maps of stratospheric minor species from asynoptic satellite measurements by utilizing a photochemical box model and trajectory analysis. Kagawa and Hayashida [submitted to J. Geophys. Res.] named it Chemical Species Mapping on Trajectories (CSMT). The CSMT incorporates; trajectory mapping; [Morris et al., 1995, 2000] with a photochemical box model. Minor constituents are time-integrated in a photochemical box model along trajectories that start from satellite measurement points until a target time. Combining a chemical model with trajectory mapping allows creation of synoptic maps of short-lived species as well as long-lived species. We applied CSMT to study the mechanism of Arctic ozone loss in the late winter and early spring of 1997, combined with Improved Limb Atmospheric Spectrometer (ILAS) data. The ILAS instrument was developed by the Environmental Agency of Japan (EA) on board the Advanced Earth Observing Satellite (ADEOS) that was launched in August 1996. ILAS successfully observed ozone and ozone-related species such as nitric acid, nitric dioxide, nitrous oxide, water vapor, methan and aerosols over both polar stratosphere during from November 1996 through June 1997 [Sasano et al., 1999]. The CSMT approach with initialization by ILAS-observed ozone, nitric acid, and nitrous oxide made it possible to map long- and short-lived minor species over the polar stratosphere. Comparison with ozonesonde and/or satellite data validated CSMT-derived ozone and other data, proving reliability of the scheme. The chemical ozone loss amount was estimated by using the chemical model, resulting the maximum rate of ozone loss being about 34 ppbv/day in late February, and the integrated ozone loss from 13 January to 31 March 41 %, when averaged over the polar vortex. The derived ozone loss rates and integrated ozone loss are fairly consistent with the results of other studies. The CSMT scheme is a simple but useful method to make assimilated maps of chemical species, and has a good potential to various applications including detailed analysis of chemical mechanisms in the atmosphere. MC05/07P/A09-006	1640

ON THE INFLUENCE OF THE LARGE-SCALE EDDY FLUX VARIABILITY ON INTERANNUAL AND DECADAL OZONE CHANGES

Axel GABRIEL, Gerhard SCHMITZ (Leibniz-Institut fuer Atmosphaerenphysik an der Universitaet Rostock e.V.)

The influence of the variability of large-scale eddy heat and momentum fluxeson interannual and decadal changes in the zonal mean ozone distribution is investigated based on a two-dimensional (2D) circulation model with interactively coupled transport and chemistry. The model is a 2D version of the3D GCM ECHAM. The large-scale eddy fluxes are prescribed in terms of monthlymean eddy mixing coefficients that are derived from ECMWF ReAnalysis (ERA).The results show that the eddy-forced changes in the lower stratosphericresidual circulation and eddy mixing processes induce coherent interannual anddecadal changes in temperature and ozone that covers much of the observed temperature and ozone variability at mid- and polar latitudes. The seasonaland vertical structure of the observed northern hemispheric zonal mean ozonetrend is captured in a remarkable way. It is shown that the induced midlatitudeozone changes are mainly related to the changes in the eddy mixing processes,and that the induced polar ozone changes are mainly related to the induced changes in the lower stratospheric temperature. It is also shown that the feedback of the varying zonal mean ozone to the zonal mean temperature play san essential role in reproducing realistic decadal temperature changes atpolar latitudes.

MC05/07P/A09-007	1700

CHEMICAL OZONE LOSS AND TRACER EVOLUTION IN THE ELEVEN ARCTIC WINTERS BETWEEN1991/92 AND 2001/02 DERIVED FROM HALOE OBSERVATIONS

Tilmes SIMONE[1], Rolf MUELLER[1], Jens-Uwe GROOSS[1], Ulrich SCHMIDT[2], James M. RUSSELL III[3], Yasuhiro SASANO[4] ([1]Institute of Stratospheric Research (ICG-I), Juelich, Germany, [2]University Frankfurt, Germany, [3]Hampton University, Hampton, USA, [4]National Institute for Environmental Studies, Japan)

Chemical ozone loss in the eleven Arctic winters between 1991/92 and2001/02 is calculated from HALOE satellite measurements using theozone-tracer correlation technique. First results of the winter2002/03 will also be shown. The early winter ozone-tracer referencefunction is deduced from HALOE and ILAS measurements and balloonobservations for nine out of eleven years. Additionally a constantempirical relation function between two long-lived tracersCH$_4$ and HF valid for the entire lifetime ofthe vortex is derived for eleven years between 1991/92 and 2001/02from HALOE. An evolution of the early winter ozone-tracer referencefunctions between 1991/92 and 2001/02 is apparent as well as theevolution of the relation functions between CH$_4$ andHF. Thus, the growth rate of HF at different stratosphericaltitudes can be estimated from HALOE observations. Using ofthegrowth rate of CH$_4$ and HF for each year tocombine early vortex observations from several winters, an earlywinter reference function is calculated for two winters (1997/98 and2000/01) where no observations are available inside the earlyvortex. The chemical ozone loss is deduced from deviations of theearly winter ozone-tracer reference function in the course of thespring. The relation between the area of possible existing PSCs(A$_{PSC}$) in the Arctic vortex and calculated ozone loss ineleven years indicates, that A$_{PSC}$ and ozone loss arerelated. However, we do not find a simple linear relationship.

MC05/07P/A09-008	1720

CHEMICAL OZONE LOSS MECHANISM IN WINTER/SPRING OF 1997 OVER THE ARCTIC DERIVED BY CSMT ANALYSIS: ON RELEVANCE TO DENITRIFICATION

Sachiko HAYASHIDA[1], Akiko KAGAWA[1], Sachiko KAWASE[2], Nao IKEDA[2] ([1]Faculty of Science, Nara Women's University, [2]Graduate School of Human and Culture, Nara Women's University)

Chemical Species Mapping on Trajectories (CSMT) is a new technique combining a chemical box model and trajectory analysis [Kagawa and Hayashida, submitted to JGR]. The CSMT incorporates Trajectory Mapping [Morris et al., 1995, 2000] with a photochemical box model, and minor constituents are time-integrated in a photochemical box model along trajectories that start from satellite measurement points until a target time. (See also our companion paper on CSMT scheme). The photochemical box model was generated by the tool developed by the Atmospheric Chemistry Division of the National Center of Atmospheric Research (ACD/NCAR). The chemical solver called RODAS was applied with 59 chemical species, 101 gas-phase reactions, 48 photodissociations, and 7 heterogeneous reactions. We also included PSC growth governed by the temperature change along trajectories. Super-cooled ternary solutions (STS) and nitric acid trihydrate (NAT) are suumed based on thermodynamic equilibrium. Though there are many uncertainties in the PSC formation mechanism and our PSC scheme is still preliminary, our model can involve denitrification implicitly, because actual data of denitrified gaseous nitric acid can be used as initial values. In this study we utilized Improved Limb Atmospheric Spectrometer (ILAS) data to investigate the effects of denitrification on chemical ozone loss. ILAS could observe ozone and ozone-related species including nitric acid, nitric dioxide, nitrous oxide, water vapor, methane and aerosols over both polar stratospheres from November 1996 through June 1997. Irie et al. [2001derived a significant denitrification of 43 % at 19 km (near 475 K) in late February of 1997 over the Arctic. In our study the chemical box model was initialized by ILAS-observed ozone and nitric acid, and the chemical ozone loss rate was estimated based on the chemical model along with the change in nitric acid. The ozone loss rates in late February are scattered considerably with high and low values in late February, indicating that denitrification caused two opposite processes: (1) prolonged activation of chlorine due to less NOx and (2) low additional activation of chlorine due to less PSC formation. Recently version 6 of ILAS data was released including ClONO2 as a new product. ClONO2 can be used to identify each air parcel as activated or deactivated in the form of chlorine. Preliminary analysis shows CSMT-derived ClONO2 well correlated to the ILAS-observed ClONO2. CSMT-based analysis incorporating actual nitric acid and ClONO2 data will throw new light on chemical processes in polar ozone destruction. [References] Irie, H. et al., J. Geophys. Res., 106, 23139-23150, 2001. Morris, G.A. et al., J. Geophys. Res., 100, 16491-16505, 1995. Morris, G.A. et al., J. Geophys. Res., 105, 17825-17894, 2000.

MC05/07P/A09-009	1740

DYNAMICAL INVESTIGATION OF OZONE MINI-HOLES DURING WINTER OF NORTHERN HEMISPHERE

Koki IWAO, Toshihiko HIROOKA (Department of Earth and Planetary Sciences, Kyushu University)

Ozone mini-holes are localized and transient (several days) depletion phenomena of column ozone amount which often appear over northern Europe. Especially on 30 November 1999, a extremely low total ozone value of 165 DU was recorded between Scotland and southern Scandinavia with the Total Ozone Mapping Spectrometer. This value is the lowest in mid- to high-latitudes of the Northern Hemisphere since the observation started in 1979. These ozone mini-hole episodes are known to be caused mainly by dynamical processes rather than chemical processes. In order to reproduce approximate total ozone distribution in the data-missing region, the dynamical reconstruction of 3D ozone was performed. From 3 kinds of satellite ozone data and daily potential vorticity (PV) distributions, the relationship between ozone mixing ratio and equivalent latitude (EL) can be calculated on 16 isentropic surfaces. We reconstruct the ozone 3D distribution on 30 November 1999 from the spatial EL distribution and this relationship averaged for 2 months. On the basis of the reproduced 3D ozone data, we examine several dynamical processes contributing to ozone mini-holes, i.e., air uplift in the lower stratosphere and adiabatic advection of ozone-poor air. The local uplift of airmass throughout this level contributes to form these mini-holes by driving ozone-rich stratospheric air out of the column. Quantitative analyses on this effect explain about a half of total ozone depletion for the event on 30 November 1999. Remaining half depletion is due to horizontal advection on isentropic surfaces: The displacement of polar vortex toward Europe in the middle stratosphere and polarward intrusion of low-latitude air due to Rossby wave breaking around tropopause transport ozone-poor air to the mini-hole region. Similar results are obtained for other severe mini-hole cases.

CLIMATOLOGICAL FEATURES OF STRATOSPHERIC STREAMERSSIMULATED WITH THE BERLIN CLIMATE MIDDLE ATMOSPHEREMODEL (FUB CMAM)

Kirstin KRUEGER, Ulrike LANGEMATZ, John Lee GRENFELL (Institute for Meteorology, Free University Berlin)

M

Stratospheric processes and their role in the development of the future ozone layer are an essential aspect in climate change. Besides the fundamental chemical processes, transport processes are an important factor determining the global distribution of atmospheric trace gases, such as ozone. The influence of dynamical processes on strength and variability of the observed total ozone decrease at mid-latitudes, especially in the northern hemisphere, is still an open question. The purpose of this study is to investigate the influence of air mass exchange through streamers/tongues on ozone at mid-latitudes. The occurrence of streamers can determine the amount of total ozone in mid-latitudes, whether through transport of natural low ozone from the tropics to the mid-latitudes (tropical-subtropical streamer) or chemically processed air from polar to mid-latitudes (polar vortex streamer). For this reason a streamer climatology has been produced to investigate the frequency of both types of streamers with a 10-year climatology of the Berlin Climate Middle Atmosphere Model.

A CONNECTION THE STRATOSPHERIC QUASI-BIENNIAL OSCILLATION WITH APPEARANCE AND VANISHMENT OF EL NIÑO / LA NIÑA EVENTS

Makoto INOUE (Department of Earth Information Mathematical Sciences, The Graduate School of Integrated Basic Sciences, Nihon University, 3-25-40 Sakurajousui Setagaya-ku Tokyo 156-8550 JAPAN)

It is widely recognized that the existence of the quasi-biennial oscillation(QBO)changes westerly and easterly wind in the stratosphere above the Tropics on average every 27 months. Many papers describe the cause ofEl Niño events.For example, it is widely known that westerly wind bursts weaken easterly wind over the tropical Pacific and consequently lead to El Niño events,and this view enabled forecast of 1997 El Niño event. On the other hand, appearance of El Niño was also predicted in 2002. But behavior which was apparently seen in 1997 El Niño event was hard to appear and appearance of 2002 El Niño event was unexpectedly delayed. Although finally El Niño event has occurred in 2002, it seems appearance and vanishment of ENSO events can not be predicted accurately even if researchers continue to observe only the ocean and troposphere as usual. There is a study interannual variations of temperature at the tropical tropopause associate with both ENSO and QBO, but few studies refer to direct connection QBO with ENSO.This study takes notice of the connection appearance/vanishment months of ENSO events with vertical structure of equatorial zonal wind. First of all, in 1982 Walker circulation was weakened because a stratospheric easterly component propagated into the upper troposphere in May and an El Niño event has started.But easterly component propagation from stratosphere to the upper troposphere would not always cause El Niño events.This necessary condition is to form the critical fields in the troposphere whether is likely to become El Niño events by means of westerly bursts *etc*.or not. On the other hand,since a strong stratospheric westerly component propagated into troposphere in May 1998, it obliged to finish an El Niño event and simultaneously caused a La Niña event. Speaking to May 1998, Yangtze River Severe Floods started in earnest. This El Niño / La Niña events before and after change are large-scale and representative. The stratospheric QBO contributed to change from an El Niño event to a La Niña event.This change seems to have disturbedan atmospheric circulation above the Tropics and caused East Asia local downpours and severe floods unprecedented in history. It was a significant factor that the lower stratospheric zonal wind component in May which is monsoon change time propagated into the upper troposphere, since few ENSO events appeared when they propagated in another months.

IMPROVED SAGE II WATER VAPOR INVERSION

Larry W. THOMASON[1], Nina IYER[2], S.P. BURTON[2] ([1]NASA Langley Research Center, [2]Science Applications International Corporation)

Public versions of SAGE II water vapor data exhibit some problems,including strong sensitivity to enhanced aerosol and seasonalvariability unlike other stratospheric data sets as well as anapparent bias near the hygropause. A new modification to the watervapor inversion technique has been developed which addresses these problems. Water vapor is measured with the SAGE II instrument using asingle filter-based channel, nominally at 935 nm. It is hypothesized that the spectral response of the filter underwent a significant change in the first few years after launch. This is in accordance with evidence that the physically similar NO_2 channel,nominally at 448 nm, also underwent a change in wavelength after launch. The NO_2 retrieval was reworked and resultedin significant improvement in NO_2 in version 6.1. Asimilar change in the water vapor channel would affect the apparent strength of the water vapor feature as well as the contributions ofother components such as molecular and aerosol scattering. It was found that a single constant wavelength adjustment is adequate toyield reasonable agreement with a water vapor climatology from HALOEfor the period of 1986 through the present except immediately following the Pinatubo eruption when aerosol interference remains aproblem. An additional improvement is made by allowing slightly different aerosol clearing models for the post-El Chichon period andthe post-Pinatubo period. Water vapor data in this newest version showmarked improvement over earlier versions.

MC05/07P/D-004	Poster	1400-211

ESTIMATION OF TURBULENT OZONE FLUXES FROM THE MIDDLE ATMOSPHERE THROUGH THE TROPOPAUSE OVER SHIGARAKI, JAPAN

Nikolai M. GAVRILOV[1], Shoichiro FUKAO[2] ([1]Saint-Petersburg State University, Atmospheric Physics Department, Petrodvorets, St. Petersburg, 198504, Russia, gavrilov@pobox.spbu.ru, [2]Kyoto University, Center for Research and Atmospheric and Space Research, Uji, Kyoto 611, Japan, fukao@kurasc.kyoto-u.ac.jp)

A numerical simulation has been used to verify the hypothesis about the influence of sharp change of vertical temperaturegradient near the tropopause on the increase of the amplitudes of IGWs propagating upward from the troposphere, wave breaking and generating of increased turbulence, which may make the middlelatitude tropopause more transparent for the transport ofadmixtures between the troposphere and stratosphere. An increasein the turbulent diffusivities at altitudes near and abovetropopause is usually observed with the MU radar in Shigaraki, Japan (35 N, 136 E). Turbulent diffusion coefficient calculated and measured with the MU radar are of 1 - 10 m²/s indifferent seasons. They lead to the estimation of vertical ozoneflux from the stratosphere to the troposphere of the order of (1- 10) 10¹⁴ m⁻² s⁻¹, which is comparable with the usually supposed ozone downward transport with the general atmosphericcirculation. Therefore, local enhancements of IGW intensity andturbulence at tropospheric altitudes over mountains due to theirorographic excitation and due to other wave sources may lead tothe changes in tropospheric ozone and the total ozone over different regions.

STRATOSPHERIC SUDDEN WARMINGS IN THE SOUTHERN HEMISPHERE : A COMPARISON BETWEEN EVENTS IN 2002 AND 1988

Akiko MORI, Akiko SAKAI, Toshihiko HIROOKA (Department of Earth and Planetary Sciences, Kyushu University)

In late September 2002, an unprecedented major stratospheric sudden warming occurred in the Southern Hemisphere.This warming was accompanied with the split of the polar vortex as well as the Antarctic ozone hole.Moreover, the seasonal march of the winter in 2002 was very unusual: Planetary wave activities were very strong and an oscillatory change of the polar night jet with a typical time scale of about 10 days was observed throughout the winter season prior to the sudden warming. Correspondingly, ozone hole was not so much developed. Similar features were also observed in the winter of 1988, although such a split of the polar vortex didn´t occur. It is very interesting to see the similarity as well as the difference between the two winters in terms of ozone distributions as well as stratospheric dynamics. Hence, we compare observational features of the events in 2002 and 1988 by using the NCEP/NCAR reanalysis data and the NOAA/TOMS total ozone data. We find that the planetary wave of zonal wavenumber 1 was very active in the stratosphere for both the winters; the strong wave activity in 2002 was seen from the beginning of the winter season, whereas that in 1988 was seen only after the end of July. The wavenumber 2 component was also active in 2002, whereas it was relatively weak in 1988 through the winter season. Such strong wave activity of wavenumber 2 brought about the split of the polar vortex. As a result, the above-mentioned periodic oscillation of the polar night jet was more conspicuous in 2002; the major warming occurred in late September in 2002, whereas an intense but minor warming occurred in the end of August in 1988. On the other hand, the intensity of ozone hole in terms of ozone hole areas and minimum column ozone amounts was weak in both the years; it was weaker in 1988. However, the area of low temperature less than 195 K, which is a threshold value for the formation of polar stratospheric clouds (PSCs), was almost the same in the two years. Nevertheless, we can say that the impact of the warmings to the general circulation and the ozone hole intensity seems to be larger in 2002, if taking account of the trend during the last two decades towards a stronger, colder and stable polar vortex.

MC05/07P/D-006	Poster	1400-213

THE OZONE MINIMUM OVER THE SUBTROPICAL NORTHWESTERN PACIFIC IN WINTER

Han JIANYU[1], Koji YAMAZAKI[1], Masanori NIWANO[2] ([1]Graduate School of Environmental Earth Science, Hokkaido University, [2]Dept. of Geophysics, Kyoto University)

The total ozone amount is generally low in the tropics and the zonal minimum lies in the Northern subtropics (20N,140E) in winter. Over the subtropical northwestern Pacific, the prominent ozone minimum less than 235DU is clearly seen.Since there is few studies on this ozone minimum, we examine the vertical structure of this ozone minimum. Using TOMS and HALOE/UARS data we found there is two distinct ozone minima in stratospheric, one at 10-15hPa and the other at 40-60hPa.Two vertical ranges are responsible for the northwestern subtropical ozone minimum. Although the middle stratospheric minimum (10-15hPa) is stronger than the lower stratospheric minimum (40-60hPa), but the lower stratospheric contribution for the total ozone is larger than the middle stratosphere because of density effect. The minimum in the lower stratosphere is probably caused by northward advection of an ozone-poor air from the equatorial region, which is brought from the troposphere (Randel et al., 2001). In the lower stratosphere, the ozone mixing ratio increases with latitude. Thus northward advection from the equator to the subtropics reduces the ozone in the subtropics. In the middle stratosphere, the ozone maximum is located at about 10S and the ozone density decreases toward northern high-latitudes. The northern subtropical tropical Pacific is located to the south of Aleutian High and it is a reasonable hypothesis that this anticyclonic circulation brings an ozone-poor air to the subtropical Pacific.A simple 2-dimensional chemical-transport model confirms this hypothesis.

CHARACTERISTICS OF INERTIO-GRAVITY WAVES OVER THE SOUTH PACIFIC OCEAN

Miho YAMAMORI[1], Kaoru SATO[2] ([1]Center for Climate System Research, University of Tokyo, [2]Arctic Environmental Research Center, National Institute of Polar Research)

It is now widely recognized that the atmospheric gravity waves play acrucial role in determining the global-scale fields of wind andtemperature in the middle atmosphere.However, our knowledge of the gravity waves over the ocean is limited,because of lack of observations. A radiosonde observation campaignMeSSO2001 (a meridional scan of the stratosphere over the ocean in2001) was performed over the middle Pacific, during about 1 monthcruise of Hakuho-maru, the research vessel of Ocean Research Instituteof the University of Tokyo, in December 2001. By launching Vaisala RS80-15GH radiosondes, vertical profiles oftemperature, horizontal winds and humidity were successfully obtainedin a latitude range from 28N to 48S at almost the same interval of 1 degree.In this study, characteristics of inertio-gravity waves in the uppertroposphere and lower stratosphere in the sub- and extra-tropics over the South Pacific Ocean were investigated by using the horizontal wind and temperature data at 31 points from 17 to 48S along the 160W meridian. We defined gravity wave components as those extracted by abandpass filter having cutoff wavelengths of 500 m and 5 km. The magnitude of potential energy associated with the gravity waves was about one fourth of that of kinetic energyon average. The kinetic energy was large around 35S and 15--20 km. Wave parameters were estimated by hodograph analysis together with thedispersion relation. It was noted thatenhanced kinetic energy was often due to near-inertial waves.The dominant direction of horizontal propagation was southward (poleward), with bias of eastward. The probability that the propagation direction was between 120 and210 clockwise from north was about 40% above 18 km. Sources of gravity waves were estimated for distinctive cases basedon the group velocity vectors with the aid of the operational analysisdata and IR image of geostationary satellite. The northward (equatorward) propagating waves having relatively largevertical group velocity observed in the sub-tropical lowerstratosphere were possibly associated with a cutoff cyclone existing tothe south of the vessel at those times.The southward propagating waves with large amplitudes observed inthe sub-tropical upper troposphere were likely generated in associationwith a vigorous convection in the South Pacific Convergence Zone.

SEMI-ANNUAL OZONE VARIATION IN THE MESOSPHERE OBSERVED OVER TSUKUBA, JAPAN

Tomoo NAGAHAMA[1], Hideaki NAKANE[1], Yasumi FUJINUMA[1], Hideo OGAWA[2], Akira MIZUNO[3], Yasuo FUKUI[3] ([1]National Institute for Environmental Studies, [2]Department of Earth and Life Sciences, Osaka Prefecture University, [3]Department of Astrophysics, Nagoya University)

We present results of continuous observations of the vertical ozone profiles between 38 and 76 km in altitude, which have been made with the millimeter-wave radiometer at the National Institute for Environmental Studies (NIES) in Tsukuba, Japan (36.1N, 140.1E) since October 1996. We analyzed temporal variations of ozone at various altitudes and newly revealed the features of a semi-annual variation between 56 and 68 km. The ozone mixing ratio in this region peaks in January and July, and the amplitude of the semi-annual variation at 60 km was estimated to be 13% of the annual average, which is about half the value of 28% observed at 76 km. The phase of the semi-annual variation from 56 to 76 km inverts suddenly at 68 km, suggesting that these semi-annual variations of ozone are not induced by the downward propagation of a single dynamical wave, but are caused by different mechanisms in the regions above and below 68 km. The ozone mixing ratio at 60 km correlates well with the inverse of the temperature at 65 km, indicating that the semi-annual variation of ozone at 60 km is mainly caused by the corresponding variation in temperature. Further details of the ozone temporal variations and comparison with physical properties are presented.

SIMULATION OF INERTIAL INSTABILITY IN APRIMITIVE EQUATIONS MODEL

Diane PENDLEBURY, Timothy J. DUNKERTON (NorthWest Research Associates)

Equatorial inertial instability simulated in middle atmosphere models is characterized by vertical gridscale structures in the zonal-mean winds and temperature. This paper will examine the three-dimensional structure of the instability. It will be shown that the instability has a zonal wavenumber dependence that is selected by the winter-hemispheric planetary waves impinging upon the zero-wind line. The breakdown of the unstable region will be examined, along with the effects on the zonal-mean state. Modification of the potentialvorticity gradient on the summer side of the equator by inertial instability creates a region of barotropically unstable flow that leads subsequently to the excitation of two-day waves. It will be demonstrated that the inertial instability also generates small-scale travelling waves. Examination of the dispersion relation suggests that these are upward propagating gravity waves. The possible effect of these waves on the mesospheric circulation due to critical layer absorption and generation of Eliassen-Palm flux convergences will be shown.

SENSITIVITY OF STRATOSPHERIC OZONE TO MEAN CIRCULATION IN AN OZONE REANALYSIS SYSTEM BASED ON A CTM

Kazuyuki MIYAZAKI[1], Toshiki IWASAKI[1], Kiyotaka SHIBATA[2], Osamu CHIBA[2], Tsuyoshi SEKIYAMA[2], Kotato ORITO[2] ([1]Department of Geophysics, Graduate School of Science, Tohoku University, Japan, [2]Meteorological Research Institute, Japan)

To reproduce global ozone distribution, we are developing an ozone reanalysis system based on a CTM. This system showed realistic temporal variations but did systematic error. We studied impacts of changing meteorological parameters to be nudged into GCM. Nudging temperature field in addition to horizontal wind field weakens the mean meridional circulation and degrades reanalyzed ozone.

FORCING MECHANISMS OF THE STRATOPAUSE SEMIANNUAL OSCILLATION

Hiroshi KUBO (Department of Earth and Planetary Sciences,Kyushu University)

The stratopause semiannual oscillation(SAO) in low latitudes is well known phenomena.It is also well known that the zonal momentum forcing by the meridional wind and the easterly eddy momentum deposition by planetary waves play an important role in the SAO.However,the contribution of kelvin waves and gravity waves to the zonal wind accelerationof the SAO is still uncertain.In this study,forcing mechanisms of the SAO are investigated by using UKMO assimilated data(1992-2001).The momentum balance is diagnosed by using theTEM momentum equation. The results are as follows. The easterly acceleration in the equatorialregion during the solstice is mainly due to planetary waves and the meridional advection.On the other hand,the westerly acceleration during the equinox is likely due to the gravity wave drag.International variation of the SAO is also examined.It is clearly seen that the interannual variation in the SAO is related to the phase of the underlying quasi-biennial oscillation(QBO). Our result shows that the EP-flux divergence due to planetary waves and Kelvin waves plays an important role in the interannual variation of the SAO. Namely, during thewesterly phase of the QBO at 20hPa,the easterly acceleration due to the EP-flux divergence in the equatorial stratopause is relatively strong. The role of gravity wave drag in the SAO is examined by using a general circulation model(GCM) developed at Kyushu University. In the GCM,the gravity wave drag parameterization by Hines is used to calculate effects of the gravity wave.The contribution of the gravity wave drag to the SAO will be discussd.

OZONE DEPLETION OBSERVED AT TSUKUBA, JAPAN IN FEBRUARY 2001

Isao MURATA[1], Nobutaka KOBAYASHI[1], Hideaki NAKANE[2], Hiroshi FUKUNISHI[1] ([1]Department of Geophysics, Graduate School of Science, Tohoku University, [2]National Institute for Environmental Studies)

Considerable ozone depletion has been observed in the Arctic polar vortex since 1990s. Because of strong planetary wave activity in the Arctic region, the edge of the polar vortex occasionally attains to mid-latitudes. We investigated the effect of the Arctic ozone depletion in the mid-latitude region from the correlation analysis of O_3, HCl, HNO_3 and HF vertical column densities observed at Tsukuba, Japan (36.0°N , 140.1°E) with a high-resolution Fourier transform infrared spectrometer (FTIR). This FTIR has been operated since December 1998. The spectral resolution of the FTIR (Bruker 120M) is 0.0035 cm⁻¹. The spectral fitting algorithm to derive the vertical column densities is based on the SFIT program developed by Rinsland and is improved with a vertical shift procedure of the initial profile to minimize the residual of the spectral fitting. The derived O_3 vertical column densities agree with those measured by the Dobson spectrometer at the nearby (1 km apart) station within differences of 2 to 3 %. The spectra measured from December 1998 to October 2001 are used in this analysis. Correlations of column density variations between pairs of O_3 and HF, HCl and HF, and HNO_3 and HF are good indicators of the chemical changes of O_3, HCl, and HNO_3. These four species are all distributed mainly in the stratosphere. One of these species, HF is chemically very stable and hence a good tracer of the transport process. The other species, O_3, HCl, and HNO_3 are also relatively stable in the chemical processes in mid-latitudes. Therefore, variations in the column densities of these three species and HF usually show positive correlations. The correlations of O_3 and HCl to HF on February 20 to 23, 2001 are found to be lower than in other periods. It is indicated that O_3 and HCl on these days were chemically depleted. However, the correlation between HNO_3 and HF showed no significant variations. A potential vorticity analysis showed that Tsukuba was located in the

boundary region of the polar vortex on these days. The backward trajectory analysis indicated that the observed air masses at the potential temperatures of 475 K and 550 K came from inside the polar vortex. It is suggested that the chemically perturbed air masses arrived above Japan due to the distortion of the polar vortex.

CORRELATION BETWEEN OZONE AND POTENTIAL TEMPERATURE AND ITS DEPENDENCE ON SEASON AND LATITUDE

Katsuyuki NOGUCHI, Takeshi IMAMURA, Koh-ichiro OYAMA (The Institute of Space and Astronautical Science, Japan)

The seasonal and latitudinal variations of the correlation between the small-scale structures of ozone mixing ratio and potential temperature are investigated using ozonesonde data. Ozone distribution in the lower stratosphere is disturbed mainly by atmospheric motions since the chemical lifetime of ozone in this region is on the order of several months. Recently the backward trajectory method with the aid of meteorological assimilation data has successfully explained that the distinct structures of ozone profiles are mainly caused by horizontal advections associated with planetary waves. Ozone structures with vertical scales of <1km are less focused, due to the limit of the vertical resolutions of assimilation data, although they appear more frequently in the vertical profiles of routine ozone observations. The present study investigates the role of vertical and horizontal advections in creating small-scale structures of ozone profiles with statistical methods. We extract small-scale ($<$2km) structures of ozone, temperature, and wind velocity from the ozonesonde data distributed by the World Ozone and Ultraviolet Radiation Data Centre. The contributions of vertical and horizontal advections are inferred from the statistical analysis of the correlation between ozone mixing ratio and potential temperature. The candidates for the dynamical processes that cause those advections are also discussed.

EFFECT OF A CONVECTIVELY INDUCED GRAVITY WAVE DRAG PARAMETERIZATION ON HEAVY RAIN CASES SIMULATED BY MESOSCALE MODEL(MM5)

So-Young KIM, Hye-Yeong CHUN (Department of Atmospheric Science, Yonsei University)

Vertically propagating gravity waves can accelerate or decelerate the mean flow at the levels where wave breaking occurs. Convection is one of important sources of gravity waves. Even though mesoscale models for numerical weather prediction are developed with high resolutions, gravity waves forced by individual convective cloud cannot be entirely resolved. Therefore convectively induced gravity wave drag is better to be parameterized in the mesoscale model. In this study, a parameterization of gravity wave drag induced by cumulus convection (GWDC) proposed by Chun and Baik (1998) is implemented in the PSU/NCAR mesoscale model MM5, and effect of the GWDC on numerically simulated heavy precipitation cases in Korean peninsular is investigated. Two heavy rain events associated with Jangma front on 23-25 June 1997 and convection bands on 5-6 August 1998 are considered. The numerical experiments are conducted in a two-way nested grid system with horizontal grid spacings of 45km in an outer domain and of 15km in an inner domain. In order to investigate effect of the GWDC, two types of simulations with (GWDC) and without (CTL) the parameterization are performed. In the GWDC simulation, cloud-top wave stress is distributed in major convective regions. The magnitudes of diabatic heating rate and resultant cloud-top wave stress are large where deep cumulus cloud exists under relatively weak wind and stability condition. Impact of the GWDC parameterization in horizontal wind field is strong along the main convective regions. The magnitude difference between the GWDC and CTL is significant at the levels above clouds, and it extends down to the lower atmosphere through the change of horizontal divergence/convergence pattern. The impact of the GWDC parameterization is stronger in the inner domain mainly by the large value of diabatic heating rate. Improvement of the model performance by including the GWDC parameterization will be presented by comparison of the model results with observations.

STRATOSPHERE DYNAMICS OBSERVED BY MST RADARS.

Hubert LUCE[1], Michel CROCHET[1], Francis DALAUDIER[2], Shoichiro FUKAO[3], Mamoru YAMAMATO[3] ([1]LSEET, Toulon-Var University, La Garde, France, [2]Service d'Aeronomie du CNRS, Verrieres le Buisson, France, [3]Radio Science Center for Space and Atmosphere, Kyoto University, Kyoto, Japan)

Mesosphere-Stratosphere-Trosphere (MST) pulsed radars are powerful remote sensing tools for the study of the lower atmosphere dynamics from synoptic scale of motion down to the small scale of turbulence. They are particularly well adapted for the monitoring of the tropopause and its foldings, and for the tracking of mesoscale structures such as meteorological fronts via reflectivity and wind observations at high spatio-temporal resolution. They are also proper instruments for continuously observing mountain and inertia-gravity waves and turbulence up to about 20-25 km. Such abilities are of interest for providing estimates of the vertical transport of mass and energy through the lower atmosphere and for a better understanding of the contribution of the meso and small scale processes on atmospheric chemistry, for example. This paper is devoted to report results of ST radar measurements, mainly with the Japanese Middle and Upper (MU) atmosphere radar in different observational modes. Attention is drawn to observations performed during a radar-balloon campaign called MUTSI which took place in 2000 near the MU radar. Careful comparisons between both of the observations permitted us to validate the performances of the ST radars for wind measurements with high accuracy and spatio-temporal resolution. The paper also deals with stability, gravity wave and turbulence observations by MU radar discussed in light of high resolution (10 cm) temperature profiles measured by balloon. Such high-resolution profiles also give direct information on disturbances from waves down to the smallest scales of turbulence. They permitted us to analyze in detail the relationship between the characteristics of the radar echoes and the reality of the temperature field. In particular, it was found that turbulent mixing structures such as those revealed by the temperature profiles give rise to intense isotropic radar echoes in the tropopause region. These turbulent layers clearly arise through either gravity-wave breaking or instabilities produced by stratified shear flows resulting from the passage of a meso-scale wind disturbance at the jet-stream height. Similar turbulent events have been found within the stratosphere. Even though the structures are less extended vertically, they seem also to arise through shear instabilities. In most cases, these dynamic instabilities seemed to be triggered by a dominant gravity wave, classically observed at the MU radar latitude. The turbulent mixing was also identified as one of the sources of the generation of strong temperature gradients. They are so thin that they cannot be resolved using standard radar modes of observation. Dual and multiple frequency domain interferometry techniques are presently developed and offer the possibility to improve the radial resolution performances of the ST radars. Some results from the MU radar and the Equatorial Atmosphere radar (Indonesia) are shown. They clearly indicate that the ST radars tend to be a complete instrument for observing directly from the largest down to the smallest scales at all latitudes.

MODEL THERMAL RESPONSE TO MINOR ENERGY SOURCES AND SINKS

Victor I. FOMICHEV (Department of Earth and Atmospheric Science, York University)

The original middle atmosphere radiative scheme of the Canadian Middle Atmosphere Model (CMAM) included solar heating due to absorption by O_3 and O_2 and infrared cooling in the 15 micron CO_2 and 9.6 micron O_3 bands. During the past few years this scheme has been updated by inclusion of such processes as chemical heating, infrared H_2O cooling, sphericity effect in solar heating, and solar heating in the near-infrared CO_2 bands. All of these energy sources/sinks can be considered as minor ones either in terms of their magnitude, or in terms of the limited height region where they are of importance, or both. To examine the thermal response of the middle atmosphere, a version of the CMAM with an interactive gas-phase chemistry scheme has been used in a series of multi-year experiments for conditions of perpetual July. Contribution of each of the minor sources/sinks to the energy budget of the middle atmosphere, thermal response of the model and its statistical significance will be presented in the paper.

CHANGES IN TROPICAL UPWELLING: A POSSIBLE CAUSE FOR CHANGES IN STRATOSPHERIC WATER VAPOR

Karen H. ROSENLOF (NOAA Aeronomy Laboratory)

Increases have been noted in Northern Hemisphere middle latitude stratospheric water vapor over an extended period of time. However, over the past two years, a substantial decrease has been observed in tropical HALOE data in the 100-70 hPa layer. Similar decreases in the lower stratosphere are also seen in the frost point balloon observations taken by the NOAA Climate Monitoring and Diagnostics Laboratory in Boulder, Colorado, USA. (~40N) The decrease in water vapor appears to be the result of significant decreases in tropical tropopause temperatures as noted in assimilated model output (NCEP/NCAR reanalysis, UKMO/UARS analysis). There are also indications in the operational radiosonde data that there has been a decrease in tropical cold point temperatures. The recently observed decrease in lower stratospheric water vapor is confined vertically to pressures higher than 50 hPa. Increases are still apparent in water vapor in the middle and upper stratosphere as observed by HALOE and the Boulder water vapor sonde data. Possible changes in the mean meridional circulation in the tropics will be presented as a mechanism to explain temporal changes in observed stratospheric water vapor.

COUPLED MODELING OF THE DYNAMICS AND CHEMISTRY OF THE MIDDLE ATMOSPHERE

Byron A. BOVILLE, R.R. GARCIA, D. KINNISON, D.R. MARSH, R.G. ROBLE, F. SASSI (National Center for Atmospheric Research)

There are many fascinating scientific questions which require models that span the atmospheric domain from the surface to the thermosphere and include both dynamics and chemistry. Several such models are either already in use or are being developed. One of these is the Whole Atmosphere Community Climate Model (WACCM2), which simulates the atmosphere from the surface to the lower thermosphere (140 km) and includes coupled dynamical and chemical models. The dynamical model is an upward extension of the Community Atmosphere Model (CAM2) using the Lin and Rood finite volume dynamical core. The chemical model incorporates a comprehensive middle atmosphere ozone chemistry based on MOZART III. Differences will be discussed between simulations using observed climatological ozone; prognostic ozone; and ozone prescribed from the climatology of the prognostic run. The emphasis will be on the interactions between dynamics and chemistry. Both the effects of dynamics on the chemical evolution and the effect of chemistry on the dynamics will be discussed.

MC05/08A/A09-004 — 1000

INVESTIGATION OF CHEMICAL AND DYNAMICAL COUPLINGS USING THE WHOLE ATMOSPHERE COMMUNITY CLIMATE MODEL (WACCM)

Douglas Edward KINNISON, Rolando G. GARCIA, Byron A. BOVILLE, Fabrizio SASSI, Dan R. MARSH, Ray ROBLE (Atmospheric Chemistry Divison, National Center for Atmospheric Research)

An accurate prediction of future global change must account for the changes in the middle atmosphere chemical system (e.g., O3 and H2O distributions). Until recently, climate models have represented chemical processes in an overly simplified or decoupled manner. At the National Center for Atmospheric Research (NCAR), the Whole Atmosphere Community Climate Model (WACCM) has been developed to address the impact of dynamical and chemical couplings relevant to the stratosphere, mesosphere, and lower thermosphere. This model includes a detailed representation of middle atmosphere chemical processes. The chemical mechanism includes 48 species and approximately 120 chemical and photochemical reactions. The species are included within the OX, NOX, HOX, ClOX, and BrOX chemical families; alongwith CH4 and its degradation products. Heterogeneous processes on sulfate aerosols and polar stratospheric clouds (Type 1a, 1b, and 2) are included. Dehydration and denitrification on these aerosols are also represented. In this study we will describe the WACCM model and show results from a multi-year simulation that couples dynamics and chemistry. Detailed model and data comparisons will be shown representing diurnal and seasonal distribution of key middle atmosphere constituents. These results will be contrasted with a control simulation where model-derived constituents, particularly ozone, are replaced with climatological distributions.

MC05/08A/A09-005 — Invited — 1050

MIXING AND DEHYDRATION NEAR THE TROPICAL TROPOPAUSE: INFERENCES FROM RECENT WORK

Steven C. SHERWOOD (Yale University)

Debate continues on the role of convection in mixing and/or dehydrating the region near the tropical tropopause. Superficial attempts to infer how high above the surface tropical convective mixing remains important yield conflicting results, depending on the constituent examined. A previous model (Sherwood and Dessler, 2001), was able, however, to correctly predict features in the vertical distributions of water vapor, ozone, and cloud using an explicit overshooting-mixing scheme. Here I will discuss the the likely details by which dehydration in convective elements would occur. I will also present more recent model simulations that examine the seasonal cycle and transport of isotopes of water. These new simulations remove the most troubling obstacles to convection´s being a dominant dehydration process. Athough the simulations cannot rule out alternative dehydration mechanisms, they do show that convective fluxes must at least reach closer to the cold point than many have assumed.

A STRATOSPHERIC SPRINKLER OVER THE MARITIME CONTINENT - AN APPROACH BY TRAJECTORY CALCULATION

Koji YAMAZAKI[1], Hiroaki HATSUSHIKA[2] ([1]Graduate School of Environmental Earth Science, Hokkaido University, [2]Central Research Institute of Electric Power Industry)

A trajectory analysis by the AGCM-simulated three dimensional wind and temperature is done for investigating the path of the air with low water vapor from the tropical troposphere into the tropical stratosphere in the boreal winter. Tropospheric parcels are advected upward to the bottom of the tropical tropopause layer (TTL) mainly from the troposphere over the maritime continent and the western tropical Pacific, namely the ˝stratospheric fountain˝ region. Around the tropopause, there are strong easterlies and the cold search region tilts eastward with height. A down-slope flow over the upward bulged isentropic surface produces the downward-velocity over Indonesia. In addition, reduction of longwave heating over deep convection suppresses upward motion. Because of the time-mean downward motion over the maritime continent around the tropopause, it seems to be hard to ascend directly to the stratosphere in this region. Strong anticyclonic circulation tends to trap air parcels in the tropical western Pacific and it makes parcels pass the equatorial cold region several times during the slow ascent in the TTL. This slow spirally ascending motion (sprinkler) brings about low humidity in the stratosphere. In addition, transient disturbances, especially low frequency disturbances, produce intermittent upward motions over the fountain region and they dehydrate the air effectively. Both the spiral ascent and the transient mechanisms are the keys of the dehydration process around the TTL. An interannual variation of entered water vapor mixing ratio into the tropical lower stratosphere with the ENSO signal is also estimated. The La Nina years are more dehydrated than the El Nino years.

THE INTERFACE BETWEEN THE TROPICAL TROPOSPHERE AND STRATOSPHERE

Ian A. FOLKINS (Dalhousie University)

The tropical troposphere is often thought of as well mixed by deep convective overturning up to about 17 km, the height of the highest cloud tops. However, the upper tropical troposphere exhibits a number of properties that we commonly think of as being stratospheric: lapse rates that strongly deviate from moist adiabatic, a seasonal temperature cycle that is in phase with the Brewer Dobson circulation, ozone mixing ratios that increase with height, and positive clear sky radiative heating rates. It may therefore be appropriate to think of the boundary between the tropical troposphere and the stratosphere as a layer rather than a discrete boundary. In this way of thinking, the detrainment rate plays an important role in characterizing the decrease in convective outflow as you approach the stratosphere from below, and in interrelating the emergence of the various stratospheric properties.

BALLOON-BORNE OBSERVATIONS OF OZONE AND WATER VAPOR IN THE TROPICAL TROPOPAUSE LAYER - RESULTS FROM SOWER CAMPAIGNS

Masato SHIOTANI (Radio Science Center for Space and Atmosphere, Kyoto University)

In view of the lack of ozone and water vapor observations in the tropical upper troposphere and lower stratosphere (UT/LS), the Soundings of Ozone and Water in the Equatorial Region (SOWER)/Pacific mission has been conducted. This is intended to improve our knowledge on the ozone and water vapor distributions by making coordinated balloon borne observations in the Pacific region along the equator. The SOWER bases are at San Cristobal, Galapagos, Ecuador and Christmas Island, Kiribati supplementing the on-going program at Watukosek, Indonesia. The observations have been started as a basis of campaigns, the first of which was realized in March 1998. Since then, roughly two-week long campaigns have been conducted mostly in the period of February-March and September-October to capture the atmospheric behavior during local rainy/dry seasons and strong/weak pumping from the extratropical stratosphere. For the ozone measurement, we use the meteorological balloon-borne electrochemical concentration cell (ECC) ozonesondes. For the water vapor measurement, we use three different balloon-borne sensors (often at the same time), i.e., 1) the relative humidity sensor of the meteorological radiosonde, 2) a Swiss-made commercial chilled-mirror hygrometer named ˝Snow White˝, and 3) a US-made chilled-mirror hygrometer developed at National Oceanic and Atmospheric Administration (NOAA). So far our results from these campaigns have been contributing to the understanding of the stratosphere-troposphere exchange, especially on issues of the tropical tropopause layer. These results are briefly summarized in the following and will be detailed in the talk. i) Our water vapor soundings have revealed for the first time the seasonal and regional characteristics of water vapor distributions in the tropical UT/LS region. For example, observations at San Cristobal show that in March-April, water vapor concentrations are low and nearly saturated around the tropopause, but that in September the concentrations are high and often sub-saturated. ii) Soundings in the Galapagos provided an observational evidence that the equatorial Kelvin wave around the tropopause acts as a dehydration pump for the stratosphere. This process may be one of the important mechanisms that control the stratospheric water vapor concentrations, hence the stratospheric photochemistry. iii) We have been making several intercomparison campaigns of the three water vapor sensors as introduced previously. This is very important for the current scientific community because we now have no established water vapor sensor for monitoring the tropical UT/LS regions. We

are focusing especially on the ˝Snow White˝ hygrometerfor this purpose and improving this sensor.

MC05/08P/A09-002   1430

HOW DO AIR AND HUMIDITY ENTER THE STRATOSPHERE?

Andrew GETTELMAN[1], Tim J. DUNKERTON[2] ([1]National Center for Atmospheric Research, [2]Northwest Research Associates)

It is well accepted that air and humidity enter the stratosphere around the tropical tropopause. Exactly how, when and where are not well understood. This limits our prognostic ability to understand changes to the stratosphere. Some of the important processes for determining how air and humidity enter the stratosphere are: convective transport, horizontal motions and stratospheric transport. For water vapor, cold temperatures and cirrus ice clouds are also important. But which are the dominant processes of interest on various timescales? In this study it is argued that the basic features of troposphere to stratosphere exchange can be understood on a global scale through the use of large scale models, and some parameterizations of small scale processes. A suite of models tied to observations are used to explore how air enters the stratosphere. A 3D chemical transport model with realistic chemistry and idealized tracers is used to examine the spatial and temporal locations that contribute to the stratospheric ´tape recorder´ in humidity. The sensitivity of the stratosphere to changes in the driest (tropical western pacific in December-February) and wettest (Asian Monsoon region in July-September) regions of the Tropical Tropopause Layer is analyzed and the source regions of the 'tape recorder' signal are decomposed. These simulations are compared to observations of clouds, water vapor, ice, and stable isotopes of water vapor. The simulations are also compared to more detailed models and observations of the tropopause region and the lower stratosphere. The implications for trends in stratospheric water vapor, as well as stratosphere-troposphere exchange of water vapor and other trace species around the tropopause are examined.

MC05/08P/A09-003   1450

OBSERVING THE TROPOPAUSE TRANSITION LAYER IN THE TROPICS WITH THE HIGH RESOLUTION DYNAMICS LIMB SOUNDER (HIRDLS) ON NASA'S AURA SPACECRAFT

John C. GILLE[1], Alyn LAMBERT[1], Douglas KINNISON[1], Aaron LEE[2], Kenneth STONE[2], John BARNETT[3] ([1] NCAR, [2]University of Colorado, [3]Oxford University)

The High Resolution Dynamics Limb Sounder (HIRDLS) will be launched on the Aura spacecraft in early 2004. It has been designed to achieve higher vertical and horizontal resolution in retrieved quantities than has previously been available. The vertical resolution results from a narrow (~1.2 km) vertical field of view, oversampling, and low noise which allows deconvolution of fine scale structure. In addition, correcting for gradients along the line of sight results in results with high accuracy. We illustrate this with simulations of operational retrievals of 3-D model fields over the W. Pacific, showing the capability to retrieve temperature and water vapor structures in the vicinity of the tropopause only a few hundred meters in thickness.

MC05/08P/A09-004   1510

INTRASEASONAL VARIATIONS OF HUMIDITY AND THIN CIRRUS CLOUDS IN THE TROPICAL UPPER TROPOSPHERE

Nawo EGUCHI[1], Masato SHIOTANI[2] ([1]Graduate School of Environmental Earth Science, University of Hokkaido, [2] Radio Science Center for Space and Atmosphere, University of Kyoto)

Distributions of upper tropospheric humidity, thin cirrus clouds andmeteorological fields associated with the intraseasonal oscillation are investigated using UTH (Upper Tropospheric Humidity) data from MLS (Microwave Limb Sounder) on board UARS (Upper Atmosphere Research Satellite) at 215 and 146 hPa. The presence of thin cirrus clouds is inferred from the UTH data when relative humidity is over 100%. This is justified by comparing with the UARS CLAES (Cryogenic Limb Array Etalon Spectrometer) aerosol data. Five Intraseasonal Oscillation events are clearly observed during the two boreal winters from October 1991 to April 1993. Composite analyses on the distributions of humidity and thin cirrus clouds for these episodes are performed on the basis of the bandpass filtered outgoing longwave radiation (OLR) data with a period of 20-80 days. Eastward moving high humidity regions with a phase speed of about 5 m/s are found over the central Indian ocean and near the date line. The high humidity region at 146 hPa exists in the western hemisphere and expands more horizontally than at 215 hPa. When convection is mature, the thin cirrus cloud frequency becomes larger in the tropical Western Pacific and its high frequency region moves around the global. Temperature anomaly field consists of zonal wave-number 2 or 3 components at both levels. The positive (negative) region at 215hPa (146hPa) proceeds (moves behind) the convective area with about 10 degrees (5 degrees). The correlation between temperature anomalies and water vapor anomalies at 215hPa (146hPa) is positive (negative) over the convective area. The structure of temperature anomalies associated with the intraseasonal oscillation resembles that due to the Kelvin wave. The negative anomalies are over the convective area and tilt eastward and upward. The temperature anomalies change sign at 200 hPa over the convective area. The enhanced humidity area extends to near the tropopause by the deep convection. Then it extends further westward and northward from the convective area because of the horizontal transport. There are drier regions of subsidence on each side of the convective region.

MC05/08P/A09-005   1530

SEASONAL AND INTERANNUAL VARIATIONS OF THE TROPOPAUSE TEMPERATURE AND HEIGHT OVER INDONESIA

Noriko OKAMOTO[1], Manabu D. YAMANAKA[2], Shin-Ya OGINO[3], Hiroyuki HASHIGUCHI[3], Noriyuki NISHI[4], Tien SRIBIMAWATI[5] ([1]Graduate School of Science and Technology, Kobe University, Japan, [2]Graduate School of Science and Technology, Kobe University, Japan, and Frontier Observation Research System for Global Change, Japan, [3]Radio Science Center for Space and Atmosphere, Kyoto University, Japan, [4]Graduate School of Science, Kyoto University, [5]Agency for the Assesment and Application of Technology, Indonesia)

Seasonal and interannual variations of tropospheric and lower stratospheric temperature including CPT (Cold Point Tropopause) have been investigated based on operational rawinsonde data at 11 stations over Indonesia and 22 stations in surrounding region during 1992-1999, and comparisons with NCEP reanalysis data are also made. Upper tropospheric and lower stratospheric temperature over Indonesia has annual variation which has lower (higher) in northern winter (summer) and peak to peak difference is approximately 5 K. This annual variation is the same as that at other equatorial region reported in previous studies. CPT over Indonesia is usually lying between 100hPa and 70hPa. In longitudinal direction, CPT temperature is almost uniform in northern summer but has difference of about 4 K which is lower in eastern part (130E) and higher in western part of Indonesia (100E) in

northern winter. In latitudinal direction, CPT temperature is highest over 0-5S and lower in higher latitudes (15N and 15S), and the temperature difference between over the equator and higher latitudes is larger in northern winter (about 3 K) than in northern summer (about 2 K). Similar latitudinal structure is clearly seen at 100 hPa level, and temperature has symmetrical structure about the equator. However this symmetrical structure is not appeared in NCEP reanalysis data especially in northern summer, and difference from rawinsonde data becomes larger with southward (4 K in 15S). As interannual variations, two kinds of variation are clearly confirmed. One is the variation correlated with ENSO, and the other is monotonical change. During normal (non-El Nino and -La Nina) period from July 1992 to April 1997, temperature below than 100 hPa altitudes increases year by year and the increasing rate becomes maximum (0.23 K/year) at 200 hPa level. On the other hand, lower stratospheric temperature decreases year by year and increasing rate is especially low at 50 hPa (-0.84 K/year) and 70 hPa (-0.82 K/year). During thus period, CPT temperature varies in inverse phase with CPT height correlated with QBO, and decreases year by year keeping with longitudinal structure mentioned above. However after the period, El Nino situation started in May 1997, both CPT temperature and height have positive anomaly and longitudinal structure also becomes unclear. In the troposphere, large positive anomaly appears in October 1997 (when El Nino came to mature stage) and continues until the end of the El Nino.

MC05/08P/A09-006   1620

POSSIBLE CROSS-TROPOPAUSE TRANSPORT PROCESSES IN THE TROPICS OBSERVED BY THE EQUATORIAL ATMOSPHERE RADAR IN INDONESIA

Shoichiro FUKAO, Masatomo FUJIWARA, Masayuki K. YAMAMOTO, Takeshi HORINOUCHI, Hiroyuki HASHIGUCHI (Radio Science Center for Space and Atmosphere, Kyoto University)

Dynamical transport across the tropical tropopause region directly or indirectly controls the stratospheric photochemistry and the Earth´s radiative balance by determining the concentrations of minor constituents and particles there. However, the mechanism has not been well understood yet due to scarcity of observations. In this paper, we discuss two processes that seem to be related to this mechanism, Kelvin-Helmholtz instability and breaking of an equatorial Kelvin wave, obtained with the Equatorial Atmosphere Radar in Indonesia (EAR; 0.20°S, 100.32°E, 865 m above sea level).First, the EAR observed a persistent strong eastward wind shear (10-50 m/s/km) of westward wind in November 2001, and the radar echo layer tilted downward to the west in the region 0-1 km above the tropopause. The vertical wind was always upward in the same region. During the same period, the Richardson number was continuously less than 0.5 and occasionally less than 0.25, indicating that the Kelvin-Helmholtz instability frequently occurred there. The existence of the tilted radar echo layer can be explained by KHI billows. Also, the observed updraft has been found spurious, being caused by the KHI-induced tilted echo layer in the strong westward wind. Second, a significant enhancement of turbulence was observed with the EAR in the tropopause region intermittently for about 5 days during November 19-23. The turbulence intensity estimated from the power spectral width during the period was up to a factor of five times larger in kinetic energy than that in other periods. Further analyses have confirmed that the enhanced turbulence was convectively generated in the breaking phase of an equatorial Kelvin wave. Between July and December 2001, we observed three more prominent cases of the turbulence generation by the same breaking Kelvin waves in the tropopause region.

MC05/08P/A09-007   1640

OBSERVATIONS IN THE TROPICAL TROPOPAUSE REGION WITH THE EQUATORIAL ATMOSPHERE RADAR

Masayuki YAMAMOTO[1], Masayuki OYAMATSU[1], Takeshi HORINOUCHI[1], Masatomo FUJIWARA[1], Hiroyuki HASHIGUCHI[1], Mamoru YAMAMOTO[1], Shoichiro FUKAO[1], Manabu YAMANAKA[2] ([1]Radio Science Center for Space and Atmosphere, Kyoto University, [2]Graduate School of Science and Technology, Kobe University/Frontier Observational Research System for Global Change)

Now there are many controversies about the airmass motions in the tropical tropopause layer (TTL). The Equatorial Atmosphere Radar (EAR), located at the equator in West Sumatra, Indonesia (0.2 degrees south, 100.32 degrees east, 865 m above mean sea level), is a 47-MHz clear-air Doppler radar. The EAR has been observing three-dimensional wind velocities and the intensity of turbulent eddies with half the radar wavelength (about 3m) in the troposphere and the lower stratosphere (2-20km) since July 2001 [Fukao et al., 2003]. So far, the EAR has been observed the enhancement of turbulence due to an equatorial Kelvin wave [Fujiwara et al., 2003] and the frequent occurrence of the Kelvin-Helmholtz instability (KHI) around the tropical tropopause [Yamamoto et al., 2003]. In this paper, we show that the EAR has the ability of determining the tropopause height and the observational result especially in the region 0-1km above the tropopause. A clear-air VHF Doppler radar receives the strong echo around the tropopause due to the rapid increase of static stability in the region. The scattered signals in the region comes from the horizontally stratified echo layer (Frenel reflection). By using these properties, we determined the tropopause height (Radar Tropical Tropopause: RTT) from the height profiles of echo power and echo power aspect ratio. The height of RTT was compared with the height of lapse-rate tropopause determined by the radiosonde soundings at Kototabang, and its correspondence was excellent. The height of RTT was almost corresponding to the maximum of the westward wind (20-35m/s), and the strong vertical shear of zonal wind (10-50m/s/km) was observed in the region 0-1km above RTT. The spectral width, which indicates root-mean-square turbulent motion of the 3-m eddies, increased in the region (0.5-0.9 m/s in northward beam and 0.7-1.2 m/s in eastward beam). The spectral width observed in the zonal direction was greater than that in the meridional direction, because the vertical shear of horizontal wind generates turbulence and the vertical shear of zonal wind was stronger than that of meridional wind. Yamamoto et al. [2003] showed that vertical wind measured with the vertical beam was continuously upward in the region 0-1 km above the tropopause in November 2001, and it contained a spurious-updraft component caused by the tilted echo layer generated by the KHI billows and the strong westward wind. Upward wind measured with the vertical wind in the region 0-1 km above the tropopause was observed throughout July-December 2001, which suggests the frequent occurrence of KHI not only in November 2001 but also in the long term. To avoid the effects of spurious vertical wind component caused by tilted echo layer generated by KHI billows and the strong westward wind, vertical wind was calculated with two symmetric meridional beams (NS vertical wind), which is little effected by the tilted echo layer and the horizontal wind to the vertical wind measurement. The NS vertical wind also showed updrafts with the magnitude of 1-5 cm/s.

WATER VAPOR AND AEROSOL EXTINCTION VARIATIONSASSOCIATED WITH THE EQUATORIAL KELVIN WAVE IN THE TROPICAL TROPOPAUSE LAYERAS OBSERVED IN HALOE DATA

Masanori NIWANO (Department of Geophysics, Kyoto University)

The occurrence of cirrus clouds and dehydration in the tropical tropopause layer (TTL) has a close relationship with seasonal cycle and an increasing trend of water vapor in the stratosphere. Water vapor and aerosol data from the satellite, baloon and lidar measurements have documented variations in the distribution of cirrus clouds within the TTL on a broad range of timescales. However, the spatial variation of cirrus clouds related to large scale intraseasonal variations, such as the equatorial Kelvin wave or the Madden-Julian Oscillation (MJO), has received little attention in the TTL. This work examines the occurrence of cirrus clouds associated with the short term variations in the TTL, using water vapor and aerosol extinction data (version 19) from the Halogen Occultation Experiment (HALOE) measurement. Temperature data are taken from rawinsonde measurements over Singapore to validate the occurrence of cirrus clouds. The cirrus cloud altitude is here defined by the log-pressure height where the vertical gradient of extinction at 5.26 μm ($d \log_{10} \beta$ /dz) excesses 0.28 km⁻¹ with altitude decreased. The analysis is focused on two tropical measurements of 20 to 28 January 1993 (case 1), and 23 December 1998 to 1 January 1999 (case 2), during which cirrus clouds tied with the equatorial Kelvin wave appear just above the tropopause. Both in the two cases, the isolines of water vapor and aerosol extinction shows longitudinal distribution with planetary zonal wave number ~2 and its maximum vertical displacement of about 6 km (from 70 to 150 hPa) around the TTL. The longitudinal structure tilts eastward with height, so that its vertical wave length is ~18 km, which is identified with the equatorial Kelvin wave connected to the outgoing longwave radiation (OLR) anomalies. Over Singapore, temperature perturbation is descending with time with a period of 20-25 days, and cirrus clouds correspondingly appear in the region of cold temperature anomalies. It is stressed that, in case 2, a water vapor decrease by 1-2 ppmv and an extinction enhancement by an order of ~1 are simultaneously observed up to 60 hPa where wet anomalies of water vapor of 4.5-5 ppmv exist. The occurrence of cloud top around 60 hPa nearly coincides with the upper extension of the region less than 195 K due to the equatorial Kelvin wave perturbation. This result demonstrates the tight connection between planetary scale variation and the occurrence of cirrus clouds in the TTL, suggesting the potential role of the equatorial waves in dehydration and ozone destruction on the cirrus clouds within the TTL.

MC05/08P/A09-009 — 1720

TROPOSPHERE- STRATOSPHERE INTERACTION DURING A TROPICAL CYCLONE PASSAGE OVER INDIA

Mrudula G, Mohan Kumar K (Department of Atmospheric Sciences,Cochin University of Science and Technology)

Zonal and meridional momentum flux transport during the passage of a tropical cyclone over Indian sub-continent has been studied. The cyclonic storm, which formed on October 14, 2001 in the west central Bay of Bengal developed into a deep depression on October 15th morning. This system further intensified into a cyclonic storm on same day evening, crossed over MST radar site at Gadanki (13.5°N, 79.2°E), India, on October 16th morning. The MST radar daily observations of 30-minute duration (0930-1000 hrs LT) from 11 – 21 October 2001 and special observations of 1 hour duration from October 15th at 0930 hrs LT to October 16th at 1630 hrs LT between 3.75 and 21 km with an altitude resolution of 150 m have been used for the study. The horizontal velocity components show considerable changes in the upper troposphere and lower stratosphere during the passage of the cyclonic storm, whereas the vertical velocity shows strong upward motion in the 11 -12 km region. The zonal wind anomalies observed prior to the formation of the tropical cyclone seems to propagate upwards from the middle troposphere to the lower stratosphere. The transport of zonal and meridional momentum fluxes is calculated and presented. The zonal momentum transport is generally downward before the arrival of the tropical cyclone over Gadanki. Upward transport of zonal momentum flux starts in the middle troposphere (8 km) from October 13th onwards in association with the approach of the storm. As the cyclonic intensity increases the upward transport also extend to greater heights even upto the stratosphere. The maximum upward transport of zonal momentum flux is noted at the tropopause level on October 16 during the time of the overhead passage day of cyclone at the station. Before the development of the cyclone the meridional momentum flux transport is downward and changes to upward in lower levels from October 11th onwards, which becomes stronger as the storm approaches the station. The upward transport of meridional momentum flux is also maximum (~18m²s⁻²) at the tropopause level on the day of passage of cyclone over the station. After the passage of the cyclone the vertical transport of momentum fluxes returned to its prevailing downward direction.

MC05/08P/A09-010 — 1740

VHF RADAR OBSERVATIONS OF TROPICAL TROPOPAUSE AND ITS TEMPORAL VARIABILITY

Siddarth Shankar DAS¹, Mrudula G², Pramod Kumar KHANDAPAL³, A.R. JAIN¹ (¹National MST Radar Facility, ²Cochin University of Science and Technology, ³University of Allhabad)

Entrance of various chemical compositions and minor constituents from troposphere to stratosphere and vice-versa take place through tropical tropopause, which play a significant role in the troposphere-stratosphere exchange/dynamics. This makes the study of temporal and spatial variation of tropical tropopause so important to understand its various dynamical properties. Generally height of tropopause is determined from Radiosonde measurement, but it is limited in time resolution, since observations are taken only twice per day (0000 GMT & 1200 GMT). Thus the studies related to short period variability of tropical tropopause, which is important for the small-scale stratosphere-troposphere exchange are not possible by using existing conventional method. Also it is very difficult to get Radiosonde observation during convection and cyclone period, which play a major key role in Stratospheric-Tropospheric exchange (STE). At these situations detection of tropopause height by using remote-sensing technique, such as atmospheric radar, which are applicable in any of the above-mentioned weather condition can be adapted. In this paper we have used two different methods for the determination of tropopause height by using VHF-radar and compared each of them with the conventionally detected tropopause height derived from Radiosonde. These methods show consistency for both diurnal and day-to-day variation in tropopause height. Diurnal variation of tropopause during monsoon period is correlated with the tropopause temperature. The present results shows the minimum in both tropopause height as well as tropopause temperature at ~0400 hrs (LT). There is a simultaneous change in the environmental lapse rate, which is observed to be minimum during that period. Our results show the net upward mass-flux during the diurnal cycles at tropopause level. The detailed results of these studies will be presented in this paper.

MC05/09A/A09-001 — 0900

MODEL EVALUATION ON EFFECTIVE TRANSPORT ACROSS THE EXTRATROPICAL TROPOPAUSE USING TRACER RELATIONSHIPS

Jennifer Chu-Feng WEI¹, Laura L. PAN², Douglas E. KINNISON², Rolando GARCIA², Donald J. WUEBBLES¹ (¹Department of Atmospheric Sciences, University of Illinois at Urbana-Champaign, ²National Center for Atmospheric Research)

There remain significant uncertainties in understanding the chemical and physical processes that controls ozone and other constituents in the upper troposphere and lower stratosphere (UT/LS), or the tropopause ± 2 ~ 3 km region. One way to understand the transport characteristics associated with a wind field is to study the long-lived tracer distribution produced by the wind field through advection and mixing. The primary focus of our calculations is to examine the correlation of chemical tracers, such as N2O, O3, CO, NOy, H2O and CH4, in the UT/LS region using the new fully coupled troposphere, stratosphere and mesosphere version of the three-dimensional global scale chemical-transport model, MOZART 3 (Model for OZone And other Related Tracers, version 3). Studies are particularly aimed at evaluating the model transport in comparison with available measurements made by satellite instruments and by various aircraft campaigns, ozonesondes, and balloon experiments. Our intention is to carry out a comprehensive and systematic analysis of the UT/LS region in order to understand the relative roles of chemistry and transport for the distribution of key chemical constituents like ozone and water vapor in the UT/LS region.

MC05/09A/A09-002 — 0920

TROPOSPHERE-TO-STRATOSPHERE EXCHANGE AND THE WATER VAPOUR BUDGET IN THEEXTRA-TROPICAL LOWERMOST STRATOSPHERE

Michel S. BOURQUI, Heini WERNLI, Michael SPRENGER (Institute for Atmospheric and Climate Science, ETH Zurich)

The net downward transport across the extra-tropical tropopause is, in asynoptic perspective, the result of upward fluxes of tropospheric air and,to a larger extent, downward fluxes of stratospheric air. As far as watervapour is concerned, it is necessary to separate these two opposite fluxesbecause they have very different concentrations of H2O.The total upward transport of moist tropospheric air across the tropopausemay have important implications for the water vapour budget of the lowermoststratosphere. The tropospheric contribution to the water vapour budget inthis region is however not clearly understood yet and is the focus of thisstudy. The problem is addressed here using a Lagrangian perspective ofthe flow. The technique, based upon ECMWF re-analysis data, enables tosystematically trace air parcels and identify cross-tropopause exchangeevents. In the first part of the talk, the estimation of an upper bound for themass of water vapour transported from the troposphere to the stratospherebased upon the temperature at exchange locations will be discussed.And in the second part, first results will be shown from a water vapourbudget estimated by investigating the history of the air parcels foundin the lowermost stratosphere.

MC05/09A/A09-003 — 0940

MIDLATITUDE CROSS-TROPOPAUSE TRANSPORT OF WATER VAPOR AND TRACE CHEMICALS BY DEEP CONVECTIVE STORMS

Pao K. WANG (Department of Atmospheric and Oceanic Sciences, University of Wisconsin-Madison)

This paper shows the simulation results of cloud top plume transport process using a 3-D cloud dynamical model with explicit microphysics. The plume above thunderstorm phenomenon often observed by higher resolution satellite visible and IR images is successfully simulated. Analysis of the model results indicates that water vapor can be transported from the cloud into the stratosphere when the gravity waves caused by vigorous convection in the storm break. The breaking waves send water vapor through isentropic surfaces that are strongly distorted already by the updrafts. Characteristics of the simulated plumes and that observed by satellites show good agreement that lends strong support for the proposed process. This finding indicates that water vapor can be transported through the tropopause that is often considered impenetrable due to the strong stability of the overlying stratosphere. This could have important implications in global climate process and atmospheric chemistry. Water vapor is the most important greenhouse gas in the atmosphere and its radiative effect in the stratosphere is orders of magnitude higher than in the troposphere. In addition, water vapor at the stratospheric level serves as the source for strong oxidants such as OH and HOX radicals that are related to ozone destruction. Recent observational studies indicate that the lower stratospheric water vapor concentration increased by 1 to 1.5% annually in the midlatitudes in the last 35 years. The mechanism proposed here may serve as a key process in the possible explanations for the observed trend. Transport of inert chemical species that are less susceptible to the freeze- drying effect of the cold tropopausal temperatures are also investigated. A preliminary simulation using the same model but for inert tracer transport by these storms show that this is indeed the case.

CHANGE IN STRATOSPHERE/TROPOSPHERE EXCHANGE IN A DOUBLED CO2 CLIMATE

Warwick NORTON¹, Alan IWF² (¹Atmospheric Physics, University of Oxford, ²Rutherford Appleton Laboratory)

A middle atmosphere GCM coupled to a slab ocean has been used to examinechanges in stratosphere/troposphere exchange in a doubled CO2 climate.Changes in transport from the troposphere to stratosphere of water vapour andtropospheric source gases, and transport from the stratosphere to troposphereof ozone, are diagnosed. Hence predictions are made of possible future changesin stratospheric water vapour and tropospheric ozone. Changes in theBrewer-Dobson circulation, Hadley circulation, tropopause temperature, andeddy mixing across the tropopause are analysed to understand the changes intransport.

ASYMMETRY IN TRACER VARIATIONS DURING THE WESTERLY AND EASTERLY SHEAR PHASES OF THE QBO IN THE TROPICAL STRATOSPHERE

Wookap CHOI¹, Hyunah LEE² (¹Seoul National University, ²NCAR)

Concentrations and distributions of stratospheric aerosol, hydrogen fluoride and ozone from

the Halogen Occultation Experiment (HALOE) on the Upper Atmosphere Research Satellite (UARS) are used to investigate features associated with transport by the secondary meridional circulation induced by the quasi-biennial oscillation (QBO). The points of maxima in the divergence and convergence of the QBO-induced meridional velocity at the equator are identified from the meridional gradients of the tracers. Such points can be identified from the tracer fields in the westerly shear zones but not in the easterly shear zones. There are features of tracer fields associated with asymmetry between the easterly and westerly shear phases. The asymmetry seems to be mainly due to reversal of the direction of the secondary vertical motion. The temporal variation of tracer concentration at the equator is determined mainly by vertical advection, which is significantly larger during the westerly shear phase of the QBO than during the easterly shear phase, since the QBO-induced equatorial sinking motion amplifies the vertical gradient. Thus, the vertical advection associated with the secondary circulation has a stronger influence on the equatorial tracer variation during the westerly shear phase than during the easterly shear phase.

SEASONAL AND QBO VARIATIONS OF ASCENT RATE IN THE TROPICAL LOWER STRATOSPHERE AS INFERRED FROM HALOE TRACE GASES

Masanori NIWANO[1], Koji YAMAZAKI[2], Masato SHIOTANI[3] ([1]Department of Geophysics, Kyoto University, [2]Graduate School of Environmental Earth Science, Hokkaido University, [3]RASC, Kyoto University)

Mean meridional circulation in vertical velocity is indirectly estimated from the calculations of radiative heating rates or wave forcing, while the accurate calculation can not be achieved in the equatorial lower stratosphere due to uncertainties in the both two kinds of calculations. Water vapor data from the satellite and in-situ measurements give us an opportunity to estimate ascent rate in the tropical lower stratosphere. The extensive studies of vertical velocity using trace gases succeeded to derive seasonal cycle and the quasi-biennial oscillation (QBO). However, there is no systematic analysis of ascent rate as a function of altitudes, latitudes, and frequency. In this study, time and spatial variations in ascent rates are investigated, using water vapor (H_2O) and methane (CH_4) data from the Halogen Occultation Experiment (HALOE) measurements since 1991. The ascent rate is inferred from the ascending seasonal variations of $[H_2O] + 2[CH_4]$ (H). By calculating a vertical lag-correlation between the H profiles at a certain and the adjacent time steps, the ascent rate is estimated for every latitude, altitude and time. The ascent rate variations are not the same as variations of the actual vertical velocity, but a good indicator of the actual one within the subtropical barries. The derived ascent rate exhibits two kinds of dominant variations within ±15° of the equator: the one is seasonal cycle and the other is interannual variation with a period of nealry two years, being consistent with the QBO variations. The amplitudes of the seasonal and QBO components are relatively similar (0.05-0.10 mm $^{-1}$), but exhibit quite different meridional structures. The seasonal cycle shows vertically in-phase variations with northern a winter maximum (0.2-0.4 mm s^{-1}) and a summer minimum (0.15-0.2 mm s^{-1}) between 20-60 hPa, and the ratio of ~2 in the range of 20-40 hPa. The latitudinal distribution is characterised by 1) an early appearance of the well-known subtropical summer maximum of ascent rate and 2) a double peak structure around 10-15°N and S during the northern winter. On the other hand, The QBO component of ascent rate shows tropically confined variations and a rapid downward propagation, whereas mass attenuation estimated from vertical mass flux presents much slower downward propagation. The phase dependency of the QBO anomalies is observed, such that the descent anomalies exhibits a structured variation symmetric about the equator, while the ascent anomalies have a tendency to propagate latitudinally. This can be tightly connetcted with the phase dependency of the QBO acceleration. An examination of amplitude and phase of variations in the ascent rate and temperature emphasizes that the radiative damping timescale is considerably long (40~100 days) below 40 hPa.

THE QUASI BIENNIAL OSCILLATION: ANALYSIS OF THE NEW ERA-40 DATA AND A GCM STUDY

Charlotte PASCOE[1], Lesley GRAY[2] ([1]Rutherford Appleton Laboratory, [2]The University of Reading)

The new 40-year ECMWF reanalyses and a stratosphere resolving globalcirculation model have been used to investigate the influence of the equatorial quasi biennial oscillation (QBO) on stratospheric and tropasphericcirculation and variability. The model is a 64 level version of the UK Met Office Unified Model 4.5 with a top level at 0.01 hPa. The model has been used to perform three simulations. The first simulation imposes a QBO momentum forcing of specified period which has been confined to the lower stratosphere below 35 km. The second, deep QBO, simulation has equatorial QBO momentum forcing throughout the depth of the stratosphere. The third simulation is a control run where no modification of the equatorial wind has been made. In this way we can test the relative influence of the lower and upper equatorial stratosphere. The response of the wintertime polar stratospheric vortices to the three equatorial wind regimes will be discussed and validated using the new ECMWF era-40 data. Tropospheric circulation changes in response to the equatorial forcing will also be addressed.

KELVIN WAVE IN MERIDIONAL CIRCULATION AND LATERAL TRANSPORT OF ZONAL MOMENTUM

Takeshi IMAMURA[1], Takeshi HORINOUCHI[2] ([1]Institute of Space and Astronautical Science, Japan, [2]Radio Science Center for Space and Atmosphere, Kyoto University, Japan)

The solution of the equatorial Kelvin wave in the meridional circulation was obtained for the first time, using a perturbation theory, based on the primitive equations on the equatorial beta-plane. In this study, the meridional circulation is supposed to exist in the basic state and is not neglected in the linearized wave equations, in contrast to the conventional linear wave theories which assume meridional circulation to be the second order with respect to the wave amplitude. The wave solution was obtained analytically, after separating the vertical dependence from the horizontal dependence under the assumption that the mean flow is independent of height. The result shows that the wave is modified to have a non-zero meridional wind disturbance, which is absent when the background atmosphere is at rest. The combination of the meridional and zonal winds induces a meridional flux of zonal momentum in the upstream direction of the background north-south flow. When a Kelvin wave is present in a cross-equatorial circulation, the wave transports momentum from the winter hemisphere to the summer hemisphere. In the upper branch of the Hadley circulation, the wave transports zonal momentum equatorward. It was also shown that the non-acceleration theorem does not hold in the presence of a non-negligible meridional circulation: the EP flux divergence can be non-zero even when the wave transience and dissipation are absent. Implication of the results for the terrestrial and Venusian atmospheres is discussed.

QUASI-STATIONARY PLANETARY WAVES IN THE UPPER MESOSPHERE

Anne K. SMITH (National Center for Atmospheric Research)

Observations and models indicate that quasi-stationary planetary wavesextend as high as the mesopause. They occur more regularly in thewinter hemisphere and can have large amplitude even above the altitudewhere the mean zonal wind reverses. Numerical modeling resultsindicate that two processes are responsible: 1) propagation ofplanetary waves forced in the troposphere into both the winter andsummer mesosphere, and 2) in situ generation by gravity wave dragperturbations associated with filtering by variations in stratospheric winds.

WHAT DAMPS THE VERTICALLY PROPAGATING DIURNAL TIDE IN THE MESOSPHERE AND LOWER THERMOSPHERE?

Charles MCLANDRESS (University of Toronto)

The Canadian Middle Atmosphere Model (CMAM) is a comprehensive general circulation model that extends from the Earth´s surface to approximately 200 km and contains all important physical processes relevant to the region up to and including the lower thermosphere. Since the model generates a broad spectrum of waves in the troposphere, as a result of solar radiative heating and the release of latent heat by convection, it is a useful tool for examining the mechanisms which couple the troposphere and lower thermosphere. In particular, the model has been shown to be able to reproduce the observed seasonal behaviour of the vertically propagating migrating (Sun-synchronous) diurnal tide. In this presentation we will focus on the mechanisms responsible for damping the tide in the mesosphere and lower thermosphere, by examining the effects of convective instability and wave-wave interactions. As in earlier studies with the CMAM, a mechanistic tidal model is found to be useful in interpreting the general circulation model results.

MC05/09P/A09-003   1500

GLOBAL DISTRIBUTIONS OF DIURNAL AND SEMI-DIURNAL TIDES: OBSERVATIONS FROM HRDI-UARS OF THE MLT REGION AND COMPARISONS WITH GSWM 2002 (MIGRATING, NON-MIGRATING TIDES)

Alan H. MANSON[1], Chris MEEK[1], Maura HAGAN[2], Xiaoli ZHANG[2], Yi LUO[3] ([1]ISAS, University of Saskatchewan, [2]NCAR, Boulder, CO, U.S., [3]Canada Centre for Remote Sensing, NRCan, Ottawa, Canada)

HRDI (High Resolution Doppler Interferometer-UARS) winds data have been analyzed in 4° - latitude by 10° - longitude cells at 96 km to obtain global contour maps of solar-tidal amplitudes and phases, and also mean winds. The solstices June-July (1993), December-January (1993 - 1994), and one equinox (September-October, 1994) are shown. The 24-h Diurnal tide maximizes near 20-25° latitude, has significant seasonal changes with equinoctial variability, and very clear longitudinal variability. Maxima are very clear over the oceans. In contrast the 12-h Semi-diurnal tides maximize near 40-55° latitude, have very strong seasonal changes with winter maxima, and more modest longitudinal changes. The similarities with MLT (mesosphere-lower thermosphere) radar observations (90 km) are satisfactory. Mean winds are consistent with expectations and show clear poleward flow from summer to winter hemispheres in the solstices. A tidal zonal wavenumber spectral analysis has been applied. For the Diurnal tide, as well as the dominant s=1 migrating component, there are spectral peaks at s=2, 0, -2, -3; and for the Semi-diurnal tide, as well as the dominant s=2 migrating component, there are more frequent non-(solar) migrating spectral peaks at s=4, -2. Comparisons are made with the Global Scale Wave Model (2002/3), which now incorporates migrating and non-migrating tides, and offers monthly outputs. For the Diurnal tide the strongest non-migrating spectral feature (94 km) is at s=-3, while for the Semi-diurnal tide spectral peaks are frequently at s=4, -2. There is a detailed discussion of the spectral features, their seasonal variations, and the similarities with the HRDI tidal data.

MC05/09P/A09-004   1520

THE GENERATION OF STATIONARY WAVES AND NONMIGRATING TIDES IN THE UPPER ATMOSPHERE

Elsayed R. TALAAT[1], Hans G. MAYR[2], Jeng-Hwa YEE[1], John S. MENGEL[3], Ruth S. LIEBERMAN[4], James M. RUSSELL III[5], H.S. PORTER[6] ([1]The Johns Hopkins University Applied Physics Laboratory, [2]Goddard Space Flight Center, [3]Science Systems & Applications, [4]Colorado Research Associates, [5]Furman University, [6]Furman University)

Nonmigrating tides are planetary-scale waves of periods that are integer fractions of a day (diurnal, semidiurnal, etc.) and are not sun-synchronous (migrating). Nonmigrating tides in the upper mesosphere are traditionally thought to be mostly forced from below through solar radiation absorption by tropospheric water vapor and stratospheric ozone. Modeling studies have suggested that nonlinear interactions between the migrating tide and stationary planetary waves may generate nonmigrating tides of greater or equal strength to those forced from lower atmosphere heating. We investigate the different forcing mechanisms using a Numerical Spectral Model that incorporates HinesAEDoppler Spread Parameterization for small-scale gravity waves. We further examine recent satellite measurements for the relationship between stationary waves and nonmigrating tides.

MC05/09P/A09-005   1540

ON THE EASTWARD TRAVELLING WAVENUMBER TWO IN THE NORTHERN STRATOSPHERE

Kirstin KRUEGER[1], Steven PAWSON[2] ([1]Institut fuer Meteorologie der Freien Universitaet Berlin, [2]UMBC GEST CENTER)

Disturbances in the middle atmosphere are often interpreted inthe framework of waves superimposed on a zonal-mean flow. Thispaper presents an analysis of travelling waves in the northernhemisphere stratosphere, concentrating on planetary wavenumber two (W2). Space-time spectral analysis reveals the existence of a substantialeastward-travelling planetary W2 at high latitudes in winter.While a similar feature is well documented in the southern hemispherestratosphere, where it is observed in most winters, this northernhemisphere counterpart is less common and has not been examined in detail.A climatology of occurrence of the wave is given for the northernstratospheric winter. It is denoted as the quasi-16-day eastwardtravelling W2, because of its dominant periodicity, which ranges fromabout one to three weeks. Although the wave has some similarities withthe southern hemispheric wave, there is much larger interannual andintraseasonal

variability in the northern hemisphere. The paperwill emphasize the variations in the spatial and temporal structureof this wave, as isolated in meteorological analyses of radiosonde andsatellite data. The possible role of these travelling waves inpreconditioning the stratosphere as a precursor to sudden stratosphericwarmings in both hemispheres will be discussed.

INTERACTION BETWEEN MEDIUM-SCALE TROPOPAUSAL WAVES AND SHORT-PERIOD DISTURBANCES TRAPPED AROUND THE POLAR VORTEX EDGE

Yoshihiro TOMIKAWA[1], Kaoru SATO[2] ([1]Research Center for Advanced Science and Technology, University of Tokyo, [2]National Institute of Polar Research)

Tomikawa and Sato [2003] has first described the characteristics of short-period (< 1 day) disturbances with zonal wavelengths of about 2,000 km observed around the polar-night jet. They are considered to be Rossby waves latitudinally trapped in the large potential vorticity gradient around the polar vortex edge. In this presentation, the horizontal distribution of short-period disturbances is interpreted in terms of interaction with medium-scale tropopausal waves that have zonal wavelengths similar to the short-period disturbances [Sato et al., 1993]. The horizontal distributions of those disturbances exhibit a high positive correlation from May through August, suggesting that there is a relationship between those disturbances. The form of their interaction is diagnosed using three-dimensional wave activity flux. It shows that there is a net vertical convergence of wave activity flux around the polar-night jet throughout the year, indicating the transport of wave activity from the upper troposphere into the lower stratosphere due to those disturbances. The baroclinic coupling between those disturbances is suggested as a possible mechanism for upward transport of wave activity and amplification of short-period disturbances in the lower stratosphere. The other possible mechanisms and their characteristics will also be discussed in the presentation.

ISENTROPIC EXPRESSION OF ELIASSEN-PALM FLUX

Toshiki IWASAKI, Daisuke TANAKA (Graduate School of Science, Tohoku University)

We are developing a diagnostic scheme of wave-mean-flow interactions and mean-meridional circulation based on mass-weighted isentropic zonal mean states. This is a full extension of the transformed Eulerian mean (TEM) to exactly represent finite-amplitude effects of waves and to solve lower boundary conditions. This work demonstrates capability of diagnosing objective analyses, such as NCEP/NCAR reanalysis, and basic characteristics of isentropic expressions. A most significant difference from the TEM is in the vertical component of the EP flux near the lower boundary at mid-latitudes. In the free atmosphere, the isentropic Eliassen-Palm (EP) flux is almost similar to that of TEM. However, an exception is found around the polar vortex, where finite-amplitude effects may not be negligible. In case of the TEM, enormously large vertical flux comes out from the ground surface, because small amplitude approximations break down due to intersection of isentropic surfaces with the ground. In case of the new scheme, it becomes the mountain torque at the lower boundary, increases with height up to the middle troposphere and decreases above. The low level divergence and upper level convergence drive the extratropical direct circulation in the troposphere. In the NH winter, the EP flux is composed mainly of stationary ultra long waves (wave number 1-3) and transient long waves (wave number 4-7). A part of ultra long waves propagate through the tropopause and drive the direct circulation in the stratosphere. The EP flux of the transient waves is consistent with linear solutions of baroclinic instability waves. In the SH winter, on the other hand, stationary ultra long waves are not active. Thus, we can make a consistent analysis of the EP flux from the ground surface to the stratosphere. The energetics of the mass weighted isentropic zonal mean states is formulated. The potential energy of the zonal mean states is converted into the zonal mean kinetic energy, by driving the direct mean meridional circulation. Zonal mean kinetic energy is converted into eddy potential energy and kinetic energy through wave-mean flow interactions. Thus, we can get very straightforward interpretation of energy conversions among zonal mean parameters.

MC05/09P/A09-008   **1700**

INTRASEASONAL OSCILLATIONS OF THE ZONAL WIND NEAR THE MESOPAUSE OBSERVED WITH MF AND METEOR RADARS IN THE TROPICS

Fusako ISODA[1] ([1]Radio Science Center for Space and Atmosphere(RASC), Kyoto Univ., [2]Department of Physics and Mathematical Physics, University of Adelaide, [3]Indonesian National Institute of Aeronautics and Space (LAPAN))

We studied the behavior of intraseasonal oscillations (ISO) of the zonal wind in the equatorial mesosphere and lower atmosphere (MLT) using simultaneous observations during 500 days from January 1, 1996 with a meteor radar at Jakarta (6oS, 107oE) and two medium frequency (MF) radars at Pontianak (0oN, 109oE) and Christmas Island (2oN, 157oW). Phase difference of the ISO between Pontianak and Christmas Island is very small in spite of the longitudinal difference of about 90o, which suggests that the ISO in the equatorial MLT region is a variation of zonal mean flow. At Jakarta, the amplitude of the ISO of the zonal wind is smaller than that observed at other two equatorial sites. The peak of the ISO amplitude appears at 82-84 km at Jakarta, while it was at 88 km at other two sites. We also investigated long-term variation of the ISO of the zonal wind using Jakarta meteor radar data observed from January 1993 to October 1999. Inter-annual variation is dominant in the ISO amplitude. A relation between the ISO of the zonal wind and zonal amplitude variations of the diurnal tide is suggested. However, gravity wave activity in the MLT region did not correlate with the ISO in the zonal wind. The outgoing longwave radiation (OLR) in the tropical troposphere, which can be considered as an index for excitation intensity of the atmospheric waves, is compared with the Jakarta data in the MLT region. A relationship between the OLR and the ISO of the mean zonal wind is also suggested.

A THEORETICAL STUDY OF IONIZATION DURING NOCTILUCENT CLOUD

Dipak K. CAKRABARTY (Centre for Environment Survey)

Noctilucent cloud (NLC) occurs mostly in the high latitude region during summer. Several campaigns have been conducted by various authors to understand this phenomenon. These have revealed the existence of many interesting features. Important among them is bite-out of electrons without any change in positive ion density but increase in water molecules in the clustered ions. It is now established that NLC contains ice particles. Measurements have also revealed that there is a drastic decrease in temperature and a decrease in atomic oxygen density. It is likely that there would be an increase in ozone and water vapor density and a decrease in OH density. In this paper, first, available observed information is briefly mentiond. Then this information is plugged in an ion chemical scheme in which both positive

and negative ions are included. It is shown that atomic oxygen blocks the detachment of electrons from O_2^-, the precursor negative ion. A decrease in temperature further reduces the detachment of electrons from other negative ions. This causes the decrease of electron density or electron bit-out at the altitude of NLC. Positive ion density is, however, not affected. It is shown that if there is a sufficient decrease of temperature (by less than ~ 20K), then in the following reactions forward reaction rate f becomes fast and back reaction rate r become very slow making cluster ions with n as large as 50.

MC05/09P/A09-010   **1740**

CHEMICAL AND DYNAMICAL RESPONSE OF HIGH LATITUDE MIDLLE ATMOSPHERE TO SOLAR PROTON EVENT: 3D MODEL STUDY

Alexei A. KRIVOLUTSKY[1], Tatyana Yu. VYUSHKOVA[1], Anna V. KLYUCHNIKOVA[1], Adolf EBEL[2], Alexsander A. KUMINOV[1], Georgy R. ZAKHAROV[1] ([1]Department of Atmospheric Chemistry and Dynamics, Central Aerological Observatory, [2]Institute for Meteorology and Geophysics, University of Cologne)

3-D middle atmosphere general circulation model (developed in Cologne and installed now at CAO), and 3-D chemical global transport model developed at CAO were used to calculate the response of ozone (and other species), wind and temperature regime after one of the strongest solar proton event (SPE) of 23rd solar cycle. This event occurred in November 2001. It was assumed in photochemical scheme that each pair of ions created at high latitude middle atmosphere by solar energetic protons born approximately one molecular of NO and two molecular of OH, which disturb photochemical system in the stratosphere and mesosphere. Corresponding ionization rates caused by SPE has been calculated using high time-resolution satellite measurements of solar proton fluxes from the board of GOES-10. Calculated ionization rates showed that the maximum of ionization placed in the mesosphere and conserved about three days after the beginning of SPE. 3-D photochemical calculations showed that ozone was strongly reduced in the mesosphere region (about 80% with minus), but corresponding "tail" of disturbances existed more than 10 days after SPE. Some difference between ozone response over south and north polar regions have been revealed by simulations. Calculated ozone response has been introduced into dynamical model. Such ozone depletion caused by SPE leads to the disturbances of heating and cooling. The results of general circulation model simulations which used the results of photochemical calculations showed that calculated changes in zonal wind caused by SPE equaled about 2 m/s in the mesosphere, and corresponding changes in temperature equaled less than 1 K in this region. Some difference in dynamical and temperature response between north and south polar region have been revealed also in model simulations.

STRATOSPHERIC SUDDEN WARMING IN THE SOUTHERN HEMISPHERE IN 2002 AND ITS PREDICTABILITY

Toshihiko HIROOKA[1], Akiko MORI[1], Hitoshi MUKOUGAWA[2] ([1]Department of Earth and Planetary Sciences, Kyushu University, [2]Disaster Prevention Research Institute, Kyoto University)

In late September 2002, there occurred an unprecedented major stratospheric sudden warming in the Southern Hemisphere. The abrupt elongation and subsequent spectacular split of the stratospheric polar vortex was observed during the time sequence of the event. Such enhancement of the zonal wavenumber 2 component is very rare in the Southern Hemisphere stratosphere. Hence, by using the stratospheric assimilated data operationally produced by the Japan Meteorological Agency (JMA), we investigate dynamical features of the event, paying the special attention to the vertical linkage between the upper troposphere and stratosphere. It is found that planetary waves of both wavenumber 1 and 2 were very active in the upper troposphere and vertical propagation of planetary waves frequently occurred throughout the winter season prior to the major warming. Correspondingly, zonal mean westerlies in the upper troposphere were generally weaker than the usual through the period. Such vertical propagation of planetary waves brought about periodic deceleration of the westerly polar night jet with a typical time scale of about 10 days in the stratosphere. Among them, the deceleration occurred after the end of July were relatively large and gave rise to the sequential occurrence of minor warmings. As a consequence, the polar vortex were gradually weakened and became more vulnerable to planetary wave activities. Eventually, the major warming occurred in late September; the conditions necessary for the major warming were in fact the results of several minor warmings during mid-to-late winter. Moreover, we examine the predictability of the event by the use of operational one-month forecast data set based upon the JMA Numerical Weather Prediction Model. We also discuss precursor agents promoting the upward propagation of planetary waves and triggering the major warming event by comparing the predicted field with the observation.

MC05/10A/A09-002   **0900**

WHY DID THE 2002 SOUTHERN HEMISPHERE WARMING HAPPEN?

Richard SWINBANK[1], Adam SCAIFE[1], Neal BUTCHART[2], David JACKSON[1], Michael KEIL[1], Hazel THORNTON[1] ([1]NWP, Met Office, [2]CR, Met Office)

In late September 2002, a major sudden warming was observed in theSouthern Hemisphere for the first time since records began. Theevolution of the warming was captured well by the Met Officestratospheric analyses. During the event the polar vortex was splitin two, in a similar way to a northern hemisphere wavenumber-2warming. In the classic picture, a stratospheric warming is preceded bya pulse of wave activity from the troposphere that decelerates thewinds in the vortex. In 2002 unusual conditions persisted throughoutmost of the preceding months, with vacillations in the zonal wind ofamplitude about 20m/s. By contrast, in most previous winters thestratospheric westerlies varied much more gradually, and vacillationsonly occurred for limited periods, if at all. These vacillationsare very similar to what is seen in idealized experiments with asteady troposphere and suggest that stationary wave forcing may havebeen larger than usual. We suggest that the unusual vacillatingregime preconditioned the stratosphere and made it more susceptibleto the pulse of wave activity that led to the major warming.

MC05/10A/A09-003   **0920**

ON THE TROPOSPHERIC ORIGINS OF UPWARD PROPAGATING ROSSBY WAVE TRAINS INVOLVED IN THE 2002 SOUTHERN HEMISPHERE MAJOR WARMING EVENT

Kazuak NISHII, Hisashi NAKAMURA (Department of Earth and Planetary Science, Graduate School of Science, University of Tokyo, Hongo 7, bunkyou-ku Tokyo, 113-0033 Japan)

As unusual event of major stratospheric sudden warming occurred in the Southern Hemisphere in late September of 2002, leading to breakdown of the polar vortex and the

subsequent shrinking and breakup of the Antarctic hole. Time evolution of the warming is studied in this study through diagnosing the NCEP/NCAR reanalysis data, with particular emphasis on the three-dimensional structure and propagation of planetary waves. In our analysis two specific forms of a phase-independent pseudomomentum flux were utilized for depicting the propagation of quasi-stationary Rossby waves. One is Plumb´s flux that is defined for the zonally uniform westerlies and therefore suited for instantaneous depiction of the propagation of the planetary waves as a whole. The other defined by Takaya and Nakamura for the zonally varying westerlies is suited for instantaneously depicting the propagation of a quasi-stationary Rossby wave trains that consist of circulation anomalies. Fluctuations associated with fast-moving synoptic-scale disturbances have been removed by applying 5-day moving average to the data time series, and anomalies are defined as departures of the 5-day running means from 31-day running means that represent the slowly varying seasonal cycle. In that year, the 20-hPa polar-night jet (PNJ) was unusually weak already in early August. Three minor warming events that occurred intermittently during the period of late August through mid-September gave rise to further weakening of the stratospheric PNJ. A diagnosis based on the two wave-activity fluxes indicates that a tropospheric blocking ridge persistent around the Drake Passage was likely the primary source of upward propagating Rossby wave trains involved in those minor warming events. The upward wave-activity emanation was enhanced in association with the intensification of the ridge. The breakdown of the polar vortex in late September immediately followed the upward propagation of a strong quasi-stationary Rossby wave train through the moderately strong PNJ that had been occurring since 19 September from the tropospheric blocking ridge developing over the southeastern Atlantic. In association with that wave train, streamfunction anomalies exhibited an apparent westward tilt with height between the blocking ridge and anticyclonic anomalies that formed in the lower stratosphere. Wave activity was injected into the developing blocking anomalies from a tropospheric quasi-stationary Rossby wave train propagating eastward from the South Pacific into the South Atlantic.

MC05/10A/A09-004   0940

PREDICTABILITY OF STRATOSPHERIC SUDDEN WARMINGS

Hitoshi MUKOUGAWA[1], Hirokazu SAKAI[2], Toshihiko HIROOKA[3] ([1]Disaster Prevention Research Institute, Kyoto University, [2]Graduate School of Environmental Earth Science, Hokkaido University, [3]Department of Earth and Planetary Sciences, Kyushu University)

Although the basic mechanism of the stratospheric sudden warmings(SSWs) was shown by Matsuno (1971), our understanding on the events isstill incomplete. Among others, the comprehensive theory on theamplification of tropospheric planetary waves, which has beenfrequently documented before the onset of SSWs has not beenestablished as yet. Moreover, very few studies examined thepredictability of SSWs by using operational weather prediction models(e.g. Mechoso et al., 1985). In this study, by using the operationalone-month forecast data set based upon the Japan Meteorological Agency(JMA) Numerical Weather Prediction Model (NWPM), we examine thepredictability of wavenumber 1 major SSW events occurring in December1998 and December 2001. The forecasts are performed on every Wednesdayand Thursday by conducting ensemble integrations from 13 initialconditions (one control run without initial perturbation and 12perturbed runs). The associated triggering process in the troposphereand the dynamical influence on the tropospheric circulation during theSSW events are also investigated. At first, the time evolution of the Root Mean Square Error on the 10hPa height field over the Northern Hemisphere for the controlforecasts as a function of forecast day shows linear growth suggestinga prolonged predictability of the stratospheric circulation, incontrast with the troposphere. In fact, these SSW events are correctlypredicted by the NWPM initialized more than two weeks before thewarming peaks. Moreover, for the SSW in December ´01 with the warmingpeak on 25 December, we find a distinct variation in the sensitivityof the prediction for the warming to the initial condition prior tothe SSW event: Forecast spread between ensemble members starting from6 December was extremely large while that from 12 December was smalland all the members succeeded in predicting the occurrence of the SSWevent. The forecast spread prior to the SSW in December ´01 is studied indetail. The principal spatial pattern of the spread corresponds to abarotropic zonal-mean zonal wind variation with maxima around 80N and60N in the troposphere. This variation is intimately connected withthe enhancement of the upward propagation of the wavenumber 1planetary wave, which in turn gives rise to the SSW. We also discussthe relation between the tropospheric zonal flow variation and theblocking revealed by the analysis on the ensemble forecast.

MC05/10A/A09-005   1000

LONG-TERM VARIABILITY OF THE ANTARCTIC VORTEX AND OZONE HOLE: HOW CLOSE IS THE UM TO PRODUCING A SH MAJOR WARMING?

Peter BRAESICKE, John PYLE (Centre for Atmospheric Science, University of Cambridge)

The unprecedented Antarctic ozone hole of 2002 raises a number of important questions including the likelihood of such an event and the role of chemistry in producing it. We analyse four twenty year integrations with the Met Office Unified Model (UM) using a simple stratospheric chemistry. One integration uses the modelled ozone interactively in the radiation scheme, the other three experiments are sensitivity integrations using climatological ozone. We will describe the differences in southern hemisphere (SH) winter variability between the experiments. Even though there is no major warming in the SH (as defined by WMO) in the 80 years modelled, we find one exceptionally early and strong warming in the integration with interactive chemistry. This warming is analysed in detail to establish the role of the interactive ozone scheme in producing the warming.

MC05/10A/A09-006   1040

QUASI-PERIODIC VARIATIONS OF THE POLAR VORTEX DUE TO WAVE-WAVE INTERACTION IN THE SOUTHERN HEMISPHERE STRATOSPHERE

Yasuko HIO, Shigeo YODEN (Department of Geophysics, Kyoto University)

In the Southern Hemisphere (SH) stratosphere, quasi-stationary planetarywave of zonal wavenumber 1 (hereafter Wave 1) and eastwardtraveling Wave 2 with the period around 15 days are active in late winter. Instability of the polar night jet is believed to be an important process for the generation of Wave 2, while Wave 1 is generated in the troposphere and propagated into the stratosphere. We investigate the behaviors of Wave 1 andWave 2 in the SH winter stratosphere focusing on the wave-wave interactions. With the NCEP/NCAR Reanalysis dataset for 24 years (1979-2002), we could extract some typical interaction events and find some common features. The observed transient Wave 1 for these events travels eastward with the same angular velocity as that of Wave 2 changing its amplitude periodically. The transient Wave 1 has a nodal structure in mid-latitude. The traveling Wave 1 and Wave 2 are in phase with the stationary Wave 1 simultaneously. The traveling Wave 1 has its minimum amplitude, when it is in phase or out of phase with the stationary Wave 1. Furthermore, the transient Wave 2 has a maximum amplitude when the three waves are in phase. These phenomena are seen in the periods when the zonal mean PV gradient is nearly zero in mid-latitudes and both amplitudes of the stationary Wave1 and traveling

Wave2 are large. The mechanism of the periodic amplification of these waves isinvestigated with a global barotropic model with zonal-flow forcing and dissipation. Sinusoidal surface topography is assumed with a single zonal wavenumber 1 in the model SH and the prescribed zonally symmetric equilibrium state is set so as to satisfy the necessary condition of barotropic instability. In some parameter range, the eastward traveling Wave 2 due to barotropic instability are dominant, as well as the stationary Wave 1 generated by the topographic effect. As a result of the interaction between these waves,similar eastward traveling Wave 1 is found as to both the periodicity and the latitudinal structure observed in the real atmosphere. The correspondence between the observation and the model experiment confirms that the observed phenomena are due to the wave-wave interaction between the stationary Wave 1 and the traveling Wave 2 and that the generation of the traveling Wave 2 is strongly connected with the jet profile.

NEW MESOSPHERE WIND MEASUREMENTS AT THE SOUTH POLE: A LOOK AT THE ANTARCTIC MESOSPHERE RESPONSE TO A STRATOSPHERIC WARMING

Susan Kathryn AVERY[1], James AVERY[1], Scott PALO[1], Robert VINCENT[2], Damian MURPHY[3], Richard WALTERSCHEID[4] ([1]University of Colorado, [2]University of Adelaide, [3]Australian Antarctic Division, [4]Aerospace Corporation)

A new meteor radar was established at the South Pole and has been operational for one year. The radar is at an ideal location for providing ground-based information in support of the TIMED satellite mission as well providing an excellent opportunity to more thoroughly examine the dynamics of the Antarctic through an integrated analysis with other Antarctic radar observations. Preliminary data analysis has focused on the characterization of various wave motions observed in the wind data. Additional analysis is focused on the mesosphere response to the stratospheric warming that peaked 25 September 2002. This presentation will provide a description of the wave motions present at the South Pole during the stratospheric warming event. An initial analysis incorporating additional Antarctic radar data will also be presented.

MC05/10A/A09-008   1130

PLANETARY WAVE ACTIVITY IN THE MIDDLE ATMOSPHERE ABOVE DAVIS, ANTARCTICA DURING THE 2002 AUSTRAL SPRING

Andrew R. KLEKOCIUK[1], Andrew J. DOWDY[1], Robert A. VINCENT[2] ([1]Australian Antarctic Division, [2]Department of Physics and Mathematical Physics, Adelaide University)

The development of unusually strong planetary wave activity in the Antarctic stratosphere during late August 2002 led to the rapid warming and dramatic erosion of the polar vortex over the subsequent two months. Measurements of temperatures and winds over particular altitude regions from the ground to the mesopause above Davis Antarctica (68.6°S, 78.0°E) using a variety of techniques,combined with analysis of global NCEP/CPC operational data and NOAA/POES temperature soundings, have been used to investigate the characteristics and extent of the atmospheric disturbance during this event. At Davis, the signature of a 12-day wave in temperature was apparent throughout the atmosphere, including the mesopause region and surface, with peak amplitudesnear the 20hPa level (~25km altitude). NCEP/CPC stratospheric data suggest that the wave was primarily associated with a zonal wavenumber 1 planetary wave at high southern latitudes which also received periodic intensification from a wavenumber 2 feature. During late September, Davis balloon-sonde wind data in the lower stratosphere showed a reversal in the zonal flow and a strong poleward meridional flow. These are characteristics common to Sudden Stratospheric Warmings of the Arctic winter atmosphere, but which are rarely seen in the Antarctic. Rayleigh lidar temperatures between 30km and 70km altitude indicate that the 12-day wave penetrated into the lower-mesosphere, and was associated with a vertical disturbance having a dominant wavelength of approximately 50km. The lidar measurements also revealed several smaller scale vertical wave-like temperature perturbations with downward phase progressions in the stratosphere and lower mesosphere during this time. The most significant of these included an inversionof amplitude ~10K in the lower mesosphere during late August, and a warm perturbation of amplitude ~20K and vertical extent (FWHM) of 5km during mid-September. The relationship between theses features and the planetary wave activity in the lower stratosphere, with particular regard to implied heating rates, is examined. In addition, the middle atmosphere conditions above Davis during the Austral spring of 2002 are compared with previous years.

MC05/10A/A09-009   1150

A PARAMETER SWEEP EXPERIMENT ON THE EFFECTS OF THE QBO PHASE ON STRATOSPHERIC SUDDEN WARMING EVENTS

Yoko NAITO, Shigeo YODEN (Department of Geophysics, Kyoto University)

The occurrence of stratospheric sudden warming (SSW) eventsis a dominant component of the intraseasonal variabilityof the wintertime stratospheric circulationin the northern hemisphere.Observational studies have showed thata time-mean state of the winter stratosphere is influencedby the equatorial quasi-biennial oscillation (QBO). The aim of the present study is to investigatethe effect of the QBO on the occurrence of SSWsby analyzing daily dataobtained in long time integrationsof a simple global circulation model.An idealized zonal mean zonal momentum forcingis assumed in the equatorial stratosphere in the modelto investigate QBO effects on the intraseasonal variability.Phase of the perpetual "QBO-wind" forcing is changedas an experimental parameter in the present study,by contrast with our previous study (Naito et al., accepted to JAS)in which magnitude of the forcing was changed.Eight integrations are performed for 12,000 daysunder perpetual winter condition. Polar temperature in the upper stratosphere shows thatSSWs occur more frequently in the easterly phasethan in the westerly phase,consistent with the observational result.Increase of the occurrence of SSWs from the westerly phaseto the easterly phase through the easterly shear phaseis relatively gradual compared withthe decrease through the westerly shear phase.Composite analysis of SSW events also showsdependence on the phase of the QBO.Propagation of planetary wavesbased on the Eliassen-Palm flux analysisis discussed with estimation of statistic significance.

MESOPAUSE DYNAMICS FROM THE SCANDANAVIAN TRIANGLE OF RADARS WITHIN THE PSMOS-DATAR PROJECT

Alan H. MANSON[1], C.E. MEEK[1], C.M. HALL[2], S. NOZAWA[3], N.J. MITCHELL[4], D. PANCHEVA[4], W. SINGER[5], P. HOFFMANN[5] ([1]Institute of Space and Atmospheric Studies, University of Saskatchewan, Canada, [2]Tromso Geophysical Observatory, University of Tromso, Norway, [3]Solar-Terrestrial Environment Laboratory, University of Nagoya, Japan, [4]Department of Electronic and Electrical Engineering, University of Bath, UK, [5]Leibniz-Institute of Atmospheric Physics, KAElungsborn, Germany)

M

The 'Scandinavian Triangle' is a unique trio of radars within the DATAR Project (Dynamics and Temperatures from the Arctic MLT (60-97km) region): Andenes MF radar (MFR, 69N, 16E); Tromsø MF radar (70N, 19E) and Esrange MW radar (MWR, 68N, 21E). The radar-spacings range from 125-270 km, making it unique for studies of wind variability associated with small-scale waves, comparisons of large-scale waves measured over small spacings, and for comparisons of winds from different radar systems. As such it complements results from arrays having spacings of 25 km and 500 km that have been located near Saskatoon. Analyses show that while the wind speeds from the two MFRs are within 5%, the MWR speeds are larger (median annual factors of 1.6 at 97km, 1.1 at 85km), consistent with earlier studies at Tromso-Andenes. The ratios vary with height and season. Wind directions and tidal phases agree very well across the Triangle. Annual climatologies for the year 2000 of mean winds, solar tides, planetary (PW) and gravity waves are presented, and as expected, are very similar in general features across the Triangle. The 12-h tide has a climatology very similar to that at middle latitudes, but with smaller amplitudes e.g. factors of 1-2 during the autumn maximum. The 24-h tide has amplitudes about half the size of the 12-h tide, and the climatology indicates the increasing dominance of the evanescent S(1,-1) mode. Comparisons with the latest version of the GSWM are included. Variabilities of these climatologies across the Triangle are somewhat greater than those of the Canadian-500km Triangle. The 16-d and 2-d PWs are discussed in some detail. In particular the 2-d PW winter activity is greater than in summer. There are again modest, but statistically significant, differences between the contour plots/climatologies for the three radars, indicating spatial and temporal intermittency of the local wind oscillations associated with these global scale PW structures.

ON THE INFLUENCE OF THE QUASI BIENNIAL OSCILLATION IN THE UPPER EQUATORIAL STRATOSPHERE

Lesley J. GRAY[1], Sarah SPARROW[2], Charlotte PASCOE[3] ([1]Meteorology Dept., Reading University, U.K., [2]Oxford University, U.K., [3]Rutherford Appleton Laboratory, U.K.)

The quasi biennial oscillation (QBO) in the lower equatorial stratosphere has been observed for many years from radiosonde data. However, the characteristics of the QBO in the equatorial upper stratosphere above 35km are less well known. Recent modelling work and analysis of a 24-year period of rocketsonde data have suggested that the QBO in the upper equatorial stratosphere is relatively small but appears to have a significant influence on the frequency and amplitude of stratospheric sudden warmings in the northern winter-time. The height region of this QBO influence (35-50 km) is also the region dominated by the semi-annual oscillation (SAO). Recent model and rocketsonde data analysis will be summarised. Further analysis of the upper equatorial QBO in the newly available 40-year ECMWF re-analysis will be described, with particular emphasis on it's influence on the strength and timing of the SAO. Model studies, including both a stratosphere mesosphere model and a full GCM will be explored to investigate possible mechanisms for the equatorial influence on the northern high latitudes in winter.

ISSUES IN STRATOSPHERE/TROPOSPHERE DYNAMICAL COUPLING

Mark P. BALDWIN (Northwest Research Associates)

Although variability in the stratosphere is driven mainly by planetary-scale waves that originate in the troposphere, some of the most interesting aspects of stratosphere / troposphere coupling involve feedbacks in which the tropospheric circulation is affected by conditions in the stratosphere. These feedbacks are important on two timescales: intraseasonal and long-term trends. Over periods of one week to two months, observations show a strong statistical relationship between circulation anomalies in the lowermost stratosphere and changes to the phase of the Arctic Oscillation. Following changes to the circulation of the lowermost stratosphere, the Arctic Oscillation tends to be biased for up to two months. The effect only happens during the extended winter season, when planetary-scale waves are able to create large circulation anomalies in the stratosphere. The effect on the Arctic Oscillation could be useful not only for statistical forecasts, but could, in principle, be incorporated in numerical extended-range weather predictions. If the stratospheric circulation changes due to increasing greenhouse gasses, ozone loss, or other effects, how will the troposphere be affected? This remains an open question, in part because data records are not long enough to answer the question and in part because climate models do agree on the trends within the stratosphere. Most climate models are forecasting a trend toward a more positive Arctic Oscillation, but the reasons for this trend are model dependent; the trend in the Arctic Oscillation could be driven by either tropospheric or stratospheric processes. A related question that has not been answered is whether or not it is necessary for climate models to fully resolve the stratosphere. If a fully-resolved stratosphere is necessary to simulate future tropospheric climate, what are the implications of using, as we do today, climate models that have limited representations of the stratosphere?

STRATOSPHERIC- AND TROPOSPHERIC MODES IN THE ARCTIC OSCILLATION

Kunihiko KODERA, Yuhji KURODA (Meteorological Research Institute)

The leading EOF of the sea-level pressure in the northern hemisphere is known as the Arctic Oscillation (AO). The AO is first considered as a seesaw in the geopotential height field between the polar region and midlatitudes from the surface to the stratosphere. However, the AO signal in the troposphere is not necessarily related to the stratospheric circulation. There exist two types of the AO: the one (stratospheric type) is connected to the stratospheric circulation and the other (tropospheric type) is trapped within the troposphere. Both types can also be characterized as a seesaw in zonally averaged zonal wind field, but one is a seesaw between 35°N-65°N involving the polar-night jet, and the other is in lower latitudes 30°N-55°N more related to the subtropical jet. Development of patterns during the winter is also very different. Anomalous zonal-mean zonal winds propagate down from the stratosphere for the stratospheric type, but anomalies develop in from the Pacific sector of the troposphere for the tropospheric type. Because of the similarity in spatial structure of these modes in the troposphere, in particular in the Atlantic sector, it is not always easy to separate by conventional techniques. However, occurrence frequency of the two modes might be dependent on the basic state, which can be affected by changes in external forcings or boundary conditions. Accordingly the two modes of variability are studied by stratifying winters according to the phase of the solar and ENSO cycles.

DOWNWARD PROPAGATION IN THE SOUTHERN HEMISPHERE

David W.J. THOMPSON[1] ([1]Department of Atmospheric Sciences, Colorado State University, [2]Northwest Research Associates)

In this talk, I will discuss the observed relationships between the strength of the Southern Hemisphere (SH) stratospheric circumpolar flow and the circulation of the troposphere. It will be demonstrated that: 1) large amplitude events in the SH stratosphere frequently propagate downwards to tropospheric levels where they are reflected as a bias in the SH annular mode; 2) that the observed coupling between the SH stratospheric and tropospheric circulations has implications for both weather prediction and climate change over the high latitudes of the SH; and 3) that the breakdown of the SH stratospheric polar vortex during the sudden stratospheric warming September 2002 was accompanied by pronounced anomalies in the SH annular mode that persisted for more than a month.

ON THE RELATIONSHIP BETWEEN THE WINTER STRATOSPHERE AND THE TROPOSPHERIC ARCTIC OSCILLATION

Rolando R. GARCIA, Byron A. BOVILLE, Fabrizio SASSI (National Center for Atmospheric Research)

Recent work on large-scale patterns of atmospheric variability indicates that the state of the stratosphere during northern winter is significantly correlated, at positive lag, with the tropospheric Arctic Oscillation (AO). Specifically, periods when the polar night vortex is strong are followed by periods of positive AO index, and vice-versa. Because this relationship has predictive potential for tropospheric circulation patterns it is important to understand how it is produced. We examine several multi-year integrations of the Whole Atmosphere Community Climate Model (WACCM) to show that the stratosphere/AO relationship is present in the model, and we analyze the behavior of Eliassen-Palm fluxes and other circulation diagnostics in an attempt to establish a causal connection between the stratosphere and the AO.

LARGE ENSEMBLE EXPERIMENTS ON THE STRATOSPHERE-TROPOSPHERE COUPLED VARIABILITY

Shigeo YODEN (Department of Geophysics, Kyoto University)

We have perform numerical experiments with an idealized troposphere-stratosphere global circulation model to investigate internal variability of the winter stratosphere which arises from the vertical dynamical coupling (Taguchi, Yamaga and Yoden, 2001; Taguchi and Yoden, 2002a,b,c). Although the model is simplified in some ways, it explicitly describes dynamical processes related to the vertical coupling: excitation of planetary waves by the surface topography and their interaction with baroclinic eddies in the troposphere as well as their upward propagation and interaction with the mean zonal flow in the stratosphere. Recently similar model was also used to study the effects of equatorial QBO on stratospheric sudden warming events (Naito, Taguchi and Yoden, 2003). Recent progress in computing facilities enabled us to perform some parameter sweep experiments in which many trials of computations in parameter space were done by sweeping the value of a control parameter (Yoden, Taguchi and Naito, 2002). For example, the sign and intensity of the equatorial zonal wind forcing were sweeped in 9 runs in Naito et al.(2003). In addition, it became much easier than before to make long time integrations. They obtained over 1,150 examples of stratospheric sudden events in total in contrast to the number of the observed major warming events (about 20 in the past 50 years). A large number of such ensembles makes it possible to use a large sample method in statistical tests instead of a small sample method with Student´t t-test, so that it is not necessary to assume the equality of the variances of two populations. This kind of ˝new˝ statistical approach based on large ensemble experiments, which is new in a sense that it has become possible very recently for ordinary people, might be applied for the discussion of the rarity of the stratospheric sudden warming event in the southern hemisphere in September 2002. If we use the dataset of 1,000-year integrations by Taguchi and Yoden(2002c), extreme warm events over 3 times [standard deviation] might appear about 28 years in 1,000 years because the probability distribution is highly skewed. If it were Gaussian distribution, the events over 3 times [standard deviation] is less than 2 years in 1,000 years.

UPWARD AND DOWNWARD INJECTION OF ROSSBY WAVE ACTIVITY ACROSS THE TROPOPAUSE: A NEW ASPECT OF TROPOSPHERE-STRATOSPHERE LINKAGE

Hisashi NAKAMURA, Kazuaki NISHII (Department of Earth, Planetary Science, University of Tokyo)

Behavior of quasi-stationary anomalies observed in the lower stratosphere of the Southern Hemisphere during austral late winter of 1997 is studied. The anomalies are defined as daily lightly-low-pass-filtered departures from the seasonal cycle of that year. A wave-activity flux and refractive index for stationary Rossby waves are utilized, both defined locally for the zonally varying westerlies under WKB-type assumptions. Unlike the conventional one, our framework enables us to pinpoint the tropospheric origin, if exits, of particular lower-stratospheric anomalies. We adopt this framework, recognizing that in the lower stratosphere the mean polar-night jet (PNJ) exhibits a clear zonal asymmetry in the presence of zonal-wavenumber 1 component of planetary waves. In our framework, the persistent component is included in the basic state in which slowly varying anomalies are embedded. Therefore propagation of stationary Rossby wave trains that constitute those anomalies may be either upward or downward, depending upon location and time. Though only in a qualitative sense, the validity of the WKB-type assumptions may be given a posteriori with reasonable geographical correspondence between wave packets and local waveguides. Submonthly fluctuations in the lower stratosphere were often associated with a zonally confined wave train emanating upward from localized, quasi-stationary anomalies in the troposphere including a blocking ridge. Three-dimensional propagation of the wave train is found sensitive to the local waveguide structure. The distribution of the lower-stratospheric submonthly variability thus exhibits significant zonal asymmetries, reflecting those in the PNJ structure and in the distribution of tropospheric disturbances. Seasonal evolution of the PNJ and that in the tropospheric intraseasonal variability strongly modulated the activity of lower-stratospheric subseasonal fluctuations. Specifically, local overlapping of the stratospheric PNJ with a tropospheric subpolar jet forms a localized vertical waveguide that acts as a ˝chimney˝ through which wave activity accumulated in the troposphere is allowed to propagate upward into the stratosphere, followed often by the formation of a wave train propagating eastward along the lower-stratospheric PNJ. If another such chimney forms in the exit of the PNJ, wave activity associated with a lower-stratospheric wave train would be allowed to propagate downward into the troposphere, contributing to blocking formation or

large-scale cyclogenesis. Typical examples of that local downward influence of stratospheric anomalies include an event of large-scale, quasi-stationary cyclogenesis that occurred around August 10 off the Antarctic coast to the south of Australia. A substantial contribution was made to that cyclogenesis through downward wave-activity injection from a lower-stratospheric Rossby wave train that had emanated from a tropospheric blocking ridge far upstream over the southwestern Pacific. Another example is given where wave-activity injection from lower-stratospheric cyclonic anomalies contributed positively to the formation of a blocking ridge southwest of New Zealand in late September.

MC05/10P/A09-008   1740

EFFECTS OF POLAR VORTEX PERTURBATIONS ON TROPOSPHERIC WINTER CIRCULATION

Kevin HAMILTON[1], Georgiy STENCHIKOV[2], Mark BALDWIN[3] ([1]IPRC, University of Hawaii, [2]Rutgers University, [3]Northwest Research Associates)

Interest in the dynamical influence of the circulation in middle atmosphere on the troposphere has had a resurgence largely due to recent observational studies that findevidence for downward propagation of large-scale perturbations in the extratropical circulation from the stratosphere to the troposphere. In particular, anomalies in the Arctic Oscillation (AO) index tend to propagate downward so that, on average, a weak vortex (warm pole) conditionin the stratosphere is followed later by a positive AO index in the tropospheric circulation. The same general tendency is also found in control integrations of at least some atmospheric GCMs. The existence of a significant downward dynamical link of this sort would have implications for both seasonal prediction and sustained climate change. However, there is no guarantee that the tendency for downward propagationof anomalies across the tropopause reflects an actualphysical effect of the stratospheric flow on that in thetroposphere. In geophysics there are numerous examplesof phenomena showing phase progression actually oppositeto the physical propagation of disturbances. This paper will report first on results from a series of model integrations performed with initial conditions that areperturbed from those in a control run, but with theperturbation restricted to the extratropical stratosphere.In particular, the GFDL ˝SKYHI˝ model is applied in a series of winter seasonal integrations, each with initial condition taken from early winter in one year a long control run, but with a strong perturbation arbitrarily added to the stratosphericpolar vortex. Another somewhat different set of experiments has been undertaken with a version of the model which includes an extra zonally-symmetric momentum source in the tropical stratosphere. The momentum source is designed to force the tropical stratospheric circulation to resemble that actually observed for the period 1978-1999. The results of these experiments will be examined to see if the imposed QBO in the tropics has a detectable effect on the extratropical tropospheric circulation.

SIMULATIONS OF THE EFFECT OF SOLAR VARIABILITY ON THE TROPOSPHERE AND MIDDLE ATMOSPHERE

Kiyotaka SHIBATA, Kunihiko KODERA (Meteorological Research Institute)

Solar irradiance is not constant but varies with various time scales. One of the most distinct variations is the 11-year cycle, in which irradiance change amplitude is, on average, by about several percent in ultra-violet region, while it varies little in longer wavelengthregion. Irradiance variations in in ultra-violet region affect radiative heating and ozone concentration around thestratopause and above, which in turn affects underlying atmosphere through dynamical processes. This study investigates the effects of solar maximum and minimum on the stratosphere and troposphere using MRI/JMA98 GCM. The model is a T42L45 version, which is triangularly truncated at 42 total wavenumer in horizontal and has 45 layers from the surface to 0.01 hPa(about 80 km) in vertical. Experiment are made for solar maximum,normal and solar minimum conditions, respectively, over 21 years. Solar irradiance changes are incorporated in the radiationscheme, while ozone change is prescribed in the model. Two data are taken from 2-D chemical transport models (GISS and Imperial College) usedseparately. Other experiment are also made to investigate the effectsof model top height and interactive chemistry.

MC05/11A/A09-002   Invited   0900

OBSERVED HIGH FREQUENCY GRAVITY WAVES IN THE MESOSPHERE; SEASONAL VARIATION OF THEIR DIRECTIONALITY AND DAMPING

Gary R. SWENSON, Alan Z. LIU (Electrical and Computer Engineering, U of Illinois)

Dissipation of Atmospheric Gravity Waves (AGWs) is a dominant driver for the summer to winter meridional circulation in the mesosphere. Airglow observations from U of I andother groups around the globe are gathering information on the high frequency (HF) portion of the AGWs regarding directionality and wave amplitudes. Significant differences are being observed in winter versus summer, at mid and low latitudes. In addition, correlative studies at Maui, HI have begun to investigate the wave dampingwith altitude of HF waves, from which accelerations with altitude are calculated. Considering the observed seasonal difference in wave directionality as well as the altitudes and magnitudes of wave induced acceleration, we are beginning to gather insight into the roles AGWs play in the process of driving the residual circulation. These combined effects will be discussed.

MC05/11A/A09-003   Invited   0930

GLOBAL OBSERVATIONS OF GRAVITY WAVE PROPERTIES AND CONSTRAINTS FOR GCMS

M. Joan ALEXANDER (NorthWest Research Associates, Inc., Colorado Research Associates Division)

Global models require parameterization of the effects of gravity waves that are either not resolved or not accurately generated in these models. The parameterizations require input parameters that describe the properties of the waves such as their phase speeds, propagationdirections, and horizontal wavelengths. These input parameters have been poorly constrained allowing a very broad range for "tuning" these parameterizations and the effects of the parameterized waves inmiddle atmosphere models. In recent years, a variety of global data sets from satellite and balloon measurements have provided new information on the global properties of gravity waves in the lower stratosphere that should aid in constraining parameterizations. Each observation and data analysis technique includes a corresponding unique set of observing constraints that make each sensitive to only aportion of the gravity wave spectrum that may be present in the lowerstratosphere. In addition, gravity waves tend to be generated atintermittent intervals, and this intermittency introduces

an additional observational bias that favors the observation of slow vertical group speed waves. These slow vertical group speed wave stend to carry smaller momentum flux than their high vertical group speed counterparts, rendering them potentially far less important to the net momentum budget for parameterized gravity waves than the observations would imply at face value. This talk will summarize some of these recent global gravity wave data sets and the constraints forgravity wave parameterization input parameters that they can provide.

MC05/11A/A09-004   1000

GRAVITY WAVE DRAG ESTIMATION USING A VARIATIONAL METHOD. TECHNIQUE DESCRIPTION AND TWIN EXPERIMENTS

Manuel PULIDO, John THUBURN (Department of Meteorology. University of Reading)

The stratospheric circulation is strongly influenced by the drag from breaking and dissipation of gravity waves. Numerical global atmospheric models can not resolve these waves, so they must be parameterised. Progress in developing parameterisations requires information about the actual drag field in the atmosphere. However it is very difficult to infer the climatology of the actual drag field from observations, and so far budget studies have given information only on the zonal mean of the zonal component of the drag on seasonal time-scales. Here, the authors present a new technique to estimate the drag term. Using variational data assimilation principles, a cost function which measures the mismatch between the observed variables (e.g temperature or wind fields) and the model variables is minimised. The control variable which is varied to minimise the cost function is the three dimensional field of wave drag. Thus, the optimal value which minimises the mismatch is the estimated forcing field. The adjoint model used to obtain the gradient of the cost function has recently been developed from a three-dimensional dynamical model of the stratosphere. The model is based on the fully nonlinear, hydrostatic primitive equations, with an isentropic vertical coordinate and a hexagonal-icosahedral horizontal grid. Other features are the potential vorticity is used as a conserved prognostic variable, and it has a realistic parameterisation of radiative transfer. In this work we present the adjoint model description and a series of twin experiments where the observed fields are obtained from the model evolution with a prescribed forcing term. This prescribed drag term corresponds to simple analytical functions. The details of the minimisation process in a case study are presented. By means of the twin experiments the sensitivity of the final state to different forcing configurations is analysed (this implies not only how well the technique can estimate the drag field but also how important it is for numerical models to have a good estimation of the parameters). The quality of the estimation as a function of the temporal window length is examined. The preliminary results shows that the technique has the potential to diagnose three-dimensional time varying fields of zonal and meridional components of gravity wave drag from observations.

MC05/11A/A09-005   1050

GLOBAL DISTRIBUTION OF GRAVITY WAVE MOMENTUM FLUX DERIVED FROM CRISTA SATELLITE DATA

Manfred ERN[1], P. PREUSSE[1], M.J. ALEXANDER[2], S.D. ECKERMANN[3] ([1]ICG I, Forschungszentrum Juelich, Juelich, Germany, [2]Colorado Research Associates, Boulder, USA, [3]Naval Research Laboratory, Washington, USA)

Based on temperature altitude profiles measured by the CRISTA satelliteamplitudes, vertical wavelengths and phases of gravity waves (GWs) were retrieved bya combination of maximum entropy method and harmonic analysis. Furthermore, the horizontal wavelengths of the GWs were derived by comparingthe phases of GWs in adjacent altitude profiles. From these results altitude profiles of the absolute value of thevertical flux of horizontal momentum have been estimated.There are significant differences between distributions of thetemperature variance and distributions of the momentum flux. For example, global maps of the momentum flux show a pronouncednorthward shift of the equatorial maximum whereas temperature variancemaps of the tropics/subtropics are nearly symmetric with respect to theequator. Similar results can be found at different altitudes. These findings point out that the distributions of horizontaland vertical wavelength are very important for global structures of themomentum flux. Vertical profiles of momentum flux are presented and compared toGW models on the basis of regional averages.

MC05/11A/A09-006   Invited   1110

CONVECTIVELY FORCED INTERNAL GRAVITY WAVES AND THEIR PARAMETERIZATION IN GENERAL CIRCULATION MODELS

Hye-Yeong CHUN, In-Sun SONG (Department of Atmospheric Sciences, Yonsei University)

Characteristics of gravity waves induced by mesoscale convective storms and the gravity wave sources are investigated by simulating two-dimensional squall lines using a cloud-resolving numerical model. In the convective storms, there are two types of wave sources-nonlinear sources in the form of the divergences of momentum and heat flux, and diabatic source. The magnitude of the nonlinear source is 2-3 times larger than the diabatic source, especially in the upper troposphere. However, the magnitude of waves in the stratosphere induced by each wave source is comparable, with similar spectral characteristics of vertical wavelength (6.6-9.9 km), horizontal wavelength (10-100 km), and period (8-80 min). This is because the vertical propagation condition of linear internal gravity waves, in both the troposphere and stratosphere, restricts wave sources in the horizontal wavenumber and frequency domain, and therefore all of the forcing cannot generate gravity wave that can propagate up to the stratosphere. Compared with the diabatic sources, the nonlinear sources are inefficient in generating linear gravity waves that propagate vertically into the stratosphere. A formulation of cloud-top wave momentum flux induced by diabatic source with respect to different phase speed is derived analytically, and effects of basic-state wind shear and magnitude of cloud-top wind on the momentum flux is investigated. Wave filtering by critical level and wave propagation condition will be discussed.

MC05/11A/A09-007   1140

CONVECTIVELY GENERATED MESOSCALE GRAVITY WAVES SIMULATED THROUGHOUT THE MIDDLE ATMOSPHERE

Takeshi HORINOUCHI (Radio Science Center for Space and Atmosphere, Kyoto University)

A three-dimensional simulation was conducted with a cloud-resolvingmodel to investigate mesoscale convectively-generated gravity waves that propagate to the middle atmosphere. The model covers a horizontal domain of 200 km x 200 km with a 1.5 km resolution with the cyclic boundary condition for both dimensions. The vertical coverage is from the surface to 120 km with the top 20 km being the sponge layer, and the vertical resolution is 0.5 km above the mid troposphere. This isthe first cloud resolving modeling covering the hole vertical range ofthe middle atmosphere. In order to simulate under a realistic background condition, a horizontally uniform forcing is added basedon radiosonde observations during

M

the TOGA COARE Intensive Observation Period. The surface is assumed to an ocean with a uniform temperature. It is found that both individual convective turrets and mesoscale convective systems excite gravity waves, resulting in a broad scale distribution. Waves excited by the former have conically shaped phase surfaces as previously reported and are conspicuous up to around the stratopause. Waves excited by the latter dominate in the MLT region. Frequent wave breaking is found above 85 km, where convective instability is found typically in the initial stage, leading to unstable shear with billows resembling the ripple-type structures observed frequently in airglow imaging. The sensitivity of the results is investigated by using higher resolution runs and by changing subgrid-scale turbulence parameterization. We are currently conducting numerical experiments with a significantly larger horizontal domain, and the results will be presented in the talk.

SEASONAL VARIATIONS OF GRAVITY WAVE VARIANCE OBSERVED BY CLAES

Peter PREUSSE[1], M. ERN[1], S.D. ECKERMANN[2], M.J. ALEXANDER[3], J.L. MERGENTHALER[4] ([1]ICG-I, Forschungszentrum Juelich, Juelich, Germany, [2]Naval Research Laboratory, Washington, USA, [3]Colorado Research Associates, Boulder, USA, [4]Lockheed Martin Advanced Technology Center, Palo Alto, USA)

Gravity wave variances in CLAES temperature data are isolated by a 0-6 wavenumber Kalman filter. Resulting vertical profiles of temperatureresiduals are analyzed by a combination of Maximum Entropy Method (MEM)and harmonic analysis for gravity waves (GWs).This is the same method previouslyemployed to study GWs in CRISTA data. We obtain nearly 1.5 years ofcontinuous GW data between 34S and 34N and good coverage at higherlatitudes depending on UARS yaw maneuvers. Results are compared toCRISTA data and interpreted for different wave sources. A time series ofzonal mean GW variance shows quiet summer and enhanced winter values atmid and high latitudes, the shift of the tropical maximum of GW variancearound the equator and a burst of wave variance atstratopause altitudes in Februaryof both years investigated, i.e. 1992 and 1993.

GRAVITY WAVES IN A GENERAL CIRCULATION MODEL

Masaaki TAKAHASHI, Yoshio KAWATANI (Center for Climate System Research, University of Tokyo)

Gravity waves have important roles in the general circulation of the middle atmosphere. There are many observational studies of gravity waves. But, the global characteristics of gravity waves are still unknown, because gravity waves have small time and special scales. In the present study, numerical results of gravity waves in a high resolution general circulation model are discussed. The model is a CCSR/NIES atmospheric general circulation model. The horizontal resolution is T106 with about 100km resolution. Then, several hundreds km scale gravity waves are resolved. The vertical resolution is 60 layers from the surface to about 50 km altitude with about 550m resolution in the upper troposphere and lower stratosphere. The cumulus convective parameterization is Arakawa-Schubert scheme. The model is run for 2 years and gravity wave activity for 11-16 June is analyzed. Model output data is each one hour for the analysis. Gravity waves in the lower stratosphere are examined. Recently, satellite data about potential energy of gravity waves are obtained. Then, we can see the global features of potential energy of gravity waves in the lower stratosphere. There are special places of strong gravity wave potential energy. There are also special places of strong gravity wave kinetic energy in higher latitudes. We will present why the strong gravity wave energy in each place is produced.

GRAVITY WAVE DISTRIBUTION ALONG THE EQUATOR IN A HIGH RESOLUTION AGCM

Koichiro TSUJI, Masaaki TAKAHASHI, Yoshio KAWATANI (Center for Climate System Research, University of Tokyo)

It is recognized that the quasi- biennial oscillation in the equatorial lowerstratosphere (QBO) is mainly maintained by upward propagating gravity waves excited by cumulus convection in the troposphere. Although the QBO is a global- scale phenomenon along the equator, gravity waves affecting the QBO have smaller horizontal scales. Therefore, gravity wave activities in the equatorial region are not expected to be uniform along the equator. It is interesting to study the local characteristics of equatorial gravity waves and their contribution to the QBO. Up to now, there have been no observational data which enable us to analyze short scale (-1000km wavelength,-1day period) gravity waves globally and continuously. In this study, numerical experiments were performed in order to investigate the gravity wave distributions and its effects on the zonal wind in the equatorial lower stratosphere using a high resolution GCM (CCSR/NIES AGCM ver.5.6) with 3 hours output interval. As a result, at the easterly accelerating phase of the QBO, remarkable un-uniform distribution was seen in the vertical wave momentum flux u´w´in the equatorial lower stratosphere. Eastward wave momentum fluxes were located mainly over the Indian monsoon region. On the other hand, westward wave momentum fluxes were located mainly over the Eastern Pacific and the Atlantic. Therefore, the waves over the Eastern Pacific and the Atlantic mainly contribute to the production of the simulated QBO in this season. Spectral analysis showed that the westward propagating gravity waves having the period of about 1-2days are dominant in this region.

A SIMULATION STUDY OF GRAVITY WAVES GENERATED BY TYPHOON WINNIE

Zeyu CHEN[1], Peter PREUSSE[2], Michael JARISCH[1], Manfred ERN[2], Dirk OFFERMANN[1] ([1]Department of Physics, University of Wuppertal, [2]Research Center Juelich, ICG-I)

During the CRISTA II mission (08 to 16 August, 1997), a super typhoon Winnie (hereafter referred to as Winnie) was evolving over the tropical north west pacific ocean. Over Winnie a stratospheric temperature perturbation is observed by CRISTA and believed to be gravity waves (GWs)as the feature matches the dispersion relation of GW. To study the relation between Winnie and the temperature perturbation, a numerical simulation with the Penn/NCAR MM5 model was carried out. We observe two kinds of GWs generated in the simulation. First we find wave generation due to horizontal wind shear at altitudes range of 16-25 km, in which tropical west wind reversed to east wind at 5N latitude. Simulation results show that GWs were generated from the convergent area relating to the wind shear and propagated in two opposite directions, southwestward in the equatorial westerly background and northeastward in the easterly wind northward of the wind shear. Corresponding

structures are found in the CRISTA data. Second we consider waves generated by Winnie. Simulations start atthe evolving stage of Winnie (UT 00:00, 7 August). Winnie wasclassified as typhoon after UT 00:00 10 August. The critical features ofthe real typhoon have been captured by the simulation, includingmoving trend, intensity, and evolving stages. After Winnie haddeveloped into typhoon state, model results show pronounced GWs in thestratosphere, and the wave amplitudes grow with upward propagation. The waves show a curved front propagating radially awayfrom the storm center. In the easterly background flow eastwardpropagating waves are amplified and prominent at higher altitudes (25 kmaltitude). It is indicated that the waves are generated by the interactionbetween the stratospheric background flow and the typhoon related´obstacle effect´.

EFFECTS OF HURRICANES ON THE STRATOSPHERE: EVIDENCE OF GRAVITY WAVE ACTIVITY FROM CAMEX-4 IN SITU MEASUREMENTS AND MESOSCALE MODELING

Eric A. RAY[1], Karen ROSENLOF[1], Erik RICHARD[1], Ken KELLY[1], M.J. MAHONEY[3], Joan ALEXANDER[4] ([1]NOAA, Aeronomy Lab, [2]CIRES, University of Colorado, [3]Jet Propulsion Laboratory, [4]Colorado Research Associates)

In situ and remote measurements from the ER-2 aircraft during the CAMEX-4 mission contain features which suggest the stratosphere is disturbed by wave activity above hurricanes. The predominant waves produced by hurricanes are thought to be gravity waves. The propagation of gravity waves above tropical convective storms inferred from radiosonde data has been shown to have a significant impact on the energy balance of the lower stratosphere in several previous studies. However, very few measurements exist in the stratosphere above hurricanes. In this study we use ER-2 in situ and microwave temperature profiler measurements as well as NCAR/PSU MM5 simulations of Hurricanes Erin and Humberto to deduce the gravity wave activity and impact on the stratospheric energy balance above the hurricanes.

WAVE ACTIVITY IN THE TROPICAL TROPOSPHERE AND LOWER STRATOSPHERE OBSERVED WITH THE EQUATORIAL ATMOSPHERE RADAR

Fumitaka TSUJINO, Masayuki YAMAMOTO, Masatomo FUJIWARA, Hiroyuki HASHIGUCHI, Mamoru YAMAMOTO, Shoichiro FUKAO (Radio Science Center for Space and Atmosphere, Kyoto University)

The tropics is the region where convective activities are very active, because of a strong solar heating and water vapor supply from the ocean. These convective activities generate equatorialwaves, which have a significant influence on the global-scale atmospheric circulation. Especially, equatorial Indonesia is one of the regions where convective activities are very prominent in the tropics.The Equatorial Atmosphere Radar (EAR), which is newly installed at Kotota bang, West Sumatra, Indonesia (0.2 degrees south, 100.32 degrees east, 865m above mean sea level), can observe three-dimensional wind velocities in the whole troposphere and the lower stratosphere (2-20km)with good time and height resolution of about 85 sec and 150m,respectively. The EAR has been continuously operated since July 2001.The purpose of this research is to clarify the seasonal variations of the equatorial waves in the troposphere and lower stratosphere over equatorial Indonesia. The principal data used for this study are three-dimensional wind velocitie sobtained with the EAR for the period from July to December 2001. We classified four height regions for the wind spectral analysis : lower troposphere (2-5km), middle troposphere(5-10km), upper troposphere (10-15km) and lower stratosphere (15-20km). At the lower troposphere, spectral peaks at 1 day were seen at allwind components. Spectral densities of meridional and zonal windcomponents at 1 day increased during the observational period. Spectralpeaks of meridional and zonal wind components at 4-5 daysmatched the typical period of mixed Rossby-gravity waves. These spectraldensities at 4-5 days decreased during observational period. Themagnitude of spectral densities of zonal wind component was large at the period of > 15 days. This enhancement ofspectral densities was considered to be associated with IntraseasonalOscillation (ISO). At the lower stratosphere, spectral peaks at 1 day were alsoseen at all wind components. Spectral peaks at 4-5 days were also seen atmeridional and zonal wind components. The time variations of spectral peaksat 4-5 days were almost the same as at the lower troposphere. Themagnitude of spectral densities of zonal wind component was large at theperiod of > 6 days, while enhancement in meridional wind component was notseen. Thus it isconsidered that this spectral enhancement was associated with the equatorialKelvin waves. In order to see the relation of equatorial waves and cumulusconvection, we investigated infrared equivalent blackbody temperature(TBB) and wind data by National Centers for Environmental Prediction reanalyses (NCEP wind).There was a good correlation between TBB and NCEP vorticity at 500hPa. Thedaily variations of TBB were large when spectral peaks at 1 day at the lowertroposphere were large. It is also noticed that NCEP westward wind at300hPa and 70hPa over the Western Pacific agreed well with thespectral peaks at the period of > 6 days period. When NCEPwestward wind at 300hPa and 70hPa over the Western Pacific became weak,spectral densities at the period of > 6 days decreased.

CHARACTERISTICS OF ATMOSPHERIC WAVES OBSERVED WITH RADIOSONDES DURING DAWEX CAMPAIGNS

Toshitaka TSUDA (Radio Science Center for Space and Atmosphere (RASC), Kyoto University)

As one of the international observation campaign of SPARC, DAWEX (Darwin Area Wave Experiment) was conducted in October-December, 2001 to observe characteristics of atmospheric gravity waves excited by tropical convection. We conducted radiosonde campaigns with a duration of 120 hours for 3 times on October 15-19, November 15-20 and December 11-16, 2001. During these IOP's we launched radiosondes every 3 hours from 3 sites; Garden Point on the Tiwi islands (Pirlangimpi) (11.4S, 130.3E), the Darwin weather station of BOM (12.4S, 130.9E) and a civilian airport in Katherine (14.5S, 132.5E). This paper is concerned with the behavior of atmospheric gravity waves analyzed by using intensive radiosonde observations during DAWEX. In the lower stratosphere at 15-20 km strong wind velocity fluctuations with a period of about 84 hours were detected in the 3 campaign periods. Gravity waves with a vertical scale shorter than about 3 km were enhanced at 15-20 km and above about 25 km, showing coherent downward phase propagation between the 3 sites. However, the wave activity was significantly depressed at 20-25 km. We will discuss a relation between the height variations of gravity wave intensity and the background conditions

DAWEX EXPERIMENT: OBSERVATIONAL ANALYSIS OF WAVES AT DIFFERENT SCALES

Alejandro DE LA TORRE[1], Toshitaka TSUDA[2] ([1]Departamento de Fisica, FCEN, Universidad de Buenos Aires, ARGENTINA, [2]Radio Science Center for Space and Atmosphere, Kyoto University, Uji, Kyoto, JAPAN)

A set of radiosoundings launched simultaneously from three stations in Northern Territory, Australia (Darwin Area Wave Experiment, DAWEX Experiment) is analysed. During the experiment, three periods were considered: (1) October 13-18, (2) November 15-20 and (3) December 11-16, 2001. Eight launches per day and site were released, and a total of 360 profiles during this experiment. The possible existence of critical levels interacting with quasi stationary waves and mixing layers found near the tropopause is analyzed. The significance of cloud-top mixing driven by radiative cooling across the top of anvils in these mixing layers is considered. A systematic wave structure observed in the altitude intervals (15, 20) and (25, 30) km and a negligible variance between them is observed. The wave amplitudes are larger in the meridional wind and a systematic near to zero mean wind around the tropopause is appreciated. A spectral analysis reveals two prevailing low frequencies in the wave structure. A wave selection near the tropopause and possible trapping and reflexion effects there are considered.

MC05/11P/A09-008   1700

GRAVITY WAVE ACTIVITIES OVER A SMOOTH SOURFACE WITH LITTLE CONVECTION

Yoshio KAWATANI[1], Masaaki TAKAHASHI[1], Surendra Kumar DHAKA[2], Toshitaka TSUDA[3] ([1]University of Tokyo, [2]Department of Physics, Rajdhani College, University of Delhi, [3]Radio Science Center for Space and Atmosphere, Kyoto University)

In order to understand the climate variability and atmospheric general circulation, it is important to consider the dynamical interaction between troposphere and stratosphere through gravity waves. Recently, satellites provided the global characteristics of the gravity waves by extracting the temperature disturbances (cf., Tsuda et al. 2000). In general, large potential energy (Ep) is found in tropical regions between 20°N and 20°S. Interestingly, they noticed regions around the tropical Atlantic (~ 0°-30°W, 0°-10°S) with large Ep. This is a region with little convection or topographic source of gravity waves. The mechanism for the formation of this energy remains uncertain. It is difficult to investigate all physical quantities simultaneously in observations. In this study, we used an atmospheric general circulation model with the resolution T106L60 in order to understand the mechanism for the presence of high-energy over the Atlantic Ocean. We investigate the activity of gravity waves for one week in June, when the Indian summer monsoon is typical and intense. The model well simulated the distribution of the precipitation such as the separation between ITCZ and SPCZ, and the Baiu front (cf. Kawatani and Takahashi 2003). The simulated global distribution of Ep is quite similar to that observed in the GPS/MET experiment, and large Ep is also found over the Atlantic Ocean (cf., Tsuda et al., 2000, Kawatani et al., 2003). It is found that gravity waves with a time period of 24 hours are excited around the Bay of Guinea in a region of large moist heating extending vertically up to 10-13 km. The gravity waves propagate upward from this region with a bias toward the south and are manifested as large energy fluxes in the cross equatorial region. Enhanced energy fluxes are therefore simulated at 20-30 km altitude over a region with no significant source of gravity waves.

OBSERVATIONAL FILTER FOR GRAVITY WAVE CHARACTERISTICS OBTAINED FROM GPS RADIOOCCULTATION SOUNDINGS

Christian MARQUARDT (Met Office)

Retrievals of GPS based radio occultation soundings providestratospheric temperature profiles with high verticalresolution. Consequently, data from, e.g., the GPS/MET mission havebeen used to infer about the global distribution of gravity wavecharacteristics and vertical wave number spectra in the stratosphere. The standard ˝dry temperature˝ retrieval which is usually implemented,however, suffers from a high sensitivity to measurement noise. Thismakes the distinction between gravity wave signal and instrumentalnoise difficult. Also, no ˝observational filter˝ for gravity waveobservations with radio occultation soundings is currently known. A high-resolution variational retrieval of radio occultation datawhich allows the estimation of gravity wave parameters in the lowerstratosphere is presented. Compared to the standard approach, thevariational framework provides a more detailed understanding of thesignal-to-noise issue. The gravity wave observational filter for thevariational retrieval is discussed. Preliminary results of a 2 yearclimatology of the global distribution of gravity wave activityobtained from the German satellite CHAMP are presented.

A MODEL SIMULATION OF MOUNTAIN WAVES IN THE MIDDLE ATMOSPHERE AND ITS COMPARISON WITH MICROWAVE LIMB SOUNDER OBSERVATIONS

Jonathan H. JIANG, Stephen D. ECKERMANN, Dong L. WU, Jun MA (Jet Propulsion Laboratory)

Topography-related wintertime stratospheric gravity waves in both Northern and Southern Hemisphere are simulated using the Naval Research Laboratory Mountain Wave Forecast Model (MWFM). The results agree well with the observations from Upper Atmospheric Research Satellite Microwave Limb Sounder (MLS). Both the MWFM simulation and MLS observations found strong wave activities over the high-latitude mountain ridges of Scandinavia, Central Eurasia, Alaska, southern Greenland in Northern Hemisphere, and Andes, New Zealand, Antarctic rim in Southern Hemisphere. These mountain waves are dominated by wave modes with downward phase progression and horizontal phase velocities opposite to the stratospheric jet-stream. Agreements of minor wave activities are also found at low- to mid-latitudes over Zagros Mountains of Middle East, Colorado Rocky Mountains, Appalachians, and Sierra Madres of Central America. Some differences between the MWFM results and MLS data are explained by different horizontal resolution between the model and observation, and the fact that MLS may also see the non-orographic wave sources, such as mesoscale storms and jet-stream instabilities. The findings from this model-measurement comparison study demonstrate that satellite instruments such as MLS can provide global data needed to characterize mountain wave sources, their inter-annual variations, and to improve gravity wave parameterizations in global climate and forecast models.

THE EARLY CENTURY WARMING N THE ARCTIC - A POSSIBLE MECHANISM

Lennart BENGTSSON[1], Vladimir SEMENOV[1], Ola M. JOHANNESSEN[2] ([1]Max-Planck-Institut fuer Meteorologie, [2]Nansen Environmental and Remote Sensing Center)

The huge warming of the Arctic that started in the early 1920s and lasted for almost two decades is one of the most spectacular climate events of the 20th century. During the peak period 1930-1940 the annually averaged temperature anomaly for the area 60°N-90°N amounted to some 1.7°C. Whether this event is an example of an internal climate mode or externally forced, such as by enhanced solar effects, is presently under debate. Here we suggest that natural variability is the most likely cause with reduced sea ice cover being the main reason of the warming. A robust sea ice-air temperature relationship was demonstrated by a set of four simulations with the atmospheric ECHAM model forced with observed SST and sea ice concentrations. An analysis of the spatial characteristics of the observed early century surface air temperature anomaly revealed that it was associated with similar sea ice variations. We have further investigated the variability of Arctic surface temperature and sea ice cover by analyzing data from a coupled ocean-atmosphere model. By analyzing similar climate anomalies in the model as occurred in the early 20th century, it was found that the simulated temperature increase in the Arctic was caused by enhanced wind driven oceanic inflow into the Barents Sea with an associated sea ice retreat. The magnitude of the inflow is linked to the strength of westerlies into the Barents Sea. We propose a positive feedback sustaining the enhanced westerly winds by a cyclonic atmospheric circulation in the Barents Sea region created by a strong surface heat flux over the ice-free areas. Observational data suggest a similar series of events during the early 20th century Arctic warming including increasing westerly winds between Spitsbergen and the northernmost Norwegian coast, reduced sea ice and enhanced cyclonic circulation over the Barents Sea. It is interesting to note that the increasing high latitude westerly flow at this time was unrelated to the North Atlantic Oscillation, which at the same time was weakening.

WHY DOES PRECIPITATION DECREASE INITIALLY IN TRANSIENT RESPONSE TO CO2 DOUBLING?

Akira NODA[1], Kazuki YAMAGUCHI[2], Takao UCHIYAMA[1], Sachiko YAMAKI[1] ([1]Climate Research Department, Meteorological Research Institute, [2]Tokyo Electric Power Company)

Precipitation decreases just after CO_2 concentration of the atmosphere is doubled. This response is opposite to what is expected from equilibrium response to CO_2 doubling. Two mechanisms have been proposed to explain the decrease in precipitation for the transient response: - The heat content of land is much smaller than that of ocean, so that the heat low will be dominant over land, providing subsiding air over ocean to suppress the evaporation from the sea surface. (Land-sea effect) - The main effect of CO_2 on longwave cooling in the troposphere is to reduce the longwave cooling due to water vapor through the spectral overlap at 15 micron band, resulting in the reduction of convective heating to keep the heat balance in the troposphere. (CO_2 effect) In the radiative convective one-dimensional atmosphere, evaporation and precipitation decrease due to CO_2 effect because no land-sea effect exists. In the three dimensional atmosphere both effects can work. In order to identify the relative importance, ensemble experiments have been made with doubling CO_2 and with 2% increase in solar constant. As a result, the globally averaged land-sea effect is estimated to be twice larger than the CO_2 effect in the initial response as estimated from precipitation averaged over ocean grids. However, the reduction in precipitation lasts only about one year due to the former effect. After this initial response, the latter effect remains to suppress the precipitation over oceans more than five years. Finally enhanced greenhouse effect of water vapor evaporated from the ocean surface dominates the tropospheric response and precipitation increases to maintain the heat and mass balances in the troposphere.

MC08/07A/B17-003   1015

ESTIMATING UNCERTAINTY IN THE RESPONSE TO DOUBLED CO2 USING A LARGE ENSEMBLE OF GCM VERSIONS

David M.H. SEXTON, James MURPHY, David N. BARNETT, Mark J. WEBB (Hadley Centre, Met Office)

For a given emissions scenario, GCM predictions of climate change are subject to uncertainties arisingfrom the representation of climate system processes in the model and the effects of natural variability.These uncertainties imply a probability distribution of outcomes for a given climate variable, whichmust be specified before quantitative risk assessments can be made. In principle such distributions canbe estimated from large ensembles of GCM predictions. In practice this has not hitherto been possibledue to a lack of computing power with the result that only crude uncertainty estimates are currentlyavailable, based on a handful of models run at different centres. Another stumbling block has been alack of objective methods of assessing the reliability of predictions from different models, or ofidentifying plausible model versions in the first place. Preliminary results will be presented from a new project aimed at addressing these issues. Frequencydistributions of changes in the equilibrium response to doubled CO2 will be illustrated using anensemble of versions of the Hadley Centre´s coupled atmosphere/mixed layer ocean model, eachdistinguished by a change to a parameter controlling a key atmospheric process. This will be comparedto distributions obtained from an ensemble of predictions produced using the same version of themodel with varying initial conditions, thus allowing the relative uncertainties associated with naturalvariations and process uncertainties to be estimated. The effect of weighting model versions accordingto simulation quality will be discussed.

MC08/07A/B17-004   1030

THE GLOBAL STATIONARY WAVE RESPONSE TO CLIMATE CHANGE IN A COUPLED GCM

Mingfang TING[1], Renu JOSEPH[1], Paul J. KUSHNER[2] ([1]Department of Atmospheric Sciences, University of Illinois at Urbana-Champaign, [2]GFDL/Princeton University, Princeton, New Jersey)

The stationary wave response to global climate change in the Geophysical Fluid Dynamics Laboratory´s ″R30″ coupled ocean-atmosphere GCM is studied. An ensemble of climate change simulations that use a standard prescription for time-dependent increases of greenhouse gas and sulfate aerosol concentrations is compared to a multiple-century control simulation with these constituents fixed at pre-industrial levels. The primary response to climate change is to zonalize the atmospheric circulation, that is, to reduce the amplitude of the stationary waves in all seasons. This zonalization is particularly strong in the boreal summer over the tropics. In January, changes in the stationary waves resemble that of an El Niño, and all months exhibit an El Niño-like increase of precipitation in the central tropical Pacific. The dynamics of the stationary wave changes are studied with a linear stationary wave model, which is shown to simulate the stationary wave response to climate change remarkably well. The linear model is used to decompose the response into parts associated with changes to the zonal mean basic state and with changes to the zonally asymmetric ″forcings″ such as diabatic heating and transient eddy fluxes. The decomposition reveals that at least as much of the climate change response is accounted for by the change to the zonal mean basic state as by the change to the zonally asymmetric forcings. For the January response in the Pacific North-American sector, it is also found that the diabatic heating forcing contribution dominates the climate change response, but is significantly cancelled and phase-shifted by the transient eddy forcing. The importance of the zonal mean and of the diabatic heating forcing contrasts strongly with previous linear stationary wave models of the El Niño, despite the similarity of the January stationary wave response to El Niño. In particular, in El Niño, changes to the zonal mean circulation contribute little to the stationary wave response, and the transient eddy forcing dominates. The conclusions from the linear stationary wave model apparently contradict previous findings on the stationary wave response to climate change response in a coarse resolution version of this model.

MC08/07A/B17-005   1045

THE EFFECT OF AEROSOLS ON GLOBAL WARMING ESTIMATED FROM MULTI-CGCM RUNS AND MULTI-EMISSION SCENARIO RUNS

Akira NODA, Takao UCHIYAMA, Sachiko YAMAKI (Climate Research Department, Meteorological Research Institute)

We have examined the effect of the negative radiative forcing due to the direct effect of sulfate aerosols on global warming by comparing results from common scenario runs with 7 coupled atmosphere-ocean general circulation models (CGCMs) and from multi-scenario runs with a new version of MRI-CGCM. Each result from common scenario runs is consist of a run forced by increases in CO2 alone and that obtained by increasing CO2 and aerosol concentration exactly or approximately following IPCC IS92a scenario. The future scenario assumes that the atmospheric equivalent CO2 concentration increases at a compound annual rate of about 1%, while the atmospheric aerosol concentration almost levels off after 2050, so that the CO2 forcing alone increases linearly at the same rate between the two runs during the second half of the 21st century. A comparison is made for the difference in trend and mean during the period. The most dominant geographical response due to the cooling effect of aerosols appears as a reduction of the magnitude of global warming patterns simulated with the CO2 only forcing. During the second half of the 21st century, a significant larger warming trend in surface temperature is found for the aerosol plus CO2 run than for the CO2 only run in winter over the polar region in the Northern Hemisphere. As for the multi-scenario runs we have estimated three-dimensional atmospheric sulfate aerosol distributions due to anthropogenic emissions for the present and for SRES scenarios (A1B, A1T, A1FI, A2, B1 and B2), where a chemical transport model (MASINGER) developed at MRI (Tanaka et al., 2003) was used off-line. Since the model intercomparison shown above indicates that the primary effect of aerosols depends on global mean radiative forcing, we have calculated the radiative forcing for each scenario. Some preliminary results from the multi-scenario runs suggest that the scenario dependency of spatial global warming pattern is weak.

MC08/07A/B17-006   1120

REGIONAL CLIMATE CHANGE PROJECTION OVER JAPAN IN WINTER DUE TO GLOBAL WARMING USING AN MRI-CGCM1/ REGIONAL CLIMATE MODEL NESTING SYSTEM

Yasuo SATO[1], Kazuyo MURAZAKI[1], Hidetaka SASAKI[1], Seiji YUKIMOTO[2], Akira NODA[2], Ayako TAKEUCHI[3], Shinya KOBAYASHI[3] ([1]Atmospheric Environment and Applied Meteorology Research Department, Meteorological Research Institute, Japan Meteorological Agency, [2]Climate Research Department, Meteorological Research Institute, Japan Meteorological Agency, [3]Climate Prediction Division, Climate and Marine Department, Japan Meteorological Agency)

A regional climate model (RCM) experiment was performed to obtain regional climate change projection over Japan in winter due to global warming using the MRI/JMA regional climate model, whose lateral boundary conditions were supplied from the results of a transient CO_2 experiment performed by the MRI- CGCM1. The horizontal resolution of the atmospheric part of the MRI-CGCM1 is 5 ° by 4 ° in the longitudinal and latitudinal directions and 15 levels in the vertical. That of the oceanic part has 21 vertical layers, 2.5 ° longitudinal resolution, and variable latitudinal resolution ranging from 0.5 ° at the equator to 2.0 ° at 12 ° latitude and further poleward. The MRI/JMA regional climate model with 40 km resolution is integrated in a time-slice manner only in January for 20 years for both control ($1\times CO_2$) and doubling CO_2 conditions using the results of the Asian regional climate model with 120 km resolution which was generated by outputs of the MRI- CGCM1 transient CO_2 experiment with an increasing CO_2 concentration of 1%/year compound rate. Results over the Japanese Islands are analyzed only for winter. The RCM results with 40km resolution are much improved especially on precipitation distribution in comparison with 40 km-interpolated CGCM results. A regional climate change projection on precipitation shows a decrease along the Japan Sea side of the Japanese Islands, on one hand an increase along the Pacific Ocean side of them, which can be interpreted that cold air outbreak from the Siberian High in winter is weaken under the doubling CO_2 condition. At the same way, snowfall amount decreases along the Japan Sea side. On the other hand, precipitation off the south coast of the Japanese Islands increases under the doubling CO_2 condition because of increasing of the storm track precipitation, that is, the northward shift of the storm track in winter in a climatological sense.

IMPACT OF POSSIBLE FUTURE CLIMATE ON COASTAL WINDS, STORM SURGES AND WAVE CONDITIONS IN THE NORTH SEA

Hans VON STORCH, Frauke FESER, Arnt PFIZENMAYER, Burkhardt ROCKEL, Ralf WEISSE, Katja WOTH (Institute for Coastal Research, GKSS Research Center, Geesthacht, Germany)

Using time slice simulations with T106 global models (EU project STOWASUS) as well as a regional climate model (EU project PRUDENCE) detailed scenarios of plausible future wind conditions in the North Sea and in the Baltic Sea are presented. The impacts of the changing wind statistics on water levels, storm surge severity and wave conditions are discussed. The results are used to discriminate between present natural variations and first indicators of anthropogenic climate change.

SOUTH WEST AUSTRALIA PAST AND FUTURE RAINFALL TRENDS

Bertrand Olivier TIMBAL (Bureau of Meteorology Research Centre)

A statistical method, based on the idea of analogous synoptic situations, is used to study the observed rainfall trends in South West of Western Australia.The method has been developed and optimised by relating patterns of atmospheric field (predictors) to stations records of rainfall (predictands) in the South West of WesternAustralia, for both rain occurrences and daily rain amounts. When tested on observational data, the analogue method is able to reproduce partially the observed trend and theinter-annual variability observed during the past 50 years, showing the sensitivity of the analogue approach to changed climatic conditions. Similar results are obtainedover the entire record period and when data are splitted into a development and a validation period to ensure a proper cross validated examination of the method´s skill. Among the parameters considered, the set of predictors has one of the most important impacts on results. It is demonstrated that moisture fields explain an important partof the obsreved trend.The model is then applied to three state-of-the-art coupled models´ simulation of the current climate. The improvement when using the statistical downscaling tool overdirect model grid-average outputs is shown to be substantial. Most of the model biases are removed and realistic probability distribution functions atstation level are obtained. The method is then applied to altered climate conditions; the impact of large scale model uncertain responses and model sensitivities arequantified using the various coupled models. Future trends for rainfall estimated by direct GCM outputs are compared with downscaled projections. A general agreement isfound; uncertainties are smaller amongst projections when the downscaling technique is used. All projections agree on a reduction of total rainfall in winter andspring for most stations in this part of the continent following global climate change.

REGIONAL REGIMES WITH DROUGHT AND EXTREME WET CONDITIONS: POSSIBLE CHANGES IN XXI CENTURY FROM MODEL SIMULATIONS

Igor I. MOKHOV[1], Jean-Louis DUFRESNE[2], Vyacheslav Ch. KHON[1], Herve LE TREUT[2], Vladimir A. TIKHONOV[1] ([1]A.M.Obukhov Institute of Atmospheric Physics RAS, [2]Laboratoire Meteorologie Dynamique du CNRS)

Possible regional changes of drought and extreme wet conditions in the XXI century relative to the XX century from simulations of a coupled atmosphere-ocean general circulation model IPSL-CM2 with a carbon cycle for the 1860-2100 period are analysed. The scenario with the carbon dioxide emissions due to fossil and land use from observations up to 1990 and the IPCC SRES98-A2 emission scenario from 1990 to 2100 in these simulations were used. Model simulations of extremal meteorological conditions were tested in comparison with observations in spring-summer from the end of the XIX century up to the end of the XX century in the European and Asian regions at the middle latitudes. An analysis is performed in terms of different indices characterizing anomalously warm and dry (or cold and wet) conditions. The changes in characteristics of the drought and wet regimes in summer between XXI and XX centuries were estimated from model simulations for East (EER) and West (WER) European regions. Model results display that the increase of temperature in the XXI century is accompanied in both regions by the decrease of precipitation and wet regime index and by the increase of drought indices. There are remarkable differences in changes for EER and WER. Model simulations show the interannual variability increase in the XXI century for temperature in both regions and for precipitation in WER, while the variability decrease for precipitation in EER. Drought indices display the general variability increase, while wet conditions index shows the interannual variability decrease.

THE FUTURE CHANGE OF THE VARAIBILITY AND EXTREMES OF DAILY RAINFALL EVENTS DURING THE INDIAN SUMMER MONSOON SIMULATED IN A GLOBAL TIME-SLICE EXPERIMENT

Wilhelm MAY (Danish Meteorological Institute)

The possible future change in the variability and extremes of daily rainfall during the Indian summermonsoon as a consequence of the anticipated increase in the concentrations of the importantgreenhouse gases is investigated. This is done on the basis of a global time-slice experiment withthe ECHAM4 atmospheric GCM at a high horizontal resolution of T106, corresponding to a gridspacing of about 120 km. The first time-slice (period: 1970-1999) represents the present-dayclimate and the second (2060-2089) the future climate after roughly a doubling of the atmosphericCO_2 concentration relative to present-day values. During the two time-slices monthlymean values of the sea surface temperatures, the sea-ice extent and the sea-ice thickness originating from atransient climate change simulation with the ECHAM4/OPYC coupled model at a low horizontalresolution of T42 (corresponding to a grid spacing about 300 km) have been prescribed as lowerboundary forcing to the atmospheric GCM. In addition to some basic properties, such as thefrequency of wet days (defined as days with precipitation) as well as the mean and the variability ofrainfall occurring on wet days, the characteristics of extreme daily rainfall events are investigated bymeans of percentiles as well as via theoretical distributions, namely the Generalized Extreme Valueand the Generalized Pareto distributions. For the future, the time-slice experiment predicts an increase in the rainfall associated withextreme daily rainfall events in the entire Indian region, except for the central part of the Indianpeninsula. This future increase is to about the same extent related to an increase in the intensity ofextreme rainfall events and to an increase in the frequency of such extreme events. The magnitudeof the future change in the rainfall originating from extreme rainfall events (relative to the change inthe overall rainfall) varies conspiringly from region to region. This indicates the need to explicitlyassess the future changes in the extremes of the monsoon rainfall, rather than inferring them from thechanges in the mean rainfall. The comparison with observational rainfall data (GPCP) shows thatECHAM4 is able to simulate the variability as well as the extremes of daily rainfall during the Indiansummer monsoon under present-day climate conditions quite well. Therefore, the future changes inextreme daily rainfall events predicted in the time-slice experiment have a high degree of credibility.

FUTURE PROJECTIONS OF EAST ASIAN CLIMATE USING MULTI-MODEL ENSEMBLES OF IPCC SRES SCENARIO SIMULATIONS

Seung-Ki MIN, E-Hyung PARK, Won-Tae KWON (Climate Research Laboratory, Meteorological Research Institute, Korea)

Future climate over East Asia (20-50ºN, 100-145ºE) is projected using multi-model ensemble of selected coupled climate model (CCM) simulations based on IPCC SRES A2 and B2 scenarios. Analyzed variables include annual and seasonal mean temperature and precipitation over East Asia. Before projecting future climate, model performances are evaluated with the simulations of present-day climate (defined as 1961-1990). Multi-model ensemble projections are constructed from high-performance CCMs, which are selected considering bias, RMSE and Taylor diagram analyses. After removing models with large bias and RMSE, CCMs which have a higher similarity to observations in spatial pattern and variability amplitude, are selected in the Taylor diagrams. As a result of model evaluation, CSIRO Mk2, ECHAM4/OPYC, GFDL_R30_c, and HadCM3 are selected as high-performance models for the simulation of temperature and precipitation over East Asia. Multi-model ensemble projections from high-performance CCMs show that East Asia will experience warmer and wetter climate in the 21st century. Area-averaged temperature changes for three 30-year periods (2020s, 2050s, and 2080s) simulated by A2[B2] scenario ensemble are 1.2[1.3], 2.4[2.3], and 4.0[3.0]ºC and precipitation changes are -0.5[0.5], 2.0[1.8], and 6.1[3.3]%, respectively. Spatial patterns indicate that both temperature and precipitation increases are larger over the continental area than the ocean. In general, the areas with a large inter-model variability are in accord with the areas of large climate change, and there is too large inter-model variability in precipitation change patterns such that its amplitude is as much as ensemble mean. A marked difference (larger than inter-model variability) in projected patterns between A2 and B2 scenario ensembles appears in the 2080s temperature field with a larger amplitude located in the northern continental area. However, no significant differences can be found between precipitation patterns of A2 and B2 scenario ensembles because of a dominant inter-model variability.

PROJECTIONS OF CLIMATE CHANGE OF EXTREME EVENTS IN THE 21ST CENTURY OVER EAST ASIA

Zong-ci ZHAO[1], Akimasa SUMI[1], Chikako HARADA[1], Toru NOZAWA[2] ([1]Center for Climate System Research, University of Tokyo, [2]National Institute for Environmental Studies, Tsukuba, Japan)

In the recent years, four new IPCC scenarios of emission such as SRESA1, SRESA2, SRESB1 and SRESB2 have been inputed to the CCSR/NIES climate model system. The projections of climate change over East Asia in the 21st century have been calculated. In this research, we concentrated on the projections of several extreme climate events in the 21st century such as maximum and minimum temperatures, frequency of strong rainfall, extra-tropical cyclones, tropical cyclones and typhoons over East Asia. As projected by the CCSR/NIES model system, comparing to 1961~1990, the significant warming of 3.0~14.3C for SRESA1, 3.0~15.6C for SRESA2, 2.0~10.1C for SRESB1 and 2.0~11.6C for SRESB2 in the last 30 years (2071~2100) of the 21st century over East Asia has been noticed. The distributions of precipitation change for 2071~2100 minus 1961~1990 by the different scenarios were more complicated than the temperature change. It might be getting drier over the most part of Japan and the lower branch of Yangtze River of China as simulated by the model with SRESA2. It might be getting wetter in the most north and west parts of East Asia have been found. Both Tmax and Tmin over East Asia increase obviously due to the human activities in the 21st century. To compare the last 30 years (2071~2100) with 1961~1990, SRESA2 caused the warmest situation by about 3.5~13.9C in East Asia and SRESB1 responded for a smallest warming by about 2.5~8.9C among four scenarios. In this research, the frequency of strong rainfall, extra-tropical cyclones, tropical cyclones and typhoons over East Asia have been also investigated.

MC08/07P/B17-004   1445

THE INTENSIFICATION AND SHIFT OF THE NORTH ATLANTIC OSCILLATION IN A GLOBAL WARMING SCENARIO SIMULATION

Zeng-Zhen HU, Zhaohua WU (Center for Ocean-Land-Atmosphere Studies)

The impact of global warming on the spatial and temporal character of the North Atlantic Oscillation (NAO) is investigated with a ECHAM4/OPYC3 CGCM global warming scenario simulation. It is shown that the meridional pressure gradient over the North Atlantic is significantly strengthened, and the two centers of action of the NAO, the Icelandic low and the Azores high, are intensified and shifted northeastward by 10° to 20° in latitude and 30° to 40° in longitude in the global warming scenario. The strengthened meridional pressure gradient results in a tendency toward the positive phase of a modified NAO index and an enhancement of its intensity. The shift of the centers of action leads to a failure in capturing the NAO change with the traditional definition of the NAO index. The intensification of the NAO is tied up with zonal mean state change, and the changed zonal mean state alters stationary wave propagation that is associated with the shift of the centers of action of the NAO. In addition, it seems that the variances and frequencies of NAO variation at inter-monthly to interannual timescales are not affected much by the global warming. Warmed tropical oceans and intensified stratospheric polar vortex are the candidate mechanisms to interpret the NAO change in the global warming scenario.

MC08/07P/B17-005   1520

THE CHANGE OF THE GLOBAL WATER CYCLE AROUND 2050 SIMULATED BY THE MRI GCM

Masahiro HOSAKA[1], Akio KITOH[1], Yasuhiro MURATA[2], Yukimasa ADACHI[1] ([1]Meteorological Research Institute, [2]Graduate School of Science, Hokkaido University)

We conducted the simulations under the conditions of 1980-2000 and 2040-2060 with the MRI AGCM, and compared the results with respect to the global water cycle. The differences of the conditions are the prescribed distributions of the SSTs and the aerosols, and the amount of the greenhouse gases. The SSTs are obtained from the SRES A2 scenario simulation of the MRI coupled GCM. The 6 hourly data output are stored and analyzed. As in the coupled GCM case, the surface air temperature becomes warmer over the high latitude regions than the low latitude regions, and the amount of the precipitation increases mainly over the middle-high latitudes. There is positive high correlation between the pattern of the precipitation and that of the soil moisture in the annual mean values. As for the seasonal march, the length of the snow-covered season gets shorter because of the warming. By using the 6 hourly data, we analysed changes in extreme precipitation events such as rainfall days, drought duration, heavy precipitation and changes of probability distribution of precipitation. It is found that there are areas such as East Asia where continuous no-rainfall days increase although in spite of the increase in mean prcipitation by global warming.

REGIONAL CLIMATES UNDER DIFFERENT WARMING SCENARIOS: EFFECTS OF DYNAMICS AND THERMODYNAMICS

Pier Luigi VIDALE, Cornelia SCHWIERZ, Daniel LUETHI, Christoph FREI, Christoph SCHAER (Institute for Atmospheric and Climate Science ETH)

The effects of climate change near elevated terrain still represent a very open research question, since the climate of elevated terrain regions is modulated by the interaction of the atmospheric circulation with orography at several temporal and spatial scales. In Europe, processes over the Alps, for instance, also influence the climate of neighboring regions through low-level blocking, lee cyclogenesis, the alteration of large scale storm tracks and induced advection/convection/subsidence patterns. In this climate change study we address the European regional impacts of these processes by performing multi-year sensitivity experiments, using the CHRM Regional Climate Model, forced at the lateral boundaries with data from different large scale analyses. In the first experiment we drive the model with data from a surrogate warming scenario, in which dynamical processes are left unchanged (i.e. the storm amount and tracks are kept fixed); in the second experiment we force the model with large scale analysis from a GCM simulation, integrated under a full SRES A2 scenario. By contrasting these experiments, and analyzing in reference to a standard current climate simulation (driven with perfect lateral boundary data from the ECMWF Re-Analysis project), this approach allows us to distinguish climate features and processes that can be attributed to different dynamical and thermodynamical processes in the region. The main results are analyzed in terms of changes in storm tracks, together with precipitation and cyclone frequency/intensity climatologies. We then turn to the long-term statistics of daily precipitation over the Alpine region, currently an important theater of intense storms, also associated with extreme events. The variability of these processes on the monthly and seasonal time scale are also discussed.

SIMULATION OF THE RECENT ANTARCTIC PENINSULA WARMING IN THE IPSL-CM2 COUPLED GCM

Sebastien CONIL[1], Claudio MENENDEZ[2], Carolina VERA[2] ([1]LMD, [2]CIMA Buenos Aires)

Over the second half of the 20th century, Antarctic Peninsula stations show a strong warming trend, while stations in other areas of Antarctic show no significant trend or slight cooling. This recent warming correlates with the major reduction in sea-ice extension in the Bellingshausen Sea. The collapse of a large portion of the Larsen B ice shelf seems to be another consequence of this unprecedented warming. This observed positive trend of the Antarctic Peninsula temperature has been a critical climatic change with an order of magnitude greater than global mean warming. It is essential to understand the main processes controlling the climate in this region and to represent these in climate models in order to anticipate whether the trend will remain in the next 100 years. The main issue of this study is to examine the ability of a realistic global climate model to reproduce the main features of the Antarctic Peninsula climate and the observed regional change. We assess two different possible mechanisms that could be responsible of this change. The first is related with changes in the large-scale atmospheric circulation over the Southern Ocean while the second is related with changes in the sea-ice cover and the oceanic circulation and their interactions with the atmosphere. We use a state-of-art ocean-atmosphere general circulation model (IPSL/CM2) which includes coupled-to-land and -ocean carbon models to simulate the evolution of climate from 1860 to 2100 with no flux corrections. Two 241-y simulations were carried out, a control and a scenario simulations. The control run displays no significant drift of the global mean surface temperature while the scenario run present an increase of the global temperature consistent with the observations. Furthermore the most important features of the Southern Hemisphere climate are also well reproduced by the model in the control simulation as well as in the scenario simulation. Moreover, the two simulations present close realistic representations of the leading patterns of SH circulation low-frequency variability. The dominant modes of the simulated atmospheric variability is the well known Antartic Annular Oscillation or High Latitude Mode while the second leading pattern is similar to the Pacific South American pattern. The response of the SH circulation to transient anthropogenic greenhouse warming mainly consists in an increase of the meridional pressure gradient between the high and mid latitudes, modulated by a wave-3 like pattern. That structure, which characterizes the linear trend of the SH circulation resembles the leading mode of interannual variability. The model is also able to reproduce some of the observed warming in the vicinity of the Antarctic Peninsula contrasting with the slight cooling of the East Antartica. The regional change in the near surface temperature simulated around the Antarctic Peninsula is related to the modification of the mean atmospheric circulation but also to change in its leading modes of variability. The reduction of sea ice cover in this region and the local ocean-atmosphere-sea ice interactions also contribute to amplify the regional climate change.

CLIMATE CHANGE SCENARIOS FOR THE ARCTIC REGION BASED ON COUPLED GLOBAL CLIMATE MODEL SIMULATIONS

Stanislav V. VAVULIN (Voeikov Main Geophysical Observatory, Saint-Petersburg, Russia)

Global coupled Atmosphere Ocean General Circulation Models (AOGCM) are widely acknowledged as the principal, most promising, and fast developing tools for simulating the response of the global climate system to increasing green-house gas (GHG) concentrations. Current AOGCMs « provide credible simulations of climate, at least down to sub-continental scales and over temporal scales from seasonal to decadal » (IPCC, 2001), and, as a class, provide useful projections of the future climate. The main sources of uncertainty in climate scenarios based on AOGCM projections are : (1) uncertainties in future emissions of GHG and aerosols (emissions scenarios), and in conversion of the emissions to atmospheric concentrations and to radiative forcing of the climate ;(2) uncertainties in the global and regional climate responses to emissions from different GCM simulations ; and (3) uncertainties due to inaccurate representation of regional and local climate, and application of different methods of regionalising AOGCM results . Scenarios are presented of the 21st century climate change based on simulations with five AOGCMs forced with the IPCC SRES B2 emission scenario. The simulations cover late 20th and entire 21st centuries. Surface air temperature, precipitation and sea level pressure over the northern polar region are considered. The three 20-year time slices are focuses in the 21st century : 2011-2030,2041-2060, 2071-2090. The time slices centered at 2020, 2050 and 2080 are representing correspondingly the near-term, mid-term, and longer-term outlooks for future changes *References* McAvaney, B.J., C. Covey, S. STATISTICAL DOWNSCALING OF GENERAL CIRCULATION MODEL OUTPUT FOR DRAINAGE DESIGN PURPOSES

Yiping GUO (Department of Civil Engineering, McMaster University)

Climate simulation with general circulation models (GCMs) incorporating increased greenhouse-gas concentrations indicates that a warmer climate could result in an increase in extreme precipitation events. Engineered drainage facilities for urban and rural areas are designed for the safe passage of flood flows resulting from extreme rainfall events. The impact of climate change on the functioning of our drainage systems may need to be assessed using output from GCMs. The current GCMsAEoutput has a temporal resolution of a day. This temporal resolution is not adequate for urban and rural catchments with response times in the order of minutes to hours. A statistical downscaling approach is proposed for estimating the intensities of rainfall with durations appropriate for drainage facility design from those predicted by GCMs with daily time steps. Using the proposed approach, intensity-duration-frequency (IDF) relationships representing future climate conditions can be developed from GCM predicted precipitation time series for a location of interest. These IDF relationships can be used to assess the adequacy of existing drainage systems under future climate change and to assist in the development of mitigation and adaptation alternatives.

ARE THE REGULARITIES IN CLIMATE CHANGE FIELDS?

Roman M. COROBOV (Institute of Geography, Moldavian Academy of Sciences)

The main challenge of climate change modeling - downscaling of General Circulation Model (GCM) projections - is proposed to address through identification of some regularities in climatic variables expected change. Using Moldova as a case study, it is shown that these regularities exist and they may be used both for spatial and temporal downscaling. As GCM projections, Australian, Hadley and Canadian modeling centers´experiments were selected. To identify spatial regularities, dependencies of surface air temperature and precipitation changes on geographical latitude and longitude were studied. As a rule, there is a statistically significant, strong correlation between latitude and these variables´projections. This correlation is described very well by the second order polynomials, the form and parameters of which are different for each variable, month, GCM, and time-slice. Mathematically formalized dependence of variables change on latitude was used for development of an algorithm for constructing the climate change fields with the different level of resolution. For temporal downscaling, or transition from GCM monthly projections to the daily ones, the annual course of the first was studied. The best approximation of temperature curves is the fourth degree polynomial (adjusted coefficients of determination are 97-99% with statistical significance less 0.001). For precipitation curves these values, depending on modeling experiments and time horizons, are from 50 to 80% with smaller statistical significance but less than 0.05-0.10. Availability of such temporal regularities gives an opportunity to calculate likely temperature and precipitation values for every day that is a reliable alternative to weather generators.precipitation values for every day that is a reliable alternative to weather generators.

MC08/07P/B17-011   1710

ON THE DEVELOPMENT OF A REGIONAL CLIMATE MODEL FOR THE CENTRAL EUROPE

Tomas HALENKA[1], Radan HUTH[2], Ladislav METELKA[3], Richard MLADEK[4], Ales FARDA[1], Stanislava KLIEGROVA[3], Jan KYSELY[2], Lucie POKORNA[2], Zuzana HUTHOVA[4], Martin JANOUSEK[4] ([1]Department of Meteorology and Environment Protection, Fac. of Mathem. and Physics, Charles University, [2]Institute of Atmosperic Physics, Prague, Czech Republic, [3]Czech Hydrometeorological Institute, branch Hradec Kralove, Hradec Kralove, Czech Republic, [4]Czech Hydrometeorological Institute, Prague, Czech Republic)

The project with the aim to develop a regional climate model (RCM) for the territory of central Europe, which has been overlooked by regional climate modelling studies recently has been launched in 2001 in the Czech Republic. The RCM is being developed by modifications of the numerical weather prediction (NWP) model ALADIN, run operationally at the Regional Centre of LACE (Limited-Area Modelling in Central Europe) in Prague. It concentrates on the area of central Europe and is intended in close future to serve as a source of climate change scenarios on a regional and local scales for countries in that region, especially for the Czech Republic. The uniqueness of the RCM is in its very fine horizontal resolution of about 20 km, which is at the high end of current RCMs. The ALADIN model proves to be integrable for longer time periods, far beyond its current operational use (up to 48 hours), after only minor modifications of rather a technical nature are implemented as well as the first attempts with modification of physical parameterizations. The presentation will summarize validation of recent experimental runs of the RCM, nested in the operational assimilations by the ARPEGE NWP global model, representing observed conditions, both for monthly experiments in summer and winter seasons and for one year simulations. The influence of a treatment of lower boundary conditions, interpolation at lateral boundaries, the effects of repeated restarts of the RCM as well as some sensitivity tests of parameterization are studied. The validation concerns (i) the upper-air fields, (ii) surface temperature and precipitation at the dense station network in the Czech Republic, as well as against continental-scale gridded climatologies, and (iii) vertical cross-sections. During the development, supporting tests were completed with the RegCM2 concerning the modelling sensitivity to geometry of the model area. Moreover, we use the RegCM2 to test the methodology for planning and organizing the experiments. Finally, to understand the ability of RCM's to describe the extremes the distribution of climate parameters based on longer period experiments are compared to real ones.Future activities in the development of the RCM will also be outlined in the presentation.

CHANGES IN EXTREME TEMPERATURES IN NORTHERN CHINA SINCE 1951 AND ITS RELATIONSHIP TO REGIONAL WARMING

Zhuguo MA, Congbin FU, Xiaobo REN (Institute of Atmospheric Physics, Chinese Academy of Sciences)

Based on observed daily mean surface air temperatures from 110 stations in China, changes in the frequency and intensity of extreme temperatures of northern China in the period 1951-2000 have been analyzed. Results indicate that the frequency with which minimal temperature are attained decreases remarkably, butthat this trend begins at different times across the region. The frequency and magnitude of maximal temperatures has no obvious trend up to the 1990s; after that time, an increase in the frequency can be found. Results of annual maximaltemperatures show no trends over the dataset period in most regions of northernChina except for a decreasing trend in the west of northwestern China. There isdramatic reduction of total days below 0oC surface temperature in northern China, with delayed seasonal freezing and earlier seasonal warming. Regionally, the reduction in frequency of extreme temperature minima, and an increase in annualtemperature minima in northern China is closely related to the current warming trend since the 1990s.

FLUX ADJUSTED COUPLED MODELS FOR CLIMATE CHANGE EXPERIMENTS

Nicholas E. FAULL[1], David STAINFORTH[1], Myles ALLEN[1], Jamie KETTLEBOROUGH[2], James MURPHY[3] ([1]Atmospheric, Oceanic and Planetary Physics, University of Oxford, [2]Rutherford Appleton Laboratory, Didcot, [3]Hadley Centre, Met Office)

Quantifying uncertainty in climate change prediction requires large ensembles that deal with model uncertainty. Such ″perturbed physics ensembles″ require the initialisation of large numbers of drift-free coupled climate models. The ocean component of a coupled model typically requires a long spin-up period in order to reach equilibrium. We demonstrate a technique for obtaining approximately drift-free coupled models without the need for a new ocean spin-up when the fast components of the model (atmosphere, land-surface scheme) are perturbed. Using the flux adjusted Hadley Centre model, HadCM3L, we apply a linear correction to the atmosphere-ocean fluxes analogous to that of the standard ″flux-correction″ method used in coupled models. This approach enables us to investigate a much wider range parameter space than would otherwise be possible if we were to spin-up models individually. Flux adjusted coupled models may be used as a basis to form a perturbed physics ensemble of coupled models which could then be used for climate change experiments.

MC08/08P/D-003   Poster   1400-159

WEATHER AND FOREST FIRES NEAR YAKUTSK (EAST SIBERIA) IN 2002

Hiroshi HAYASAKA[1], Sergey TASHCHILIN[2], Abushenko NIKOLAY[2], Keiji KIMURA[3] ([1]Hokkaido University, [2]Institute of Solar Terrestrial Physics Irkutsk, [3]Tokyo Metropolitan University)

The Taiga of Siberia is one of the largest contiguous forest areas in the world. In 2002, a large number of forest fires occurred in taiga near Yakutsk, the eastern part of the Russian Federation. Forests in taiga become very flammable from spring to fall because total precipitation amount is only less than 300mm. In addition, temperature rise due to global warming will make good conditions for forest fire. From now on, fire incidence in high latitude will likely increase due to ongoing global warming. To protect taiga from unnecessary forest fires, it is important to investigate the trends and characteristics of not only forest fire occurrences but also weather conditions in this area. This paper describes one of the causes of the unprecedented occurrence of forest fires near Yakutsk in 2002. Weather conditions in Yakutsk such as temperature, rainfall, humidity, wind direction, and wind speed were analyzed in detail, and a strong correlation between fire occurrence and weather conditions was established. Fire occurrence was determined by processing satellite images. Daily satellite images for the area around Yakutsk were processed to show how the forest fires spread in the Yakutsk forest region. The results imply that ongoing global warming may promote the frequency of the forest fires occurring near Yakutsk.There are a few reports describing recent fire trends around Yakutsk from the viewpoint of climate. There are several papers that describe forest fire trends in Russia. Unfortunately, the papers did not provide much detail of the relationship between fires and climate. M. D. Flannigan and B. M. Wotton indicated that forest fires are strongly linked to weather in a review paper. However, they did not refer to Russian fires and weather, and there are no papers related to Russia in the references.The following conclusions may be drawn from discussion of forest fires in Yakutsk.1. Fire season (from May to September) precipitation amount has shown a gradual decrease from 1994. Daily mean precipitation amounts in the fire season reduced to half in the past nine years. Forest fires in Yakutsk would become active under these precipitation trends. At the same time, winter (from October to April) precipitation amounts increased suddenly from 1999. These anomalous trends may be due to the ongoing global warming.2. Relatively strong, dry, and high temperature winds from the south would be a cause of fires in May.3. Once fires occur, they would spread via spotting fires.4. Under conditions of small precipitation amounts, fires can survive until the end of the fire season, and smoldering combustion in the forest floor may play an important role to sustain fires.5. Catastrophic fires may occur when stable high pressure weather with low dew points are established by a stationary ridge above Yakutsk.

DEVELOPMENT OF AN INDEX TO QUANTIFY CLIMATE MODEL PERFORMANCE AND ITS APPLICATION TO PREDICTING CLIMATE CHANGE

David M.H. SEXTON, James MURPHY, David N. BARNETT, Mark J. WEBB (Hadley Centre, Met Office)

GCM predictions of climate change are subject to uncertainties in there presentation of the climate system by the model, as well as uncertainty due to natural variability and emission scenarios. To assess the uncertainty due to model physics in the equilibrium response to doubled CO2 levels, we have run alarge ensemble of coupled atmosphere/mixed-layer ocean integrations forced by 1xand 2x CO2 concentrations. Each member of the ensemble differsfrom the Hadley Centre´s standard configuration, HadSM3, by perturbing one ofthe model parameters that controls one of its key atmospheric processes. Thisensemble provides a good starting point for estimating the probabilitydistribution of equilibrium response to doubled CO2. However, an importan tissue in estimating such a probability distribution is that we need an objective method to ensure that the more realistic ensemble members have a greater relative contribution. We present a preliminary version of an index designed to measure how well aclimate model simulates present-day mean climate. The index is based on 32 different climate variables which cover a broad range of features in the atmospheric climate. The effect of weighting the probability distribution to simulation quality will be discussed. The present ensemble will eventually be extended to include members whereby several parameters are simultaneously perturbed, so that our ensemble samples the parameter space more thoroughly. But this must be done in a cost-effectivemanner. We will also demonstrate a method that uses the index to predictintegrations of multiple parameter perturbations that are likely to well simulate the mean present-day climate and are therefore worth running. For a model to be used for prediction of climate change, it is a necessary but not sufficient condition for it to simulate the mean climate well. We will discuss further development of the index so that it can measure more precisely the ability of the model to predict climate change.

MC11/10A/B19-002   0900

EVALUATION OF AMPLITUDE-PHASE CHARACTERISTICS OF SURFACE AIR TEMPERATURE ANNUAL CYCLE: CLIMATE MODELS VERSUS REANALYSES

Alexey V. ELISEEV[1], Maria S. GUSEVA[2], Igor I. MOKHOV[1], Konstantin G. RUBINSTEIN[3] ([1]A.M.Obukhov Institute of Atmospheric Physics RAS, [2]Geographycal Faculty, M.V.Lomonosov Moscow State University, [3]Russian Hydrometcentre)

Climatology and interannual variability of the amplitude-phase characteristics (APC) for surface air temperature (SAT) are studied using two ensembles of atmospheric general circulation models (AGCMs) and coupled climate models (CMs) and compared with the data of NCEP/NCAR and ERA reanalyses for 1958-1998 and 1979-1993 respectively. The first ensemble consists of the AGCMs (HadAM3, RHMC-T21 and RHMC-T40) forced by the prescribed interannually varying sea surface temperatures. The second ensemble consists of the coupled CMs (ECHAM4/OPYC3, HadCM3 and IAP RAS CM) which are forced by the observed greenhouse gases and sulphate atmospheric loading for the XIX-XX centuries. The APC studied are amplitudes of the annual and semiannual AC harmonics, moments of zero- and pi-phases (when SAT equals its annual mean value in spring and autumn, respectively) and interval of exceeding (the period when SAT is higher than its annual mean value). The data of reanalyses show the distinct features of SAT AC APC in different regions (e.g. in the regions of the atmospheric centres of action and in the region near the snow-ice boundary). Generally, two studied reanalyses show the results which agree to each other except in the polar regions. The studied AGCMs ensemble generally reproduces the gross peculiarities of the SAT AC APC except in the polar regions. For RHMC AGCM the higher spatial resolution resulted in the improved simulation of the characteristics of the SAT annual cycle. Among the studied CMs, ECHAM4-OPYC3 and HadCM3 also generally reproduces the climatology and variability of SAT AC APC. The features found for the latter model are very similar to those exhibited by the atmosphere-only version (HadAM3) in the experiment with prescribed sea surface temperature. IAP RAS CM simulates well this climatology over the continents but fails over the oceans.

MC11/10A/B19-003   0920

FINE STRUCTURE OF THE ANNUAL CYCLE: A DISCRIMINATING TEST OF MODELS

Brian E. MAPES[1], In-Sik KANG[2] ([1]Climate Diagnostics Center, [2]Seoul National University)

The annual cycle is an ideal test of climate models. Its radiative forcing is strong and precisely known, with a dominant annual harmonic and slight semiannual harmonic. The response of the climate system to this forcing is complex, and poses a graduated set of challenges for climate models. Unlike subtler forms of climate variability, the annual cycle is strong enough that small ensembles and short runs suffice to define model performance.Every serious model has a credible representation of some ˝easy˝ aspects, such as the annual harmonic of low-level temperature. Harder issues, such as the semiannualvariation of subtropical jets and angular momentum, or the dominant ter-annual cycle of surface pressure over the oceans, begin to separate better from worse models -- but still within the context of a phenomenon common to all. Similarly, monsoons and other rainfall features provide both easy and harder tests of moist physics. The mean annual cycles of 13 climate models at daily or pentad resolution, from both AMIP-type runs and coupled ocean-atmosphere simulations, have been probed with harmonic and wavelet analysis tools for features seen in reanalyes and other observationaldata sets. Both easy and hard phenomena have been examined. A selected set of discriminating tests (not too easy, not too hard) will be shown in an attempt to define theforefront of model accuracy. A PC with a comprehensive, interactive analysis tool and all data sets will be on hand for demonstration, allowing real-time ˝coffee-break science.˝

MC11/10A/B19-004   0940

COMPARISON OF RECENT RE-ANALYSES USING OBJECTIVE FEATURE TRACKING OF SYNOPTIC SCALE WEATHER SYSTEMS: HOW BELIEVABLE ARETHE RE-ANALYSES?

Kevin HODGES[1], Brian HOSKINS[2], Lennart BENGTSSON[3], Jim BOYLE[4] ([1]ESSC, University of Reading, [2]Dept. of Meteorology, University of Reading, [3]Max Planck Institute for Meteorology, [4]PCMDI, Lawrence Livermore)

In order to use atmospheric re-analyses for evaluating climate model behaviour it is important to understand which aspects of the re-analyses are robust. An objective feature tracking analysis has been applied to four recent re-analyses to identify synoptic scale weather systems and compare their representation in the different re-analyses. The four re-analyses that are explored are ERA15, NCEP/NCAR, NCEP/DOE and NASA/GEOS1. The comparison is conducted using spatial statistics for storm distributions and mean attributes. In addition a direct track-by-track comparison is made between the track ensembles from the different re-analyses. Differences are discussed in the context of the model-assimilation combination used for each re-analysis. In general the results for the NH winter, lower troposphere show that the different re-analyses compare well for systems identified in both MSLP and vorticity at 850hPa with very similar distributions of storms. The spatial mean intensities indicate that ERA15 is weaker around the main orography related to the use of an orographic parameterization not used in the other re-analyses. The direct ensemble comparison show that there are a core of systems that correspond well amongst all the re-analyses with a good correspondence in intensity and position together with a number of

weaker systems that correspond less well and which are sensitive to the available observations and the way they are assimilated. These weaker systems appear to have a small contribution to the mean attributes although they may be cumulatively important hydrologically. In the SH winter the comparison highlights the greater uncertainty in the representation of weather systems associated with the sparser observational database. Also the diagnostics for MSLP indicate differences with the circumpolar pressure trough in the SH in the different re-analyses. Above 500hPa the representation of weather systems are found to be sensitive to the assimilation methodology as indicated by the use of optimal interpolation in ERA15. This manifests itself by the poor representation of systems at the tropopause compared with the other re-analyses which used more sophisticated assimilation systems. In the tropics there is also considerable uncertainty highlighted by the large differences in the Easterly Wave activity amongst the re-analyses, in particular for NCEP/DOE compared with NCEP/NCAR with the introduction of a new boundary layer parameterization. In addition we have conducted experiments with the ERA40 re-analyses system to explore the impact of different observing systems and their impact on the re-analyses. This includes experiments with a satellite only, terrestrial only and surface only observing system. Results of applying the tracking analysis shows the relative importance of these observing systems in particular the equal importance of the satellite and radiosonde observations and the dominance of the satellite system in the SH. In general the surface only observing system leads to a poor representation of the weather systems. If time permits a comparison with AMIP models will also be presented.

MC11/10A/B19-005   1000

DEVELOPING A NEW CLIMATE MODEL FOR THE MET OFFICE - HADGEM1

Gill MARTIN, Vicky POPE, Rachel STRATTON (Hadley Centre, Met Office)

The Met Office has undertaken an ambitious programme of model development to produce their next generation of numerical models for weather forecasting and climate research. The project is well advanced. This study will show the first results from the climate version of the model, focussing on the atmospheric component. The new atmospheric model includes substantially improved representations of physical processes, increased functionality and higher resolution. Major improvements are the use of semi-Lagrangian instead of Eulerian dynamics to advect both dynamical and tracer fields, new boundary layer, convection, gravity wave drag and microphysics schemes, and major changes to the land surface (including tiled surface characteristics) and cloud schemes. Processes available in the standard version of the model for the first time include the direct and first indirect radiative effects of aerosol,RG12 RG12 the sulphur cycle, atmospheric chemistry, dynamic vegetation. The results of a preliminary evaluation of the new atmospheric model will be shown. Early results indicate improvements in cloud-radiative properties, boundary-layer properties and the representation of tracers. Sensitivities to horizontal and vertical resolution, and the impact of particular physics changes will be described. The problems associated with combining so many new features will also be discussed.

MC11/10A/B19-006   1040

VALIDATING THE PHYSICS OF HADLEY CIRCULATION SEASONALITY IN MODELS

Kerry Harrison COOK (Dept. Earth and Atmospheric Sciences, Cornell University)

The validation of model processes and mechanisms is needed to support model improvement and the evaluation of a model's ability to properly simulate climate change. This paper reports on an investigation of the Hadley circulation dynamics, and examines the physical processes that cause the observed seasonality of the MMC.The Hadley circulation has a well-know seasonal cycle, consisting of alternating solstice states with a dominant winter cell and equinox states with two cells of comparable strength divided by the equator. Applications of axisymmetric models of the atmospheric circulation associate this seasonal behavior with differences in the applied zonally uniform forcing. In particular, the strength of the Hadley circulation in axisymmetric models is enhanced when the heating is off the equator, and also when it is more concentrated.The Hadley circulation in an AGCM with realistic, prescribed surface features does not duplicate these axisymmetric model results. The correlation between the latitude and concentration of the heating in the axisymmetric models occurs because the applied heating distribution is unrealistic, being too sharply peaked near the equator. This heating shape causes a primary response in the vertical velocity field, as the diabatic heating is balanced by adiabatic cooling. In contrast, the GCMs heating is more broadly distributed through the tropics and is not zonally uniform. The response to such heating involves horizontal advection and the influence of a significant Coriolis force. The driving mechanisms of the MMC seasonality are similar to those in the GCM, and not similar to the axisymmetric model.

MC11/10A/B19-007   1100

EXPLORING THE DIURNAL CYCLE OF PRECIPITATION IN AN AQUAPLANET MODEL:A POTENTIAL TESTBED FOR MODEL PARAMETRIZATIONS?

Stephen WOOLNOUGH[1], Brian HOSKINS[2], Julia SLINGO[1] ([1]NCAS Centre for Global Atmospheric Modelling, [2]Department of Meteorology, University of Reading)

The diurnal cycle is a strongly forced mode of the atmosphere, yet the diurnal cycle of precipitation in the Tropics is poorly represented in most GCMs. The processes that determine the diurnal cycle of precipitation are not well understood and the extent to which the important processes are represented in GCMs is not clear. This paper will explore the oceanic diurnal and semi-diurnal harmonics of tropical precipitation in an aquaplanet GCM, representing the simplest forcing conditions for the diurnal cycle of precipitation. The performance of the model will be compared to the limited observations of the diurnal and semi-diurnal harmonics of tropical convection over the open ocean and the processes that determine the diurnal cycle of tropical convection in the model will be examined. In particular, the relationship of the precipitation signal to the diurnal and semi-diurnal pressure tides will be considered. The dependence of the representation of these harmonics (both phase and amplitude) on the closure of the convection scheme will be described. The extent to which the different representations of the diurnal cycle of precipitation can be used as a measure of the relative performance of convection schemes in the light of forthcoming improvements in the observations of the diurnal cycle of tropical convection will be discussed.

MC11/10A/B19-008   1130

USING AN AQUA-PLANET MODEL TO INVESTIGATE MODEL SENSITIVITIES

Rachel A. STRATTON (Hadley Centre, Met Office)

During the development of the Met Office´s new climate model, HadGEM1, an aqua-planet version of the atmospheric model proved a useful tool to help investigate and understand the model´s behaviour in the tropics. HadGAM1 differs significantly from the previous Hadley Centre model HadAM3. Not only are the model dynamics completely different (semi-Lagrangian, semi-implicit instead of Eulerian, split-explicit) but so are the horizontal and

vertical resolutions and most of the physical parametrisations. Aqua-planet runs exploring, in particular, the sensitivity of the convection scheme in HadGAM1 were compared with HadAM3 to understand differences in the tropical precipitation. The sensitivity of the HadGAM1 simulation to horizontal resolution and timestep were also investigated. Initially most of the aqua-planet runs were done using sea surface temperatures which were symmetrical about the equator. Further sensitivity studies have looked at the model´s response to an idealised warm pool, an idealised cold tongue on the equator and the impact of adding tropical islands.

MC11/10A/B19-009   1150

PROBABILISTIC CLIMATE FORECASTING USING DISTRIBUTED COMPUTING

Dave FRAME (University of Oxford)

The current generation of atmosphere-ocean general circulation models (AOGCMs) are capable of simulating many large-scale features of present-day climate and recent climate change with a high degree of accuracy. However, these models contain large numbers of adjustable parameters whose values are poorly constrained by the available data and which are known, individually, to have a significant impact on simulated climate. We do not know the extent to which a different choice of parameter-settings, or entire parameterization schemes, may provide an equally realistic simulation of 20th century climate but a different forecast for the 21st century. In principle, the problem is simple: vary these ˝underdetermined˝ parameters and repeat the simulation and forecast in order to obtain a spread of forecast climates that are consistent with recent climate change. The challenge of such a perturbed-physics ensemble is that the number of underdetermined parameters is large (potentially in the hundreds, although expert judgement can be used to prioritise a few dozen). The chaotic nature of AOGCMs precludes the use of linearisation techniques to identify 'pathological' parameter-perturbations, and it has already been shown that the impact of multiple perturbations is not additive. This leaves no alternative to a 'brute-force' exploration of a high-dimensional parameter-space requiring potentially very large numbers of long integrations of the climate model.Currently available supercomputing resources are completely inadequate for such a full-scale perturbed-physics ensemble climate forecast. Fortunately, distributed computing (utilising idle processing capacity on personal computers volunteered by businesses and the general public) provides an effective alternative for this kind of large-scale Monte Carlo simulation. The climate*prediction.*net project aims to harness the power of idle home and business PCs to make the first fully probability-based 50-year forecast of human induced climate change using a full-scale 3-D atmosphere-ocean climate simulation model.

VALIDATING AND UNDERSTANDING THE RADIATIVE AND DYNAMICAL FEEDBACKS IN THE NCAR CCSM

De-Zheng SUN, Tao ZHANG, John FASULLO, Andres ROUBICEK (Climate Diagnostics Center, NOAA-CIRES)

Climate feedbacks determine the sensitivity of the climate system to an external perturbation, affect the mean climate, and control the amplitude of naturalvariability. Thus validating and understanding climate feedbacks in climate models are of critical importance. Here we compare the radiative and dynamicalfeedbacks from the two most recent versions of the atmospheric component of the NCAR CCSM--the NCAR CAM1 and CAM2--with those from observationsover the equatorial Pacific cold-tongue. The observational data are from ERBE and the NCEP reanalysis. The model data are from simulations with the observedtime-varying SST as the boundary conditions. Both the CAM1 and CAM2 capture the positive feedbacks from the greenhouse effect of water vapor and clouds. The water vapor feedback in both the CAM1and CAM2 is somewhat larger than that from observations. The feedback from the greenhouse effect of clouds is stronger than observations in CAM1, but weakerthan in observations in CAM2. Larger errors are found in the feedback from the short-wave forcing of clouds. While observations show a strong negativefeedback from the short-wave forcing of clouds (-7.8 Wm-2), the feedback from the short-wave forcing of clouds in CAM2 is positive (+3.4 Wm-2K-1). The signof the feedback from the short-wave forcing in CAM1 is correct, but the strength is less than half of the observed value (-3.0Wm-2K-1). Consequently, the netatmospheric feedback in both CAM1 and CAM2 over the cold-tongue region are strongly positive (+5.1 Wm-2K-1 in CAM1 and +6.7Wm-2K-1 in CAM2) whilein the real atmosphere it is strongly negative(-6.4Wm-2K-1). Both the CAM1 and CAM2 captures the strong negative feedback from the atmospheric transport(the vertically integrated transport of total energy), though the feedbacks from the models are somewhat weaker. The feedback from the atmospheric transport iscloser to observations in CAM1 than in CAM2. A further analysis with the aid of the ISCCP data suggests that the apparent errors in the cloud feedbacks may be related to an excessive response in the upper levelclouds to changes in the SST. Causes for the model-data discrepancies are further explored by comparing the feedbacks with those from a GFDL model.

MC11/10P/B19-002   1420

EVALUATING CLOUD RESPONSE TO CLIMATE CHANGE

Keith D. WILLIAMS[1], M.A. RINGER[1], C.A. SENIOR[1], A. SLINGO[2] ([1]Met Office, Hadley Centre, [2]ESSC, University of Reading)

It is widely believed that the radiative feedback from clouds remains as oneof the largest uncertainties in determining the climate sensitivity to increasing greenhouse gas concentrations. Many model evaluation studies determine the performance of a general circulation model´s (GCMs) simulation of mean climatology with little evaluation of physical processes. Whilst it is certainly desirable that a climate model should accurately simulate the current climatology, this ability alone does not necessarily imply an accurate simulation of climate change. This study proposes a possible methodology for evaluating the cloud response to climate change simulated by GCMs. By using compositing techniques, the method attempts to identify the primary processes which are associated with the amount of cloud of a particular height and optical depth. Stratifying model data through such techniques permits the simulated climate change cloud response to be considered as a change in the population of the compositing bins. Compositing satellite observations of cloud using the same method allows the cloud amount in each bin to be evaluated and hence, an assessment can be made of the confidence in the cloud response resulting from a change in bin population. The method is illustrated using the Met Office´s Hadley Centre atmosphere GCM coupled to a mixed-layer (slab) ocean.

MC11/10P/B19-003   1440

TROPICAL CUMULUS CONVECTION AND UPWARD PROPAGATING WAVES IN MIDDLE ATMOSPHERIC GCMS

Takeshi HORINOUCHI[1], S. PAWSON[2], K. SHIBATA[3], U. LANGEMATZ[4], E. MANZINI[5], M.A. GIORGETTA[5], F. SASSI[6], R.J. WILSON[7], K. HAMILTON[8], J. DE GRANPR&EACUTE;[9], A.A. SCAIFE[10] ([1]Radio Science Center for Space and Atmosphere, Kyoto University, [2]Data Assimilation Office, NASA GSFC, Greenbelt, MD, USA, [3]Meteorological Research Institute, Tsukuba, Japan, [4]Freie Universitat Berlin, Berlin, Germany, [5]Max-Planck-Institut fur Meteorologie, Hamburg, Germany, [6]NCAR, Boulder, Colorado, USA, [7]GFDL, Princeton, New Jersey, USA, [8]University of Hawaii, Honolulu, Hawaii, USA, [9]York University, Toronto, Ontario, Canada, [10]Met Office, Bracknell, UK)

It is recognized that the resolved tropical wave spectrum can varyconsiderably among general circulation models (GCMs) and that thesedifferences can have an important impact on the simulated climate. Acomprehensive comparison of the waves is presented for theDecember-January-February period using high-frequency (three-hourly)data archives from eight full GCMs and one slightly simple model participatingin the GCM Reality Intercomparison Project for SPARC(GRIPS). Quantitative measures of the structure and causes of thewavenumber-frequency structure of resolved waves and their impacts onthe climate are given. Space-time spectral analysis reveals that thewave spectrum throughout the middle atmosphere is linked to variabilityof convective precipitation, which is determined by the parameterizedconvection. The variability of the precipitation spectrum differs bymore than an order of magnitude between the models, with additionalchanges in the spectral distribution (especially the frequency). Thesedifferences can be explained primarily by the choice of differentcumulus parameterizations: quasi-equilibrium mass-flux schemes tend toproduce small variability, while the moist-convective adjustment schemeis most active. Comparison with observational estimates ofprecipitation variability suggests that the model values are scatteredaround observational estimates. This result indicates that asignificant portion of the forcing of the equatorial quasi-biennial oscillation (QBO) isprovided by waves with scales that are not represented in present-day GCMs,since only the moist convective adjustment scheme (which has the largesttransient variability) can force a QBO in models that have noparameterization of non-stationary gravity waves. Parameterized cumulusconvection also impacts the nonmigrating tides in the equatorial region. In most of the models, momentum transport by diurnal nonmigrating tidesin the mesosphere is larger than that by Kelvin waves, being moresignificant than has been thought. It is shown that the westerly accelerations in the equatorialsemi-annual oscillation in the models examined are driven mainly bygravity waves with periods shorter than three days, with at least somecontribution from parameterized gravity waves; the contribution from theultra-fast zonal wavenumber-1 Kelvin waves is negligible. These resultsprovide a state-of-the-art assessment of the links between convectiveparameterizations and middle atmospheric waves in present-day middleatmosphere-climate models, giving physical insight into the processes ofwave generation and the indirect importance of the cumulus scheme to theclimate of the middle atmosphere.

MC11/10P/B19-004   1500

EVALUATION OF MIDLATITUDE CLOUD PROPERTIES IN A WEATHER AND A CLIMATE MODEL: DEPENDENCE ON DYNAMIC REGIME AND SPATIAL RESOLUTION

George TSELIOUDIS[1], Christian JAKOB[2] ([1]NASA/GISS, Columbia University, [2]Bureau of Meteorology Research Centre, Melbourne, Australia)

In this study, the midlatitude cloud fields produced by a climate (GISS) and a weather (ECMWF) model are evaluated against satellite observations. Monthly ensembles of model cloud property distributions for the four seasons are compared with similar ensembles from satellite retrievals. The weather model is run in both forecast and 'climate' mode in order to evaluate the importance of the exact representation of the atmospheric conditions in these ensemble comparisons. The weather and climate models are evaluated at different resolutions that cover the range used in today's climate and weather prediction simulations. Cloud property evaluations are separated into broadly defined dynamic regimes that cover the range of large-scale midlatitude motions. Quantitative evaluation tables are produced that rank the performance of the different model versions used in the study.The evaluation analysis reveals several common features between the two models. Those are the overestimation of cloud optical depth in all dynamic regimes, the underestimation of cloud cover in the large-scale descent regime and the underestimation of cloud top height in the large-scale descent regime. It is also shown that, in the radiative balance calculations, the models compensate for the overestimation of cloud optical depth through the underprediction of cloud cover. The comparison of the forecast and 'climate' runs of the ECMWF model shows remarkably similar statistical properties of the clouds in the two runs. The analysis of runs with different resolutions reveals large improvement when going from a 4ox5o 9-layer to a 2ox2.5o 32-layer run with the GISS GCM, much of which is caused by the increase in vertical resolution. A comparison of a T42 and a T106 run of the same vertical resolution with the ECMWF GCM does not show considerable differences between the two model versions.

MC11/10P/B19-005   1550

A STATISTICAL COMPARISON OF ECMWF FORECASTED CLOUD FIELDS WITH EARTH OBSERVING SYSTEM (EOS) SATELLITE OBSERVATIONS

Kuan-Man XU (Atmospheric Sciences)

Climate model simulations are usually validated against gridded monthly-mean satellite observations. Numerical weather forecasts are validated against surface observations, at least, at the daily time scale. In both types of validations, the gridded data are used, which represent an area over hundreds of kilometers in the horizontal direction. In this study, a new approach is proposed to validate subgrid-scale statistical properties of mesoscale cloud systems against those identified from Earth Observing System (EOS) satellite data. The forecasted cloud fields from the European Center for Medium-range Weather Forecasts (ECMWF) are validated in this study. A large set of cloud, radiation and precipitation data that are matched with simultaneous atmospheric state data from ECMWF is used for this purpose. A "cloud object" technique has been deployed to produce such a data set at the NASA Langley Research Center. Specifically, this technique classifies EOS satellite data into distinct cloud systems over contiguous regions of the Earth for a given type of cloud systems (e.g. trade cumulus, transition stratocumulus, solid stratus, and deep convection). These regions can be thought of as snapshots of cloud systems. The ECMWF data contain a set of forecasted cloud fields, which includes the vertical profiles of cloud water mixing ratio, cloud ice mixing ratio and cloud fraction. Since the ECMWF grid size (0.5625x 0.5625 degrees) is much larger than the footprint size of satellite data (an average size of 23.5 km x 4.6 km), each ECMWF grid is further divided into smaller subgrids (30 of them) in order to properly compare the statistics of ECMWF forecasted cloud fields with the satellite observed cloud systems. A major assumption for facilitating this comparison is that the maximum-random overlap assumption is used to distribute the ECMWF cloud fields horizontally and vertically (Klein and Jakob 1999). The broadband radiative fluxes and cloud optical properties of each ECMWF subgrid column are obtained using radiative transfer

parameterization from the Fu-Liou radiation code (Fu and Liou 1993). The same criteria used for identifying satellite cloud systems are then used to select the ECMWF subgrids for computing probability density functions (PDFs) of cloud properties and radiative fluxes. Preliminary results indicates that most PDFs of cloud properties and radiative fluxes of deep convection for ECMWF agree with those of satellite observations to some extent. The ECMWF forecasted clouds tend to deeper and cooler than those observed, at least, for the March 1998 period. The ECMWF does not produce the dependence of PDFs on the cloud-system sizes as revealed by the satellite data. More detailed results will be presented for other cloud-system types and other periods.

EVALUATE CLOUD SIMULATION ASSOCIATED WITH MIDLATITUDE CIRCULATION SYSTEMS IN A CLIMATE MODEL

Cheng-Ta CHEN (Department of Earth Sciences, National Taiwan Normal University)

Cloud fields and concurrent dynamical structures associated with extratropical cyclones in a general circulation model are investigated during the cool season (October to March). An ensemble approach is used for constructing the respective anomaly patterns in the storm track region of the northwestern Atlantic. The simulated composite patterns are in many respects similar to those derived from satellite cloud data and operational weather analyses. The results agree also reasonbly well with traditional conceptual frameworks for the organization of clouds in the vicinity of warm and cold frontal zones. The vertical structure and wave characteristics of various dynamical, thermal and hydrological fields reveal the typical patterns found in observed baroclinic wave disturbances such as a westward tilt with height of pressure anomalies and an eastward displacement of the upper tropospheric clouds relative to the center of largest upward motion at 500 hPa. However, this displacement is not as distinct as in the observations. Similar to indications from surface weather reports, the largest precipitation anomalies are simulated westward of the reference site defined by the largest anomaly in cloud water path and cloud optical thickness, respectively. The changes in cloud cover, cloud water, humidity and temperature during the passage of a synoptic scale weather disturbance have a distinct impact on the energy budget with a pronounced seasonality in all components except for the longwave radiation. Due tochanges in the fluxes of sensible heat, latent heat and shortwave and longwave radiation, the atmospheric column in most parts of the cyclonic systems is cooled in winter and heated in summer. On the other hand, extratropical cyclones cause anomalous surface heating in winter and cooling in summer.

EVALUATION OF UPPER TROPOSPHERIC WATER VAPOR IN THE NCAR CCM3 COMMUNITY CLIMATE MODEL USING MODELED AND OBSERVED HIRS RADIANCES

Michael J. IACONO, Jennifer S. DELAMERE, Eli J. MLAWER, Shepard A. CLOUGH (Atmospheric and Environmental Research, Inc.)

Upper tropospheric water vapor (UTWV) simulated by the National Center for Atmospheric Research Community Climate Model, CCM3, is evaluated by comparing modeled, clear sky, brightness temperatures to those observed from space by the High-resolution Infrared Radiation Sounder(HIRS). The climate model was modified to utilize a highly accurate longwave radiation model, RRTM, and a separate module simulating HIRS radiances, both developed for the Atmospheric Radiation Measurement (ARM) Program. The radiance module applies physics that are consistent with RRTM to calculate brightness temperatures in the NOAA-7 HIRS 6.7 micron water vapor channel (CH12) and the 14.2 micron temperature channel (CH04). The utilization of radiation models that are evaluated with ARM measurements addresses the objective of improving radiative transfer in general circulation models and enhances the effectiveness of evaluating GCMs with observations. Simulations with CCM3 were performed for the period 1982-1984 following the Atmospheric Model Intercomparison Project (AMIP) protocol to provide a basis for evaluating the water vapor distribution over a wide range of atmospheric conditions. Brightnesstemperature differences of 2 K or less in CH04 indicate that CH12 differences are primarily due to water vapor rather than cloud effects or temperature variations. Regionally, CCM3 exhibits considerable positive and negative differences of 5-10 K in CH12 that are apparent in both convective and dry sub-tropical areas. This suggests that significant moist and dry discrepancies in UTWV amount of 50 percent or more are present in CCM3. Comparison to HIRS radiances provides a considerably more effective and comprehensive means of globally evaluating GCM-simulated UTWV on various time scales than surface-based water vapor measurements.

TOWARD EXPLOITING COMMUNITY STANDARD EXPERIMENTS FOR CLIMATE MODEL EVALUATION

Peter GLECKLER, K. SPERBER, K. TAYLOR (Program for Climate Model Diagnosis and Intercomparison, Lawrence Livermore National Laboratory)

Evaluating the overall performance of climate models is a difficultchallenge. General circulation models of the atmosphere (AGCM) and theocean (OGCM) are becoming increasingly complex and exhibit a wide range ofstrengths and weaknesses. Additionally, untoward complications arise whenthese models are coupled together, necessitating diagnosis of thecomponent models to isolate the source of the errors. Numericalexperimentation, often in the form of sensitivity experiments, is thefundamental approach toward understanding an individual model´s behavior. As a complement to this approach, the examination of a collection ofdifferent models can help to distinguish which model biases are unique toa particular model from those that are commonplace. Additionally,collective evaluation of models helps to monitor improvements instate-of-the-art climate models. At PCMDI, we are exploiting a hierarchyof community-standard experiments to assess model behavior andperformance. Making use of our open-source diagnostic tools, we areproducing comprehensive diagnostic reports on simulations endorsed byworking groups of the World Climate Research Programme (WCRP). Theexperiment analyzed include the Aqua-Planet Experiment (APE), AtmosphericModel Intercomparison Project (AMIP), and Coupled Model IntercomparisonProject (CMIP), each of which are experiments that are complementary forunderstanding land/ocean and air/sea interaction. We will describe ourapproach toward synthesizing a wealth of diagnostics for evaluating theoverall performance of climate models.

STATUS OF MIDDLE ATMOSPHERE-CLIMATE MODELS: RESULTS FROM SPARC-GRIPS

Steven PAWSON[1], Kunihiko KODERA[2] ([1]UMBC GEST Center, [2]Meterological Research Institute)

The middle atmosphere is an important component of the climate system, primarily because of the radiative forcing of ozone. Middle atmosphericozone can change, over long times, because of changes in the abundanceof anthropogenic pollutants which catalytically destroy it, and becauseof the temperature sensitivity of kinetic reaction rates. There is thusa complex interaction between ozone, involving chemical and climaticmechanisms. One question of interest is how ozone will change over thenext decades, as the ˝greenhouse-gas cooling˝ of the middle atmosphereincreases but the concentrations of chlorine species decreases (becauseof policy changes). A major obstacle when addressing this questionconcerns the climate biases in current middle atmosphere-climate models,especially their ability to simulate the correct seasonal cycle athigh latitudes, and the existence of temperature biases in the global mean. This paper will present a summary of recent results from the ˝GCM-RealityIntercomparison Project for SPARC˝ (GRIPS) initiative. A set ofmiddle atmosphere-climate models has been compared, identifying commonbiases. Mechanisms for these biases are being studied in some detail,including off-line assessments of the radiation transfer codes andcoordinated studies of the impacts of gravity wave drag due tosub-grid-scale processes. An overview of recent results from theensemble of models will be presented, along with numerical experimentsundertaken with one or more models, designed to investigate themechanisms at work in the atmosphere. The discussion will focus ondynamical and radiative mechanisms in the current climate, but implicationsfor coupled ozone chemistry and the future climate will be assessed.

ASSESSMENT OF GCM-CALCULATED RADIATIVE FLUXES BASED ON LAND-BASED OBSERVATIONS

Martin WILD (Institute fo Atmospheric and Climate Science ETH)

Many uncertainties still exist regarding the distribution of radiative energy within the global climate system, and its representation in General Circulation Models (GCMs). This study uses surface observations taken from the Global Energy Balance Archive (GEBA, WCRP-Water Project A7) and Baseline Surface Radiation Network (BSRN/WCRP) located at the author´s institute, in order to identify systematic errors in GCM-calculated radiative fluxes within the framework of the Atmospheric Model Intercomparison Project (AMIP II). The presentation will summarize recent results from the AMIP II diagnostic subproject No. 32 ´Surface and atmospheric radiative fluxes´. To date, these include an excessive insolation at the land surface in the GCMs, typically in the range of 10-20 Wm^{-2}, which is particularly pronounced at low latitudes. Additional comparisons with top-of-atmosphere fluxes from the Earth Radiation Budget Experiment (ERBE) collocated with the surface radiation sites, suggest that the excessive surface insolation is predominantly related to an underestimated absorption in the GCM atmospheres rather than to errors in the planetary albedo. Evidence is presented that a lack of absorption in the cloud-free atmosphere contributes to the underestimated absorption of solar radiation in the atmosphere. This is based i) on direct comparisons of the GCM clear-sky surface fluxes with observed clear-sky climatologies at selected sites and ii) on off-line validations of the GCM radiation schemes for clear-sky conditions. Furthermore, in heavily polluted areas, the inadequate representation of absorbing aerosol in GCMs contributes to the lack of shortwave absorption in the GCM atmospheres. This is evidenced using radiation sites in Equatorial Africa during the biomass burning seasons, where the model biases are further enhanced by up to 30-40 Wm^{-2} regionally. Within the longwave radiation components, the downward flux at the surface is affected with the largest uncertainties in the models. New observational data from BSRN suggest that the longwave downward radiation is typically underestimated in GCMs and Reanalysesat higher latitudes, but less so at lower latitudes. This results in a too strong meridional gradient in the model-calculated longwave downward radiation. These findings are consistent with offline calculations performed with the GCM radiation codes under clear sky conditions, suggesting that the emission of the cloud-free atmosphere is responsible for much of these biases. A common problem in many GCMs is therefore an excessive surface insolation, which iscompensated by underestimated longwave downward radiation, leading to a superficiallycorrect net radiation by error cancellation. This error cancellation no longer applies on zonal, regional, seasonal or diurnal scales, causing substantial problems in the simulatedsurface climates.

USING AMIP MODELS TO SIMULATE THE EARTH ROTATIONAL PROPERTY OF POLAR MOTION

David A. SALSTEIN[1], Jolanta NASTULA[2] ([1]Atmospheric and Environmental Research, Inc., [2]Space Research Center of the Polish Academy of Sciences)

Monthly mean results from 19 different general circulation models from the second phase of the Atmospheric Model Intercomparison Project, covering the period 1979-1995, based on the protocol of forcing only by a prescribed set of sea surface temperatures, are used to study the relationship of the atmosphere to the wobble of our planet as it rotates on its axis. Using surface pressure fields, we calculate the models*Eexcitations for the Earth´s polar motion. This motion has been tied strongly to changes in the atmospheric mass distribution, though the ocean plays a role as well. Parallel to the conservation of angular momentum in the axial direction that links atmospheric angular momentum to length-of-day variations, the values of angular momentum in the equatorial plane would be related to these polar motions, which are determined by a number of modern space-geodetic methods. Both global and regional values of polar motion excitation have been determined. We investigate the seasonal and interannual variability of the polar motion excitation term, including the spread among models, the standard deviation of which appears to vary by up to a factor of two. We check how well do models represent observations by comparing model-based excitations with those based on the NCEP-NCAR reanalyses for the same period, as well as directly with geodetic excitations, when taking account the ocean as well. Our earlier regional results of atmospheric excitations in the reanalysis revealed that such atmospheric excitations are particularly strong over certain land regions like Siberia and North America, and so we examine such geographic regions for similar variability in the AMIP-2 models. Different physical properties, including land surface parameterizations, are used for the various models and we seek, as part of a diagnostic effort within AMIP, to determine the most effective set of physical modeling mechanisms for the (three-dimensional) fields of angular momentum and the related Earth rotational parameters of interest.

INTERCOMPARISON OF STATIONARY WAVES IN AMIP-2 GCMS AND THEIR MAINTENANCE MECHANISMS

Mingfang TING, Renu JOSEPH (Department of Atmospheric Sciences, University of Illinois at Urbana-Champaign)

Atmospheric and coupled ocean-atmosphere general circulation models (GCMs) are used extensively in understanding climate change and in making seasonal predictions. However, differences in model physics and numerics cause different GCMs, and sometimes the same GCM at different resolutions, to produce different atmospheric circulation patterns. In particular, climatological stationary wave simulations in GCMs differ considerably from each other, and quite often, from observations. Stationary waves and their changes are closely related to the local climate and climate change. It is therefore crucial to assess and understand how well climatological stationary waves are simulated in the various models and the sensitivity of stationary wave simulation to different parameterization schemes and model resolutions.In this study, we have compared the seasonal cycle of the climatological stationary waves in several AMIP-2 models. Considerable differences were found in the stationary wave spatial structure as well as amplitude throughout the seasonal cycle among the different models and between each model and the NCEP/NCAR reanalysis. Furthermore, the maintenance mechanisms of the climatological stationary waves in six of the AMIP-2 models have been examined using a nonlinear stationary wave model and compared to the NCEP/NCAR reanalysis. In general, diabatic heating has been the primary forcing mechanism in them consistent with the reanalysis. The relative importance of the orographic forcing and the diabatic forcing varies among different models and that of the reanalysis. This is mainly due to discrepancies in the surface zonal mean zonal wind simulations. We will show that some models may have obtained a better overall simulation of the stationary waves due to compensating errors in the orographic forcing and the diabatic forcing.

AMIP II SIMULATIONS OF SURFACE AIR TEMPERATURE AND PRECIPITATION: VALIDATION AND INTERCOMPARISON

Jeong-Woo KIM[1], Jeong-Hyun PARK[2], Ho-Jeong SHIN[1] ([1]Department of Atmospheric Sciences and Global Environment Laboratory, Yonsei University, [2]Remote Sensing Division, Korea Meteorological Administration)

The observed and AMIP II-simulated normal annual mean, seasonal mean, and seasonal difference of surface air temperature and precipitation are shown on the scatter and Taylor diagrams for the globe and East Asia. The following questions are pursued in particular: Is the Gaussian distribution the rule over the ensemble of the AMIP II simulations? To what extent can the confidence in the ensemble average be ascertained through inter-model structure of simulations? Present inter-model differences among the ensemble members seem to be an impediment to our understanding of the climate system. We will discuss on the suggestions that effort should be exercised in the reduction of the inter-model differences an improved understanding.

MC11/11A/B19-007   1050

ON THE PERSISTENT MOISTURE DIVERGENCE DURING COOL FROM THE INDIAN SUBCONTINENT

Ho-Jeong SHIN, Jeong-Woo KIM (Department of Atmospheric Sciences and Global Environment Laboratory, Yonsei University)

According to recent studies (e.g. Shin et al. 2003), both NCEP/DOE and ECMWF reanalyses data show persistent moisture divergence during cooler two-thirds of a year, but most AMIP II models fail to reproduce this feature. We have analyzed this problem, and would like to present probable reasons for this discrepancy.

MC11/11A/B19-008   1110

THE EFFECT OF CONVECTIVE TRIGGERING IN THE TROPICAL ATMOSPHERE SIMULATED BY ATMOSPHERIC GCM

Tsuneaki SUZUKI, Seita EMORI, Teruyuki NISHIMURA, Shinji MATSUMURA (Frontier Research System for Global Change)

The convection does not always occur, even if the atmosphere is conditionally unstable. It is necessary that certain mechanisms lift the air parcel to the level of free convection. The convective trigger function expresses such subgrid-scale behavior of air parcel. Although the triggering process is one of essential processes in convection, the cumulus parameterizations for atmospheric general circulation models (AGCM) ignore the convective triggering. However, recent studies show that the introduction of simple convective triggering such as relative humidity criterion improves the tropical intraseasonal oscillation (ISO) and the distribution of tropical precipitation simulated by the AGCMs.In order to investigate the role of convective triggering in the simulation by AGCM, we introduce the convective trigger function similar to that proposed by Hong and Pan (1998). The convection trigger function is formulated on the basis of the obvious physical mechanisms, i.e., surface inhomogeneities (SI), turbulence-induced buoyancy (TB), large scale convergence (divergence) in source layer (LS). In addition, we consider the effect of the convective triggering caused by gust front (GF) using the model of Qian et al. (1998). Therefore, we are able to understand the influence of each convective triggering mechanism separately. The AGCM used in this study is developed at the Center for Climate System Research (CCSR) of the University of Tokyo and the National Institute for Environmental Studies (NIES), and adopts the simplified prognostic Arakawa-Schubert scheme as a cumulus convection parameterization. The simulations are performed with T106 horizontal resolution and 20 levels in the vertical (T106L20). We investigated the result of simulations, especially, the tropical ISO and the variation of precipitation in the monsoon regions. The CCSR/NIES AGCM with the resolution of T106L20 simulates the ISO well except for the coherence of the signal. The ISO becomes more coherent by introducing the LS or GF triggers with the trigger by SI. The LS trigger enhances the seasonal variability of the ISO. However, the signal of the ISO is suppressed, when the effect of LS or GF becomes larger in convective triggering. The simple homogeneous trigger only by SI intensifies the strength of the ISO regardless of season. The time-longitude diagram of observed precipitation in the monsoon regions reflects the westward traveling wave. In the simulation without convective triggering, the monsoon precipitation tends to stagnate at certain longitude and the structure of wave propagation does not appear clearly in the precipitation pattern. The precipitation obviously reflects the westward traveling wave by introducing only the simple trigger of SI. The prevailing period of wave found in the precipitation diagram changes by the addition of other triggering mechanisms. The effect of LS enhances the appearance of longer-period wave in the precipitation pattern and the effect of GS favors shorter-period wave.

EFFECT OF MICROPHYSICAL PROCESSES ON THE SIMULATION OF THE MADDEN-JULIAN OSCILLATION (MJO) IN GCM

William K. LAU, H.T. WU (Laboratory for Atmospheres, NASA/GSFC, Code 910)

Recent studies have shown that the propagation and structure of MJO in GCMs are strongly dependent on the parameterization of physical processes. In this paper, we validate the Sundquist cloud water parameterization in the GEOS-GCM against TRMM observations, with focus on the effects on the propagation and structure of the model MJO. Based on joint probability distribution function of rainrate and columnar cloud liquid water from TRMM, we estimate an autoconversion time scale of about 200-1000 s and a critical cloud liquid water content of 0.5 AE.2 mm. The GEOS-GCM indicates an autoconversion of order of 1500-3600 s and a critical cloud liquid water content of less than 0.2 mm. This suggests that the GEOS-GCM has less efficient rain production than observed. The reduced rain conversion results in higher cloud liquid water content in the tropical atmosphere, less pronounced eastward propagation, and stronger stationary component. On the other hand, bring the rainfall efficiency closer to the observation leads to a more robust eastward propagating signal, and time scale for super-cloud clustering closer to the observed. The causes of the sensitivity of the dynamical regimes to the microphysics parameterization in the GCM and the need to better understand microphysical processes in the simulations of MJO , and the global hydrologic cycle will be discussed.

MC11/11A/B19-010   1150

HOW WELL DO MODELS REPRESENT OCEANICFORCING OF NORTH ATLANTIC CLIMATE?

Mark John RODWELL[1], Claude FRANKIGNOUL[2], Holger POHLMANN[3], Martin STENDEL[4], Rowan T. SUTTON[5], Laurent TERRAY[6] ([1]Hadley Centre, UK Met Office, [2]LODYC, Universite Pierre et Marie Curie, Paris, France, [3]Max-Planck-Institut fuer Meteorologie, Hamburg, Germany, [4]Danish Meteorological Institute, Copenhagen, Denmark, [5]CGAM, Department of Meteorology, Reading University, UK, [6]CERFACS, Toulouse, France)

Lagged covariance analyses suggest that North Atlantic sea-surface temperatures (SSTs) have forced a signal in the observed North Atlanticatmospheric circulation. A similar analysis of the Hadley Centre´s HadAM3 atmospheric model reveals very similar forced circulation patterns althoughthese are possibly too weak in the cold half of the year. To get a better understanding of the strength and uncertainty of the instantaneous forcing by North Atlantic SSTs, a carefully controlled experimentusing several atmospheric models has been conducted. The models used were two versions of the HadAM3 (one with a perturbed Charnock parameter), Meteo-France´s ARPEGE3 model and the Max Planck Institut fuer Meteorologie´s ECHAM4 and ECHAM5 models. The SST anomaly forcing patternsfor each month were derived from a lagged maximal covariance analysis of the observations in order to optimise the anticipated strength of theatmospheric signal. The difference between two 20-year simulations of each model was calculated, one simulation with a negative version of the SSTanomaly pattern. The results are remarkably similar for all models throughout the annual cycle. This gives some confidence that the models represent quite well theNorth Atlantic forcing of climate. European surface temperature anomalies of 2K and southern US and South American precipitation anomalies of 1mmper day are quite robust across models. An increase in the Charnock parameter appears to increase the temperature response over Europe. Surfacelatent heat flux anomalies over the entire North Atlantic respond to the imposed SST anomalies although precipitation anomalies are much stronger inthe tropics. For autumn, winter and spring, HadAM3 experiments with just the tropical SST anomalies produce similar extratropical responses, althoughthe autumn response is somewhat weaker. The latent heat fluxes forced by extratropical SST anomalies appear to re-enforce the precipitationanomalies induced by the tropical SST forcing. Extratropical SST anomalies appear to play a stronger local role in summer although the models agreeless well in the precise response pattern.

MODELLING OF EXTRATROPICAL ENSO TELECONNECTIONS AND THE LINK WITHTROPICAL PRECIPITATION

Hilary SPENCER, Julia SLINGO (Centre for Global Atmospheric Modelling, Department of Meteorology, University of Reading)

There is much evidence that El Nino and La Nina lead to significantatmospheric seasonal predictability across much of the globe. However, despite successful predictions of tropical Pacific SSTs,atmospheric seasonal forecasts have had limited success. Inparticular, the observed, perhaps non-linear, atmospheric reponse toENSO in the North Pacific/ North America region is not modelledaccurately by many atmospheric models. However, the high signal tonoise ratio in this region makes diagnosing the errors difficult. Thisstudy investigates model errors in the atmospheric model, HadAM3, byanalysing composites of similar El Nino and La Nina events at theirpeak in December to February (DJF) and through their decay in March toMay (MAM). Composites of very similar El Nino and La Nina events at their peak inDecember to February (DJF) are created in order to find thestatistical significance of the difference between the model andobservations in the tropics and extratropics. The large scale,tropical ENSO teleconnections are modelled accurately by HadAM3 duringDJF but the strongest extratropical teleconnection, that above theNorth Pacific during winter, is modelled inaccurately. The AleutianLow is frequently observed to shift eastwards during El Nino but themodelled response always consists of a deepening of the low without ashift. This is traced to small errors in the sensitivity ofprecipitation to SST in the tropical Pacific, which does not displayenough variability so that the precipitation is always too high overthe warmest SSTs.The errors in both the tropical Pacific precipitation and NorthPacific response are found to reduce dramatically when verticalresolution is increased from 19 to 30 levels. This improvement leadsto the possibility for more useful studies of the linearity of theresponse and the influence of SST anomalies in different regions onthe extratropical response. In MAM, following the peak of an El Ninoor La Nina, atmospheric anomalies are observed to decay rapidly. Themodelled ENSO response in DJF persists into MAM, making theextratropical anomalies in MAM too strong. This inaccuracy is againlikely to be due to the high modelled sensitivity of tropical Pacificprecipitation to SST which is not significantly improved with enhancedvertical or horizontal resolution in MAM.

EVALUATING AMIP2 MODEL SIMULATIONS OVER THE AUSTRALIA REGION

Huqiang ZHANG[1], A. HENDERSON-SELLERS[2], P. IRANNEJAD[2], S. SHARMEEN[2], T. PHILLIPS[3], K. MCGUFFIE[4] ([1]BMRC, Melbourne, Australia, [2]ANSTO Environment, Sydney, Australia, [3]PCMDI, Livermore, CA, USA, [4]Applied Physics, UTS, Sydney, Australia)

Sixteen AGCM model simulations from the Atmospheric Model Intercomparison Project II (AMIP2) are analyzed over the Australian region as part of Diagnostic Subproject 12. This work is focused on assessing how well surface climate and fluxes over this region are simulated in current AGCMs and the possible impact of land-surface modelling on model predictability. Observational datasets are used in the model validation and the Linear Error in Probability Space (LEPS) score is calculated in assessing the skill of the models in simulating surface climate anomalies for the 17-year period (1979 to 1995). Numerous differences are found among the models and between models & observations. Some of these can be linked to the complexity of land-surface schemes used. Results reveal that the characteristics of climatic memory gain from land-surface processes (e.g. soil moisture) exhibit different features in the sixteen models. Specifically, models with simple bucket-type soil hydrology schemes, which tend to exhibit rapid decay of soil water anomalies, exhibit too weak an influence on forecasts of surface climate anomalies resulting from changed soil moisture conditions.

MC11/11P/B19-002   1420

EVALUATION OF THE REGIONAL ETA/SSIB MODEL IN MODELING NORTH AMERICAN CLIMATE

Yongkang XUE[1], Ratko VASIC[2], Zavisa JANJIC[3] ([1]Department of Geography, Department of Atmospheric Sciences, University of California, Los Angeles, [2]Department of Geography, UCLA, CA, USA, [3]NCEP, NOAA, Camp Springs, MD, USA)

This study evaluates the North American climate simulations of the Regional Eta/SSiB model using observational and reanalysis data. It is important to understand the predictability of the regional climate model and the dominant factor(s), which may affect its predictability. To achieve these goals, a series of sensitivity studies has been designed to explore the role of variety of factors in regional climate simulations. These factors include domain size, horizontal resolution, different lateral boundary conditions (NCEP reanalysis, ECMWF reanalysis, NOAA GCIP reanalysis, GCM outputs), sea surface temperature (SST) and its diurnal variation, deep soil conditions, and convective parameterizations. The summer of 1998 is selected for the experiments. In this study, we mainly focus on the model simulations of the precipitation and other relevant hydro-meteorological variables. The results show that the domain size, SST, and lateral boundary conditions have the crucial impact on the simulations. In the domain size experiment, a set of domains has been selected for testing. The domain that covers only continental U.S. produces the best simulations in the temporal evolution and the spatial distribution of the precipitation. When the domain is expanded to the oceans, although the model is still able to produce reasonable large-scale circulation, the simulation of the intensity and the spatial distribution of the precipitation deteriorate dramatically when the ocean areas become large. The lateral conditions are also crucial for simulations. Only the GCM lateral boundary conditions produce the proper precipitation over ocean. In addition, the sensitivity study reveals that the diurnal variation of SST could also improve the simulation for precipitation over ocean. The change of horizontal resolutions from 80km to 48 km does not make significant differences in the model simulation. The impacts of these factors on other climate variables, such as wind, humidity, and temperature will also be presented.

PRECIPITATION OVER COMPLEX TOPOGRAPHY: AN EVALUATION AND INTERCOMPARISON OF REGIONAL CLIMATE MODELS

Christoph FREI, Juerg SCHMIDLI (Insitute for Atmospheric and Climate Science, ETH)

Regional Climate Models (RCMs) are promising tools for climate downscaling from General Circulation Models. Accurate downscaling of precipitation is of primary interest in applications, but modeling the involved processes is demanding, especially over complex topography. This study evaluates and compares 5 RCMs with regard to their representation of the precipitation climate over the 1100x700km mountain range of the European Alps. Four limited area models and one variable-resolution global model are considered, all with a grid spacing of 50 km. The model integrations extend over a 15-year period and are forced by reanalyses at their boundaries. The observational reference is based on 6400 rain gauge records (10-50 stations per model grid box) over the same period, from which objective analyses have been generated that are compatible with the resolution of the climate models. Evaluation statistics encompass seasonal mean precipitation and several statistics characteristic of drought and heavy precipitation. Results are discussed with regard to the climatological bias and the skill in the reproduction of interannual variability. The results point to remarkable differences in the model performance in summer. Three of the models underestimate summer mean conditions significantly. Though more accurate in the mean, the two other models exhibit compensating errors in the precipitation frequency distribution. Interestingly, the model errors are very similar between the two models with the same dynamical core (but different parameterizations) and they differ considerably between the two models with similar parameterizations (but different dynamics).

MC11/11P/B19-004   1500

SENSITIVITY OF THE EAST ASIAN SUMMERTIME CLIMATE TO SURFACE WATER CAPACITY DISTRIBUTION

Hyung-Jin KIM, Jeong-Woo KIM (Department of Atmospheric Sciences and Global Environment Laboratory, Yonsei University)

Soil moisture is one of the major sources of the atmospheric water vapor, and affects the land surface characteristics such as albedo, heat capacity and evapotranspiration (Smith et al. 1974), thus relating to the net surface energy balance. Therefore using realistic surface water capacity in GCMs should be relevant to simulating seasonal and longer time scale climate (Fennessy and Shukla 1999). At present, however, a number of AGCMs (for examples, 11 of 33 AMIP II AGCMs) use a single-layer bucket model to deal with soil moisture, and a constant maximum water capacity is uniformly prescribed in about two-thirds of these AGCMs including YONU AGCM. In this paper, we will present some of the salient results on our experiments in which our model runs with field capacity varying with surface types. We will discuss the sensitivity of the East Asian summertime climate to various distributions of the maximum water capacity over the region of East Asia. In particular, the summertime thermal low, and water and energy budget over the East Asia will be examined.

MC11/11P/B19-005   1520

PREDICTABILITY AND UNCERTAINTY IN A REGIONAL CLIMATE MODEL: LESSONS FROM PERFECT MODELS AND PERFECT DATA

Pier Luigi VIDALE, Daniel LUETHI, Christoph FREI, Sonia I. SENEVIRATNE, Christoph SCHAER (Institute for Atmospheric and Climate Science ETH)

The evaluation of the quality and usefulness of climate modeling systems is dependent upon an assessment of both the limited predictability of the climate system and the uncertainties stemming from model formulation. In this study a methodology is presented that is suited to assess the performance of a regional climate model (RCM), based on its ability to represent the natural interannual variability on monthly and seasonal time scales. The methodology involves carrying out multi-year ensemble simulations (to assess the predictability bounds within which the model can be evaluated against observations) and multi-year sensitivity experiments using different model formulations (to assess the model uncertainty). As an example application, experiments driven by assimilated lateralboundary conditions and sea surface temperatures from the ECMWF re-analysisproject (ERA-15, 1979-1993) were conducted. While the ensemble experimentdemonstrates that the predictability of the regional climate varies stronglybetween different seasons and regions, being weakest during the summer andover continental regions, important sensitivities of the modelingsystem to parameterization choices are uncovered. In particular, compensating mechanismsrelated to the long-term representation of the water cycle are revealed, in whichsummer dry and hot conditions at the surface, resulting from insufficient evaporation, can persist despite insufficient net solar radiation (a result of unrealistic cloud-radiative feedbacks).

MC11/11P/D-001   Poster   1400-194

HOW MUCH THE ADVECTION SCHEME AFFECTS CLIMATE SIMULATION WITH AGCM

Xindong PENG[1], Feng XIAO[2] ([1]Earth Simulator Center, [2]Tokyo Institute of Technology)

Spectral method is widely used in global AGCM model; the Legendre transform is proved to be very expensive when apply to high resolution climate simulation in the AFES (AGCM For Earth Simulator) T1279, though it achieved a 26.58 TFLOPS of operation speed. Also, the spectral discretization introduces oscillation or dispersion error. An alternative, by adopting the Conservative Semi-Lagrangian scheme with Rational function (CSLR), is considered to improve the transport computation. As the first step, tracer quantities (water vapor and liquid water) are implemented with the CSLR to improve the model accuracy and computational efficiency. In the frame of AFES T106L20, some simplified advection tests and a real general circulation run are carried out. In the asymmetric non-divergence current, passive advection tests show that the spectral leap-frog (SLF) type discretization always express a local message with global information. For a sharp distribution, oscillation in concerning with SLF is very large; positive definite is got in the CSLR tests, however. With Arakawa-Schubert cumulus parameterization, two 20-year integrations of T106L20 model of AFES with the SLF and CSLR were run over the Earth Simulator. Seasonal precipitation, with CMAP data as reference, shows a great improvement of global rainfall pattern by the CSLR, especially the tropical rainfall distribution in ITCZ. The ITCZ band in both the eastern Pacific and western Atlantic oceans is well reproduced with the new scheme; and the precipitation in the Indian ocean is also refined somewhat. With the model resolution rising, vapor distribution will be sharply simulated with the mesoscale effects in the model. The local characters of model atmosphere become more important for climate simulation. The sophisticated transport scheme helps us to produce more realistic numerical productions. For a further understanding of the impact of advection scheme, T319L32 runs with both the SLF and CSLR. The ITCZ rainfall shows a similar pattern as in T106; and the CSLR indeed improved the seasonal climate simulation largely. Some mesoscale impact on weather systems, such as Meiyu (Baiu) fronts and tropical cyclones is being analyzed. It is worthy noting that the application of the CSLR is not only to extend integration time step, but also to provide accurate treatment of advection. Because the present scheme CSLR is a conservative one, global quantity conservation is ensured for the integration, which is important for climate simulation. A summary of the simplified advection tests and the real general circulation run show that the realistic transport of water vapor with sophisticated scheme affects the model results evidently.

ANALYSIS OF REGIONAL CLIMATE MODEL PERFORMANCE FOR THE ARAL SEA AREA. COMPARISON WITH OBSERVATIONS

Elisaveta Lazarova PENEVA, Emil Vassilev STANEV (Dept. of Meteorology and Geophysics, University of Sofia, Sofia, Bulgaria)

The Aral Sea level changes during the last 40 years present one of the most drastic example globally about the possible consequences of man-induced environmental changes. From numerical point of view this region presents a good opportunity to study the model performance and complicated atmosphere-land-sea interactions in desertification areas, where the model parametrisation and schemes are not well tuned. Meteorological observations in Aral Sea region exist only in several locations and has irregular time resolution, in particular for the last decade of 20th century, thus model results are very usefull if applicable for this area. In this study we use NCAR/PSU regional climate model (RegCM2) and the initial data and boundary forcing is based on the 6-hour NCEP reanalysis data, including air temperature, wind and humidity, surface pressure and sea surface temperature. Several numerical experiments are run for one winter and one summer months with horizontal resolution of 50 and 30 km. Additional experiments have been run, using the option to couple RegCM2 with a lake model in order to represent more adequately the Aral Sea surface temperature, e.g. thermal air-sea exchange. The results from different experiments are validated against regional climatic data, including air temperature and precipitation, measured in several meteorological stations during the period 1961-1990 and the skill of the model in representing the climate specifics is analysed.

MC11/11P/D-003   Poster   1400-196

GCM SIMULATIONS OF THE HEAT AND WATER BUDGETS OVER MAJOR RIVER AND THE CASPIAN SEA WATERSHEDS

Petr V. SPORYSHEV, Valentin P. MELESHKO, Tatyana V. PAVLOVA, Veronika A. GOVORKOVA (Dynamic Meteorology Department, Voeikov Main Geophysical Observatory)

The aim of the study is to assess performance capability of the AMIP-II GCMs in simulation of surface heat and water budget seasonal cycles over major watersheds of the world. The progress was also evaluated in development of GCMs for the last decade on the basis of intercomparison of model performance under the first and second phases of AMIP.Seventeen models were selected for the intercomparison that participatedin the both

phases of AMIP, and their outputs were available for analysis: CCCma, CNRM, COLA, DNM, ECMWF, GISS, GLA, JMA, MGO, MPI, NCAR, NCEP, SUNYA, UGAMP, UKMO, UIUC. Eight watersheds were considered in the study: the Amazon, the Baltic basin, the Congo, the Mississippi, the Volga, the Ob, the Enisei, and the Lena. A comparison with observations indicates that AMIP-II models are more successful in simulation of seasonal variations of the surface radiation and temperature fields over most of watersheds as compared to AMIP-I. The intermodel scatter of surface air temperature (SAT) seasonalities distinctly reduced in AMIP-II models. The scatter of precipitation is also smaller in AMIP-II, although the improvement is less pronounced than that of the SAT. Correlation of the computed precipitation fields with observation is generally less than that for the temperature. It is important to note that observed precipitation datasets produced from different sources differ significantly, and for some watersheds the differences between them are of the same magnitude or even larger than that of the model simulations. A special attention was given to the Caspian Sea basin. The sea is located in a large continental depression about 27 meters below the global mean sea level with no surface outlets. Its water level is sensitive to climatic variations, and can serve as an indicator of long-term climatic trends. We discuss not only the accuracy of model simulation of climatic seasonal cycle, but also the model ability to reproduce longterm and interannual variability of the hydrological regime of the region. The results of the 11-member ensemble of 50-year experiments with the MGO GCM forced by observed SST, are used here as additional support. The experiments were performed in accordance with the requirements of the C20C (the Climate of the 20-th Century) project.

MC11/11P/D-004 Poster **1400-197**

AN ASSESSMENT OF SEASONAL PREDICTABILITY IN SUMMER BY USING THE NCC/IAP COUPLED ATMOSPHERE-OCEANIC GENERAL CIRCULATION MODEL

Yihui DING, Qingquan LI, Zuqiang ZHANG (National Climate Center, China Meteorological Administration)

Seasonal predictability is investigated using a global atmosphere-ocean coupled model at National Climate Center, China Meteorological Administration. Seasonal hindcast experiments and validations of the abnormal climate in China during the summertime of 1982-2000 were conducted by using this coupled model. More than six months' ensemble integrations were performed from three consecutive days of initial condition preceding target summer season of each year. A set of indexes characterizing different predictive skills was used to assess systematically and quantitatively the predictive performance of the model. The model verification has indicated that the model has some certain capability in predicting seasonally the rainfall and temperature over China as well as the large-scale circulation in the North Hemisphere in summertime. The model prediction is better than climatological prediction and persistence prediction. During 1982-2000, the Hit Rate of Anomaly Sign scores of the seasonal predictions of the summer rainfall over China range between 40% and 70%; the Root Mean Square Skill Scores are all above zero; the Operational Skill Scores range from 55 to 80; the Skill Scores are all above zero; and 19-year average of Anomaly Correlation Coefficient of rainfall is 0.02.In the Asian monsoon region, except that the rainfall forecast for Iran has relatively large error (about 8%-12%), rainfall anomaly percentages usually range from   to   in other regions. The model performances of summer rainfall prediction vary in different regions of China. In general, the prediction of rainfall tendency in both East China and West China are reasonable. Among the five sub-regions of East China, the model predictive skills are higher in the Big Bend of the Yellow River and North China than in Northeast China, South China and the Yangtze and Huaihe River Basin. In view of anomaly correlation coefficient, the model skill in seasonal prediction of the summer temperature are relatively higher in West China, North China, the regions between the Yangtze River and the Yellow River, as well as the southeast part of Northeast China. The model's capability to reproduce the large-scale summer circulation in the Northern Hemisphere and the global sea surface temperature were also investigated. The averaged anomaly correlation coefficient of 500hPa geo-potential height over Asian monsoon area (50°E-160°E,0-30°N) in summer is 0.45. The correlation coefficients of 4-6 month lead forecast of summer (JJA) sea surface temperature anomaly are relatively high in the tropical Pacific Ocean, Indian Ocean, and Atlantic Ocean as well as some regions of the Northern Pacific and the Northern Atlantic Ocean.

MC11/11P/D-005 Poster **1400-198**

THE MODELING OF OROGRAPHICAL EFFECT ON THE FORMATION OF DRY CLIMATE IN NORTHEASTERN ASIA

Tomonori SATO[1], Fujio KIMURA[2] ([1]Japan Science and technology corporation / University of Tsukuba, [2]Institute of Geoscience, Tsukuba University and Frontier research system for global change)

Broadly spread arid regions exist between 15 degree and 35 degree in both northern and southern hemisphere. The subsidence branches of Hadley circulation are believed to have the relation with the formations of these arid regions. In Northeastern Asia, however, arid and semi-arid climate distribute over remarkably higher latitude, namely from 30 degree to 50 degree, characterized as Steppe in Central Asia or Mongolia, Taklimakan desert and Gobi desert. Broccoli and Manabe (1992) investigated the influence of Tibetan plateau upon the maintenance of the dry climate in midlatitude Asia using GCM. They concluded that the plateau is the main reason for these arid/semi-arid areas although its mechanism depends on the season. It is well known, however, that the seasonal variations of precipitation are different in Midlatitude Asia, especially between the eastward and westward regions from the Tian-Shan mountain range. Large unknown part still remains in the mechanism which maintains dry climate in Northeastern Asia. A Regional Climate Modeling System (RAMS) is used to simulate the precipitation in Northeastern Asia in warm with (CTL) and without eastward topography of the Tian-Shan and the Altai Mts. (NOM). The model simulates the synoptic disturbances during each whole month of June and January of 1998, by using NCEP/NCAR reanalysis as a boundary condition. The convection parameterization and microphysical parameterization are used together to predict the synoptic scale disturbances in high spatial resolution. The arid region with small amount of precipitation, less than 10 mm/month, is produced in CNT run, which corresponds well with satellite estimated data of GPCP. The water vapor transported into the arid region is mainly supplied from the northwestern part of Tian-Shan mountain ranges, although the amount of water vapor seems evidently decreased when it is going over the mountain ranges. Thus, the mountain ranges looks as if they act as a moisture sink in warm season. Nevertheless, the monthly precipitation of MON run shows that the arid region still exists, even though the mountain ranges were omitted in the model so that the water vapor is allowed to be brought into the arid region. This means that the reason of warm season aridity in the Taklimakan desert is not always cause by the trap of moisture by the mountain range. The meridional-time cross section of vertical motion at 85E reveals the prominent diurnal variation of upward motions over Kunlun Mts., while gentle downward motions are found over Taklimakan desert. A couple of upward and downward motion is emphasized when the synoptic scale front are passing though this region, which causes the enhanced subsidence over the Taklimakan desert. The subsidence results to decrease the precipitation there.

ORDER IN THE LOW-FREQUENCY PLANETARY WAVE DYNAMICS

Dmitry Mikhailovich SONECHKIN, Nadejda Nazarovna IVACHTCHENKO (Hydrometeorological Research Center of Russia)

The hydrostaticity and geostrophycity phenomena are well known during many times. But until quite recently nobody knew is there any specific order in the atmospheric low-frequency dynamics (within the inverse energetic cascade of the atmospheric macroturbulence) in addition to the above phenomena. Experiments with very long integrations of some atmospheric toy-models (Sonechkin, 1984: Stochasticity in the atmospheric general circulation models, Hydrometeoisdat, L., 280 pp.- in Russian) shown that an essential reduction of the dimension of the model attractors in comparison with the dimension of the model state-space itself is caused by temporal synchronizations of the phases and amplitudes of the modeled planetary waves, i.e. the model attractors are constructed from the only synchronized motions (SM). The nonsynchronized motions (NSM) are also possible in the models, but because of their great instability these are observable during rather short initial time periods of the model integration. Later, SM has been recognized in the real-world planetary wave dynamics in the geopotential height fields of the Northern Hemisphere. A fingerprint of the phenomenon is even seen in the day-to-day planetary wave motions as a rather high correlation between pairs of instantaneous values of the wave phases and amplitudes. But, the phase synchronization looks like an almost functional relationship for 5-day mean geopotential height fields. Another kind of the order in the low-frequency atmospheric dynamics consists of geographical localization of wave phases. This phenomenon is well known for the ultra-long waves. But, it turns out that a similar localization is a property of the short synoptic waves too. This latter phenomenon may be explained as an effect of the prevailence of the topographic instability in comparison with the baroclinic one for these waves.A hypothesis has been brought up that NSM and nonlocalized motions, which are excited in forecasting models as a result of artificial nonadjustments of initial data, are one of the basic sources of the weekly predictability loss in the present-day forecasting models. Thus, a forced synchronization and localization must help to overcome this limit. A model (called quasi-synchronous) developed at the Hydrometeorological Research Center of Russia confirms this hypothesis.

CLIMATE, VEGETATION, AND CO2 DYNAMICS IN THE HOLOCENE: EXPERIMENTS WITH CLIMATE SYSTEM MODEL OF INTERMEDIATE COMPLEXITY

Victor BROVKIN, Martin CLAUSSEN, Eva BAUER (Climate System Department, Potsdam Institute for Climate Impact Research)

Multiple proxy data reveal that the early to middle Holocene, ca. 8 to 6 kyr BP, was warmer than the pre-industrial period in most regions of the northern hemisphere. This warming is presumably explained by the higher summer insolation in the northern hemisphere owing to changes in the orbital parameters. Subsequent cooling in the late Holocene was accompanied by significant changes in vegetation cover and an increase in atmospheric CO_2 concentration. The essential question is whether it is possible to explain these changes in a consistent way accounting for the orbital parameters as the main external forcing for the climate system. We investigate this problem using the computationally efficient model of climate system, CLIMBER-2, which includes models for oceanic and terrestrial biogeochemistry. We found that changes in climate and vegetation cover in the northern subtropical and circumpolar regions can be attributed to the changes in the orbital forcing. Externally driven climatic changes in these regions have been amplified by climate-vegetation feedbacks. Explanation of the atmospheric CO_2 record requires an additional assumption of excessive $CaCO_3$ sedimentation in the ocean during the Holocene. For the last 1,000 years, reconstructions of external natural and anthropogenic forcings (solar activity, volcanism, CO_2 emissions, land cover changes) are much more precise than for the previous part of the Holocene. We extended the Holocene simulation by applying these additional forcings during the last millennium. Simulated surface air temperatures for the Northern Hemisphere correlate reasonably well with reconstructed temperatures (Mann et al., 1999). The long-term decrease in temperature from approx. 12 to 17th century within the model is largely attributed to changes in the solar forcing. Anthropogenic forcings impose significant climate changes after 1800. A warming due to elevating CO_2 concentration is attenuated by the cooling due to historical land cover changes. Results suggest that the land cover forcing contributed to a stabilisation of the temperature during the second half of the 19th century, and has damped the warming in the 20th century.

NATURAL AND ANTHROPOGENIC CLIMATE CHANGE OVER THE PAST 300 YEARS: THE ROLE OF HISTORICAL LAND COVER CHANGE

H. Damon MATTHEWS, Andrew J. WEAVER, Katrin J. MEISSNER (School of Earth and Ocean Sciences, University of Victoria)

The effect of natural and anthropogenic influences on global climate over the past three centuries is explored using the UVic Earth System Climate Model. The initial focus is on a detailed sensitivity analysis of the radiative forcing of climate by historical land cover change. Two independent historical land cover datasets are used to force the model under varying model configurations, making use of a simple land surface model. These runs are then compared to results using a more comprehensive land surface and dynamic vegetation model. The effect of historical land cover change is further compared to the effects of natural influences (solar orbital and insolation changes and volcanic aerosols) and other anthropogenic influences (greenhouse gasses and sulphate aerosols) on the climate system. These processes are all combined in a series of transient climate simulations to generate a complete picture of global climate change over the past 300 years.

MC12/07A/B19-003   1015

INFLUENCE OF LAND SPECIFICATION TO THE BERINGIAN CLIMATE OF THE EARLY HOLOCENE

Aaron R. RIVERS[1], Amanda H. LYNCH[2], Patrick J. BARTLEIN[3] ([1]CIRES/ University of Colorado, [2]PAOS/ CIRES/ University of Colorado, [3]University of Oregon)

The sensitivity of the simulated climate to postulated surface conditions during the early Holocene in Beringia is studied with a single column model (SCM) and regional climate model (RCM). Climate metrics important to vegetation development, including summer mean temperature, soil moisture availability, and the timing of the spring thaw, are used to identify feedbacks between surface conditions and paleoclimate. The SCM is forced with output from a GCM simulation representing 11 ka, and a range of surface conditions, including vegetation, thaw lakes, and soil type, are varied to determine surface parameters most strongly influencing the simulation. These results are used in RCM simulations to further identify three-dimensional feedbacks that are absent in the SCM experiments. An analysis of the sensitivity of the climate to the land specification identifies important features of the Beringian landscape for paleoclimate simulations.

HOLOCENE VARIATIONS IN TREE COVER AND LEAF AREA INDEX IN NORTH AMERICA

John W. WILLIAMS (National Center for Ecological Analysis and Synthesis, University of California Santa Barbara)

Understanding the consequences of Holocene land cover change upon climate history and variability requires accurate and quantitative maps of the Holocene vegetation. Biome-based descriptions of the vegetation are adequate for analyzing atmosphere-vegetation feedbacks at global scales, but at smaller spatial extents, within-biome heterogeneity in vegetation structure can significantly affect climate. By calibrating modern pollen samples against AVHRR-derived maps of tree cover and leaf area (LAI), quantitative estimates of LAI and tree cover for simple plant functional types have been produced for boreal and eastern North America for the past 21,000 years at a 50 km resolution and a thousand-year time step. A 'hierarchical analog technique' enables tree cover reconstructions even for times and places where fossil pollen samples are compositionally unlike any modern pollen samples, by condensing pollen taxa to plant functional types and rechecking for analog matches. Cross-validation analyses for the modern pollen data show that the hierarchical analog technique reproduces the present-day distribution of needleleaved and broadleaved tree cover with a high degree of accuracy. Total tree cover and LAI has increased in North America since the last glacial maximum, particularly in the eastern forests as both needleleaved and broadleaved tree coverages have increased. Holocene shifts in land cover include a continued infilling of the northern forest, leading to a connection between the eastern and western boreal forest by 6,000 years ago. This new generation of land cover products for the late Quaternary enables increasingly detailed examinations of vegetation-atmosphere feedbacks at regional to continental scales.

BETULA POLLEN IN THE LAPTEV SEA SHELF SEDIMENTS AS HOLOCENE CLIMATIC INDICATOR

Olga D. NAIDINA[1], Henning A. BAUCH[2] ([1]Department of Biostratigraphy, Institute of the Lithosphere of Marginal Seas, Russian Academy of Sciences, [2]Department of Paleoceanography, Alfred-Wegener Institute for Polar and Marine Research)

Absolute pollen analysis with morphological investigation of pollen indicators using scanning electron microscopy (SEM) wascarried out on sediment samples of the core PS51135 from the eastern Laptev Sea. Several AMS dates indicate that deposits accumulated since 11142 cal.ka to 5301 cal.ka. The pollen recordof the core PS51135 could be separated into several zones. Fromalternating birch pollen values these diagram can be divided intoseveral cooling and warming events. SEM analysis of birch pollen from the Holocene deposits in the Laptev Sea suggest that it is possible to reliably separate shrub birch-type pollen from treebirch-type pollen.The main component of birch pollen from thecore PS51135 belong to shrub birch from taxa typical of tundra zones. Given the close relationsip between oscillations in birch shrub/tree-line and mean summer temperature in Arctic Siberia, it should therefore provide a valuable proxy summer temperature indicator for the Holocene in northern Yakutia.

MC12/07A/B19-006   1115

SIMULATION OF NATURAL MILLENNIAL-SCALE CLIMATE VARIABILITY FROM THE EARLY HOLOCENE (8 KYR BP) TO THE PREINDUSTRIAL PERIOD (1700 AD) USING THE MCGILL PALEOCLIMATE MODEL

Yi WANG[1], Lawrence A. MYSAK[1], Zhaomin WANG[1], Victor BROVKIN[2] ([1]Department of Atmospheric and Oceanic Sciences, McGill University, [2]POTSDAM INSTITUTE FOR CLIMATE IMPACT RESEARCH (PIK))

Multiple proxy data reveal that the middle Holocene (6 kyr BP) was warmer than the early Holocene (8 kyr BP) as well as the preindustrial period (1700 AD) in most regions of the Northern Hemisphere. This warmth is somewhat counterintuitive because the summer insolation was decreasing during this time. Cooling in the late Holocene (after 6 kyr BP) is hypothesized to be due mainly to the astronomical forcing. This cooling was also accompanied by significant changes in vegetation cover (i.e., treeline retreat from northern high latitudes; the desertification of the Sahara/Sahel region) and a small but gradual increase of atmospheric CO_2 concentration (from 260 ppm to 280 ppm). The early-to-middle Holocene warming, on the other hand, is hypothesized to be due in part to ice-albedo feedback in Northern America, associated with decreases in the Laurentide ice sheet, which completely disappeared by 6 kyr BP. The snow-vegetation-albedo feedback is also hypothesized to have played a role in this early warming event. To test the above hypotheses, the earlier geophysical McGill Paleoclimate Model has been coupled to the vegetation model known as VECODE (VEgetation COntinuous DEscription, one of the simpler dynamic global vegetation models), and a number of sensitivity experiments have been performed. The model results illustrate the role that Northern Hemisphere land cover changes played in explaining the natural millennial-scale climate variability from the early Holocene (8 kyr BP) to the preindustrial period (1700 AD).

MESOSCALE MODELING OF THE AFRICAN HUMID PERIOD

Kerry Harrison COOK, Nicholas J. NEARY (Dept. Earth and Atmospheric Sciences, Cornell University)

During the last glacial period, dry conditions prevailed over Saharan and Sahelian Africa, somewhat drier than today. But beginning around 14.5 ka BP, the region became progressively more moist. Numerous large lakes dotted the landscape of what is now the Sahel until about 5.5 ky BP, and the Sahara/Sahel boundary was about 5 farther north. The African Humid Period occurred at a time of higher summertime insolation in the Northern Hemisphere, and this forcing has been associated with an intensification of the African monsoon. However, GCM simulations suggest that a consideration of additional factors and/or feedbacks within the climate system is required to fully understand the African Humid Period.A mesoscale climate model (MCM) is developed for studying the African Humid Period. By modeling climate on smaller space scales (10´s of kilometers) than is possible with a GCM, the space scale of the modeling is brought close to that of the geological record. This provides a better opportunity for model validation, and for the modeling to aid in the interpretation of geological evidence. Also, the MCM provides an improved simulation of the present day climate of northern Africa, since the physical parameterizations can be optimized for the region and the strong surface moisture and temperature gradients that characterize this region are resolved.A series of MCM integrations is used to compare the African climate of 6 ky BP with today´s climate, and to explore the sensitivity to various assumptions about the surface boundary conditions. Unlike GCM simulations of the African Humid Period, the MCM produces excessive precipitation over the present-day Sahel and Sahara regions with 6 ky BP solar insolation, surface vegetation, and atmospheric CO2 levels. The addition of colder sea surface temperatures off the west coast, as suggested by ocean cores, improves the model´s agreement with geological reconstructions. There is some evidence that colder water occupied the Gulf of Guinea during the African Humid Period, but the MCM simulation suggests that this is inconsistent with the reconstructions of higher lake levels in Ghana.

LATE HOLOCENE CLIMATE VARIATIONS AND THEIR RELATIONSHIP TO FORCING MECHANISMS

Raymond Stuart BRADLEY (Department of Geosciences, UMASS, Amherst)

Numerous paleoclimatic records indicate that climate changed significantly around ~4,000 ± 500 years B.P. In some cases, the change is essentially a step function (˝abrupt climate change˝); elsewhere, the change is more gradual. Here, a set of well-dated records from a wide geographic network are used to assess the nature of large-scale climatic changes over this period, and to place those changes in the context of probable forcing factors.

MC12/07P/B19-002   1445

REGIME OF CAUCASUS MOUNTAIN GLACIERS DURING HOLOCENE OPTIMUM: FIRST EXPERIENCE OF ESTIMATION

Maria Dmitrievna ANANICHEVA, Natalia V. DAVIDOVICH (Department of glaciology, Institute of geography, Russian Academy of Sciences)

For the first time an estimation of regime and condition of mountain glaciers in the periods of interglacial (the extensive warming) is presenting. All existing global paleo-climatic maps show the mountain countries as a field of simple interpolation of the data referring to the surrounding plains and foothills without account for mountain specificity and in particular high-mountainous glacier-nival zone. On an example of the Bolshoy Caucasus during Holocene optimum (5-6 thousand years ago) the calculations and analysis, carried out by the authors, show that the deviations of the high mountains characteristics and that of mountain belts located lower, appreciably differed. In comparison with present time the B. Caucasus high mountains are characterized by better expressed humid climate, and foothills and bottom zones of mountains – by more dry one. And it is important that warming was stronger at the center of the mountain country, than on its periphery or foothill plains. Therefore the methodological conclusion is: it is illegitimate to use the temperature-humidity anomalies of continuos plains' climate without additional amendments at any paleo-glaciologic reconstruction. With the help of glacio-climatic method, developed by the authors (which is practically the only possible for the periods of climate optimum, when there were not any geomorphologic traces of the former glaciers survived) the reconstruction of mass balance, altitudes of glacio-morthological levels, temperature of air over the glacier zone is conducted. The main conclusion consists of the statement that in conditions of significant warming the glacial belt did not disappear, yet shifted upwards. The increase of the equilibrium line might reach 150-200 m, and the glaciers' terminuses – 300-400 m. Despite of a higher values of these parameters, summer air temperature enhanced as much as 1-1.50C, and the mass exchange intensity increased at 20-30 % compared to the present time conditions.

MC12/07P/B19-003   1500

A CARBONATE MOUND POPULATION ON THE WESTERN MARGIN OF THE PORCUPINE BANK: EVIDENCE FOR NORTH ATLANTIC PALAEOCLIMATIC CONTROLS ON A COLD-WATER CORAL ECOSYSTEM

Brian M. O'REILLY[1], Peter W. READMAN[1], Patrick M. SHANNON[2] ([1]Dublin Institute for Advanced Studies, 5 Merrion Square, Dublin 2, IRELAND, [2]Department of Geology, University College Dublin, Dublin 4, IRELAND)

Coral reefs are normally associated with warm water tropical regions of the Earth, but during the last decade or so large-scale carbonate build-ups, which resemble tropical reefs in many respects, have been recognized in the northeast Atlantic stretching from Norway to Iberia. The cold-water coral species Lophelia pertusa and Madrepora occulata, are the main framework constructers of these build-ups and unlike tropical corals flourish far below the photic zone at water temperatures of between 4° and 12° C. They are a significant reservoir or sink for excess carbon dioxide and their growth is potentially important in regulating climate change. The detailed structure of one such cold-water carbonate mound population was resolved along the western margin of the Porcupine Bank, west of Ireland, during a deep-tow TOBI (Towed Ocean Bottom Instrument) sidescan sonar survey, undertaken on behalf of the Irish Petroleum Infrastructure Programme. They are circular to elliptical in shape and range in size from 50 to 850 m across and are up to 300 m high and large-scale sedimentary bedforms at 700-900 m water depth envelope the larger mound structures. The bedforms are produced by the strong NE-flowing contour-parallel currents. A change to a more elliptical shape as the size of the mounds increases suggests that streamlining effects caused by the strong pole-ward bottom currents influence the geometry of the mound structures. The frequency distribution of the mound sizes is close to a power law and there is a systematic tendency for them to become gradually more elongate as they increase in size The distribution is ultimately determined by the biological growth rate of the mound frameworks and the rate at which the coral framework builders colonise the substrate. Initially bottom currents are important in establishing a suitable environment for the growth of carbonate mounds and the establishment of embryonic mound settlements as they transport

M

nutrients into the framework and keep it free of sedimentary debris. There are also negative feedback effects on coral growth from fluid drag forces. The development of streamlined elliptical forms in the evolving mound population minimises the inhibiting effects of these forces. A model for the development of the population, incorporating the effects of bottom currents, allows its age structure to be derived. There is an interesting coincidence between certain properties of the observed distribution of mounds, the age structure of the entire population predicted by the model, and climatic change in the late Pleistocene and Holocene. This suggests that there is a subtle but well-defined correlation between the growth and colonization patterns of the biological species, comprising the mound population, with climate change and related variations in the strength (and perhaps direction) of these bottom currents.

TRANSIENT SIMULATION OF ABRUPT CLIMATE CHANGE INDUCED BY FRESHWATER INPUT FROM LAURENTIAN ICE SHEET TO THE NORTH ATLANTIC OCEAN

Pavel Alekseevich TOROPOV[1], Alexander Victorovich KISLOV[1], Sergey Nikolaevich MOSHONKIN[2] ([1]Lomonosov Moscow State Univercity, [2]Institut of the Numericals Mathematics of the Russian Academy of the Scince)

Records from different proxies suggest that large and abrupt changes of climate occurred during both glacial and postglacial periods; clear example is the Younger Dryas (YD) cold event. Broecker (1990) speculated that these changes result from changes in the thermohaline circulation of the Atlantic Ocean, which were caused by the release of large amounts of melt water from continental ice sheet. It is important that these phenomena were not explicitly influenced by Milankovitch orbital variations of solar energy input. Manabe and Stouffer (1995,1997) demonstrated that events like YD could be simulated if tremendous freshwater flux (1 Sv during 10-yr period or 0,1 Sv during 500-yr period over the latitude belt between 50 and 700 in the North Atlantic Ocean) was prescribed.Here we describe an attempt to explore this phenomenon using the oceanic Global Circulation Model (GCMO) and realistic freshwater input. Our aim is to evaluate could the phenomenon like YD be simulated.The GCMO of INM RUS is a finite-difference technique with a regular grid system which has horisontal spacing of 40 latitude x 50 longitude and 11 vertical sigma-levels. At first the control experiment during a 1,000-year time integration was carried out. Stable-state fields were used as initial conditions for the freshwater experiment. The runoff of St.Laurence river paleohydrology reconstructed as 0,35 Sv during 4-year period (..., 2000) was used to create the salinity anomaly in the two grid points of GCMO near the river mouth. Although the flux was turned off at the end of forth year, the time integration is performed over a period of 300 years.The reduction of salinity is accompanied by the development of circulation phenomenon (cyclone-anticyclone dipole) on the southeast from the input region. Its intensity is ~5% from strength of surface current. This dipole is long living structure. During 4 years it has been penetrating into seasonal thermocline and it was clearly evidenced during ~200 years after the time when freshwater flux was turned off.The change of thermohaline circulation of the North Atlantic in response to the appearance of fresh water spot was very small, insufficiently to induce just a little temperature anomaly. This is the principal result: the real melt water flux does not create strong (like YD) climate anomaly (but by the way the modelled anomaly is stronger than modern "Grate Salinity Anomaly". Our result is quite different from mentioned above the conclusion of Manabe and Stouffer (1995,1997), but their successful simulation of strong climate change are explained by the fact that unrealistic freshwater flux was used.

| MC12/07P/B19-005 | | 1545 |

BIOGEOCHEMICAL EVIDENCE OF VEGETATION CHANGES IN THE TROPICAL WETLAND DURING MID-LATE HOLOCENE

Shafi Mohammad TAREQ[1], Noriyuki TANAKA[2], Keiichi OHTA[3] ([1]Division of Earth and Environmental Sciences, Graduate School of Environmental Studies, Nagoya University, Furo-cho, Chikusa-ku, Nagoya 464-8601, Japan, [2]Frontier Research System for Global Change, International Arctic Research Center,University of Alaska, Fairbanks, USA, [3]School of Environmental Science, The University of Shiga Prefecture, 2500 Hassaka-cho, Hikone, Shiga 522-8533, Japan)

Evidence of changing vegetation in the tropical wetland (Rawa Dannau, west Java, Indonesia) over the past 7428 years is illustrated by the ratio of lignin CuO-oxidation products as well as carbon preference index (CPI) and mean carbon number (MCN) of hydrocarbon, together with stable carbon isotope (δ13C) and bulk organic geochemistry. The vertical profile of lignin phenol ratios (S/V and C/V) and lignin phenol vegetation index (LPVI) with calibrated radiocarbon (14C) ages showed that there were four major vegetation change events in the Rawa Dannau during mid-late Holocene. Periods of the vegetation change event displayed significant changes in organic carbon flux in the Rawa Dannau wetland, which might reflect dilution by enhanced influx of sililclastic material. The CPI of hydrocarbons (C21-C33) closely corresponded with the LPVI. The MCN calculated from hydrocarbon data (C27-C31) significantly related with other profiles (CPI and LPVI) and the signature of elemental carbon. Pollen data of a few number of pre-selected sections showed that grasses dominated during vegetation-change events. These vegetation changes in tropical area might occur due to forest fire and/or regional climate changes.

| MC12/07P/B19-006 | | 1600 |

RECONSTRUCTION OF HISTORY OF FOREST FIRE RECORDED IN PEAT DEPOSIT IN RAWA DANAU, WEST-JAVA, INDONESIA DURING MID-LATE HOLOCENE

Hiroyuki TSUJI[1], Noriyuki TANAKA[1], Shafi Mohamad TAREQ[2], Keiichi OHTA[2], Muhamad Rahman DJUWANSAH[3], Hisashi NARITA[1] ([1] Graduate School of Environmental Earth Science,Hokkaido University, [2]Hydrospheric Atmospheric Research Center, Nagoya Univ., [3]Research center for Geotechnology, Indonesian Institute of Sciences)

The woody peat core (3.62m length) collected in Rawa Danau, West-Java, Indonesia(Lat. 6°8.978´S Long. 105°58.909´E) was analyzed for elemental carbon (EC) contents, C/N ratios and stable carbon isotope composition in order to reconstructforest fire history involved in past climate change during mid-late Holocene. The EC contents ranged 0.00 to 0.06% and the six distinct peaks were found in thecore. These peaks could be ascribed to frequent and extensive forest fire events. Therelatively heavy stable carbon isotope compositions clearly coincided with high EC content. It was striking that the EC content peaks around 164.6-190.4cm depth(3000-3800 yr BP) corresponded to the heaviest δ13C. It also agreed with the rapidC/N ratio decreases. Considering the climate change in the other region around3000-3800 yr BP, there were extensive forest fire events around Rawa Danau,West-Java, Indonesia, which were probably caused by the regional climate system shiftsuch as distinctive dry season.

THE CLIMATE OF THE HOLOCENE: A GLACIOLOGICAL PERSPECTIVE

Georg Paul HOFFMANN[1], Martin WERNER[2], Gavin SCHMIDT[3], Jean JOUZEL[1] ([1]LSCE, [2]MPI for Biogeochemical Cycles, Jena, Germany, [3]Goddard Institue for Space Studies, New York, USA)

There is an increasing number of ice cores documenting climate variability on time scales from a couple of hundred years to glacial/interglacial cycles. Regionally, this important source of information is no longer restricted to polar areas. Many tropical and subtropical sites have been added in the last years providing us with a more detailed picture of climate dynamics. In this contribution I'll give an overview on the existing stable water isotope records from various sites in high and low latitudes. The common variability on a millennial to centennial time scale will be discussed and compared with our information stemming from other types of archives. Furthermore, results from studies with GCMs which were fitted with water isotope diagnostics will be presented. These GCMs were integrated in a time slice mode throughout the Holocene and, on a shorter time scale, over the last century. Analysing these results allowed us to answer 1- how to interpret the water isotope records in term of local temperature and precipitation changes and 2- in what regions the isotopes react particularly sensitive to climate phenomena such as El Nino or the Arctic Oscillation.

HOLOCENE CLIMATE VARIABILITY RECORDED IN WATER STABLE ISOTOPES FROM ANTARCTIC AND GREENLAND ICE CORES

Valérie MASSON-DELMOTTE[1], S.J. JOHNSEN[2], J. JOUZEL[1], V.I. MORGAN[3], B. STENNI[4], J.W.C. WHITE[5], F. VIMEUX[1] ([1]IPSL/CEA-CNRS LSCE, [2]Universty of Copenhaguen, Denmark, [3]Antarctic CRC, Hobart, Australia, [4]University of Trieste, Italy, [5]University of Colorado, Boulder, USA)

We use water stable isotopes (dD, d18O) measured along several Antarctic and Greenland ice cores to discuss (i) Holocene trends which can be related to local glaciological effects (elevation of the ice sheet) and insolation-related climatic changes; (ii) millennial scale isotopic variability; (iii) high frequency periodicities. For different polar locations, isotopic modelling is used to quantify isotopic fluctuations in terms of site and source temperature changes.

| MC12/08A/B19-003 | | 1020 |

ARGON AND NITROGEN ISOTOPES OF TRAPPED AIR IN GREENLAND ICE CORES AS A PALEOTHERMOMETER: APPLICATION TO ABRUPT CLIMATE CHANGE AT ~8200 YEARS BP

Takuro KOBASHI, Alexi M. GRACHEV, Jeffrey P. SEVERINGHAUS (Scripps Institution of Oceanography, University of California, San Diego)

Recently the nitrogen and argon isotopic composition of trapped air in ice cores has been developed and utilized as a paleothermometer to investigate the past abrupt climate changes (e.g., Severinghaus et al., Nature, v. 391, 141, 1998). Within the firn layer (snow layers above the air bubble close-off depth), two types of isotopic fractionation occur: "gravitational fractionation" and "thermal fractionation". Thermal fractionation is induced by the temperature difference between the surface and bottom of the firn layer. Owing to the long atmospheric residence time of inert gases (nitrogen and argon), any deviation of the isotopic composition of trapped air from that of present air must be due to these processes. The combined analyses of nitrogen and argon isotopes (15N/14N and 40Ar/36Ar) allow us to separate these two processes, and to reconstruct the past abrupt temperature changes. In addition, temperature information from trapped air solves a long-standing problem of ice age - gas age difference, allowing a direct comparison between temperature change and trace gas concentration changes (e.g., CO2 and CH4). We are developing a new method to process air for the simultaneous analysis of nitrogen and argon isotopes using a new mass spectrometer with 8 cups (Finnigan Delta XP). Previous methods required two separate analyses for argon and nitrogen. Therefore, this new method will reduce the time and ice for each analysis. We use copper at ~500 °C to remove oxygen (O2), which isobarically interferes with 36Ar, and we obtained a precision of 0.002 per mil for nitrogen, and 0.012 per mil for argon for 18 preliminary measurements of La Jolla air. We plan to apply this method with the experimentally determined constants (Grachev and Severinghaus, Geochim. et Cosmochim. Acta, v. 67, 345, 2003) to an abrupt climate change that happened ~8,200 years before present using the GISP2 ice core from Greenland. This event is especially important since it occurred during the relatively warm climate conditions of the Holocene, which may be a good analogue for possible future abrupt climate change induced by global warming.

CHANGES IN THE SEASONAL CYCLE- IMPLICATIONS FOR PALEOCLIMATOLOGY

Philip D. JONES, Keith R. BRIFFA, Timothy J. OSBORN (Climatic Research Unit, University of East Anglia, Norwich, NR4 7TJ, UK)

Instrumental temperature averages for the Northern Hemisphere show significant changes in the seasonal cycle since the 1850s. Earlier than this the only proxy climatic source capable of providing independent seasonal reconstructions is historical documentary information. Summer and winter reconstructions from this source are compared for Europe and the Far East (China, Japan and Korea), the only two regions of the world where such evidence potentially exists. All available series indicate that long-term trends in calendar-year average temperatures are dominated by changes in the winter reconstructions. Summer series from documentary sources reveal hardly any century-timescale changes. With much paleoclimatic evidence of past temperatures coming from trees, ice cores and lakes being dominated by summer conditions, millennial-scale trends are potentially being underestimated by summer-responsive proxies.

QUANTIFYING SVALBARD CLIMATE VARIABILITY SINCE 1100 THE PRESENT, LITTLE ICE AGE AND MEDEIVAL WARM PERIOD

John C. MOORE, Lomonosovfonna Ice Core Group (Arctic Centre, University of Lapland, Rovaniemi, FINLAND)

Ice cores from the relatively low-lying ice caps in Svalbard have not been widelyexploited in climatic and environmental studies due to uncertainties about the effect of melt water percolation. However a well-dated ice core with high-resolution chemical and water isotopic

data from Lomonosovfonna show the history of temperature, accumulation, and atmospheric circulation patterns influencing the Svalbard archipelago for the past 900 years. The Little Ice Age (LIA) is well documented in the ice core and the sudden termination of the event around 1920 (associated with a decrease in sea ice extent in the Barents Sea) is the single clearest signal in the ice core chemical record. The d18O data from the ice core suggests that the 20ieth century was the warmest century during the past 600 years. The earliest part of the core shows a gradual decrease in temperatures as the climate entered the Little Ice Age. The period 1100-1400 is marked by intervalsthat suggest relatively similar temperatures and conditions as the present period - these indicators include isotopic and chemical species ratios. We discuss several ˝time windows˝ for how the climate looked like at Lomonosovfonna during specific periods that are interesting. such as specific warm periods as the present, 1920s, 1930s, 1950s, 1750s and the MWP; and cold periods such as 1960s 1680s, 1780s, 1860s, 1880s. The similarity of the MWP to the 1930s or 1950s and present and the transitions between ˝climate types˝ i.e. around 1500 and 1920 are also discussed, as are comparisons with other reconstructions of high latitude climate variations over the past millennium.

MC12/08A/B19-006   1130

A NEW CALIBRATION OF THE 200-YEAR TEMPERATURE SERIES FROM ARMAGH OBSERVATORY, NORTHERN IRELAND

Christopher John BUTLER, Chloe MORRELL, Ana Maria GARCIA SUAREZ (Armagh Observatory)

Armagh Observatory has maintained three independent temperature series forextended periods of time: (1) a twice daily set of readings from an externallymounted thermometer (1796-1882), (2) a daily series of maximum and minimumtemperatures (1844-2003), and (3) a series of wet and dry temperatures measuredtwice daily from 1833. A careful reassessment and recalibration of the data fromthis site has recently been completed.The data from Northern Ireland are particularly useful because of theirlongevity, the lack of any appreciable urban effects and the strong influenceof the Atlantic Ocean. We discuss the usefullness of this long temperatureseries and compare it with similar series from European sites. The importanceof such long term data for extending the global instrumental temperature seriesprior to the mid-19th century and how they may affect our understanding of thecauses of global warming is discussed.

MC12/08A/B19-007   1145

A NEW SOURCE OF PROXY DATA FOR DAILY AND MONTHLY CLIMATIC RECONSTRUCTIONS

Dennis WHEELER, Jose Manuel Suarez DOMINGUEZ (University of Sunderland)

Several thousand logbooks of the British Navy have survived from theperiod c.1650 to 1850. They contain daily, sometimes hourly, non-instrumental, observations on wind and weather for many of the World's oceans. For watersclose to the British Isles, the possible series of data is unbroken from1685. A recently concluded project has examined the nature of these dataand derived a climatology for the most intense phase of the Little Ice Age(LIA) from 1685 to 1700. The data consist of information on wind force, winddirection and general observations on the weather. The latter two categoriesof data were described in terms consistent with those in use today. The former, however, provided problems of interpretation, and many terms, suchas 'gale' had a different meaning in late eighteenth century English. A 'dictionary' was produced using content analysis that allowed archaic terms tobe re-expressed in Beaufort Scale equivalents. The abundance of logbooks permitted replicate sampling that confirmed the internal consistency of the records. The vocabulary was found to be limited but common between recorders,opening the way for numerical analysis. The data were of high quality, with asub-daily scale of temporal resolution not matched by other contemporary sources. The derived daily data were aggregated to produce monthly summariesof wind force, wind direction, gale frequency, snow and rain. While no thermometer records were kept, the logbook entries also included usable information on the extent and intensity of cold periods and days. Correlationand principle component analysis using additional independently provided NAO indices, Central England Temperature (CET) data and contemporary pressuredata, confirmed the consistency of the logbook data through their general agreement with the independent series. The data (seventeen variables) were reduced to four principal components, on all of which the logbook datawere heavily loaded. Thermal, wind direction, and pressure field componentswere clearly identified in the structured data set; the former tending todominate over the latter, but the balance shifting between seasons and months.The overall results provided partial confirmation of existing theories of weather patterns during the LIA, but challenged some other aspects. They addedfiner, daily, detail and extended the knowledge base to include observations made at sea, where hitherto there has been very little information. It is found that the period in question was one of measurably more marked storm activity, particularly for the summer months, than is currently the case. Furthermore, the derived patterns of wind directions do not wholly support the popular theory that the LIA was a period of notable meridionality. The reconstructed picture reveals meridionality to be notable during the late winter and spring, but only sporadically so at other times of the year. Thepresence of quantifiable degrees of 'easterliness' was nonetheless stronglyassociated with the coldest months in the CET series. The procedures aresuggested to provide an excellent model on which longer term, detailed studiescan be based using derived quantifiable data from an important non-instrumentalsource that is abundant, but hitherto overlooked.

CLIWOC: A DATABASE FOR THE WORLD'S OCEANS 1750-1850: OVERVIEW AND PRELIMINARY RESULTS

Ricardo GARCIA-HERRERA[1], Dennis WHEELER[2], Gunther KONNEN[3], Maria PRIETO[4], Philip D. JONES[5] ([1]Universidade Complutense de Madrid, [2]University of Sunderland, UK, [3]KNMI, The Netherlands, [4]Instituto de Ciencias Humanas y Sociales, [5]Climatic Research Unit, University of East Anglia, Norwich, UK)

From the earliest days of deep sea sailing mariners have kept logbook accountsof their voyages. By 1750 the keeping of logbooks was almost universal amongst the officers of European ships. Although not prepared with this purpose in mind, the logbooks and the detailed observations that they contain are today of greatscientific value. One of the factors that a ship's officer needed to take into account in the successful navigation of his vessel was the weather. It required that wind force and wind direction be carefully recorded, the data being then used to determine the drift, or 'leeway', made by the ship. Mariners tended alsoto keep a careful note of other weather phenomena such as rain, thunder, fog andsnow even though they had little direct influence of navigation. Many logbooks failed to survive the rigours of life at sea, but tens ofthousands have been preserved to the present day. Some date from as long ago as the seventeenth century, and they become more abundant as time goes by. Most frequent amongst the survivors are the logbooks of vessels in the state service and in particular those of the armed services. These have now been gathered together in a number of important national archives. Those of the UK, France, Spain and the

Netherlands all possess notable collections. The observations in the ship logs of these four countries comprise in the pre-1850 period the bulk of the observations that have been taken over the world oceans.CLIWOC is a project funded by the European Union with partners from Spain, the UK, the Netherlands and Argentina. Its principal objective is to produce a database of daily oceanic weather observations between 1750 and 1850. It will be completed by December 2003. At that time, the CLIWOC database will be ready for integration with the I-COADS world database of meteorological observations 1784-present. This will significantly augment I-COADS in its early period. The CLIWOC database utilises daily observations from logbooks that represent all the World's major oceanic areas, the North and South Atlantic, the Indian and he Pacific Oceans. The original data are being processed and presented using terms that conform to present-day usage and understanding. Information is based on the most frequently recorded elements of wind strength and direction, but data will also be provided on a wider range of commonly recorded phenomena that include rain and snow, thunder, fog and even the incidence of sea ice cover. A meta-database will also allow enquirers to consult the original sources. By December 2002, more than 175,000 observations had already been included in the database, and constitute the dataset at this presentation, which will describe the space coverage reached so far, as well as the first results obtained in the quality control process. Particular attention will be paid to the consistency of the observations from ships of the same and different nationalities and the comparison with present day climatology.

THE MEDIEVAL COOL PERIOD AND THE LITTLE WARM AGE IN THE CENTRAL TROPICAL PACIFIC? FOSSIL CORAL CLIMATE RECORDS OF THE LAST MILLENNIUM

Kim M. COBB[1], Chris CHARLES[2], Hai Cheng[3], R.Lawrence EDWARDS[3] ([1]Dept. of Geological and Planetary Sciences, California Inst. of Technology, [2]Scripps Inst. Of Oceanography, [3]University of Minnesota)

Proxy climate records from around the globe indicate that climate of the last millennium was characterized by substantial low-frequency variability, yet the mechanisms that underlie such variability remain controversial. Progress towards a mechanistic understanding of low-frequency climate change involves reconstructing the global footprint of interannual to centennial climate change over the last millennium. The tropical Pacific is potentially a key player in low-frequency climate change, given the global reach of the El Niño-Southern Oscillation (ENSO). However, sparse proxy data coverage in the tropical Pacific prior to ~1600A.D. means that the role of this potent climate system in shaping low-frequency variability remains unknown. We present well-dated, monthly-resolved coral records from Palmyra Island (6°N, 162°W) that capture interannual to centennial climate change in the central tropical Pacific (CTP) over the last millennium. The U/Th-dated coral-based oxygen isotopic (δ^{18}O) records, many of which overlap in time, cover 40-150yr-long intervals during the 10th, 12th, 14th-15th, 17th, and 20th centuries. Together they document a wide range of ENSO characteristics - the most frequent, intense ENSO activity occurs in the mid-17th century, during the Little Ice Age (LIA), and the least frequent ENSO activity occurs during the 14th century. The background climate state in the central tropical Pacific, as reflected in mean coral δ^{18}O, remained relatively stable over the last millennium, with two exceptions - relatively cool, dry conditions may have persisted early in the millennium and a trend towards warm, wet conditions began in 1976A.D. By comparing the Palmyra coral timeseries to existing proxy data from other regions of the globe it is possible to extract valuable information about large-scale patterns of low-frequency climate variability over the last millennium. For example, the Palmyra coral data can be compared to proxy records from the western tropical Pacific to address whether the zonal sea-surface temperature (SST) gradient in the tropical Pacific changed during the LIA. West Pacific corals point to cooler, saltier conditions during the LIA, while the Palmyra corals imply little SST change in the CTP, such that the Pacific's zonal SST gradient may have decreased during the LIA. The MWP presents a greater challenge, because high-resolution proxy records of marine origin are no available for comparison. However, when combined with evidence of cool, dry conditions in the CTP from the Palmyra corals, select proxy records from ENSO-sensitive regions are consistent with a La Niña-like configuration of the Pacific during the MWP. If the Pacific alternated between El Niño- and La Niña-like mean states over the last millennium, then the associated changes in the pattern of large-scale atmospheric circulation would have affected temperature and precipitation patterns around the globe. Of course, this discussion does not address the origin of such low-frequency variability in the tropical Pacific, rather it suggests that the mechanisms that underlie centennial-scale variability likely involve the tropical Pacific.

MC12/08P/B19-002   1445

TOWARD RECONCILING CLIMATE CHANGE RECONSTRUCTIONS FROM BOREHOLE TEMPERATURES AND PROXY DATA: THE ROLE OF SNOW

Marshall Grant BARTLETT, David S. CHAPMAN, Rob N. HARRIS (University of Utah)

Borehole temperature-depth profiles contain information about surface ground temperatures a region has experienced in the past, and therefore provide complementary information to the more customary surface air temperature record of climate change. Using temperature-depth measurements from boreholes, researchers have been able to extend local, regional, and hemispheric estimates of surface temperature variations by several centuries prior to the onset of instrumental records of air temperature changes (Harris and Chapman [2001], Pollack and Huang [2000]). The borehole method of pre-observational climate reconstruction differs from proxy-based methods (tree ring growth patterns, coral growth, pollen counts, etc.) in two important ways. First, the physics of heat conduction in the earth is better understood than the empirical transfer functions used in proxy methods. Second, the estimated amount of warming the Earth's surface has experienced since the pre-industrial period based on the borehole record is significantly different from estimates based on proxy methods. Borehole reconstructions suggest that this warming has been on the order of 1.1 °C with approximately half of the warming occurring prior to 1850; more traditional proxy methods indicate a warming closer to 0.7 °C with most of the warming taking place in the 20th century (Pollack and Huang [2000], Mann et al [1999]). One of the suggested possibilities for reconciling these two records is that transient snow cover my bias the borehole record by introducing a spurious long-term warming signal into the ground temperature record. We have developed a simple model to investigate this possibility and have applied it on the local scale (Bartlett et al [2002]). We here extend our analysis to the regional scale by modeling snow events over the past century in the Unites States based on the snow and air temperature data available from the United States Historical Climatology Network Daily Temperature, Precipitation, And Snow Data for 1871-1997 (NOAA-NCDC NDP-070). The snow model is used to predict transient warming or cooling of the surface ground temperature due to changes in the onset, duration, and depth of snow events over the years of record in the dataset. Results illustrate that while there are some local trends in changes of onset time and duration in the snow record, these are insufficient to reconcile the

M

borehole and proxy reconstructions of climate change.

PATTERNS OF NORTHERN EMISPHERE MID-LATITUDE TEMPERATURE VARIABILITY IN A 500-YEAR CLIMATE SIMULATION WITH VARIABLE RADIATIVE FORCING

Piero LIONELLO[1], Simona DE ZOLT[2], Eduardo ZORITA[3] ([1]univ. of Lecce (I), [2]univ. of Padua (I), [3]GKSS Forschung Zentrum (D))

This study is based on a 500-year long simulation carried out with an AOGCM which computes the climate evolution from the 15th to the end of the 20th century. The simulation includes a VRF (Variable Radiative Forcing) which accounts for variations of the solar activity, volcanic eruptions and recent increase of GHG (Green House Gases) concentration. The results are compared with a 1000-year long CTR (ConTRol) simulation which is based on a constant radiative forcing, corresponding to the 1990 level. The model, called ECHO-G model, consists of the globalatmospheric model ECHAM4, at T30 resolution, and of the ocean circulation model HOPE-G, at 2.8 degs resolution. A clear (seasonal) signature of the radiative forcing variability on the temperature distribution is identified from the analysis of thefields associated with extreme radiative forcing values. The effect is present, though smaller, also on the sea level pressure fields. The dynamics behind these temperature and sea level pressure patternsare described and their importance for the temperature of the mid-latitudes in the Northern hemisphere is shown.

MC12/08P/B19-004   1515

CLIMATE CHANGES DURING THE PAST MILLENNIUM

Michael E. MANN[1], Scott RUTHERFORD[1], Gavin A. SCHMIDT[2], Drew T. SHINDELL[2] ([1]Department of Environmental Sciences, [2]Goddard Institute for Space Studies and Columbia University)

We will review recent progress in both the empirical reconstruction and modeling of climate changes in past centuries. Recent empirical reconstructions of Northern Hemisphere mean temperature changes over the past several centuries to millennium will be reviewed and compared, with an emphasis on the sensitivity of the reconstructions to the actual ″proxy″ data used as predictors, the statistical reconstruction methodology employed, and the seasonality, and spatial domain of emphasis in the reconstruction. The influence of these factors will be discussed in the context of the seasonally and spatially-specific nature of the response to known external climate forcings such as solar irradiance and explosive volcanism as revealed through recent climate modeling experiments. Implications for the scale and magnitude of climate anomalies associated with the so-called ″Little Ice Age″ and ″Medieval Warm Period″ will be discussed.

MC12/08P/B19-005   1535

A RECONSTRUCTION OF THE GLOBAL TEMPERATURE OVER THE LAST 10 THOUSAND YEARS

Jorge Sesma SANCHEZ (Hidrometerologia, Inst.Mex.Tecn Agua)

In order to provide a long-term perspective of climate, we need to be focussed on its evolution in the last thousands of years. Such a perspective encompasses the period before large-scale contamination of the global atmosphere and global-scale changes in land-surface conditions. By studying past climate variability, we can establish how the climate system varied under ″natural″ conditions, before human effects became significant on a global scale. There is considerableuncertainty about the future warming which may occur as a result of human activities, and we have to consider that it would be superimposed on a background of natural climatic variations. Although the climate of the past millennia, has been reconstructed by the integration of information taken from different sources, there are several caveats about these reconstructions. This paper will describe the techniques and data for an alternative reconstruction ofthe global climate over this period. The main sources of information for this reconstruction are instrumental global temperature records over the last 13 or 15 decades. Complementary information is taken from historical, biological and geophysical sources (archives, tree rings, ice acidity, sea levels, glacier extensions, isotopes densities, etc.). The reconstruction method is based on a linear regression done with smoothed proxy records in several stages of calibration. To estimate the parameters in each stage, a multiple linear regression is performed using the least squares method. This regression is assumed valid for the entire interval where the record is available. The calibration sequence is given by the record length. The shortest proxy record isfirst calibrated. The calibration process continues until the longest natural record has been calibrated. The proposed method also permits us to evaluate a range of the reconstructed values in each stage. The results obtained from two independent reconstructions, show an interesting, reliable and objective naturalclimate variability. The Medieval Climate Optimum, the Little Ice Age, the Industrial Period, and other interesting periods are associated with mean, minimum and maximum values of global temperatures. However, when these results are compared with previous results, great differences arise. Therefore, this study concludes with a discussion of these differences and the reliability of the available global temperature records both instrumental and reconstructed.

MC12/08P/B19-006   1610

TOWARDS AN ABSOLUTE CHRONOLOGY FOR THE MARINE ENVIRONMENT: THE DEVELOPMENT OF A 1000 YEAR RECORD FROM ARCTICA ISLANDICA

Graham T.W. FORSYTHE[1], James SCOURSE[1], Ian HARRIS[2], Chris A. RICHARDSON[1], Phil JONES[2], Keith BRIFFA[2], Jan HEINEMEIER[3] ([1]School Of Ocean Sciences, University of Wales - Bangor UK, [2]Climate Research Unit, University of East Anglia UK, [3]AMS Laboratory, University of Aarhus, Denmark)

Time-series of environmental change using geochemical (stable isotope,trace element) proxies from annually-banded marine sclerochronological (coral, mollusc) records have hitherto been constrained to the life span of live-collected individuals or to floating chronologies of approximate age constrained by independent dating methods, notably radiocarbon or uranium-series dating. The construction of a long, absolute, time-series beyond the individual life-span demands statistically significant cross-matching of time-series from different specimens or individuals. We present the first cross-matched marine sclerochronological record for NW Europe based on annual growth bands of the ocean quahog *Arctica islandica* (Bivalvia, Mollusca). Using live- and dead-collected specimens from the Fladen Ground, North Sea, long shell growth records of over 100 years have been cross-matched between individuals demonstrating a common external environmental signal driving the growth curve of individual shells within a community. We have identified some very long-lived individuals with over 250 annual growth bands and one with 268; this is the longest-lived mollusc known to science. The cross-matching of growth-series is critical since this is the only statistically reliable way to identify missing bands or multiple bands within a single year. We have successfully cross-matched dead series (with inter-shell correlation

coefficients of up to 0.68); AMS radiocarbon dates from the umbo and tip of these series support the cross-matched chronology at the one standard deviation level. These dates indicate that this cross-matched chronology covers the period between AD 1128 (range AD 1066-1182) and AD 1392 (range AD 1335-1411) within the Medieval Warm Period. We have dated shell specimens which potentially link this dated floating time-series with the cross-matched chronology of 211 years (AD 2002 to AD 1791) from live-collected specimens, and anticipate the construction of a 1000-year absolute cross-matched chronology for this area of the North Sea soon. This will enable radiocarbon dating of marine material of known absolute age to derive a continuous curve of marine reservoir change for this location through time. We also have specimens from this area which have been dated to various phases of the Holocene and into the Late-glacial, raising the probability that we will be able to construct a 10,000-year absolute chronology in the future. The successful cross-matching of *Arctica islandica* is a breakthrough which will transform our understanding of both spatial and temporal radiocarbon reservoir changes in coastal and shelf seas and which will provide an absolute chronological template for geochemical proxies of marine environmental change.

MC12/08P/B19-007   1630

YEAR-BY-YEAR RECONSTRUCTION OF CLIMATE IN THE CENTRAL KOLA PENINSULA (NORTH-WESTERN RUSSIA) SINCE AD 862 BASED ON DENDROLOGICAL AND ISOTOPE DATA

Yury M. KONONOV[1], Tatjana BOETTGER[2], Michael FRIEDRICH[3], Konstantin V. KREMENETSKY[1] ([1]Institute of Geography, Russian Academy of Sciences, [2]Department of Isotope Hydrology, UFZ Centre for Environmental Research Leipzig-Halle, [3]Institute of Botany, University of Hohenheim)

More than 300 samples of living tree cores and subfossile slices of Pinus sylvestris L. have been taken in the course of joint Russian-German field investigations in the Khibiny low mountains in the central part of the Kola Peninsula (ca. 67-68°N, 33-34°E). The collected samples permitted to compose a continuous chronological series 1139 years long, from AD 2000 to 862. At present, it is the longest chronological sequence in the region.A comparison between annual ring width and instrumental climatic records over period of 1923 to 2000 revealed a high correlation between index of annual wood growth and summer air temperature. Besides, a 10 samples of cores taken from living trees were studied by annually isotope analysis (δ^{13}C and δ^{18}O) in their late wood cellulose. Analysis of those isotopes is most promising with view to climatic reconstructions. At present a significant relationship has been established between proportion of; 13C isotope and mean summer temperature. That formed the basis for reconstructions of main warming and cooling periods over the period under consideration. Altogether there were 12 considerable cooling, each of about 10 to 20 years long. As for warmings, they were less in number (7), but longer (about 40 to 90 years long).Very strong coolings occurred twice. First one was from the beginning of the studied interval to AD 884. In all probability, it was termination of the previous, still colder period, when weather prevented any tree growth. The second cooling was in 1641 to 1654; there is a good reason for believing that it was local manifestation of the Little Ice Age.

INTRASEASONNAL OSCILLATIONS IN LENGTH OF THE DAY AND POLAR MOTION VARIABILITY. ASSOCIATION WITH CLIMATIC AND SOLAR ACTIVITY INDICES

Daniel GAMBIS, Abarca del RIO (Observatoire de Paris)

We re-investigate Length of day and Polar motion variations and their excitation at intraseasonnal time scales (Madden and Julian Oscillation and other modes at these time scales). Taking advantage of long time series provided by International Earth Rotation Service, we search for an association at these scales with tropical and extratropical indices for a better understanding of its origin. We mainly investigate its modulation in phase and amplitude and their association with tropical and extratropical indices. We also search for statistical links at these time scales with other indices like solar activity which was shown to be linked to the phenomena. We also investigate a possible triggering effect of the MJO upon the large scale ENSO.

INTRASEASONAL OSCILLATIONS IN THE SACZ: OBSERVATIONS AND SIMULATION WITH A BAROCLINIC MODEL

Simone Erotildes FERRAZ[1], Tercio AMBRIZZI[1], Alice Marlene GRIMM[2] ([1]Department of Atmospheric Sciences, University of Sao Paulo, [2]Department of Physics, Federal University of Parana)

The austral summer (DJF) is the rainy season over most of Brazil and South America (Argentina, Paraguay and Uruguay). The knowledge of the intraseasonal oscillations of the summer precipitation with alternating dry and wet phases is important for some applications and can indicate procedures that allow its prognostic. Many studies have shown that the summer precipitation exhibits a large intraseasonal variability, indicated by the analysis of the outgoing longwave radiation (OLR) (e.g., Paegle and Mo (1997); Liebmann et al.(1999); and Paegle et al. (2000)). In general, these works emphasize that the intraseasonal variations in the Madden Julian Oscillation (MJO) time scales, over the region of the South Atlantic Convergence Zone (SACZ), exhibit a dipole pattern where enhanced precipitation over the SACZ is accompanied by decreased rainfall in southern South America. This study reports observational and numerical results of the signal of the MJO in South America precipitation. The baroclinic model used in the present study is based on Hoskins and Simmons (1975), and has been used in various studies of large scale circulation. The model was integrated for 15 days and perturbated with a heating source in the west Pacific (120°E - 10°S). As initial conditions in the baroclinic model are used the meridional and zonal wind, air temperature and geopotential of December 1981. The basic data come from the NCEP-NCAR reanalysis. The results are characteristic of a propagation in wave form, with maximum signal in South America (between 5°S and 15°S) after 12 days. Lag correlations between OLR (in the same region of the forcing heating) and global meridional wind at 250 hPa confirm the numerical results.

PROPAGATION OF MJO IN ASSOCIATION WITH MOISTURE SIGNALS OVER THE WESTERN HEMISPHERE AND ITS RECURRENCE MECHANISM DURING THE BOREAL WINTER

Yukari N. TAKAYABU, Kazuyoshi KIKUCHI (Center for Climate System Research, University of Tokyo)

Since the discovery of the Madden Julian Oscillation (Madden and Julian, 1971,72), its slow propagation (~5m/s) coupled with convection in the eastern hemisphere and a fast propagation (~20m/s) in the western hemisphere have been a focus of numerous numbers of studies. Various efforts have been put to explainits propagation properties either by modifying the Kelvin wave with moist processes,or by considering effects of surface flux. However, all had some kinds of shortcoming,so could not complete the theory. Recent studies emphasize the modificationof atmospheric stability through moisture processes (e.g. Kemball-Cook and Weare,2001), as well as the air-sea interactions (e.g. Zhang 1996) in the convective phase. On the other hand, a faster Kelvin wave mode (30-40m/s) is rediscovered by Millif and Madden (1996). Matthews (2000) suggested its role in the dry phase to connect the disturbance to the next cycle. However, the mechanism of the recurrence is notclear yet. In this study, we reexamined the propagation features of MJO, especially over the western hemisphere where the atmospheric disturbance is decoupled with active convection and may be triggering the next cycle of MJO. We focused our analysis on the moisture signal, utilizing the total precipitable water data retrieved from SSM/I by Wentz algorithm. In total precipitable water data, we could find a moisture signal propagating eastward in association with MJO not only over the eastern hemisphere but also over the western hemisphere, and circulate all the wayaround the equator. Over the western hemisphere, the moisture signal was accompanying the fast free Kelvin wave mode (30~40m/s). It was shown that moisture build up is associated with the surface convergence in phase with the lower tropospheric easterly wind anomalies of the fast Kelvin wave. Elevated topographies in South America and in Africa prevent this fast mode from propagating smoothly in the lower troposphere but stop it for a while, until at last the surface signal catches up with the preceding upper tropospheric signal. Since the front of the Kelvin wave disturbance consists of surface easterly wind anomaly, it converges the near-surface moisture effectively to the east of the continent as soon as the surface signal overcomes the topography. Moisture accumulation is favored by active convection, which restarts emanating the equatorial waves. This obstruction-restart propagation of the fast mode results in the propagation speed of ~20m/s in average over the western hemisphere. After all, over the western Indian Ocean, as the Kelvin wave overcome the African topography, new convective activity connects to the next cycle of the MJO with ubiquitous supplies of moisture over the warm pool region eastward. Some results from analyses of GMS Tbb and TRMM satellite data will alsobe presented.

PROPAGATION AND THE VERTICAL STRUCTURE OF THE MADDEN-JULIAN OSCILLATION

Kenneth Robert SPERBER[1], Julia Marie SLINGO[2] ([1]Lawrence Livermore National Laboratory, PCMDI, [2]NERC Centre for Global Atmospheric Modelling, University of Reading)

The Madden-Julian Oscillation (MJO) controls tropical variability on timescales of 30-70 days. During the boreal winter/spring it is manifested as an eastward propagating disturbance, with a strong convective signature over the eastern hemisphere. We describe the space-time structure of the MJO using the National Centers for Environmental Prediction/National Center for Atmospheric Research Reanalysis, Advanced Very High Resolution Radiometer Outgoing Longwave Radiation, observed sea surface temperature, and the Climate Prediction Center Merged Analysis of Precipitation. Empirical orthogonal function analysis is used to identify the convective signature of the MJO, and regression is used to identify key relationships with the convection. Compared to analyzing contiguous years of data, the selection of years of strong MJO activity results in a more robust lead/lag structure and an increase in explained variance. The MJO exhibits a rich vertical structure, with low-level moisture convergence being well defined when the convective anomalies are strong. The westward vertical tilt is most apparent over the western Pacific. Over the Indian Ocean the system is more vertically stacked, principally due to the strong subsidence of the inactive phase of the MJO, which lies to the east of the convection. As the Kelvin wave decouples from the convection near the dateline, a sea-level low-pressure surge, previously discussed in Matthews (2000), transits the eastern Pacific and Atlantic Oceans. Here we link the zonal windstress and low-level divergence to the pressure surge. The gradient gives rise to westerlies that propagate rapidly to the east. The pressure surge may play an important role in the development of the MJO convection in the western Indian Ocean, which occurs in an easterly basic state, and conditions not consistent with the low-level moisture convergence paradigm.

THE DEVELOPMENT OF ORGANIZED CONVECTION ASSOCIATED WITH THE MADDEN-JULIAN OSCILLATION (MJO) DURING TOGA COARE

Kazuyoshi KIKUCHI, Yukari N. TAKAYABU (Center for Climate System Research, University of Tokyo)

To understand the eastward migration mechanism of the Madden-Julian Oscillation (MJO), the development of organized deep convectionassociated with an MJO during Tropical Ocean Global Atmosphere (TOGA) Coupled Ocean-Atmosphere Response Experiment (COARE) intensive observation period (IOP) was studied in details. We focused on an event in January to February, 1993, which showed a prominent eastward propagation. Using GMS IR histogram data, a composite life cycle of the organized deep convection associated with the MJO is constructed and categolized to stages. Some upper air stations over the Maritime Continent were located along the path of the organized convection, and their soundings are also utilized for the composite. Five convective stages are subjectively identified ; 1) suppressed stage with no apparent large scale forcing and scarcely any cloud activity observed, 2) shallow convection stage where most clouds populated below the melting level with a duration time of 2-3 days, 3) developing stage with penetrating convective clouds (4-8 days),4)mature stage where most clouds are concentrated in the upper tropospheric level of

---

about 240 K or less (4-6 days), and 5) decaying stage that most clouds exist from 240 K to 290 K level (5-7days). Through shallow convection stage to developing stage, there exists boundary layer convergence associated with easterly anomalies in the lower troposphere. In the shallow convection stage, moist regionare mostly confined below ~700 hPa, in association with a weak stable layer around 700 hPa. In the developing stage, the moist layer starts to penetrate above the melting level. In the transition from the shallow convection stage to the developing stage, abrupt decrease of the convective available potential energy (CAPE) is observed, ensuring the existence of penetrating convections in the latter stage, and leaving the atmosphere almost neutral for mature stage. Mature stage can be devided into two sub-stages. In the formersub-stage, about 2-3 days in the begining, the area is covered with various types of high clouds. Apparent heat source (Q1) in the mid-troposhere attains maximum at this substage, suggesting that convective activity is the strongest, so that it is the convective center of this MJO. Lower-level zonal wind changed to westerly at the beginning of this substage, and boundary layer convergence starts todecrease. In the latter sub-stage, the following 2-3 days,histogram shows high concentration of very cold cloud of about 220 K and vertically integrated Q1 changes signs to negative values.It suggests that the area is covered with anvil shields and the convective center moved away. These results suggest the crucial roles of clouds in moistening the atmosphere, besides a large-scale boundary convergence.Therefore, efficiencies of moisture convegence and modification of atmospheric stratification by clouds may control the propagation speed of MJO.

SURFACE CONVERGENCE AND THE MADDEN JULIAN OSCILLATION:CROSS-SPECTRAL CONFIDENCE INTERVALS FROM A PROBABILITY DISTRIBUTIONFOR THE SURFACE WINDS

Ralph F. MILLIFF[1], Timothy J. HOAR[2], Christopher K. WIKLE[3], Roland A. MADDEN[2] ([1]Colorado Research Associates Division, NWRA, Boulder, CO, USA, [2]National Center for Atmospheric Research, Boulder, CO, USA, [3]Department of Statistics, University of Missouri, Columbia, MO, USA)

Noise inherent in high-resolution observations of the surfacewind field is often amplified in calculations of surfaceconvergence; i.e. the spatial derivative of an alreadynoisy process. Nonetheless, we are interested to investigatelead-lag relations between surface convergence and other variablesof the Madden Julian Oscillation (MJO) propagation (e.g. SST,OLR anomaly, etc.). Traditional methods to extract reliableconvergence signals from the noisy background rely uponcomposites of several MJO events. The MJO composites are oftenbased on subjective criteria to align similar phases of the MJOin the presence of the different background states for eachevent in the composite (e.g. season, ENSO cycle, large-scaleflow and SST distributions, etc.). In this paper we compositeconvergence field estimates derived from several realizationsof the surface wind field for the same MJO event in theIndian and Western Pacific Ocean. The realizations derive froma Bayesian Hierarchical Model that blends QuikSCATscatterometer wind retrievals with coincident surface windanalyses from the NCEP FNL model. Surface wind realizationsin the posterior distribution from this model are consistentwith high-resolution variability in the scatterometer winds(likelihood), as well as with the propagating normal modes ofthe equatorial beta-plane (prior). Cross-spectral confidenceintervals (e.g. for coherence squared and phase as functionsof frequency) are reduced by averaging over several surfaceconvergence realizations.

THE MJO AND MOISTURE SENSITIVITY OF CONVECTION

David J. RAYMOND (Physics Department, New Mexico Tech)

Cumulus parameterizations in large-scale models lead to an unstablemode when the precipitation produced by convection is sensitive in arealistic way to the saturation deficit of the low to middletroposphere. This instability, in conjunction with the dynamics ofnear-equatorial convection, leads to a large-scale disturbance thatlooks very much like the Madden-Julian oscillation (MJO; Raymond, D. J.,2001: A new model of the Madden-Julian oscillation.J. Atmos. Sci., 58, 2807-2819.).Ordinary surface moisture fluxes over tropical oceans, i. e., outsideof tropical storms, take 1-5 days or more to moisten an initially dryatmosphere. If deep convective precipitation issensitive to the moisture content of the atmosphere, this in turnleads to an instability mechanism if convection itself causesmoistening -- a process which has been shown to occur under certaincircumstances. Excess convection causedby a moisture anomaly can thus cause further moistening of theatmosphere, which in turn leads to more convection. Radiativefeedbacks can enhance this instability, at least in models.Unlike more dynamically generated instability modes, disturbancesoperating via the above moisture instability are likely to propagateonly slowly, if at all, relative to the low-level winds. Sobel andHorinouchi suggest that this mechanism is responsible fortropical depression-like phenomena.Sustained deep convection near the equator tends to produce lowertropospheric, counter-rotating, cyclonic gyres on opposite sides ofthe equator. Air swept around these gyres into the equatorial regionscomes from the subtropics, and is therefore likely to be dry. Thisair begins to moisten as a result of strong equatorial surface fluxesresulting from the strong, gyre-related equatorial westerlies and thewarm equatorial sea surface temperatures. However, moistening is slowenough that this air mass can only support deep convection at the exitregion of the equatorial westerly jet according to the model of Raymond. This is to the east of the previous convection responsible for creating the existing gyre system, so the whole gyrepattern shifts to the east. According to Raymond´s results, the resulting eastward propagation is of order 5 m/s, which is typicalof the rate of eastward propagation of the MJO seen in the westernPacific. Furthermore, the moistening time of the atmosphere helpsset the characteristic length scale of the active part of the MJO ofmany thousands of kilometers. Thus, the length scale, propagationspeed, and structure are explained by this model.

SEASONALLY-INDEPENDENT EASTWARDPROPAGATION OF THE MJO

Harry HENDON, Matthew WHEELER (BMRC)

Traditionally, the MJO is defined as a convectively coupled-baroclinicdisturbance that propagates eastward along the equator. With thisdefinition, the MJO is most prominent during southern summer. Duringnorthern summer, the dominant intraseasonal variability exhibitspoleward propagation in the Asian monsoon, while eastward propagationis less apparent along the equator. Because of these dramaticseasonal differences, some researchers reserve the name MJO for thesouthern summer phenomena and treat the northern summer variability asanother type of "intraseasonal oscillation", governed by differentdynamics. The MJO is thought to result from coupling of equatorialwaves modes with convection, while interactions with land and oceanare thought to govern the poleward propagating phenomena in northernsummer. By discriminating to eastward propagating activity along theequator, we show that the dominant intraseasonal variability in bothnorthern and southern summer possesses similar equatorial structureand eastward propagation,

despite dramatically differentoff-equatorial behavior. Furthermore, by removing that part of thewind and convective variance that is coherent with the equatorialeastward propagating component, we show that the remaining northernsummer intraseasonal variability occurs at high frequency (periodsless than 30 days) and on small spatial-scales. Nonetheless, polewardpropagation is still evident, suggesting that mechanisms of polewardpropagation are independent from that of eastward propagation. Wefurther demonstrate that the MJO can be efficiently identified using aseasonally-independent index that discriminates to equatorial eastwardpropagation.

PROPAGATION OF INTRASEASONAL CONVECTIVE PERTURBATION OVER THE INDIAN OCEAN

Jean Philippe DUVEL, Remy ROCA (Laboratoire de Meteorologie Dynamique, Paris, France)

The intraseasonal variability of the convection over the Indo-Pacific region is a highly intermittent phenomenon. The propagation of these intraseasonal perturbations presents very different patterns depending on season but also from one event to another for a given season. The variability of these propagation characteristics from 1975 to present is studied using a Local Mode Analysis. It appears that the propagation characteristics during the northern hemisphere winter are much more reproducible over the Indian Ocean compared to the Pacific Ocean. The mechanism of the propagation of the perturbation over the Indian Ocean is further analysed in term of interaction between the convective perturbation, the large-scale dynamical perturbation and the SST. For a case study in January 1999, we also analyse the different convective systems embedded in the intraseasonal perturbation and the effect of these systems on the surface fluxes.

MC17/10P/B23-008   1645

THE SECOND ONSET OF INDIAN SUMMER MONSOON: A DIAGNOSTIC STUDY

Hamza VARIKODEN, Babu C. A., Joseph P. V. (Dept. of Atmospheric Sciences, Cochin University of Science And Technology)

Monsoon onset over Kerala marks the beginning of a large convective heat source on the ITCZ in the northern hemisphere tropics extending from the Arabian Sea to the West Pacific Ocean that lasts for hundred days. Accompanying it is a strong inter-hemispheric low level jetstream with peak wind speed at about 850 hPa level that transports moisture to maintain this heat source. In this paper, we have studied the surge of monsoon that occurs about 30 - 52 days after the monsoon onset that we call the "second onset". It has several characteristics different from the monsoon onset although the second onset is also associated with a convective cloud band close to the equator. Analysing 20 years (1979 – 1998) of data it is found that the mean and standard deviation of the date of the second onset is 13 July and 8 days respectively. This equatorial cloud band moves northwards faster than at onset and merges with the monsoon trough convection. The low level jet stream as at onset time is directed south-eastward from central Arabian Sea and it passes south of India to the Western Pacific, but it extends much more into the Pacific Ocean. The Arabian Sea heat source is weaker than at onset. Part of the cause for the weakening of the Arabian Sea heat source is the rapid cooling of the Arabian Sea SST after monsoon onset. The conditions in atmosphere and oceans at the time of the second onset are studied.At the second onset, the Arabian Sea branch of monsoon, its cross equatorial flow off the East African coast and the easterly trades south of the Arabian sea at 850 hPa are stronger than at the time of onset by about 15 m/s, 5 m/s and 8 m/s respectively. There is not much change over the Bay of Bengal in the wind flow. SST has cooled from onset to second onset through about 3°C in the western Arabian Sea to 1°C in the Bay of Bengal in the latitude band 10°N – 20°N. Equatorial Indian Ocean has cooled through less than 0.5°C but a band of cold water is seen between latitudes 5°N and 10°N and longitudes 70°E and 90°E due to the oceanic upwelling around the southern peninsular India and Sri Lanka and the spreading eastwards of this cold water. Convection (OLR) is apparently affected by the ocean cooling. There is a tongue of reduced convection in the latitude band equator to about 15°N in the Arabian Sea and the Bay of Bengal at second onset compared to the monsoon onset. However there is increased convection from the equator to 10°S latitude, which is the initial location of the second onset cloud band. Pre Monsoon Rain Peak, Monsoon Onset and the Second Onset are distinct events in the intra-seasonal oscillation of monsoon where east-west oriented cloud and wind anomalies are found to move northwards from the equatorial region at intervals of 30 – 50 days.

MC17/10P/B23-009   1700

NORTHWARD DEVELOPMENT AND PROPAGATION OF TROPICAL AND SUBTROPICAL 30-60 DAY OSCILLATION OVER THE WESTERN PACIFIC

Chih-Hua TSOU, Pang-Chi HSU (Department of Earth Sciences, National Taiwan Normal University)

This study attempts to investigate the relative role of adiabatic (vorticity,thermal, and static stability advection) and diabatic heating on the development and propagation of 30-60 day oscillation over the Western Pacific by using a three-dimensional streamfunction tendency equation. The results showed that the northward development and propagation of a 30-60 day wave train in the region from the equatorial Western Pacific to East Asia was primarily contributed by the effect of diabatic heating and vorticity advection.They caused cyclonic vorticity ahead (northwestward) of the 30-60 day oscillation cyclonic circulation, and anticlyonic vorticity behind (southeastward) the 30-60 day precipitation where the subsidence and anticyclonic circulation appeared. Their combined contribution enhanced the cyclonic vorticity ahead of the precipitation and led the cyclonic circulation and precipitation to develop and propagate northwestward. As the precipitation reached maximum intensity over the South China Sea/Western Pacific, the static stability effect associated with the adiabatic cooling and cooling of SST associated with the cloud-radiation effect would inhibit the development of the cyclonic circulation. The cyclonic circulation and precipitation weakened as they reached maximum intensity over the South China Sea/Western Pacific. The land-atmosphere interaction further decreases the intensity of diabatic heating by cutting off the moisture supply from the ocean.

MC17/10P/B23-010   1715

CONTRASTING CHARACTERISTICS BETWEEN THE NORTHWARD AND EASTWARD PROPAGATION OF THE INTRASEASONAL OSCILLATION DURING THE BOREAL SUMMER

Huang-Hsiung HSU, Chun-Hsiung WENG, Cheng-Han WU (Department of Atmospheric Sciences, National Taiwan University)

This study investigates the characteristics of the evolution and structure of the eastward- and northward-propagating ISO in the Indian Ocean and the westernPacific during the boreal summer. Along the equator, the near-surface moisture convergence located to the east of

---

the deep convection region appears to result in the eastward propagation of the ISO, consistent with the frictional Wave-CISK mechanism proposed in previous studies. The eastward propagation is characterized by the sequentially downstream development of deep convection occuring mainly in certain regions such as 60°E, 95°E, 120°E, 145°E, and the dateline.While the northward propagation of deep convection can be attributed to the low-level moisture convergence located to the north, this convergence is not confined in the boundary layer as suggested in previous studies. Instead, it is a deep structure extending from surface to the middle troposphere. Near-surface convergence appears only after the systems approach the land mass in the north. It is suggested that both the deep convergence in the lower free atmosphere and in the boundary layer contribute to the northward propagation. While the near-surface convergence can be attributed to the frictional convergence embedded in Rossby wave, the lifting effect of the sloping terrain and the stronger surface frictional effect over the land in South Asia may also contriubte to induce the convergence leading the deep convection. The northward propagation occurs sequentially from west to east in the following order: the Arabian Sea, the Bay of Bengal, and the South China Sea. A mechanism is proposedto explain this downstream occurrence of northward propagation.It is also found that surface sensible heating may also contribute to the northward propagation, especially in the Arabian Sea, by making the lower troposphere less stable. Laten heat flux is released to the atmosphere in the region located to the southwest of the deep convection and does not directly contribute to the destablization of the lower troposphere ahead of the deep convection. In contrast, during the eastward propagation the surface heating does not seem to precondition the lower troposphere to the east of the deep convection. Frictional convergence is seemingly the dominant factor in the eastward propagation.

A STUDY ON THE ANNUAL CYCLE OF THE TROPICAL INTRASEASONAL OSCILLATION

Min DONG, Chidong ZHANG (Department of Meteorology and physical oceanography, University of Miami)

Using the 20 year NCEP data and CCM3 (with MCRAS convection scheme) the annual cycle of the tropical intraseasonal oscillation (TIO) is studied. It is found that: 1. From the spectral and wavelets analysis on the NCEP data it is found that there are obvious annual cycle in the tropical intraseasonal variability. In winter and early spring the power of TIO has its maximum. After that the power decreasesand gets its minimum in summer. From the summer to winter the TIO power gets stronger again and finishes an annual cycle. 2. The TIO also exhibit a unique spatial distribution characteristics. Throughout whole year the TIO are active in the region from 60E through 140W, But in winter the most active TIO activities are in the south hemisphere while in summer it moves to the north hemisphere and it shift back to south hemisphere again in winter. 3. The CCM3 with MCRAS convection scheme can pretty well simulate the tropical intraseasonal variation though there are still some weakness in the ability to simulate this event. The Model can capture the main spectral characteristics and also can give an annual cycle of the tropical intraseasonal variation. But the simulated TIO signal isweaker than the observation and the phase of the annual cycle is a little bit earlier than the observation. 4. The simulated TIO is sensitive to the SST forcing and also to the monsoon circulation which is closely linked to annual cycle of the radiation change. 5. The model experiment shows the higher SST tends to produce more stronger TIO signal. The experiment also shows there are some linkage between the TIO annual cycle and the monsoon circulation.

PROPAGATION MECHANISMS OF THE INTRASEASONAL OSCILLATION

Bin WANG, Xiouhua FU, Kemball COOK (Department of Meteorology and International Pacific Research Center, University of Hawaii)

The physical processes that determine the eastward propagation of the Madden-Julian Oscillation are discussed. These processes include the interaction between precipitation heating and various vertical modes of equatorial waves, the coupling between moist Rossby and Kelvin waves, wave dispersion of equatorial wave packet induced by boundary layer friction, and atmosphere-ocean interaction. The boreal summer northward propagation in the Indian Ocean sector and the northwestward propagations of intraseasonal disturbance are depicted using finite domain wavenumber-frequency spectral analyses. The mechanisms of the northward and off-equatorial westward propagation during boreal summer are discussed. The role of sir-sea interaction in boreal summer ISO in the Indian Ocean has been studied using coupled ECHAM-4 AGCM and UH intermediate ocean model. Four 15-yr integrations were made. In the first integration, the model lower boundary conditions were observed monthly mean sea surface temperatures, and, in the second, the AGCM was coupled to the ocean model. In the third and fourth simulation, the SST climatology generated in coupled run was used to create daily and monthly mean SSTs, respectively, which were then used to drive the AGCM in an uncoupled configuration similar to the first run. The coupled run shows pronounced northward propagation of convection and circulation anomalies over the northern Indian Ocean, as in observations, while northward propagation is very weak in the uncoupled run. The northward propagating ISO is strongly coupled with underlying SST. On the one hand, the intraseasonal atmospheric convection changes the SST through the solar radiation, latent heat flux and mixed-layer base entrainment. On the other hand, the intraseasonal SST significantly feeds back to the intraseasonal convection by increased low-level convergence into the positive SST anomaly ahead of the convection anomaly. The prevalent northward rather than southward propagation of the ISO is attributed to the interactions between the summer mean state and the atmospheric disturbances in the air-sea coupling context. The stand-alone atmospheric model is driven with the daily SST generated in the coupled run is unable to reproduce the intraseasonal oscillation in the coupled run. In the coupled system (or in nature), the intraseasonal SST is both a result and a force of the intraseasonal atmospheric convection. The SST has a quadrature phase relationship with the convection. However, in the stand-alone atmospheric system, the SST is only a boundary force. The resultant atmospheric convection has almost the same phase with the underlying SST. The intensity of the SST-forced intraseasonal convection in the stand-alone atmospheric model is also much weaker than that in the coupled model. In the coupled model, the movement of the off-equatorial convection in the northern Indian Ocean is not necessarily related to the equatorial eastward-moving Madden-Julian Oscillation. On the other hand, it well follows the local SST perturbations. The positive/negative SST perturbations in the northern Indian Ocean lead active/break phases of the intraseasonal oscillation by about 2 pentads(10 days). Therefore, the SST perturbation on the intraseasonal time scale over the northern Indian Ocean is potentially a useful index to forecast the active/break spells of the south Asian summer monsoon.

MC17/11A/B23-002   0900

PROPAGATION OF THE MJO IN A COUPLED GENERAL CIRCULATION MODEL

Peter INNESS, Julia SLINGO (NCAS Centre for Global Atmospheric Modelling)

The eastward propagation of the convection associated with the MJO has never been realistically represented in an atmosphere-only general circulation model (GCM). Evidence from observations suggests that there is a link between MJO convection and sea-surface temperature (SST) anomalies, which may partly explain the phase speed of the eastward propagation of the convection. Taken together, these two pieces of evidence suggest that we need to use coupled GCMs, in which the SST can respond to forcing associated with intraseasonal variations in convection, in order to adequately represent the propagation of the MJO. This study will present a comparison of the eastward propagation of the MJO in a coupled GCM with that simulated by the atmospheric component of the GCM forced with seasonally varying SSTs. The coupled GCM produces eastward propagating convection on MJO time-scales whereas the atmosphere-only version does not. The mean climate of the GCM in the Indo-Pacific region is found to be crucial in determining whether the MJO convection extends into the West Pacific.

MC17/11A/B23-003   0920

THE STRUCTURE AND PROPAGATION CHARACTERISTICS OF THE MJO IN MRI COUPLED GCM: COMPARISON WITH OBSERVATION AND ATMOSPHERE-ALONE GCM

Kavirajan RAJENDRAN, Akio KITOH (Climate Research Department, Meteorological Research Institute, Tsukuba, Ibaraki, Japan)

The Madden-Julian Oscillation (MJO) is the dominant mode of tropical variability on intraseasonal time scales. The simulation of propagation and spectral characteristics of the equatorially trapped waves associated with the MJO in the new version of MRI coupled GCM (MRI-CGCM) is analysed. The role of coupling in modulating the characteristics of these waves are also investigated by performing an additional integration using its atmosphere-alone component. The slowly varying boundary condition, SST, used in this integration is derived from the coupled simulation. A composite structure of the MJO is studied by applying extended EOF (EEOF) analysis. Air sea coupling is found to have improved both propagation and spectral characteristics on intraseasonal time scales. Thus, the simulated MJO in the coupled model shows more realistic propagation characteristics. However, the space-time spectral analysis shows that, in the coupled model, the maximum eastward power on intraseasonal time scales for wavenumber 1 occurs at a slightly higher frequency compared to the observation. In the coupled GCM, the complex interaction between the sea surface and the boundary layer appears to result in more realistic MJO. Besides, the better simulation of MJO in the coupled GCM is also associated with a realistic simulation of climatological mean, onset and evolution characteristics of Asian summer monsoon. This implicates that the skill of the model in the simulation of seasonal mean and intraseasonal variation are associated.

MC17/11A/B23-004   0940

THREE-DIMENSIONAL STRUCTURE AND ITS MODIFICATION OF INTRASEASONAL VARATIONS OVER THE INDONESIAN MARITIME CONTINENT

Manabu D. YAMANAKA[1], Toshiki OKUDA[2], Noriko OKAMOTO[2], Fumie MURATA[2], Shuichi MORI[3], Hiroyuki HASHIGUCHI[4], Tien SRIBIMAWATI[5] ([1]Graduate School of Science and Technology, Kobe University, Japan / Frontier Observational Research System for Global Change, Japan, [2]Graduate School of Science and Technology, Kobe University, Japan, [3]Frontier Observational Research System for Global Change, Japan, [4]Radio Science Center for Space and Atmosphere, Kyoto University, Japan, [5]Agency for Assessment and Application of Technology, Indonesia)

Intraseasonal variations over the Indonesian maritime continent are analyzed based on almost daily operational rawinsonde data through a year (1995). Composite analysis around maxima of the whole-Indonesia-mean, vertical-mean humidity shows a reversal from easterly to westerly in the lower troposphere and another one from westerly to easterly in the upper troposphere, suggesting a convergence of zonal wind around the humidity maximum associated with the intraseasonal variation with a zonal wavelength larger than the zonal width (about 5,000 km) of the Indonesian maritime continent. This structure is clear in particular in the southern-hemispheric side of this region. Over such a tropospheric variation another zonal-wind variation with downward phase progression is found in particular near the equator. These structures are compared with theories/models of the tropospheric intraseasonal variations and the lower-stratospheric Kelvin waves. Differences of the structures between stations are discussed in view of the modification of intraseasonal variations over the Indonesian maritime continent, which is also suggested from our recent intense observations in Sumatera Island using 3- and 6-hourly rawinsonde launches and other instruments.

MC17/11A/B23-005   Invited   1030

THE ROLE OF SEA SURFACE TEMPERATURE FORCING IN THE ORGANISATION AND EASTWARD PROPAGATION OF MJO CONVECTIVE ANOMALIES

Adrian J. MATTHEWS (Schools of Environmental Sciences and Mathematics, University of East Anglia)

The role of sea surface temperatures (SST) in the organisation and eastward propagation of deep tropical convective anomalies within the Madden-Julian oscillation (MJO) is examined using an atmospheric general circulation model. In an ensemble of initial value experiments forced with observed composite time-dependent MJO SST anomalies, a significant response in deep convection developed within a few days, with enhanced convection over the region of positive SST anomaly. The convective anomalies then propagated eastward along with the SST forcing. This supports the theory that atmosphere-ocean coupling is important in maintaining the MJO, at least in this particular model. The implied feedback of the atmosphere onto the ocean through changes in the surface short wave and latent fluxes and surface wind stress is presented and compared with observed anomalies. The response time of the tropical atmosphere to the SST anomalies, in terms of the development of convective anomalies and their subsequent forcing of a dynamical atmospheric (equatorial wave) response, is the same order of magnitude as the time scale of the MJO SST anomalies themselves, and the dependence of the atmospheric response and of the implied ocean-atmosphere coupling to the periodicity of the SST forcing is discussed. Observed latent heat flux anomalies within the MJO are attributable to a modulation of synoptic-scale weather systems by the MJO as well as to the slowly varying MJO wind anomalies themselves. The ability of the model to reproduce this modulation and its sensitivity to the SST forcing is also discussed.

MC17/11A/B23-006   1100

WAVE-ZONAL FLOW INTERACTION IN THE MADDEN-JULIAN OSCILLATION

Masahiro WATANABE (Department of Ocean and Atmospheric Science, Hokkaido University)

A possible interaction between planetary-scale waves and zonal mean flow associated with the Madden-Julian Oscillation was examined by means of the so-called aqua-planet experiments with and without ´warm pool´ of tropical sea surface temperature. In the presence of the warm pool the model produces a broad spectral peak on intraseasonal timescale in the zonal mean wind. It was found that the zonal flow fluctuations are generated and maintained by eastward propagating waves that accumulate westerly momentum toward the equator in one phase of the MJO while emanate it toward the subtropics in the other phase. The anomalous zonal mean flow in turn encourages the convective anomaly moving eastward, but such a feedback may account only for about 10% of the propagation tendency of wave fields. The wave-zonal flow interaction in the MJO therefore appears virtually one-way from waves to the zonal mean flow.

MC17/11A/B23-007   1120

MJO-LIKE SYSTEMS IN IDEALIZED AQUAPLANET SIMULATIONS

Mitchell W. MONCRIEFF, Wojciech W. GRABOWSKI (MMM/NCAR)

Interaction between equatorially-trapped disturbances and tropical convection is investigated using a global model which applies the Cloud-Resolving Convection Parameterization (CRCP, a.k.a. super-parameterization). The CRCP represents sub-grid scale physical processes by embedding an east-west oriented two-dimensional cloud-resolving model in each column of a global model. Convection is represented explicitly. The modeling setup is a constant-SST aquaplanet, the size and rotation-rate of Earth, maintained in radiative-convective quasi-equilibrium. No large-scale organization of convection occurs outside the equatorial waveguide. Within the waveguide coherent structures characterized by deep convection at the leading edge with strong surface westerly winds to the west (westerly wind bursts) occur spontaneously. These structures resemble the Madden-Julian Oscillation (MJO) and occur in simulations with prescribed radiation and simulations with interactive radiation. Sensitivity simulations suggest that the coupling among deep convection, free-tropospheric moisture, and the large-scale flow is essential for coherence of the MJO-like structures. When large-scale fluctuations of convectively-generated free-tropospheric moisture are removed on a time-scale of hours, MJO-like structures do not develop and, if already present, disintegrate rapidly. The systems are weaker and structurally different when the two-dimensional cloud-resolving models are oriented north-south instead of east-west, suggesting that convective momentum transport is important. MJO-like structures also develop when CRCP is replaced by a traditional convection parameterization (Emanuel scheme). However, with parameterized convection the coherence is sensitive to parameters of the convection scheme. An idealized nonlinear dynamical model is formulated in order to examine the MJO-like structures at a basic level. The model analytically couples a Rossby-gyre circulation with organized convection dynamics and provides a simple analytic formula for the propagation speed of the MJO-like systems. This is distinct from formulae derived from tropical wave-theory. The dynamical model reproduces the vertical and meridional transports of zonal momentum, and the atmospheric super-rotation in the global model. These quantities are analytic functions of the propagation speed of the MJO-like systems.

MC17/11A/B23-008   1140

MODELING THE DISTINCTION BETWEEN THE MJO AND MOIST KELVIN WAVES

Richard Brian NEALE, Brian E. MAPES (Climate Diagnostics Center)

Space-time spectral results of Wheeler and Kiladis clarify that the Madden-Julian oscillation (MJO) and moist Kelvin waves are distinct phenomena, both of which occur in nature. This distinction has not been recognized in much of the modeling literature. For example, studies which conclude that a model has a too-fast MJO may actually indicate that the model lacks an MJO, but has a reasonable moist Kelvin wave. Further confusion springs from quoting round-the-world periods rather than phase speeds in aqua-planet models with a zonally symmetric equatorial warm pool. We have undertaken to construct a model, of minimal complexity and satisfying diagnosability, exhibiting both moist Kelvin waves and a slower, MJO-like phenomenon. Our working hypothesis is that tropospheric wave (density) dynamics, involving the second vertical mode of the troposphere, contain the dominant propagation mechanism in the former, while the latter is associated with a slower time scale involving moisture storage and discharge. This slow moisture time scale may involve frictional convergence in the boundary layer, and certainly must involve an interplay between shallow convection (which mixes moisture vertically and has low precipitation efficiency) and precipitating deep convection. A key question involves hysteresis: how can deep convection persist and dry out the atmosphere, even as large-scale thermodynamic conditions become apparently less favorable than those prevailing before it began?

MECHANISM OF INTRASEASONAL OSCILLATION IN THE SOUTH ASIAN SUMMER MONSOON REGION

Hae-Kyung Lee DRBOHLAV, Bin WANG (Department of meteorology, University of Hawaii)

The mechanism of boreal summer intraseasonal oscillation is examined with the zonally averaged intermediate atmospheric model (2D model). Without the ocean mixed layer, the barotropic and baroclinic mode of atmosphere can produce the oscillation in 2D model. The propagation of convection in 2D model is caused by the phase relationship between convection and barotropic divergence in the atmosphere. Most importantly, in the northern hemisphere, the vertical advection of July-mean easterly wind shear in regions of convection induces barotropic divergence (convergence) to the north (south) of convection. The resulting moisture convergence in the boundary layer induces the northward propagation of precipitation. The initiation of convection is also produced by the barotropic divergence in the atmosphere. Especially, the strong July-mean vertical motion at 10S causes convergence in the boundary layer between 10S and the equator. The baroclinic mode, on the other hand, acts to enhance existing convection.

SUBSEASONAL ATMOSPHERIC VARIABILITY AND EL NIÑO

Gabriel Andres VECCHI[1], D.E. HARRISON[2] ([1]JISAO, University of Washington, [2]NOAA/PMEL/OCRD)

The importance of atmospheric variability in the sub-seasonal band for El Niño/Southern Oscillation (ENSO) is an active area of research. In particular, it has been suggested that equatorial Pacific surface wind variability associated with the Westerly Wind Events (WWEs) and Madden-Julian Oscillation (MJO) are important in both the onset of El Niño warming, and in the termination of El Niño periods. We use a systematic definition of WWEs and a global index of MJO variability, based on 850-mb zonal wind, to investigate the structure of the average MJO and relationships between the MJO, WWEs and ENSO. As reported by others, there is no correlation between MJO activity and eastern equatorial Pacific sea surface temperature (SST) anomalies, for the period 1982-2002. We find that WWEs are very strongly connected to waveguide warming in the Pacific both statistically and in an ocean general circulation model, independent of their relationship to the MJO. When the eastern equatorial Pacific SSTs are close to climatology, western and central equatorial Pacific WWEs drive strong waveguide warming in the east. When the eastern equatorial Pacific SSTs are warmer than normal WWEs act to maintain the warm SSTs, which tend to disappear in their absence. We find, however, that we can only build a statistical or model-based connection between waveguide warming and the MJO when they co-occur with a westerly wind event. Statistical and OGCM connections between waveguide warming and the MJO are weak, and within the uncertainty in the statistics and the model parametrization. Small changes in OGCM parametrization can lead to the MJO driving either warming or cooling in the east Pacific. MJO events occurring with an equatorial WWE are associated with waveguide warming of the same magnitude as that associated with a WWE without an MJO. When an MJO with an embeded WWE is imposed on the model ocean the changes are not distinguishable from those produced by an independent WWE. Thus, the occurence of WWEs should be the focus of interest in examining the relationshp between subseasonal variability and ENSO waveguide warming. Further, we examine the relationship between WWEs and the MJO and find that there is very strong statistical case for MJO modulation of WWE activity on intraseasonal timescales, but on non-intraseasonal timescales WWEs appear to be independent of MJO. That is, the MJO redistributes the probability of WWEs within an MJO, but the occurrence of an MJO does not increase the probability of WWEs.

MC17/11P/B23-002   1420

A STATISTICAL ANALYSIS OF WESTERLY WIND BURSTS IN THE EQUATORIAL TROPICS AND THEIR INTERRELATIONSHIP WITH ENSO AND INTRASEASONAL VARIATIONS

Ayako SEIKI, Yukari N. TAKAYABU (Center for Climate System Research, University of Tokyo)

Observational features of westerly wind Bursts (WWBs) over the equatorial latitudes at all longitudes and their interrelations with MJO (Madden-Julian oscillation) and ENSO are studied, using ECMWF objective analysis data and satellite data for the period of 1979-2001. We defined WWBs, using surface 10-m zonal wind anomalies from 91-days-running-mean climatology averaged between 2.5°N-2.5°S, with cases which satisfy following criteria: anomalous westerlies exceed 5ms[-1], extend more than 10 degrees longitude, and last at least 2 days. Total number of WWBs identified in 23-year analysis period was 279. WWBs are found over the Indian Ocean and the Pacific Ocean, but not over the Atlantic Ocean. Annual composite analysis revealed that over the Indian Ocean, WWBs frequently occur with seasonal intensification of westerlies in May and around November, which are also influenced by ENSO. On the other hand, WWB occurrences over the Pacific Ocean coincide with eastward migration of the warm pool controlled by ENSO. WWBs over the Indian Ocean occur where the mean surface westerly is largest, while those over the Pacific Ocean occur most frequently where the vertical shear of the zonal wind changes from the easterly shear to the westerly shear. Significant correlations between WWB frequencies and ENSO are found by lag-correlation analysis. WWB occurrences over the Indian Ocean are seen in lag 0 month which corresponds to La Niña peak, or in lag -15 months preceding El Niño. WWBs over the western Pacific Ocean are found around lag -4 months, leading El Niño peak. WWBs occur simultaneous with El Niño over the eastern Pacific Ocean. These results suggest that WWBs occur under the preferable environment prepared by ENSO. At last, composite analysis based on WWB maximum intensity as well as subjective examinations of individual cases revealed that most of WWBs are associated with slow downs of MJO with intensification of Rossby wave response. On the other hand, in terms of MJO phase which is determined with band pass filtered 200hPa velocity potential, largest numbers of WWBs occur in the latter half of MJO convective phase. This also implies that WWBs occur in association with MJO, though there exist some regional differences in timings. Considering that most of MJO do not bear WWBs, on the other hand, we suggest that ENSO controls the environment which is preferable for structure transformations from MJO to WWBs to occur. Structure transformation mechanisms will be addressed in future studies.

MC17/11P/B23-003   1440

THE STRUCTURES OF DEEP CONVECTIONS AND THEIR ENVIRONMENT OBSERVED DURING THE ACTIVE PHASE OF MADDEN-JULIAN OSCILLATION OVER THE EQUATORIAL WESTERN PACIFIC

Hisayuki KUBOTA[1], Ryuichi SHIROOKA[1], Tomoki USHIYAMA[1], Jingyang CHEN[1], Takashi CHUDA[1], Kensuke TAKEUCHI[1], Kunio YONEYAMA[2], Masaki KATSUMATA[2] ([1]Frontier Observational Research System for Global Change, [2]Japan Marine Science and Technology Center)

The structures of deep convections and their environment were examined during the active phase of the Madden-Julian oscillation (MJO) using fine time resolution of the research vessel Mirai observation data. During the intensive observation period, MJO associated with deep convections passed through the observational area. Strong westerly wind also appeared during the active phase of MJO. Vertical structures associated with convective activity were detected using lag correlations of atmospheric parameters. Convective activity included deep convections, with a nocturnal maximum and another peak 12-18 hours earlier. Deep convections associated with the first peak developed in the daytime and decayed within a few hours. These daytime deep convections transported water vapor from lower to middle troposphere, making the environment more favorable for the more intensive deep convections that developed during the night. Westerly winds were accelerated in lower layers during both deep convections.

MC17/11P/B23-004   1500

MODULATION OF TROPICAL CYCLONE BY MADDAN-JULIAN OSCILLATION

Congwen ZHU[1], Tetsuo NAKAZAWA[2] ([1]Chinese Academy of Meteorological Sciences, China, [2]Meteorological Research Institute, Japan)

The modulation of tropical depression (TD)/storm(TS) over the Indian-western Pacific Oceans by the Madden-Julian Oscillation (MJO) has been explored for the period of September 1996 to June 1997. The present study showed that there are more (fewer) TD/TSs formed in the wet (dry) phase of the MJO except over the west North Pacific, where the TD/TS can be alternatively modulated by the eastward or westward propagating MJO. Singular Vector Decomposition (SVD) analysis has demonstrated that, coupled to the enhanced (suppressed) tropical convective anomalies, a pair of the east-west elongated cyclonic vortex in the northern (southern) hemisphere and the anti-cyclonic vortex in the southern (northern) hemisphere at 850 hPa appears over the tropical regions in both hemispheres with the westerly (easterly) wind anomalies along the equator in between. The westerly wind burst and its eastward progression, associated with the MJO, could result in a spin-up of the tropical cyclogenesis with several day interval during the wet phase of the MJO. There are two cases of twin cyclone generation, modulated by the MJO, one in the Indian Ocean in October 1996 and another over the western Pacific in May 1997. The analysis shows that the equatorial westerlies and super cloud cluster are responsible for the twin cyclogenesis.

MC17/11P/B23-005   1540

A FURTHER STUDY ON ZONAL PROPAGATION OF TROPICAL INTRASEASONAL OSCILLATION (MJO)

Chongyin LI (Institute of Atmospheric Physics, Chinese Academy of Science)

The data analyses have shown clearly that the eastward propagation is a main feature of zonal propagation in the tropical (10N-10S) atmosphere, i.e., the MJO, but sometimes the westward propagation of the MJO can be seen there. The seasonal variability is another feature of zonal propagation of the MJO. Generally, eastward propagation of the MJO is more advantageous in the Northern winter than that in the Northern summer.Other hand, the data analyses and numerical simulation also show that zonal propagation of the MJO will occur anomaly due to the impacts of some processes. Fox example, the MJO propagates eastwards very obviously in the El Nino summer. The MJO still reveal anomalous propagation westwards in the tropical Pacific area when there is abnormal strong heating field over the equatorial eastern Pacific.

OBSERVATIONAL RESULTS FOR RELATIONSHIP BETWEEN LOWER TROPOSPHERIC WESTERLY AND RAINFALL AT KOTOTABANG, WEST SUMATERA, INDONESIA

Fumie MURATA[1], Manabu D. YAMANAKA[1], Shin-Ya OGINO[1], Masatomo FUJIWARA[3], Hiroyuki HASHIGUCHI[3], Shoichiro FUKAO[3], Shuichi MORI[2], Jun-Ichi HAMADA[2], Yudi Iman TAUHID[2], Tien SRIBIMAWATI[4], Budi SUHARDI[5] ([1]Graduate school of science and technology, Kobe University, Japn, [2]Frontier observation research system for global change, Japan, [3]Radio science center for space and atmosphere, Kyoto University, Japan, [4]Agency for the assessment and application of technology, Indonesia, [5]Indonesian meteorological and geophysical agency, Indonesia)

A relationship between low tropospheric westerly and precipitation at Kototabang (100°E, 0.20°S, 865 mMSL), West Sumatera, Indonesia have been investigated. Kototabang is located on mountainous region along west coast of Sumatera Island. A Boundary layer radar have been operated there since August 1998. Besides, rawinsonde observation campaigns have been conducted therefor several times.Dominant lower tropospheric zonal wind at Kototabang was weak westerly,and strong westerly more than 10 m/s sometimes observed.Most of these strong westerlies associated with MJOs. Rainfalls at Kototabang tended to occur when westerlies was weak, and occupied most of total rainfalls.They tended to occur in the afternoon from local cloud systemsdeveloped along mountainous region.These results different from observations in Western Pacific region, where MJOs bring active convections. This implies the importance of complicated topography on making clouds. In two rawinsonde observation campaigns strong westerlies corresponded to the appearance of both low equivalent potential temperature and low specific humidity below 5 km altitude, and precipitations at Kototabang did not occur in the periods of dry air.

MC17/11P/B23-007   1620

MANIFESTATION OF MJ OSCILLATION IN THE TROPICAL ATMOSPHERIC BOUNDARY LAYER OVER AN INLAND STATION

P.K. KUNHIKRISHNAN, Praveena KRISHNAN, S. Muraleedharan NAIR (Space Physics Laboratory Vikram Sara Bhai Space Centre)

The Madden Julian Oscillation (MJO) is a planetary scale wave that traverses from west to east in roughly 40 days. It has the largest aplitude in the equatorial latitude and is discernible over the tropics and subtropics. Its signature is seen in most variables, such as the sea level pressure, zonal wind and divergent circulation. The lower atmospheric wind profiler established at National MST Radar Facility, Gadanki (13.5°N, 79.2°E) provides a continuous high resolution wind data in the first few kilometers of the atmosphere. The LAWP wind data was collected for the period March 1999 to September 2000. Analysis of the wind data collected during the period was carried out to see the signatures of MJ oscillations in the wind. The horizontal wind components (u and v) were classified into S-W monsoon (May, June, July, August and September) and winter monsoon (November, December, January, February and March) periods. The horizontal wind components were subjected to Fast Fourier transforms and wavelet analysis. Spectral analysis of data clearly shows the presence of synoptic scale oscillations and 40 to 50 day oscillation in the zonal wind. The 40 to 50 day oscillation is strong during S-W monsoon period compared to that at winter monsoon period. The 40 to 50 day oscillation is not seen in the 'v' component of horizontal wind. These long period oscillations are more prominent in the higher heights in the ABL than that in the surface layer. Wavelet analysis clearly show the temporal variation of these oscillations. When the synoptic scale oscillation and the MJ oscillations are in phase more rain is recorded in the region.

MC17/11P/B23-008   1640

AN OBSERVATIONAL STUDY ON INTRASEASONAL VARIATIONS WITH EQUATORIAL ATMOSPHERE RADAR IN WEST SUMATERA, INDONESIA

Tri Handoko SETO, Masayuki YAMAMOTO, Hiroyuki HASHIGUCHI, Masatomo FUJIWARA, Mamoru YAMAMOTO, Shoichiro FUKAO (Radio Science Center for Space and Atmosphere, Kyoto University)

The equatorial atmosphere over Indonesia seems to play an important role upon global change of the earth´s atmosphere. In order to observe the phenomena in the whole troposphere and the lower stratosphere (2—20km) in the equatorial region, we installed the equatorial atmosphere radar (EAR) in Kototabang, West Sumatera, Indonesia (0.20°S, 100.32°E). The EAR has good time and height resolutions of about 85 sec and 150 m, respectively, and has been continuously operated since July 2001. Intraseasonal variations, which is one of the most dominant variations in the tropics, has be studied using the EAR in Indonesia. Eastward propagating super cloud cluster (SCC) known as intraseasonal variation (ISV) or Madden Julian oscillation (MJO) clearly appeared in GMS IR data (T_{BB}) over the radar site (0.2°S) during June 2002. There was a good correlation between T_{BB} and 2—4 km averaged daily zonal wind obtained with the EAR on that period. Namely, when enhanced convection existed in the west side of the EAR site, easterlies or weak westerlies were observed with the EAR, and conversely when enhanced convection was situated in the east side of the EAR site, westerlies were observed. We investigated the relation between 2—4 km averaged zonal wind and variance of vertical wind obtained with the EAR. Strong variance of vertical wind was observed when easterlies or weak westerlies were observed, and conversely weak variance of vertical wind was observed during strong westerlies. Regardless of the direction of 2—4 km averaged zonal wind, variance of vertical winds weakened above the tropopause height (about 16 km).

MC17/11P/B23-009   1700

INTRASEASONAL VARIABILITY OVER TROPICAL AFRICA DURING NORTHERN SUMMER

Adrian J. MATTHEWS (Schools of Environmental Sciences and Mathematics, University of East Anglia)

The intraseasonal variability over Africa during northern summer was analyzed, using 25 years of NCEP/NCAR reanalysis and satellite data. The dominant pattern of variability was one of enhanced deep convection over the whole African monsoon region. It appeared to arise as a remote response to the intraseasonal (Madden--Julian) oscillation over the warm pool sector. Twenty days prior to the maximum in convection over Africa, there was no signal over Africa but convection was reduced over the equatorial warm pool. An equatorial Kelvin wave response to this change in warm pool convection propagated eastward and an equatorial Rossby wave response propagated westward and between them they completed a circuit of the equator and met up twenty days later over Africa, where the equatorial ascent in the Kelvin wave front and the off-equatorial ascent in the Rossby wavefront favoured deep convection. Over West Africa, the Kelvin wave component contained lower-tropospheric westerly anomalies which acted to increase the boundary layer monsoon flow and moisture supply. The westerly anomalies also increased the cyclonic shear on the equatorward flank of the African easterly jet, leading to enhanced African easterly wave and transient convective activity, which then contributed to the enhanced convection over Africa on the longer intraseasonal time scale. The implications of this intraseasonal mode for predictability over Africa is discussed.

MC17/11P/B23-010   1720

IMPACT OF FREE-TROPOSPHERIC HUMIDITY ON DEEP CONVECTION

Steve DERBYSHIRE[1], Wojciech W. GRABOWSKI[2], Isabelle BEAU[3], Peter BECHTOLD[4], Jean-Yves GRANDPEIX[5], Jean-Marcel PIRIOU[3], Jean-Luc REDELSPERGER[3], Pedro SOARES[6] ([1]Met Office, Bracknell, [2]NCAR, USA, [3]Meteo-France, Toulouse, France, [4]ECMWF, Reading, UK, [5]LMD, Paris, France, [6]University of Lisbon, Portugal)

Humidity of the free troposphere has been long recognized as an important factor modulating moist convection. The most spectacular example is the impact of dry intrusions on the tropical convection. By moistening its immediate environment, convection renders it more favorable for future convection because clouds growing in a more humid environment loose their positive buoyancy (as a result of entrainment of dry environmental air) more slowly than clouds growing in a drier environment. However, convective parameterizations, which have to be used in traditional large-scale weather prediction and climate models, are often quite insensitive to the environmental free-tropospheric humidity. This presentation consists of two parts. First, we will present results from European Community project EUROCS which, among other themes, aimed at i) documenting impact of free-tropospheric humidity on moist convection using cloud-resolving modeling approach, and ii) using these results to improve sensitivity of tradiational convective parameterizations to free-tropospheric humidity. Second, we will present results from idealized numerical simulations illustrating the impact of free-tropospheric humidity on large-scale organization on tropical convection. This can be understood as a feedback process which involves moist convection, free-tropospheric moisture, and the large-scale flow. This feedback causes perturbations in moist convection to strengthen perturbations of the free-tropospheric moisture, which, in turn, affect the spatial distribution of moist convection. The large-scale circulation, which develops in response to spatial fluctuations of convective heating, plays an important role in this feedback because, through the effect of the large-scale subsidence, it makes areas with suppressed convection even drier. Intractive radiative transfer strengthens this feedback loop considerably because more radiative cooling, and thus more subsidence, occures in dry cloud-free areas. We will argue that problems in representing this feedback loop may explain the weak intraseasonal variability observed in many large-scale weather and climate models.

SURFACE WAVE STRUCTURE STUDY USING A HIGH DENSITY NETWORK

Toshiro TANIMOTO, Kenton PRINDLE-SHELRAKE (Department of Geological Sciences, University of California, Santa Barbara)

Development of high density broadband seismic network providesnew opportunities for structure study. In this paper, we reportthe use of surface waves for structure study under the network. We report our results for TriNet, a dense seismic network inSouthern California,and report our new results on the three-dimensionalS-wave velocity structure that was constructedfrom Rayleigh and Love wave phase velocity data.Two station method was used for the phase velocity measurement, usingspectral fitting technique through perturbation of S-wave velocitystructure, specifically developed for this project.The total number of paths are about 5500 for Rayleigh wavesand 2000 for Love waves.We have taken into account some finite frequency effects in our analysis.The S-wave velocity maps show some large-scale features that aremuch more distinct than previous tomographic resultsin Southern California.There are some notable features when considering large-scale tectonics inthis region;first, there is a clearseismic velocity contrast between the Pacific plate and the North Americanplate.The North American plate side is systematically slower thanthe Pacific plate side and this velocity contrast extends at least down to the depthof about 60 km. There is no question that this contrast exceeds the Moho.In the northern part, this contrast in the upper mantle is fairlyvertical (abrupt) and is almost exactly under the San Andreas Fault. In the southern part, the contrastis under the Elsinore and the San Jacinto Fault area, somewhatwest of the San Andreas Fault.Secondly, fast velocity under the transverse range is much more pronouncedin the western part of the transverse range, rather than the part thatthe Pacific plate and the North American plate directly collide. A common interpretation of downgoing tongue, originallyproposed by Humphreys et al., may require some modificationin order to understand this feature.There is also anotherdistinct fast velocity anomaly under the northern end of the Peninsular Rangetoward south. This fast velocity anomaly appears to be almost as largeas the one under the Transverse Ranges.Thirdly, under the Eastern California Shear Zone,there are distinct slow velocity anomalies,suggesting higher temperature andlower viscosityin the lower crust.

SS03/07A/A02-002   0915

THREE-DIMENSIONAL FAULT ZONE STRUCTURE AND EARTHQUAKE LOCATIONS AT PARKFIELD, CALIFORNIA

Clifford H. THURBER[1], Steven ROECKER[2], Peter MALIN[3], William ELLSWORTH[4] ([1]Department of Geology and Geophysics, University of Wisconsin-Madison, [2]Rensselaer Polytechnic Institute, [3]Duke University, [4]U.S. Geological Survey)

Arrival-time data from about 650 local earthquakes and numerous shots are inverted for earthquake locations and 3-dimensional Vp and Vp/Vs structure of the San Andreas fault (SAF) zone near Parkfield, CA. Included are data from a temporary array of surface seismic stations installed around the SAFOD site as well as from a vertical array of geophones installed in the 2-km-deep San Andreas Fault Observatory at Depth (SAFOD) Pilot Hole, drilled in summer 2002. The primary features of the velocity models are generally consistent with those from previous local earthquake tomography studies, but with much finer detail. The P-wave structure is dominated by the velocity contrast across the SAF, with the southwest side about 20-25% faster than the northeast side. A low-Vp zone adjacent to the fault trace penetrates to a depth of as much as 9 km. Nearly all the earthquakes occur almost directly beneath the surface trace of the SAF, although to the southeast of the Pilot Hole the fault appears to step southwestward at depth. Regions of anomalously high Vp/Vs (> 2.0) are found at shallow depths along and northeast of the SAF. These high-Vp/Vs anomalies can be associated with low-resistivity features in a magnetotelluric model that is interpreted to represent fluid-saturated zones. We locate a magnitude 1.9 earthquake at a depth of 2.7 km below the surface with an epicenter within about 50 m of the surface fault trace that is a potential target event for drilling of the main SAFOD hole. Tests using ˝virtual earthquakes˝ (borehole receiver gathers of picks for surface shots) indicate that our event locations near the borehole are accurate to about 50 m in both the horizontal and vertical directions.

SS03/07A/A02-003   0930

SEISMIC VELOCITY STRUCTURE IN THE MARGIN OF THE SOUTHWESTERN JAPAN SEA OFF TOTTORI BY OCEAN BOTTOM SEISMOGRAPHIC OBSERVATION

Takeshi SATO[1], Seiichi MIURA[2], Gou FUJIE[2], Koichiro OBANA[2], Aki ITO[2], Dong-Hyo KANG[3], Shuichi KODAIRA[2], Kiyoshi SUYEHIRO[1], Yoshiyuki KANEDA[2], Takaya IWASAKI[4], Team Shikoku 2001 ([1]Deep Sea Research Department, JAMSTEC, [2]IFREE, JAMSTEC, [3]KIGAM, [4]ERI, Univ. of Tokyo)

Deep seismic structure model across a subduction zone including the island arc and back-arc basin enables us to infer the geometry of the subducting plate, the deep structure in the seismogenic zone and the formation process of the island arc in the southwestern Japan arc, from an integrated wide-angle seismic survey in 1999, it is imaged that a subducting seamount is colliding with the arc and that it may have controlled the rupture process of the 1946 Nankaido earthquake (Kodaira et al., 2000). Furthermore, the geometry of the subducting Philippine Sea plate beneath Shikoku Island is also imaged (Kodaira et al., 2002; Kurashimo et al., 2002). However, there are few seismic structure surveys from the Japan island arc to the back-arc basin in the Japan Sea. The purpose of this study is to reveal detailed information about the geometry of the subducting Philippine Sea plate and the transitional structure, which is concerned with the formational process of the Japan Sea. In August to September of 2002, an integrated onshore-offshore wide-angle seismic survey was carried out from the Shikoku Island to Japan Sea off Tottori (Oki Trough, Oki Ridge and southwestern Yamato Basin). Thirty-five ocean bottom seismographs (OBSs) were deployed with a spacing of about 6 km along the offshore survey line (about 170 km). Seismic signals from an airgun array (200 liter) and ten land-explosives (50, 100, 300, and 500 kg) were recorded by OBSs. Also, multi-channel seismic (MCS) reflection data were acquired along the line. In this presentation, we report a model on the crustal structure beneath the Japan Sea off Tottori using these data. The OBSs recorded signals from an airgun array and a part of land-explosives with high signal-to-noise ratio in the entire offshore survey line. On OBSs record sections, first arrivals with a velocity of about 8.0 km/s appear greater than 75 km. The result shows that the sedimentary layer in the southwestern Yamato Basin consists of

three layers, with velocities 1.6 km/s, 2.1 km/s and 2.4 km/s. The thickness of the sedimentary layer is about 1 km in the southwestern Yamato Basin. This sedimentary layer is interpreted as marine sediments from lower Miocene to Quaternary (Leg 127 Shipboard Scientific Party, 1990). The thickness of the crust beneath the southwestern Yamato Basin can be estimated about 12-14 km from the preliminary analysis. It is supposed that Moho deepens towards the southwestern Japan island arc.

SS03/07A/A02-004   0945

SEISMICITY, TOMOGRAPHY AND ACTIVE TECTONICS IN CENTRAL TAIWAN

Francis T. WU[1], Harley M. BENZ[2], Chien-Hsin CHANG[3], Y-h-Min WU[3] ([1]Department of Geological Sciences, State University of New York, [2]USGS, [3]CWB, Taiwan)

The background seismicity in central Taiwan between 23°N and 24.5°N had been relatively low before 1999, but the occurrence of the September 20, 1999, Chi-Chi earthquake changed the scene. Within the first ten days after the Chi-Chi mainshock more than 8000 aftershocks were recorded. These and 20,000+ later events in the area have been located by the CWB network since then. As a response to orogenic stresses these crustal earthquakes, their location and focal mechanism, reveal the response of the crust to the stresses, possibly the dislocation surfaces, and perhaps the state of the crustal materials, brittle or ductile. For these purposes precise location of the background seismicity and the aftershocks is the most important task to be performed. The Double difference method, aiming at removing both the source- and receiver-side bias, has been shown to be effective in refining locations (Waldhauser and Ellsworth, 2000). Using the catalog arrival times of P and S waves and the event locations as input, we relocated all M >2.0 events from 1993 through 2001 with this method. The spatial patterns of the relocated events appear to be much better organized than those from the HYPO71 output; diffused hypocenters coalesce into narrow belts and seismic and aseismic areas more sharply defined. The Chi-Chi aftershock data also allow us to tomographically image the same region in greater detail. In combination with focal mechanisms from the Broadband Array for Taiwan Seismology (BATS) (Kao, 2002) we can decipher a consistent orogenic process that include the upwelling of the middle crust, the down-thrusting of the lower crust as well as pervasive thrust faulting in the upper crust of western Central Taiwan.

SS03/07A/A02-005   1030

SHEAR VELOCITY STRUCTURE IN THE AEGEAN AREA OBTAINED BY INVERSION OF RAYLEIGH WAVES

Eleni E. KARAGIANNI[1], C.B. PAPAZACHOS[1], D.G. PANAGIOTOPOULOS[1], P. SUHADOLC[2], A. VUAN[3], G.F. PANZA[4] ([1]Geophysical Laboratory, Aristotle University of Thessaloniki, Greece, [2]Department of Earth Sciences, University of Trieste, Italy, [3]Centro Ricerche Sismologiche, Intituto Nazionale di Oceanografia e di Geofisica Sperimentale, Trieste, Italy, [4]The Abdus Salam International Centre for Theoretical Physics, SAND Group, Trieste, Italy)

The main target of the present study is to derive a 3D tomographic image of the shear-wave velocity structure of the crust-uppermost mantle in the Aegean area using the groupvelocities of Rayleigh wave fundamental mode. The database consists of 185 regional earthquakes recorded at broad-band stations that were installed for a period of six months in the Aegean area within the framework of a large-scale experiment. For each epicenter-station ray path an averaged group velocity has been determined using the method of frequency time analysis (FTAN) and the data are used in order to determine the local group velocities for different periods over the area covered by the seismic ray paths. Taking into account the resolution of the local group velocities, a grid of 0.5 degreewas adopted for the Aegean area and a local dispersion curve was defined for each grid point. More than 80 local dispersion curves were finally inverted using a non-linear inversion approach, deriving the corresponding 1D shear-velocity models. The interpolation of these models results in a 3D S-wave tomographic image of the crust anduppermost mantle in the broader Aegean area. In the Southern Aegean Sea, as well as in a part of the Central Aegean Sea a thin crust of approximately 20-22 km is observed, whereas the remaining Aegean Sea area exhibits a crustal thickness less than 28-30km. On the contrary, a crustal thickness of 40-46 km is observed in western Greece along the Hellenides mountain range, whereas in the eastern continental Greecethe crust has a typical thickness of about 30-34 km. Strong lateral variations of the shear-wave velocities are found throughout the Aegean area. For shallow depths ($<$10 km) low S-wave velocities are observed in the sedimentarybasins of the North Aegean Sea, of the gulf of Thermaikos and western Greece. At depths ranging from 10 to 20 km low S-wave velocities are mainly found in western Greece under Peloponnesus as well as in Rhodes. In the Southern Aegean Sea very low S-wave velocities (3.6-4.0 km/sec) are observed at depths of about 30-40 km just belowthe Moho discontinuity, while in the rest of the inner Aegean Sea and the continental Greece the uppermost mantle is characterized by velocities around 4.3-4.4 km/sec. Thislow-velocity zone in the Southern Aegean Sea can be associated with the presence of a partially melt mantle wedge in the Southern Aegean subduction zone in agreement with previous studies.

SS03/07A/A02-006   1045

LOW-FOLD SEISMIC REFLECTION IMAGE OF THE OUTER ZONE, SW JAPAN

Hiroshi SATO[1], Tanio ITO[2], Takaya IWASAKI[1], Naoshi HIRATA[1], Steven HARDER[3], Kate MILLER[3], Masazumi ONISHI[4], Yoshiyuki KANEDA[5] ([1]Earthquake Research Institute, The University of Tokyo, Tokyo 113-0032, Japan, [2]Dept. Earth Sci., Chiba Univ., Chiba, 263-8522 Japan, [3]Dept. Geological Sciences, Univ. Texas El Paso, El Paso, TX 79968-0555 USA, [4]Japex Geoscience Institute Inc., Tokyo, 112-0012 Japan, [5]Japan Marine Science and Technology Center, Natsushima 2-15, Yokosuka, 237-0061, Japan)

The outer zone of SW Japan is a classical example of accretionary complex. Deep seismic reflection profiling by low-fold reflection method, were carried out along three seismic lines in the outer zone of SW Japan; MTL 1999, Shitara 2001 and Shikoku 2002. Many seismic profiles of the toe potion of subducting system have been published, however, the internal structure of the backstop is not fully understood. To obtained detailed seismic image of the outer zone of SW Japan is important to assess the risk of large mega-thrust earthquake such as Nankai earthquake of 1946 (M 8.0) and also for understanding processes of continental growth. This experiment was performed as a part of a larger scale seismic experiment of island arc transect conducted by the Japan Marine Science and Technology Center and Joint Japanese University teams. The low-fold seismic reflection profiling was carried out using explosive sources (30 AE500 kg) . The receiver intervals were 50 to 120 m. The length of seismic lines is 12 km in MTL 98, 27 km in Shitara 2001 and 110 km in Shikoku 2002. Recording system used were CDP-cable system and Texan recorders. The geologic structure of outer zone of SW Japan shows strong similarity along the trench parallel direction. Based on the three seismic sections, the detailed crustal structure of outer zone of SW Japan were synthesized. The upper surface of the subducting Philippine Sea Plate are clearly imaged by flow-fold seismic reflection profiles. In the fore arc side of central Japan and Shikoku, the northward (back-arc side) dipping reflectors in the upper crust are dominated, interpreted as deeper extension of geologic boundaries of the accretionary complex. The outstanding feature is the existence of trench-ward dipping reflector in the

lower crust and above-mentioned northward dipping reflectors are converged to the trench-ward dipping reflector forming wedge-thrust structures. This crustal structure demonstrated by reflection pattern suggests that the main part of the accretioanry material is injected into the mid-crust of the overlying plate associated with wedge-thrusting since the late Cretaceous.

SS03/07A/A02-007   1100

CRUSTAL SECTION ACROSS THE HIDAKA COLLISION ZONE, HOKKAIDO, JAPAN, AS INFERRED FROM SEISMIC REFRACTION/REFLECTION PROFILING

Takaya IWASAKI, Research Group of HOKKAIDO TRANSECT (Earthquake Research Insttitute, the University of Tokyo)

The Hidaka collision zone, central part of the Hokkaido Island, Japan, is known as an ongoing collision zone between Kuril Forearc(KA) and the Northeast Japan Arc (NJA) since middle Miocene. A multidisciplinary project of Hokkaido Transect in 1998-2000 revealed various scale structural heterogeneity across this collision zone by seismic refraction/reflection profiling and very dense earthquake observation. A 227-km long refraction profile was undertaken to determine the whole crustal structure from NJA to KA. A series of seismic reflection lines, whose total length is 138 km, were concentrated in the central part of the refraction line to get a clear image of crustal deformation associated with the collision. The data obtained elucidated a complicated collision structure. In the eastern part of the profile, KA is covered with 0.3-4km thick highly deformed sedimentary layer, beneath which two eastward dipping reflectors are imaged in a depth range of 10-20 km, probably representing obducting middle or lower curst of KA. Actually its outcropped part has a relatively higher velocity and Vp/Vs than those of the surrounding part. Beneath these reflectors, another flat and westward dipping reflectors are situated at 25 and 25-27 km depths respectively. The obtained layer geometry forms wedge-like (crocodile) patterns, probably expressing that the crust of KA is delaminated into two or three segments beneath the Hidaka Mountains. The western part of the profile (NJA), which belongs to the fold-and-thrust belt of the collision zone, is characterized by a very thick (more than 5-10 km) sedimentary package including two or more velocity reversals. Beneath this package, the crystalline crust of NJA is traced with a slight eastward dip down to 20-25 km. The crustal image obtained is much complicated as compared with that in the southernmost part of the collision zone, where the crust of KA is delaminated into to segments forming a single wedge structure, indicating a significant regional difference in style of crustal deformation.

SS03/07A/A02-008   1115

CRUSTAL STRUCTURE AROUND THE NORTHERN PART OF THE ITOIGAWA-SHIZUOKA TECTONIC LINE (ISTL), CENTRAL JAPAN, FROM REFRACTION/WIDE-ANGLE REFLECTION DATA

Tetsuya TAKEDA, Takaya IWASAKI, Hiroshi SATO, Shin'ichi SAKAI, Takashi IIDAKA (Earthquake Research Institute, University of Tokyo)

The Itoigawa-Shizuoka Tectonic Line (ISTL) is a major structural boundary and one of the most active faults, which divides SW and NE Japan. To reveal the crustal structure around northern part of ISTL is important for better understanding of the development of Japanese islands and estimation of strong ground motion produced from deeper extension of ISTL active fault system. To reveal the crustal structure around the northern part of ISTL, the refraction/wide-angle reflection data from three seismic lines obtained in 1967-1991 were re-analyzed with adding a new seismic data carried out in Itoshizu 2002. The three dimensional feature of velocity structure of upper crust around northern part of ISTL is clearly demonstrated. Some reflectors located in the middle to lower crust were obtained by wide-angle reflection data. From a wide view, crustal structure is different between the eastern and western sides of ISTL. It is said geologically that ISTL played an important role in the Miocene opening of the Sea of Japan and bending of Japan island arc. It means that the difference of reflector distribution bounded by ISTL indicates the possibility of horizontal movement in the opening of the Sea of Japan or crustal deformation undergone by igneous activity. In the velocity structure, the layer with 4km/sec is found to have 4km depth in the western side of ISTL. It is consistent with the fact that sedimentary rocks since Miocene is thickly distributed in this area. ISTL is found to be east-dipping from gravity and reflection data. To take account that ISTL is lifting up in the east as a reverse fault at present, we think that ISTL was formed as east-dipping normal fault in mid-Miocene during initial phases and has been reactivated as a reverse fault owing to subsequent crustal shortening. Additionally, by analyzing travel times of micro-earthquakes below ISTL, we expect to obtain more detailed structure of the eastern side of ISTL, which is deformed strongly owing to crustal shortening.

SS03/07A/A02-009   1130

REFRACTION AND WIDE-ANGLE REFLECTION STUDIES BY USE OF MCS AND OBS IN MARMARA SEA, TURKEY (SEISMARMARA 2001)

Hideki SHIMAMURA[1], Anne BÉCEL[2], Jean-Claude LÉPINE[2], Tuncay TAYMAZ[3], Yoshio MURAI[1], Philippe CHARVIS[4], Yuichi NISIMURA[1], Mireille LAIGLE[2], Alfred HIRN[2], Serdar OZALAYBEY[5] ([1]ISV, Hokkaido University, [2]Sismologie Expérimentale, Institut de Physique du Globe de Paris, [3]ITU, Istanbul Technical University, Maslak, Istanbul, [4]IRD-Géosciences Azur, Villefranche, [5]TUBITAK-MAM, Marmara Research Center, Gebze)

The SEISMARMARA survey 2001 was carried out as a multi-method approach of seismic structure and activity, in the frame of the Turkish-French-Japan cooperation on the Marmara Sea, Turkey, after the 1999 Izmit earthquake occurrence on the North Anatolian Fault. MCS survey was made by the French N/O Nadir of Ifremer, and 37 OBS of ISV Hokka?Eo were deployed, in order to record airgun shots and natural earthquakes, and recovered by a Turkish vessel MTA-Sismik 1. We present the first results of modelling proceeds on the two longest, East-West lines of Leg 1. . In order to assess effects of off-line propagation in this region of strong 3D structural variation, North-South cross-lines of the MCS grid can be drawn in as well. Another E-W line along the southern rim of the Trough is modelled, tying in with the Marmara-1 borehole that reached the Upper Cretaceous limestone, the basement to the evolution of the Trough. The 8100 cu. in. capacity of the 12-airgun array of N/O Nadir, and its shooting in single-bubble mode, provided for signal strength, low frequency with relatively short signal duration. The main regional line, striking E-W along the axis of the North Marmara Through, is 120 km long and has 13 OBS. The corresponding MCS stack with 15-fold coverage, obtained at normal incidence with the 4.5 km long 360-channels digital streamer, is used for structural constraints for the shallow part in the refraction modelling. The airgun array was also shot at 20 seconds interval to give a higher, 45-fold coverage for MCS meant at finer resolution, and the comparison with velocity control given by the streamer recording in shallow water will be used too Basement topography and structure of the lower crust is sampled and modelled by these data sets. In the case of the line on the rim of the Trough, the velocity model can be compared to the MCS which gives a reasonable structural image through the whole crust. On the axial line, new critical constraints are provided on the basement and deep structure across the succession of basins and highs, where the normal-incidence MCS image is complicated by strong multiples

and off-line echoes. These results will contribute to the analysis of the structural evolution of the Marmara trough with respect to the North Anatolian Fault, and bring constraints on the depth limits of the seismogenic layer involved in earthquakes to occur in the Marmara sea part of the North Anatolian Fault. Derivation of the velocity structure provides a frame necessary to refine earthquake location procedures in general. More specifically, the analysis of shot data on the 3 components of OBSs, give prime control on the local P and S velocity heterogeneity under the OBS which will be used as input in a detailed study of the local earthquakes also recorded on these same OBSs.

SS03/07A/A02-010   1145

REFLECTION OF THE CHANGES OF THE PHYSICAL PROPERTIES OF THE EARTH CRUST IN THE BULK-SOUND AND SHEAR WAVE-SPEED VARIATIONS

Alexei GORBATOV[1], Brian L.N. KENNETT[2] ([1]Pacific Region Data Centre, IFREE, JAMSTEC, [2]Research School of Earth Sciences, ANU, Australia.)

Examination of bulk-sound and shear wave speed variations at the active boundaries of the tectonic plates may provide valuable information about the compositional or physical properties of the Earth material and mechanic of collision processes because this information can be directly compared with the results of laboratory experiments. Detailed global and regional tomographic inversions have been carried out using the arrival times for P and S wave ray paths with comparable coverage. The inversion was performed directly for bulk-sound and shear wave speed variations in the Earth´s mantle. Global inversion was performed using cells with sides of 2 by 2 degrees while for the regional tomography cells from 0.5 to 2 degrees were chosen. A simulatanoeus inversion was undertaken for both the regional and global structures to minimize the influence of surrounding structures on the regional image. The nonlinearity of the inverse problem was taken into account by using a scheme which iteratively applied three-dimensional ray tracing and linearized inversion. Detailed regional tomography of the Western Pacific region reveals prominent correlation between bulk-sound and shear wave speed balance within the slab and the average age of the subducting lithosphere in the uppermost mantle of the subduction zones. Plates older than ~90Ma are more prominent on the shear wave speed images while younger slabs are more distinctive in the bulk-sound wave speed. The 90Ma break would correlate with the subduction of the full thickness of oceanic lithosphere and hence a mature thermal regime at the trench. However this correlation can be strongly altered by thermo-mechanical process affecting the subducting slab such as in the case of back-spreading and consequent roll back of the trench. This effect is well illustrated by subduction of old slab below Tonga-Kermadec. Roll-back of the trench is high below Tonga diminishing toward the Kermadec subduction zone. Subducted slab below Tonga is dominated by bulk-sound anomalies while the shear wavespeed becomes more prominent below Kermadec. This behavior of bulk-sound and shear wave speed anomalies detected on the regional tomography of Western Pacific is consistent with the images on the global scale for the Pacific region in general. However, the most peculiar feature in this area is the strong anticorrelation between bulk-sound and shear wavespeed anomalies for the San Andreas Fault system where the zone of strongly positive bulk-sound anomalies correspond to negative shear wave speed perturbations. Observed anticorrelation may be explained by strong fracturation and partial water saturation of this zone.

SS03/07A/A02-011   1200

MELT GENERATING PROCESSES AT THE SOUTHEARN EAST PACIFIC RISE REVEALED BY THE ELECTRICAL CONDUCTIVITY STRUCTURE

Kiyoshi BABA[1], Alan D. CHAVE[2], Rob L. EVANS[2], Greg HIRTH[2], Randall L. MACKIE[3] ([1]Institute for Frontier Research on Earth Evolution, Japan Marine Science and Technology Center, [2]Woods Hole Oceanographic Institution, [3]GSY-USA, Inc.)

Electrical conductivity structure models allow us to discuss mantle dynamics based on melt and water distribution beneath a mid-ocean ridge system. The electromagnetic data from the Mantle ELectromagnetic and Tomography (MELT) experiment have been re-inverted for two survey lines. The major line crosses the East Pacific Rise at 17°S where the ridge segment is thick suggesting an abundant magma supply. The northern line crosses at 15°45´S to the north of an overlapping spreading center on a magma-starved ridge segment. The data are inverted for a two-dimensional anisotropic conductivity structure that incorporates correction for three-dimensional topographic effects on the magnetotelluric responses. The model space allows for different conductivity values in the along-strike, cross-strike, and vertical directions along with imposed constraints that the model be smooth and that the three conductivities be as close together as possible. The strength of these constraints is variable, and hence a range of models from isotropic to anisotropic can be explored. For the southern line, two end-member models (one isotropic and one anistropic) were obtained which yield similar RMS misfits. Both models have a major gross feature which is also seen in previous MELT inversions: an asymmetric conductivity structure with higher values to the west of the ridge axis. In addition, the anisotropic model is more conductive in the cross-strike direction to the east of the rise at depths of 60-150 km, is quite resistive above 60 km, and has a narrow, highly conductive pipe in the vertical conductivity located immediately beneath the ridge axis. First two features are well resolved required by the data. The last feature is not strongly required by the data. But some tests show that it seems to be something real. The anisotropic model is more consistent with other geophysical and laboratory data, and hence is preferred. These results suggest that melt exists over a wide region, but may be more highly concentrated and connected in the vertical at the ridge axis. The deep ($>$60 km) conductive region to the east of the ridgecrest is probably due to the preferred orientation of olivine under wet conditions. The flat resistive-to-conductive boundary at 60 km agrees well with the inferred depth of the dry solidus of olivine. These results suggest that the extraction of water from olivine due to partial melting substantially reduces mantle conductivity. The northern line data have been analyzed in the same manner as the southern line data. The resulting conductivity structure wll be compared with the structure of the southern line. The comparison may reveal along axis variation of the melt generation and transportation system.

THE SIMULATOR EARTH'S CRUST MAKE BY BASE OF THEORY COVER

Stanislav G. DOLGIKH (Dep. Atmosphere and Ocean)

Today, be many simulator of Earth, but all are not describe processes, which run at crust, mantle and surface marking. We developed simulator earth's crust base by theory cover. This is multi-ply spherical shell with real parameters of earth's crust/ Shell laded outside and internal forces. The model is flexible, that is why we may take into many processes which run on Earth (variation of pressure, natural oscillations of resrvoirs? Wave processes of ocean and so on). When we will take into a count all this processes, we can count a stress of shell. We will get exertions, deformations, transference, so whale shell, and so this is values at a specific dot. In the upshot, we receive physical consistent dynamic model multi-ply shell. If we will take into distributed load (atmospheric and mantle pressure), we will can get significance elastic parameters earth's crust and significance fundamental frequencies

its lays. Later, we will examine extra periodic load (vibrations and waves of ocean, atmosphere and lithosphere), impulsive force (earthquake, convulsion of nature, explosions and so on). In that case, we will get elastic parameters, all vibrations and its amplitudes of earth's crust.

ORIGIN OF GREAT DEPTHS OF THE PALAU AND YAP TRENCHES

Kazuo KOBAYASHI (Prof. emeritus, Univ. of Tokyo)

Water depths of the Palau and Yap Trenches situated in the southeastern margin of the Philippine Sea plate appear to be extraordinary in a frame of general rule that the trench is deeper as the rates of convergence are larger and ages of subducted plate are older. Water depths of these Trenches amount to 8000 m in spite of their extremely small subduction rates (0 to 6 mm/yr at Palau and 6 to 12 mm/yr at Yap) and ages of subducting Caroline plate younger than 30 Ma. Morphology of these trenches does not seem to be a relic of past tectonic activity, because repeated submersible observation verified that their landward walls are frequently collapsed to provide plenty of slumped debris toward the axial bottom of the trenches. Observed topographic and seismic profiles show thin cover of sediment, implying that slumped materials have been subducted. Abnormally close proximity of the Palau and Yap Islands to the trench axis cannot be explained by collisional mechanism, as the trench in front of the islands is so deep. A simple quantitative model of viscous mantle beneath the horizontally moving plate accompanied with short subducted slabs is postulated to elucidate the present configuration of these trenches and arcs on the basis of the GPS data indicating fast horizontal motion of the Philippine Sea plate together with the Palau and Yap trench-arc systems. Reasonable values of downward frictional stress on the frontal surface of the subducted slab derived from the hydrodynamic model may be able to explain a new type of tectonic erosion, while appreciable amount of upward (buoyant) pressure acting at the edge of the overlying plate appears to be sufficient to hold the island arcs (Palau and Yap).

SS03/07P/A02-002　　　　　　　　　　1415

VOLCANIC-HYDROTHERMAL ACTIVITIES AND SEGMENTATION STRUCTURE OF THE AXIAL RIFT IN THE WESTERN OKINAWA TROUGH

Takeshi MATSUMOTO[1], Mamoru NAKAMURA[2], Jean-Claude SIBUET[3], Chao-Shing LEE[4], Ryuichi SHINJO[2], YK00-06 Shientific Party ([1]Marine Science Department, Nippon Marine Enterprises, Ltd., [2]University of the Ryukyus, [3]IFREMER, [4]National Taiwan Ocean University, [5]Japan Marine Science and Technology Center)

The western Okinawa Trough which is characterised by an active rifting of the eastern margin of the Asian continent and is one of the key areas to describe the tectonics and dynamics of the initiation and evolution of backarc basins was surveyed by R/V YOKOSUKA and DSV SHINKAI6500 in July-August 2000 (Lequios Cruise: Cruise ID = YK00-06 Leg2) after the succession of the previous l´Atalante cruise in 1996 in the SPOT Area (east of Taiwan). The major objectives of the cruise were: (i) formation and evolution of the central rift axes, (ii) volcanic and hydrothermal activity in the trough area, and (iii) regional tectonics and dynamics of the study area. Two active hydrothermal sites were newly located through 10 dives in the study area. One is located in the SPOT area and the other on the axial zone of the Okinawa Trough off the northern coast of Miyako Island. Maximum temperature was 170C in the former case and 150C in the latter case. Both sites are characterised by active chimneys associated with sulphide deposits and chemosynthetic communities. Regional topography surveyed by the SEABEAM2112 system shows the clear segmentation of the central graben. The eastern hydrothermal site is located on the junction of the two different segment ends. The SPOT hydrothermal site is also located at the segment end of the Yonaguni Graben. On the other hand, there were no signs of recent active magmatism or hydrothermalism in the segment centres. The central knoll on the Yaeyama Graben was precisely surveyed by both SEABEAM2112 bathymetry and seafloor observation by SHINKAI6500. The result showed that the knoll is rather old althouth it has an E-W trending rift valley on the summit. The seafloor surrounding the knoll deforms as if an elastic bending due to the load of the knoll is taking place. It suggests that no more active rifting is taking place at the axis of the segment of the graben. Back-arc rifting seems to be immature and it is now in the stage of cessation of rifting and only arc volcanism with a couple of focussed magma chamber at the segment boundaries is predominant. A couple of remarkably meandering channels were located at the westernmost part of the study area on both sides of the trough axis. The most remarkable is located in the SPOT area. These are apparently developed on levees derived from sediment supply from the continent and/or the Ryukyu island arc. The active erosion along the channel is not taking place any more according to the result by a previous ROV cruise in 2000. This might be due to mass wasting along the pre-existing levees towards the trough axis due to a local seafloor current which took place when the area was shallow.

SS03/07P/A02-003　　　　　　　　　　1430

NUMERICAL SIMULATION OF TECTONIC DEFORMATION WITH DISCRETE ELEMENT METHOD (DEM)

Yasuhiro YAMADA[1], Atsushi TANAKA[2], Toshi MATSUOKA[2] ([1]JAPEX Research Center, [2]Kyoto University)

Sandbox modelling, a physical modelling technique using granular materials, can simulate the brittle behaviour of the upper crust, thus has been successfully applied to a number of geologic structures in various scales. The sandbox models can also be done as numerical simulation (digital modelling) with the Discrete Element Method (DEM), because the DEM also approximates that the geologic body as an assembly of particles. As an example of DEM simulation of large-scale tectonic deformation, the collision process of the Indian sub-continent to the Eurasian Plate was examined. We employed the geologic model by Tapponier et al. (1976) and compared our simulation results with their analogue experiments. The overall geometry and progressive development of major fault systems associated with secondary basins showed similarity between the two techniques. The fragmentation of continental blocks, a characteristic feature in the analogue models, was also reproduced by the simulation. The secondary fault systems seen in the experiments were, however, unclear in the simulation, because the size of the particles may be too large. In addition, we have extracted information of each particle, such as velocity vectors and stress fields. These can be compared with GPS and in-situ stress data, which express present deformation of the eastern Asian region. Despite the technique needs further refinements in the input parameters, application of the DEM to geologic deformations can be a powerful tool to simulate fault related structures and to analyse the deformation quantitatively.

CRUSTAL GROWTH AND RECYCLING: AN OVERVIEW OF RESULTS FROM THE CANADIAN LITHOPROBE PROGRAM

Ron M. CLOWES (LITHOPROBE and Dept. of Earth and Ocean Sciences, University of British Columbia)

The North American continent has grown through the progressive accretion, dispersal and re-aggregation of continental lithosphere in tectonic cycles spanning Archean to present times. The preserved crustal record in Canada ranges from the 4025 Ma Acasta gneisses in the northwestern Slave Province of the Northwest Territories to present oceanic crustal formation at the Juan de Fuca ridge off the west coast. The basic building blocks of the continent include: significant Middle to Late Archean crust preserved in supracrustal belts and plutonic rocks of the core of the continent (the Superior, Nain, Slave, Rae, Hearne and Wyoming cratons); the Paleoproterozoic orogenic belts that permanently welded the Archean cratons together (Trans-Hudson, New Quebec, Torngat, Wopmay, Thelon-Taltson, and Penokean); and the Mesoproterozoic Grenville, Paleozoic Applachian and Mesozoic-Cenozoic Cordilleran orogenies that border the Paleoproterozoic nucleus of the continent. In the southern part of the amalgamated continent, Laurentia, the Keweenawan rift system almost split the continent about 1100 Ma. LITHOPROBE transects have focused scientific studies on almost all of these primary features of Canada's landmass and offshore continental margins. From the new geophysical, geological and geochemical data generated by these studies, enhanced understanding of these features has been achieved. By contrasting and comparing results among the many transects, new understanding of the processes associated with crustal growth, recycling and preservation also is being derived. Accreted oceanic terranes or collages of such terranes, comprising ocean floor basalts, oceanic arcs and back arc assemblages, are fundamental building blocks in the development and growth of evolving orogens. Throughout the LITHOPROBE studies, examples abound among transects and regions ranging from Archean to Cenozoic. Subduction zones can be responsible for crustal growth through subduction underplating. Two prominent examples of such underplating have been demonstrated in western North America. Collisional processes associated with orogenic development contribute to crustal growth, but the direct evidence for the sutures resulting from the collisions is often very cryptic, as they have been metamorphosed, reworked by later deformation and intruded by marginal (Andean-type) arc magmas. These magmas, derived from subducting slabs and the mantle wedges above them, form the impressive and extensive granitoid batholiths occupying the hinterlands of orogens. LITHOPROBE studies encompass a number of these. Magmatic underplating is a known process for continental growth, but one that often is difficult to identify and establish, as the effects of the process are usually manifest in the lower crust or upper mantle. High seismic velocities, as inferred from refraction experiments and generally poor seismic reflectivity, can indicate such underplating. Lithospheric delamination and transfer of lower crust and uppermost mantle to deeper parts of the mantle is one primary process by which crustal material is recycled into the mantle. Vast volumes of crustal material are recycled and reorganized through erosion and subsequent sedimentary deposition. LITHOPROBE has some outstanding examples of these processes.

SS03/07P/A02-005　　　　　　　　　　1500

BIFROST PROJECT: FENNOSCANDIAN CRUSTAL STRAIN RATE FROM CONTINUOUS GPS OBSERVATIONS AND SEISMICITY

Hans G. SCHERNECK[1], Ruediger HAAS[1], Ronald ARVIDSSON[2], Sten BERGSTRAND[1], Jan JOHANSSON[1], Glenn A. MILNE[3] ([1]Chalmers University of Technology, [2]Uppsala University, [3]University of Durham)

Postglacial rebound appears to be the dominant component of recent crustal motionin the Fennoscandian shield. From 3000 daily solutions of GPS data in theBIFROST network we have derived a map of strain rates in the interior of theshield with values typically below 10 nano/year. Examination of the strainfield by means of a glacial isostatic adjustment model suggests that elastic extension is the dominant style of deformation in the lithosphere, controlled by horizontal displacement. Shear exists between a major axis oriented in NW-SE and a minor strain axis, that are both extending. The major and minorstrain rates stand in a proportion of 2:1.We also find that vertical motion and bending have little direct importance for strain. The NW-SE orientation of the horizontal strain rate fieldremains fairly constant within the formerly glaciated area. Superposition of a plate tectonic stress field on the stress change inferred from our study suggests that the fault stability margin for primary faults is increasing.

SS03/07P/A02-006　　　　　　　　　　1515

SOME PECULIARITIES OF THE STRUCTURE OF THE EARTH'S CRUST IN THE CENTRAL ASIA (A REGIONAL PROFILE-ROMITAN-DARBAZATAOU IS TAKEN AS AN EXAMPLE)

Oleg Petrovich MORDVINTSEV (Uzbekgeophysic)

Seismic profile Romitan-Darbazataou is located within the three main region's structures: Karakum-Tadjik massif, Southern Tien Shan geocyncline folded system, Kuramin-Fergan intermediate massif. The section is characterized by the presence of a large number of seismic boundaries of different extent. The inclination boundaries are located principally in the upper part of the Earth's crust, about 20km deep. A system of rupture disturbances covering practically the entire geological section has been revealed. The results of physico-geological modelling showed that the Earth's crusts structure has blocky-stratified character. One of the main features of the section is its heterogeneous basement:in Karakum-Tadjik massif. Its depth is 5-7km; in Southern Tien Shan- from 1km up to the surface; in Kuramin-Fergan intermediate massif-from 2 to 3km. The Earth's crusts deep horisons structure along the section is blocky, with intensive breaking, and differentiation of physical properties of rocks.The unique feature of the section is the presence of strong unconsolidated zones. The Moho transition zone, which thickness is 2,5 to 6km, is distinguished above the Mohorovichich section. Its density varies from 3,05 to 3,1 g/cm[3]. The upper mantle density increases towards Southern Tien Shan (from 3,23 to 3,26 g/cm[3]). The revealed rupture disturbances often reach Moho. Very often rupture disturbances form, very complicated systems, in which various tectonic structures ore found.

A POSSIBLE DEEP, LONG-TERM SOURCE FOR WATER IN THE NORTHERN SAN ANDREAS FAULT SYSTEM AND OTHER BROAD PLATE-BOUNDARY ZONES: A GHOST OF SUBDUCTION PAST?

Stephen Homer KIRBY[1], Kelin WANG[2], Thomas M. BROCHER[1] ([1]U.S. Geological Survey, [2]Geological Survey of Canada)

Previous work suggests that forearc mantle is serpentinized in warm-slab subduction systems because the subducting slab cools the forearc and because water from slab

dehydration of the mafic crust is released into the forearc mantle above it at depths of 40 to 80 km (See review in Kirby, Nature News & Views, 2000). Recent work by others shows that the Moho is not expressed in the Cascadia forearc of western Oregon and Wshington and suggests this is because the mantle is partially or completely serpentinized by this mechanism. Rick Blakely of the USGS has also identified a margin-parallel magnetic anomaly in Oregon at the expected position of the serpentinized forearc mantle. Magnetite, an accessory mineral in serpentinites, may be the source of this magnetic anomaly. The continental margin of northern and central California south of the Mendocino triple junction is made up of former forearc crust and mantle of the Cascadia system. We propose here that this relic serpentinized wedge in the former forearc mantle has relevance to the San Andreas fault (SAF) system to the south because this initially cold, serpentinized region is not stable after the Mendocino triple junction moves north and subduction ceases. This broad (about 100 km) wedge-shaped region should heat up by conduction and hence is expected to dehydrate over time and release water into the overlying crust. Numerical thermo-petrologic simulation of this water evolution suggests that it takes from 10 Ma to greater than 20 Ma for water source to be exhausted. The distance between the center of this unstable mantle serpentinite wedge and the fossil trench or deformation front is determined by the distance at which slab depth is about 60 km. Allowing for the breadth of this region and for the possibility of variations in original slab dip (12 to 25°), the wedge should be at a distance ranging from 50 to 250 km from the former trench. This range brackets with the range of distances between the base of the California continental slope (posited as the former position of the trench) and the traces of faults of the SAF system, suggesting that the San Andreas fault system may be positioned above this dehydrating mantle wedge. The total volume of water stored in the wedge is huge, estimated to be 0.6 to 1.2 Gm3/m of margin. Its release over time provides a deep source of water, possibly reducing the effective normal stress across this fault system, reducing the resistance to frictional sliding and, in turn, explaining the inferred low regional stresses and the lack of a heat-flow anomaly. The dehydrating wedge may also be a deep source region for serpentinite slivers that occur along the SAF System. The effectiveness of this water source in elevating pore pressures to near lithstatic (and hence lowering effective pressure and sliding resistance) depends on the distribution of permeabilities of the crust above the wedge relative to the water release rate.

EARTHQUAKE ACTIVITY IN THE MESSINA STRAIT AREA, SOUTH ITALY, POSSIBLE INTERPRETATIONS AND HAZARD IMPLICATIONS

Giancarlo NERI[1], Graziella BARBERI[2], Barbara ORECCHIO[1] ([1]Department of Earth Sciences, University of Messina, [2]Istituto Nazionale di Geofisica e Vulcanologia, Sezione di Catania, Italy)

We analyzed the recent (1978-2001) crustal seismicity of northeastern Sicily and surroundings using the local and national instrumental seismic network data. The analysis allowed us to determine the space distribution of seismogenic stress and seismic strain in the study area and to obtain information on the faults active during the investigation period. The results evidence a clear transition from an extensional regime in the Messina Strait area (maximum magnitude 7 in historical times) to a north-south compressional regime to the west (max. magnitude 6), in agreement with the regional geodynamic model assuming that north-south slow plate convergence coexists with subduction slab southeastward rollback in the study area. Based on the joint examination of (i) recent seismicity, (ii) earthquake activity in historical times and (iii) information from geology and paleoseismology taken from the literature, we evaluate the possible evolution of earthquake activity in the study area, including the possibility that the temporal cluster of strong earthquakes of 1783, 1905 and 1908 has not yet ended, in opposition to what has been recently suggested by other investigators.

LITHOSPHERIC DELAMINATION ANDBUOYANCY-DRIVEN DEFORMATIONS IN THECENTRAL APENNINES, ITALY

Abdelkrim AOUDIA[1], Alik T. ISMAIL-ZADEH[2], Giuliano F. PANZA[1] ([1]SAND Group, Abdus Salam International Centre for Theoretical Physics & Dept. of Earth Sciences, University of Trieste, Trieste - Italy, [2]Geophysikalisches Institut, Universität Karlsruhe, Karlsruhe, Germany & International Institute of Earthquake Prediction Theory and Mathematical Geophysics, Russian Academy of Sciences, Moscow, Russia)

The coexistence of two end-member deformation mechanisms (contraction and extension) has been recognized in different geodynamic frameworks worldwide, but well exposed at the surface and active nowadays only in the Italian Peninsula. Several models, invoking mainly external forces, have been formulated to explain the complex pattern of the regional deformations, observed by geophysical and geological studies. These models appeal to interactions along plate margins or at the base of the lithosphere such as back-arc extension or shear traction from mantle flow or to subduction processes such as slab pull, roll back or retreat and detachment or break-off. We combine seismic data from Central Italy to image the crust and upper mantle and to understand the complex lithospheric deformations observed in the Apennines. The well-developed low velocity zone in the uppermost mantle between the crust and the underlying continental lithosphere supports the lithospheric delamination beneath the peninsula and provides a new background for the genesis and age of recent magmatism. A finite-element modeling of deformation and tectonic stress in the imaged lithosphere shows that buoyancy solely can explain the enigmatic juxtaposed crustal contraction and extension and the unusual intermediate-depth seismicity distribution.

PORE PRESSURE RELATED SEISMICITY IN CRITICAL EARTH - A MODELOF THE PHENOMENON AND APPROACHES TO THE MEDIUM CHARACTERIZATION

Serge A. SHAPIRO, Susanne RENTSCH, Elmar ROTHERT, Miltiadis PAROTIDIS (Fachrichtung Geophysik, Freie Universitaet Berlin)

Processes of pore fluid substitutions or borehole fluid injections influence stress statesof rocks. Such processes are typical for developments of hydrocarbon or geothermicreservoirs. Recently they obtained also a central place in different scientific programslike carbon sequestrations or investigations of large scale fault systems. The observationof microseismicity occurring during such borehole fluid injections or extractions has alarge potential in understanding of physics of the seismogenic process as well as inobtaining detailed information about reservoirs at locations as far as several kilometersfrom boreholes. We show that principal spatio-temporal signatures of fluid injectioninduced microseismicity are very often in agreement with the hypothesis that thetriggering of this seismicity is caused by a diffusive process of the pore pressurerelaxation in porous (or fractured), fluid saturated rocks. If this hypothesis is correct,then there should be two physical parameters which control the spatio-temporaldistribution of the induced seismicity. One parameter characterizes the criticality of the geological medium. It can be represented as a statistic field of critical porouspressure necessary for initiating sliding on preexisting cracks. The second parameter is the hydraulic diffusivity. Theoretically and numerically we show which signatures of the spatio-temporal distributions of the seismic events must be expected and

how they are related to the critical porous pressure and to the diffusivity. We show also that thesesignatures are observed in many cases of artificial and natural pore pressureperturbations in rocks. In such situation our model of the induced seismicity providesa possibility to infer an information about hydraulic properties of rocks and theircriticality using passive seismic monitoring data. Estimates of hydraulic diffusivitytensors on large spatial scales as well as imaging of its distributions in space can be of significant importance for industrial applications and understanding of physicalproperties of geological structures. From the other hand, a characterization and anestimation of the medium criticality open new possibilities in studies of seismogenicprocesses. We results of applications of our approach to microseismic data obtained indifferent cristalline and sedimentary rocks.

SS03/07P/A02-011   1700
RHEOLOGY OF THE LITHOSPHERE INFERRED FROM POSTSEISMIC DEFORMATION IN NORTHERN JAPAN AND WESTERN US

Takuya NISHIMURA[1], Wayne THATCHER[2] ([1]Geographical Survey Institute, [2]U.S. Geological Survey)

We have modeled the postseismic deformation of the 1959 M_w7.3 Hebgen Lake earthquake which is a normal faulting event in the northern Basin and Range province, USA and the 1993 M_w7.8 Hokkaido-Nansei-Oki earthquake which is a thrust faulting event in northern Japan. The broad uplift in the epicentral area of the Hebgen Lake earthquake is measured by leveling. The transient deformation decaying after the 1993 Hokkaido-Nansei-Oki earthquake is observed by a continuous GPS network. To fit the observed deformation we calculate synthetic postseismic deformation using the relaxation response of a gravitational viscoelastic Earth to the earthquake. For a model with an elastic plate overlying a viscoelastic half-space (hereafter called two-layer model), we estimated the elastic thickness and the half-space viscosity. In the case of the Hebgen Lake earthquake, we find the elastic thickness is 38 ± 8 km. The half-space viscosity is estimated at $4\times10^{18\pm0.5}$ Pa s. The observed broad uplift cannot be explained by a physically plausible model of afterslip on and below the coseismic fault. However, local deformation across the coseismic surface rupture requires shallow afterslip reaching the surface. In the case of the Hokkaido-Nansei-Oki earthquake, both an afterslip model and a viscoelastic relaxation model can explain the observed horizontal deformation. The observed broad uplift ~100km east of the coseismic fault requires viscoelastic relaxation model. However, leveling data on Okushiri Island which is located just east of the coseismic fault show tilt of the island toward NNE and favor the afterslip model. When we assume the two-layer model, the elastic thickness is 32 ± 12km with the half-space viscosity of $2.5\times10^{18\pm0.4}$Pa s for the data set excluding Okushiri Island. We need a dual model of viscoelastic relaxation and afterslip to explain all the data. The elastic thickness in both regions is approximately equal to the local crustal thickness. We applied more complex viscoelastic structures with weak lower crust and/or strong uppermost mantle to fit the observed deformation from bothe earthquakes. However the residual misfit is not significantly smaller than the simple two-layer model. The postseismic deformation induced by the estimated viscoelastic structure decays exponentially with a time constant of a few decades. Because of coupling between the elastic layer and the viscoelastic substrate this relaxation time is significantly longer than the Maxwell relaxation time of the viscous half-space itself (a few years). Our result suggests the importance of postseismic relaxation in interpreting high precision GPS velocities. For example, our model results suggest that postseismic transient velocities from both the 1993 Hokkaido-Nansei-Oki and the 1983 M_w7.7 Japan Sea earthquakes in northern Japan are currently as large as 8 mm/yr.

SS03/07P/A02-012   1715
STRAIN ACCUMULATION MODEL ON THE ATOTUGAWA FAULT SYSTEM, AN INLAND ACTIVE FAULT SYSTEM, LOCATED IN THE HIGH-STRAIN RATE ZONE, CENTRAL JAPAN

Kazuro HIRAHARA, Mamoru HYODO, Yoichi OOI (Graduate Shool of Environmental Studies, Nagoya University)

Recently, GEONET, a nation-wide GPS network by GSI, Japan, has revealed a high-strain rate zone, NKTZ, in central Japan (Sagiya et al.,2000). Around the Atotsugawa fault located within this zone, we set a dense GPS network. In addition to GEONET observations, our 5-year-observations elucidate the detailed strain accumulation on this fault system. Here, based on numerical simulations using GeoFEM (Iizuka et al., 2002), a parallel FEM code, we present a quantitative model of strain accumulation both regionally in the 100-km-wide NKTZ and locally in the Atotsugawa fault system within NKTZ. In a regional scale, the strain accumulation in NKTZ is basically explained by the model proposed by Iio et al. (2002). They propose that the eastward subduction of the Pacific plate (PAC) beneath the Japan trench, which is located far from NKTZ, produces the strain accumulation in NKTZ beneath which the crust is weakened by water content in the lower crust. Hyodo and Hirahara (2003) execute numerical simulations in models consisting of the 30km-thick elastic crust, the viscoelastic upper mantle wedge and the subducting elastic PAC, and find another requirement to explain the observed small strain rate in the Kanto region and to produce a long-rang-transfer of the effect of the subducting PAC. That is, there are no large interplate earthquakes during a period enough longer than the relaxation time of the whole viscoelastic system. Long-term plate coupling of PAC without any rebounds due to interplate earthquakes produces the relaxed viscoelastic upper mantle and the uniformly strained elastic crust. Actually, there are almost no large interplate earthquakes off the Kanto, while the Tohoku region has smaller recurrence interval of earthquakes and the large strain is accumulated in the ocean side. We seek the local thickness of elastic crust beneath NKTZ so as to produce the observed strain rate in this zone, and obtain the thickness of 5 km. In this zone, there are micro-earthquakes and the cut-off depth is around 15 km. Thus 5km-thick elastic crust is not realistic. Recent explosion seismology suggests a possibility of low-velocity zone beneath NKTZ, and the elastic crust in NKTZ will have smaller rigidity than in the surroundings. If this is the case, using the 15km-thick weak elastic crust, we can produce the observed strain concentration. In a local scale close to NKTZ, the rate direction normal to the strike of the Atotsugawa fault is changing within a width of 100km, and the rate change is symmetric against the center. The fault-parallel rate change with a width of 40 km, however, is not symmetric, but the larger change appears in the northern size where the Atotsugawa fault system exists. And our dense GPS observations show the fault-parallel rate change occurs across the Atotsugawa fault and across the northern Ushikubi one, which seem to be creep. These features of observed rate field are explained by the model consisting of lateral structural changes within NKTZ, the weak region of the Atotsugawa fault system.

SS03/07P/A02-013   1730
CRUSTAL STRUCTURE BENEATH THE YINGGEHAI BASIN AND ADJACENT HAINAN ISLAND, AND ITS TECTONIC IMPLICATION

Shimin WU[1], Xuelin QIU[1], Gangping ZENG[2], Di ZHOU[1], Kanyua XIA[1], Saijun LIU[2], Sanyu YE[3] ([1]South China Sea Institute of Oceanology, CAS, [2]State Seismological Bureau, Hainan Branch, Haikou 570203, China, [3]GEOMAR, Research Center for Marine Geosciences, Kiel D-24148, Germany)

In the autumn of 1996, a joint team of Sino-German scientists carried out a wide-angle seismic experiment in the northwestern part of South China Sea.Two NE-SW trending wide-angle seismic profiles were surveyed across the Chinese side of the Yinggehai basin (YGHB) with Ocean-Bottom-Hydrophones (OBH) and piggyback recorded by onshore stations on Hainan Island. Detailed velocity-depth models were obtained through traveltime modeling and partially constrained by amplitude calculations. The more than 10 km thick Tertiary sedimentary infill within the YGHB can be divided in three layers with distinct velocity-depth distribution. The top layer has overall a high velocity gradient with 3.8~4.1 km/s at its bottom, consistent with advancing compaction and diagenesis. Its thickness increases gently towards the basin center, reaching 4.5 km along the southern profile. The middle layer is characterized in its most part as a pronounced low velocity zone with velocity as low as 3.0 km/s. Its thickness increases from 3.0 km to over 4.5 km from NE towards SW. The velocity at the top of the lower layer is estimated about 4.5 km/s. Despite of strong energy source used (4x12L airgun array) no seismic signals, particularly not even the highly anticipated reflection from the basement, can be observed from deeper crustal level within the basin. Towards the NE the basin is bounded sharply by a clear and deep basement fault, the so called Fault No. 1. The bordering continental crust has a constant thickness of 28 km and shows no sign for crustal thinning towards the basin center, giving clear evidence that the eastern basin boundary, Fault No. 1, is a strike-slip fault. The crustal structure obtained in this study favors clearly the hypothesis that the YGHB is a narrow pull-apart basin formed by the sinistral strike-slip faulting of the Red River Fault Zone.

POST SEISMIC CRUSTAL DEFORMATION IN KUTCH REGION OF GUJARAT, INDIA

Chappidi D. REDDY[1], Kaoru MIYASHSITA[2], Teruyuki KATO[3] ([1]Indian Institute of Geomagnetism, [2]Department of Environmental Science, Ibaraki University, Mito 310-0903, Japan, [3]Earthquake Research Institute, The University of Tokyo, Tokyo 113-0032, Japan)

The Bhuj Earthquake occurred on January 26, 2001 was a major intra-plate event in the Indian sub-continental plate. In order to estimate the distribution of strain accumulation rate and understand the physics of the earthquake processes, five GPS campaigns were made in Kutch region of Gujarat during 2001-2002. The data collected at 14 sites were organized into 24 hours segments covering a UTC day and were processed using the GAMIT/GLOBK software to estimate the velocity vectors at each site in the ITRF2000 reference frame. The velocity field clearly portrays anomalous velocity at two sites *viz.* Dhamdkapir and Ratanpar which fall either side of the epicentral track region. Compressional strain of about 0.1 micro-strain/yr has been estimated in the vicinity of the source region. Finite element modeling is attempted to facilitate interpretation of neo-tectonic movements that can generate repeated earthquakes. The results are discussed in conjunction with the geo-tectonics of the study region and other geophysical studies such as GDS, MAGSAT, magnetic etc.

P-P REFLECTIVITY MAPPING OF THE PLATE BOUNDARY IN THE JAPAN TRENCH SUBDUCTION ZONE

Gou FUJIE[1], Junzo KASAHARA[2], Ryota HINO[3], Masanao SHINOHARA[2], Kiyoshi SUYEHIRO[1] ([1]JAMSTEC, [2]Earthquake Research Institute, University of Tokyo, [3]Faculty of Science, Tohoku University)

In the Japan Trench area, many destructive earthquakes, as well asmicroearthquakes, have occurred. The Pacific plate is subductingbeneath the Japanese island arc at this Trench. It is considered thatmost of the earthquakes are caused by plate subductionmotion. Therefore, it is extremely important to clearly characterizethe physical state of the plate boundary in order to understand theseismic activity in this region.In this subduction zone, there is a low seismic region with 100km-longand 30km-wide south of latitude 39 degrees N, and we conducted seismicrefraction and reflection experiments there. We discovered aninteresting feature that implies that the P-P reflectivity of theplate boundary correlates with seismicity: we observed distinct largeamplitude reflected waves from the aseismic plate boundary locatedaround 13km deep from the oceanic surface. This intense reflectionimplies the presence of low velocity materials along the subductionplate boundary.There is another low seismic region to the north of latitude 39degrees N. This low seismic region is narrower than the one to thesouth. We placed a dense Ocean Bottom Seismometers(OBSs) with twodimensional array: Twenty-seven OBSs were deployed in a 10km x 40kmarea with 5km spacing. This dense OBS network enabled us to image thereflection phase from the plate boundary in 2D space.First, we analyzed the P-wave velocity structure with a traveltimeinversion method using traveltimes of the first arrival and severalreflection phases. Then, we computed reflected waves from the plateboundary and determined the reflection points and traveltimes. Usingthis information, we created a Move-out Seismic Record Section toimage the plate boundary reflection waves using a method like theNormal Move Out(NMO) method often used in conventional MCS analysis.In this presentation, we will show the seismic record sections of theplate boundary. Although the reflections from the northern low seismicregion are not as intense as the southern region, we observe clearreflection phases from the northern low seismic region in thesesections. This result also implies seismicity correlates well withcharacteristics of the plate boundary.

LOW INTENSITY CHARACTERISTIC OF PLATE-BOUNDARY S-S REFLECTIONS WITHIN A REGION OF INTENSE P-P REFLECTIONS AND LOW SEISMICITY ALONG THE JAPAN TRENCH SUBDUCTION ZONE

Kimihiro MOCHIZUKI[1], Junzo KASAHARA[1], Mikako NAKAMURA[1], Ryota HINO[2], Minoru NISHINO[2], Tomoaki YAMADA[1], Asako KUWANO[2], Toshinori SATO[3], Yasuyuki NAKAMURA[4], Peyman Poor MOGHADDAM[1], Toshihiko KANAZAWA[1] ([1]Earthquake Research Institute, University of Tokyo, [2]Tohoku University, [3]Chiba University, [4]Ocean Research Institute, University of Tokyo)

It has been pointed out that space distribution of microearthquakes along the forearc slope of the Japan Trench in northeast Japan is not uniform. A location map of the microearthquake epicenters determined by Tohoku University show clustered seismically active zones, which are oriented perpendicular to the trench axis. One of the clear seismic-aseismic boundaries

can be identified in latitude 39 degrees north. A seismic velocity structure survey was conducted in 1996 with one experiment line running over the boundary and parallel to the trench axis. A P-wave velocity structure model was obtained by travel-time inversion for the line (Fujie, 1999). A quite good anticorrelation between plate-boundary-reflected P-P wave intensity and seismicity was found: strong plate-boundary P-P reflected waves were observed in a region where seismicity is quite low, and vice versa (Fujie et al., 2002). They discussed that a thin layer with its thickness up to a few hundred meters and with its velocity of 3~4 km/s could explain the intense reflections at the plate boundary. Results of finite-difference waveform calculations support this estimation (Moghaddam, 2002). Understanding the characteristics of S-S reflection at the plate boundary as well as S-wave velocity structure in addition to those of P-wave would greatly help put better constraints on the physical properties along the plate boundaries. We carried out a seismic experiment in 2001 in the same region as the 1996 experiment. Thirty-nine OBSs were deployed along seven survey lines within a 30 km x 50 km region. One of the lines (Line 3) closely overlaps a part of the 1996 NS-line. Airguns were used as artificial seismic sources, and their total chamber volume was ~57 liters. Absolute orientations of OBS horizontal-component seismometers were determined using horizontal-component waveforms of the direct water-wave arrivals of the airgun shootings (Yoneshima, 2001). Substantial P-to-S conversion at the base of the sediment layer was observed by most of the OBSs. S-wave velocity structure in terms of Vp/Vs ratio along Line 3 was determined as regarding that P-wave velocity structure along Line 3 does not change much from that of Fujie et al. (2002). Velocity structure of the sedimentary layers above the acoustic basement was determined by observing the tau-p mapping of the OBS horizontal-component waveforms. The Vp/Vs ratios within the sediment layers were obtained as 5.2 and 2.3 from top to bottom. The Vp/Vs ratios within the deeper structure were assumed to be 1.8 to 1.74 as Vp varies from 4.5 km/s to 8.0 km/s. The computed travel times with respect to this Vs structure explain well the observed travel times of P-S-converted refraction arrivals. Expected arrival times of the plate-boundary S-S reflected waves were calculated with respect to the obtained Vs structure. Such intense amplitude as observed for the plate-boundary P-P reflections were not identified for the S-S reflections. Although the plate-boundary P-P intense reflections could be explained by putting a thin low-velocity layer, some additional features for S-S reflections along the plate boundary may be required, such as very low Q values for S-wave propagation.

SS03/08A/D-003   Poster   0830-162

SPATIAL RELATION BETWEEN INTERPLATE SEISMIC ACTIVITY AND THE SEISMIC REFLECTOR BENEATH THE EAST OFF BOSO PENINSULA INDICATED BY P-S CONVERTED WAVES

Hisanori KIMURA, Keiji KASAHARA (National Research Institute for Earth Science and Disaster Prevention, Japan)

For the purpose of damage mitigation in Tokyo metropolitan region of Japan, it is important to study the characteristics of large interplate earthquakes that occur, repeatedly, around Kanto district. Almost all events occurring in the shallower part of this region have thrust type focal mechanism solution with P-axis corresponding to the direction of relative plate motion between Phillipine Sea plate (PHS) and Kanto district. And thus, these events are thought to be interplate seismic activity caused by the PHS plate subducting from Sagami trough and extending beneath Kanto district.In the east off Boso peninsula, a few multi-channel seismic surveys were conducted by NIED and JNOC(Japan National Oil Corporation). By analyzing those data (Kimura and Kasahara, 1997; Kimura and Kasahara, 2001) major reflectors have been found dipping northward along the survey line coincident to the plate boundary between PHS plate and landward plate. The candidates of these reflectors may be the upper and lower boundary of oceanic crust of PHS plate or rocked sediment layer which is observed east off Izu peninsula. The profile near Sagami trough support the possibility of latter and these reflectors are observed, too. In Kujukuri region, two-way travel time of the reflected wave is about 6.0sec and 7.5sec suggesting that depth of the reflector is about 14 and 18 km which is close to earthquake hypocenters. To evaluate detailed spatial relation of major reflectors and earthquakes, we investigate the waveform data of micro-earthquakes around Kujukuri region, in detail. As a result, a remarkable phase is detected before S wave. The radial component is dominant, for this phase, and its travel time difference from that of P is slightly dependent on the change of depth and hypocentral distance. Comparing the observed travel time and calculated one we conclude that this phase corresponds to P-S converted wave at the discontinuity just above hypocenters. This interpretation is also supported by the radial component dominating of this phase. Travel time difference between S-wave and this phase is 0.2-0.3 sec for shallowest event indicating that earthquakes occur just beneath the discontinuity and do not occur exactly at the major discontinuity. From the past research such as Sekiguchi, 2000 indicates that depth of earthquakes is close to that of lower reflector. Supposing that the discontinuity corresponds to lower reflector in consideration of travel time difference between S and this phase, at the depth of upper reflector, reflected waves are excited but converted waves are not. As a cause of upper reflector, the water layer which was generated there due to plate motion could be suggested in this case. Anyway, the fact that earthquakes occur just close to discontinuity would be important to study the characteristics of interplate seismicity.

DEEP SEISMIC PROFILING OF METROPOLITAN AREAS IN JAPAN FOR STRONG GROUND MOTION EVALUATION: PRELIMINARY RESULTS OF BOSO 2002 AND SAGAMI 2003

Hiroshi SATO[1], Naoshi HIRATA[1], Tanio ITO[2], Takaya IWASAKI[1], Kazuki KOKETSU[1], Keiji KASAHARA[3], Kiyoshi ITO[4], Takeshi IKAWA[5], David OKAYA[6], Steven HARDER[7], Kate MILLER[7] ([1]Earthquake Research Institute, The University of Tokyo, [2]Dept. Earth Sci., Chiba Univ., Chiba, 263-8522 Japan, [3]National Res. Inst. for Earth Science and Disaster Prevention, 3-1,Tennodai,Tsukuba 305, Japan, [4]Disaster Prevention Res. Inst. Kyoto Univ., Gokasho, Uji, Kyoto 611-0011, Japan, [5]Japex Geoscience Institute Inc., Tokyo, 112-0012 Japan, [6]Dept EarthSciences Univ. of Southern California, Los Angeles, CA 90089-0740, USA, [7]Dept. Geological Sciences, Univ. Texas El Paso, El Paso, TX 79968-0555 USA)

The metropolitan areas in Japan, such as Tokyo and Osaka, have high risk of seismic hazards. For example, if present Tokyo is attacked by the great earthquake same as Kanto earthquake of 1923 (M7.9), the most pessimistic estimation of the economic loss reaches to 1 - 3 trillion USD. The Headquarters for Earthquake Research Promotion Japan determined to start the new program targeting the reduction of seismic hazard in the metropolitan areas. As a part of this program, the project to reveal the regional characterization of metropolitan area, including the deep seismic profiling, began from 2002 as a basically five yearsÅEproject. A long-term goal is to produce a map of reliable estimations of strong ground motion. This requires accurate determination of: source, propagation path, ground motion response. This projects focuses on identification and geometry of: source faults, subducting plates and mega-thrust faults, crustal structure, seismogenic zone, sedimentary basins, 3D velocity properties. Reconstruction of source fault and velocity models allow for more realistic 3D EQ wave simulations. All of these information will be synthesized and provided to communities involved in probablistic hazards analysis, risk assessment and societal response. In the fiscal year of 2002, deep seismic profiling was carried out along the

Boso peninsula and along the Sagami bay. The target of the experiments was the imaging of upper surface of the Philippine Sea plate and its spray faults. In Boso 2002, the image of the toe portion of subduction mega thrust was obtained using four vibroseis trucks and deeper portion were obtained by low-fold reflection profiling method using total 2,500 channels and 12 explosive sources. The obtained image clearly demonstrates the upper surface of the Philippine Sea plate. In the Sagami 2003, due to the severe traffic noise the air-gun signals were used as seismic source and signals were recorded by land geophones.

OCEAN BOTTOM SEISMOGRAPHIC OBSERVATION IN THE SOURCE REGION OF THE 1952 OFF TOKACHI EARTHQUAKE (M8.2)

Tetsuo TAKANAMI[1], Yoshio MURAI[1], Ryou HONDA[1], Yuichi NISHIMURA[1], Kei KATSUMATA[1], Hideki SHIMAMURA[1], Seizo HASEGAWA[2], Hisanaga UKI[2] ([1]Institute of Seismology and Volcanology, Graduate School of Science, Hokkaido University, Kita 10, Nishi 8, Kita-ku, Sapporo 060-0810 JAPAN, [2]Hokkaido National Fisheries Research Institute, Fisheries Research Agency, Katsurakoi 116, Kushiro 085-0802 JAPAN)

We have deployed 10 pop-up type OBSs (Ocean Bottom Seismographs) in the source region of the 1952 off Tokachi earthquake (M8.2), off Hokkaido Island in the period from July 20 to September 20, 2002. The observation area is located 50 ~ 100km landward of the southern Kuril trench where Pacific plate is subducted toward Hokkaido Island. The current seismic activity in this area is extremely low in contrast with the adjacent trench areas. On the other hand, the seismic activity off Urakawa and the Hidaka mountains, which are close to the source region of the 1952 off Tokachi earthquake, are always high owing to the collision between the Kuril and the northeast Japan arcs. Namely, it is well explained by the westward lateral migration of the Kuril forearc sliver. In order to reveal the relationship between the collision structure and the earthquake occurrence, in summer of 1999 we have deployed 21 pop-up type OBSs off Urakawa and off Tokachi of Hokkaido Island and we have merged the earthquake data with the catalog data from the dense seismological network, which was composed of 87 land stations consisting of 41 permanent and 46 temporary stations, has been maintained by the study group of seismologists in Japan Universities for the period from August 1999 to July 2001. The tomographic inversion by using a vast of picking data from the combined earthquake catalog demonstrates the clear image suggesting a delaminating structure, which is probably produced by a collision (Murai et al., 2002*). However, the tomographic inversion failed to image the structure for the source region in the 1952 off Tokchi toward the southern Kuril trench because of a sparse earthquakes occurring in the source region. By adding these picking data to the newly data from the seismological network of the present 10 OBSs, the current seismicity would be cleared and a three dimensional structure would be imaged precisely. This quiescent area off Tokachi has been recently paid attention from the viewpoint of earthquake prediction. *Murai et al., 2002, Delamination structure imaged in the source area of the 1982 Urakawa-Oki earthquake, Program & Abstract, 74th Annual Meeting, Eastern Section of Seismological Society of America, 25.

HOLOCENE SLIP RATE OF THE SUBDUCTION ZONE MEGA-THRUSTS ALONG THE SAGAMI TROUGH, CENTRAL JAPAN, ANALYZING THE HEIGHT DISTRIBUTION AND AGES OF EMERGED SHORELINE INDICATORS

Masanobu SHISHIKURA, Shinji TODA (Active Fault Research Center, Geological Survey of Japan/AIST)

Two major historical earthquakes of the 1703 Genroku Kanto Earthquake (M 8.2) and the 1923 Taisho Kanto Earthquake (M 7.9) occurred along the Sagami Trough where the Philippine Sea Plate subducts beneath the North American Plate. As a result of the coseismic crustal movements associated with these earthquakes and repeated pre-historical earthquakes, Holocene emerged shoreline indicators (e.g. emerged wave-cut bench, fossilized mollusk etc.) are observed on about 10 or more levels along the coast of the Miura Peninsula and the Boso Peninsula. The height distributions of the lower two levels of them in the Miura Peninsula indicate more than 1 m of uplift during both the 1703 and 1923 events. In the Boso Peninsula, although geodetic data show up to 2 m of uplift during the 1923 event, historical documents and the height distribution of emerged shoreline indicators suggest that the coseismic crustal movement during the 1703 event had resulted steep northward tilting accompanied with uplift of more than 5 m in the southernmost area and subsidence of ca. 1 m in the central area. According to above results, it is inferred that the fault source model of the 1703 event is composed of dual fault system (fault A and B). The fault A is same as the model of the 1923 event which has already been estimated by Ando (1974). The uplift of the Miura Peninsula (both the 1703 and 1923 events) and the Boso Peninsula (only the 1923 event) can be explained by about 6.7 m slip of the fault A. The fault B is low angle dip thrust located off the southeast of the Boso Peninsula. The unique 1703 coseismic crustal movement in the Boso Peninsula has been derived from about 12 m slip of the fault B. [14]C ages of the older paleo-shorelines above two recent levels indicate that the characteristic earthquake generated from the fault A has been occurred repeatedly about every 400 years. One of several events is the 1703 type earthquake accompanied with the slip of fault B. Recurrence interval of this type is 2000-2700 years. Therefore, the slip rate of these faults are estimated to be 16.8 mm/year (fault A) and 5.2 mm/year (fault B) respectively. These value are greatly different each other and smaller than the back-slip rate (30 mm/year) estimated from GPS data (Sagiya, 1998).

HIGH INTRA-SLAB SEISMIC ACTIVITY AND HORIZONTAL SLAB TEARING IN SOUTHWESTERN KURIL TRENCH

Hiroaki TAKAHASHI[1], Kenji HIRATA[2], Isao HASHIMOTO[3], Masayoshi ICHIYANAGI[1] ([1]Institute of Seismology and Volcanology, Hokkaido University, [2]Deep Sea Research Department, Japan Marine Science and Technology Center, [3]Sapporo District Meteorological Observatory, Japan Meteorological Agency)

We have tried to re-examine the intra-slab earthquakes occurred in southwestern Kuril trench. This region has of recent experienced several intra-slab events in the subducting Pacific plate; 1994 Sikotan (M8.2, Dep=60km), 1993 Kushiro (M7.8, Dep=100km), 1987 Hidaka (M7.0, Dep=120km), 1981 Hidaka (M7.1), and 1978 Kunashiri (M7.7, Dep=120km). From the end of 1970's, Hokkaido University (HU) began to establish a seismic network in Hokkaido Island with more than 50 stations. In 1997, HU and Sapporo District Meteorological Observatory of Japan Meteorological Agency (SD) started the real-time waveform exchange to determine the hypocenter since 1997. Our advanced seismological networks have revealed the aftershock distribution of these intra-slab events. From the hypocenter catalogue, we can identify the following features associated with the intra-slab earthquakes. Most of them have occurred on the horizontal fault plane in the subducting Pacific plate. Aftershocks clearly indicate the occurrence of faulting on the plane from the lower plane of the double seismic zone to the upper ones. Though the slab unbending is one of the candidates for the cause of these intra-slab events, some events had been occurred in the

trenchward region as the 1994 Sikotan event. We think there are some other factors that control the occurrence of the intra-slab events in this region. It should also be noted that precise aftershock distribution is one of the powerful data used to clarify the property of the intra-slab events. In the beginning, we have tried to determine the precise hypocenters of aftershocks of the 1994 Sikotan event, for which the fault plane is still in debate, by combining the seismological data of both HU and SD. The result will give the clue to understand the intra-slab events that have occurred in this region.

THREE DIMENSIONAL SEISMIC STRUCTURE BENEATH THE SOUTHERNMOST PART OF THE HIDAKA COLLISION ZONE, HOKKAIDO, JAPAN

Noriko TSUMURA[1], Shinsuke KIKUCHI[1], Katsuko SUZUKI[2], Takuro KAZUKA[1], Tanio ITO[1], Takeshi KOZAWA[3], Takeshi IKAWA[3] ([1]Faculty of Science, Chiba University, [2]Schlumberger LTD, Japan, [3]JGI Inc. , Japan)

To better understand the three dimensional structure benath the arc-arc collision and subduction system, we carried out seismic reflection survey in the Hidaka collision zone(HCZ), which is located at the junction of the northeastern Japan arc and the Kuril arc, in 2000. In this area, previous study revealed that a delamination-wedge structure has been formed due to the arc-arc collision[Tsumura et al.(1999),Ito et al.(2000)] and the Pacific plate is subducting beneath the two arcs. However the detailed geometry of the arcs and the subducting plate remained unclear. In this survey, two lines were set in the direction of NW-SE(parallel to the subduction trend of the Pacific plate), and NE-SW(parallel to the arc-arc collision). Since CMP is distributed in the 2-dimensional area because of the spatial relationship between shots and receivers, we set several stacking lines in the subduction-parallel and in the arc-arc collision-parallel directions and made quasi-three dimensional seismic profiles. From the profiles, we detected some distinctive reflections in the deeper part. Northwest-dipping strong reflections are seen around the two way travel time (TWT) 13-14s(group 1). These events are considered to be associated with the subducting Pacific plate, and it can be seen only in the shallower part of the subduction. Tentative reflections(gruop 2) exist just above the TWT where no significant reflections are seen although the upper boundary of the subducting plate is expected to pass thruogh. These events are weak but have the similar character with those which are seen in the delaminated Kuril arc crust. The other events(group 3) are also seen in the TWT 7-10s. The origin of the reflectors(group 2 and 3) is not clear. From the geologic studies on the eastern part of the Hidaka metamorphic zone, detachment faults are expected to exist in the depths of 12-15kn. And group 3 events might show the shear zone associated with suchdetachment faults in the intruded arc´s crust. On the contrary, group 2 events exsist in the extension part of the descending delaminated lower crust of the Kuril arc. It means the descending delaminated crust meets the subducting plate and lay on it beneath the survey lines.

CYCLIC RIDGE SUBDUCTION AT AN INTER-SEISMIC LOCKED ZONE IN THE EASTERN NANKAI TROUGH DEDUCED FROM ONSHORE - OFFSHORE WIDE-ANGLE SEISMIC SURVEY

Shuichi KODAIRA[1], Ayako NAKANISHI[1], Jin-Oh PARK[1], Aki ITO[1], Tetsuro TSURU[1], Yoshiyuki KANEDA[1], Takashi IIDAKA[2], Eiji KURASHIMO[2], Hiroshi SATO[2], Takaya IWASAKI[2] ([1]IFREE, Japan Marine Science and Technology Center, [2]Earthquake Research Institute, University of Tokyo)

There are significant variations in the size, especially lateral extensions, of the co-seismic rupture zones and inter-seismic locked zones. Obvious factors controlling them are still unsolved questions, even though several geophysical studies have suggested possible candidates of structural factors. In the summer of 2001 we acquired onshore — offshore integrated seismic data at the edge of the rupture zone of the 1944 Tonankai earthquake in the eastern Nankai trough. The wide-angle seismic profile is designed as total 477 km long profile, 262 km onshore and 215 km offshore. Five 500 kg and one 100 kg explosion sources were shot onshore, while 187.5 L air gun array was shot at every 100 m interval offshore. 391 land seismic stations and 70 ocean-bottom stations were recorded the seismic signal both from the land explosions and the air-gun array. Qualities of data are generally good. We can trace first arrivals from the air-gun array more than 250 km offsets. A refraction tomography is applied for the all observed first arrivals to obtained seismic velocity image. In order to obtain a seismic reflectivity image, we also applied pre-stack depth migration for the offshore data, while only NMO correction is applied for the onshore data. From the both seismic velocity and reflectivity images, we successfully obtain two trough-parallel ridge systems, i.e. cyclic ridge subduction, with thickness of 13 ~ 20 km and wavelength of 35 ~ 50 km. This remarkable feature is recognized from iso-velocity contours in the seismic velocity image and reflectors in the seismic reflectivity image, i.e., the iso-velocity contour of 4 ~ 7 km/s shows repeated broader and narrower width and the reflectors show bulges at the same positions. By comparing the location of the subducted ridge and the inter-seismic locked zone estimated by GPS data, it is recognized that the deeper subducted ridge, which is subducted beneath the back stop of the present day accretion process, is located exactly at the inter-seismic locked zone. As a conclusion, our seismic images demonstrate that the rupture during the 1944 Tonankai earthquake did not extend to the east due to strongly locking caused by the ongoing cyclic ridge subduction; i.e., this study first proves the ˝subducted seamount — strongly locking˝ hypothesis where a large scale ridge or seamount is subducted beneath a back stop in an accretion dominant subduction zone. The locked region may rupture when accumulating stress exceeds the critical strength of locking. This idea could explain why the recurrence interval of the great earthquake in the Tokai segment is longer or more obscure than the other segments. We also propose that the subducted convex shape would not produce strong coupling when the convex is located under young accretionary sediment, presumably a weaker material.

MICRO-SEISMICITY AROUND THE RUPTURE AREA OF THE 1944 TONANKAI EARTHQUAKE REVEALED BY OCEAN BOTTOM SEISMOGRAPH OBSERVATION

Koichiro OBANA, Shuichi KODAIRA, Yoshiyuki KANEDA (Institute for Frontier Research on Earth Evolution, Japan Marine Science and Technology Center)

Along the Nankai trough, southwestern Japan, the Philippine Sea plate is subducting beneath the Eurasian plate with a convergence rate of about 4 cm/year. Great interplate earthquakes caused by the subduction of the Philippine Sea plate have occurred repeatedly. Records of the great earthquakes can be seen in historical documents from the seventh century and the recurrence interval is about 100-200 years. The latest great event at the eastern Nankai Trough is the 1944 Tonankai Earthquake (Mw=8.1). On the other hand, seismicity around the rupture area of the 1944 Tonankai Earthquake is very low and hypocenters are not determined accurately by the on-land seismic network. Micro-seismicity observation is one of the ways to monitor the state of stress in the seismogenic zone. We performed a micro-seismicity observation around the rupture area of the 1944 Tonankai Earthquake. The purpose of this study is to examine the relation between the micro-seismicity, crustal stricture, and seismic rupture of the great interplate earthquake. In this

observation, we used free-fall and pop-up type ocean bottom seismographs (OBS). We deployed 26 OBSs in November 2001 and 24 OBSs were retrieved in February 2002. Clock drifts during the observation period were corrected for 13 OBSs. Arrival times of P- and S-waves at these corrected OBSs are used for the hypocenter determination. Since the other 13 OBSs could not be corrected for their clock drifts, only the time differences between P- and S-wave arrivals were used for the hypocenter determination. Earthquakes are located using a 2-D seismic velocity structure model. This model is based on an OBS-airgun seismic survey performed in our seismicity observation area [Nakanishi et al., 2002]. Around the rupture area of the 1944 Tonankai earthquake, seismicity is locally active at the toe of the accretionary prism. Hypocenters of them are located at the seaward limit of the coseismic slip area of the 1944 Tonankai earthquake. Although the depths of these earthquakes are not constrained well, they are considered to be shallower than the subducting oceanic crust. Next OBS observation is planned to improve the accuracy of the hypocenters around the toe of the accretionary prism. On the other hand, micro-seismicity in the rupture area of the 1944 Tonankai earthquake is very low. The recent GPS survey shows a fully coupled plate interface along the Nankai Trough seismogenic zone. Analyses of the seismic and tsunami waves show a uniform distribution of the coseismic slip during the 1944 Tonankai Earthquake. These facts imply an existence of a large asperity with a uniform interplate coupling.

INTERPLATE EARTHQUAKE GENERATION IN THE NE-JAPAN AND THE IZU-BONIN REGIONS: WATER RELATED MINERAL PHYSICS

Junzo KASAHARA[1], Gou FUJIE[2], Kimihiro MOCHIZUKI[1], Mikako NAKAMURA[1], Aya KAMIMURA[3], Peyman Poor MOGHADDAM[1], Ryota HINO[4] ([1]Earthquake Research Institute, University of Tokyo, [2]Japan Marine Science and Technology Center (JAMSTEC), [3]National Research Institute for Earth Sciences and Disaster Prevention,, [4]Research Center for Prediction of Earthquakes and Volcanic Eruption, Graduate School of Science, University of Tohoku)

In order to understand the physical basis of earthquake generation along subducting plate boundaries, it is important to know the asperity distribution, the physical properties of rocks, and the presence of water and hydrous phases at the plate boundary. Three seismic experiments in the Japan Trench and the Izu-Bonin Trench were carried out between 1996 and 2001. This paper describes these results and discusses plausible materials to have physical properties obtained by the comparison between observed waveform and synthetic seismogram simulation. The former survey revealed a strong correlation between aseismic zones in the Japan Trench and the intensity of seismic reflections from the subduction plate boundary. Synthetic seismogram analysis suggested that the plate boundary causing the strong seismic reflections contains a thin (~100m thick), low velocity (VP~ 2-4km /s and/ low Vs) layer. Water, hydrous clay minerals such as smectite, and/or low-temperature serpentine in the subducting plate boundary may cause intense seismic reflections. The latter survey indicated the presence of chrysotile (low temperature phase of serpentine) at the subducting plate boundary. These materials may act as a lubricant. We propose three types of subduction zones around the Japan arc with different earthquake generation characteristics. Earthquake occurrence in the three typical subduction types may be controlled by the presence of water, clay minerals and serpentines along the subduction boundaries. Dehydration of hydrous phases introduces other conditions related to earthquake generation.

INDUCED SEISMICITY STUDIES AT GEHEYAN RESERVOIR

Yun sheng YAO, Shi Jun GO, Zhong HUANG (Institute of seismology, China seismological bureau)

At Geheyan reservoir in the Qinjian Rive, Hubei Province, China, the water-induced earthquake activity's frequentness and strength have had very good synchronous relation with reservoir's water level since 1994. The intensive areas of three main earthquakes in became on the earthquake space distributes. By the research of seismogeological environment term, induced earthquake characteristic, reservoir's water level and earthquake activity etc in reservoir area, we detect that the intensive areas of three main earthquakes have the good condition to permeate and to store the groundwater. The process of reservoir to store water lead to the variety of the particular environment condition of hydrology geology, and cause the occurrence of the area's reservoir induced earthquake. Besides some few of larger earthquakes have result to the crack or the layer glide, most of microearthquake swarm belong to the falling earthquake of the karst type.BR Before happing big induced earthquake, the earthquake activity'S frequentness and b value as well as the P wave distribute of beginning move etc, all of them show the certain earthquake precursor. BR On the whole, water-induced earthquake activity at Geheyan reservoir belongs to the preface row of small earthquake cluster. Its energy releases on time is even. The position of epicenters is not relation with main fault activity inside reservoir area, but it is relation with limestone district and stress field being made by the weight carry of reservoir water. It is the typical sensitive-rñespond type's reservoir induced earthquake in really.

POSSIBILITY OF THE SERPENTINIZED MATERIAL AT THE IZU-BONIN SUBDUCTION ZONE AROUND 31∞N BY COMPARISON BETWEEN OBSERVATION AND FDM-SIMULATION

Aya KAMIMURA[1], Junzo KASAHARA[2] ([1]National Research Institute for Earth Science and Disaster Prevention, [2]Earthquake Research Institute, University of Tokyo)

The main characteristics of the Izu-Bonin subduction zone are the presence of a chain of serpentine seamounts which is exposed at the forearc slope of trench axis, and few large earthquakes (>M7.0) at shallow depth (0-100km) in spite of many large ones at greater depth (>400km). To study the causes of these characteristics we carried out a seismic refraction-reflection study at the forearc slope of the Izu-Bonin subduction zone around 31°N using chemical explosions and airgun shots. As the results of forward and inversion modeling in the study, two velocity structures were obtained along E-W and N-S survey lines which is perpendicular to and parallel to the trench axis, respectively (Kamimura et al., 2002). The result of E-W line which was designed to transect the summit of a serpentine seamount shows a low velocity area on a subducting oceanic slab and this area connects to the serpentine seamount. The interpretation of Kamimura et al. (2002) is as follows. Dehydration of hydrated oceanic crust supplies water to the wedge mantle, and peridotites of the mantle wedge were serpentinized. The serpentinized peridotites moved on the oceanic slab and were diapiring to the serpentine seamount. The serpentine on the plate boundary might act as a lubricant and decrease seismic activity along the subduction zone, and this can explain the characteristics of seismicity in this area. We calculated synthetic seismograms using the P-wave and S-wave velocity structures (2D) of Kamimura et al. (2002) and compared those to the observed seismic records. In this presentation we will show a result of the comparison. We used the ˝E3D˝ code (2D/3D elastic finite-difference wave propagation code, developed by Dr. Shawn Larsen) for the calculation of the synthetic seismograms. Grid spacing is 30 m in x and z and 1.5 msec in time. Appropriate Q structure is assumed for the general structure. Five-Hz and 0-phase Ricker wavelet was used as

source. In this result there must be a low-Q area just below the serpentine seamount, to explain the observed seismic records. It is very important to understand where serpentinites of the seamounts came from to explain the characteristics of seismicity at the Izu-Bonin subduction zone. In this presentation we are going to explain an interpretation that serpentine moved through the plate boundary and reached just below the serpentine seamount, using an existence of the low-Q area.

CONFIGURATION OF SUBDUCTING PHILIPPINE SEA PLATE BENEATH SOUTHWEST JAPAN REVEALED FROM THE RECEIVER FUNCTION ANALYSIS

Katsuhiko SHIOMI[1], Kazushige OBARA[1], Haruo SATO[2] ([1]NIED, [2]Tohoku University)

The detailed configuration of the Philippine Sea (PHS) plate subducting beneath southwest Japan is revealed from the receiver function (RF) analysis of teleseismic waveforms. We analyze data recorded at 120 stations of the High Sensitivity Seismograph Network (Hi-net) in the Chugoku-Shikoku district, western part of Japan. More than 200 earthquakes with magnitudes 5.5 or higher and epicentral distances between 27 and 90 degrees are selected for the analysis. Considering the response characteristics of the Hi-net system and the ground surface reflection, we analyze the waveform data, which are band-pass filtered in frequency range from 0.1 to 0.6 Hz. To discuss the depth of the velocity discontinuity, the RFs, which are originally estimated as time series, are converted to depth by using the IASP91 earth model. Due to the contamination by multiple reverberations in RFs, we limit the depth of the target structure to less than 60 km in this analysis. After the direct P-phase in each RF, we find remarkable later phases, suggesting the existence of the velocity discontinuities. The high density of Hi-net stations enables us to investigate the spatial continuity of a specific later phase. The results show a clear velocity discontinuity beneath the Shikoku Island. This discontinuity subducts from the south toward the north with a low dip angle. The depth of this discontinuity is 30 km beneath southern Shikoku, 45 km beneath the Seto Inland Sea and continued down to the north at about 60 km beneath center of Chugoku district. Then, we interpret this discontinuity as the upper boundary of the high velocity layer (HVL) of the PHS plate. To investigate the relationship between the spatial distributions of the discontinuities and local seismicity beneath Shikoku region, we construct the depth contour of the upper boundary of the HVL of the PHS plate. The depth contour suggests a rather complicated feature with a few ridges. These ridges are located in the extension of sea terraces of the PHS and the most significant ridge is located around the longitude of 133°E, west of which the contours are basically directed north-south, and change to west-east in the east side of it. Local earthquakes occurred beneath the western part of this ridge are located above the HVL of the PHS plate, whereas earthquakes mainly occur within the slab mantle area in the eastern part. Although we don´t use data of local earthquakes to construct the detailed configuration of the HVL of the PHS plate, we found that the local seismicity in the study region is strongly correlated with that.

GEOMETRY OF THE UPPER SURFACE OF THE SEISMIC PHILIPPINE SEA SLAB SUBDUCTED BENEATH SOUTHWEST JAPAN

Takayuki MIYOSHI, Katsuhiko ISHIBASHI (Department of Earth and Planetary Sciences, Kobe University)

We inferred precisely the geometry of the upper surface of the seismic slab of the Philippine Sea plate (PHS) subducted beneath southwest Japan based on hypocentral distribution. Despite the importance of the slab geometry for the subduction zone seismotectonics, the shape of the PHS slab had been obscure and controversial so far. We selected well-determined hypocenters for the period since Oct. 1997 from the integrated hypocenter database prepared by the Japan Meteorological Agency. Firstly, we made depth-slice hypocenter distribution maps for every 5 km depth and drew first-trial isodepth contours of the upper surface of the PHS slab assuming that the upper boundary of slab earthquake distribution roughly coincide the slab upper surface. Then, in many areas we made vertical cross sections of hypocenter distribution in the direction of inferred dip-direction of the slab, and revised isodepth contours. The main results are as follows: (1) In the region to the east of Lake Biwa, northwestward gently-dipping PHS slab reaches around the depth of 40 km, in which the disastrous 1819 slab earthquake (Ishibashi, 1999) presumably took place. To the northeast it continues to the slab beneath the central Tokai district, but to the southwest it looks separated from the slab beneath the eastern Kii Peninsula. (2) There is double seismic zone beneath the middle part of the Kii Peninsula. The slab earthquakes in this area seem to occur in oceanic crust and slab mantle. (3) The slab here is torn into two parts, with the southwestern part being underlain beneath the northeastern part. (4) In the west part of the Kii Peninsula no slab earthquake occurs deeper than 45 km, whereas just in this area a remarkable shallow crustal swarm earthquake activity exists. (5) Beneath Shikoku the slab is being subducted with gentle dip angle and forms a broad ridge. The slab looks continuous from Shikoku to Kyushu at least in the depth range shallower than 45 km, although the seismicity is low beneath the west part of Shikoku. Recently the PHS slab geometry, mainly for the shallower part than about 30 km, has been investigated by seismic refraction/reflection profiling. Those results show slab upper surface shallower than ours by 5 to 10 km in the Kii peninsula and by more than 5 km in Shikoku. In order to clarify the true slab geometry it is essentially important to know in which part of the slab, oceanic crust or mantle, the slab earthquakes are taking place in each region. We relocated slab events in the eastern Shikoku using velocity structure proposed by a seismic profiling (Kurashimo et al., 2002) and found inconsistency that the shallower main activity lay in the mantle with deeper remarkable events beneath it.

THREE-DIMENSIONAL VELOCITY STRUCTURE OF THE PINGTUNG AREA

Li-Chuin HU[1], Cheng-Horng LIN[2], Horng-Yuan YEN[1], Chau-Huei CHEN[3] ([1]Institute of Geophysics, National Central University, Taiwan, [2]Institute of Earth Sciences, Academia Sinica, Taiwan, [3]Institute of Seismology, National Chung Cheng University, Taiwan)

The Chaochou fault in the Pingtung area is one of the most important faults in southern Taiwan, and is located between the Pingtung Plain and the Central Range. According to previous studies, the Chaochou fault is considered to be a high-angle fault that dips eastward to the Central Range. From a tectonic point of view, regional stresses in the Pingtung area are controlled by two tectonic forces. The first force is the compressional stress related to the arc-continent collision between the Philippine Sea Plate and the Eurasian Plate; the second is the extensional stress related to the opening of the South China Sea to the South. Under these two mechanisms, the crustal structure beneath the Pingtung area has a complex formation. However, in examining earthquakes greater than magnitude 3 that occurred in the years between 1991 and 2001, we discover that the seismicity in southwestern Taiwan in this period was low. The question as to why this is the case is what first inspired our interest in studying this particular area. This study makes use of data collected by the Institute of Earth Sciences, Academia Sinica between August 2001 and January 2002 at 24 temporary seismic stations located near the Chaochou fault, as well

as velocity structures collected through tomography in the foothills of the Pingtung area. We hope that this study will teach us more about crustal structure of this area and will enable us to understand the reasons for low seismicity there.

SEISMICITY IN HYUGA-NADA BY TEMPORARY SEISMOLOGICAL OBSERVATION BOTH OF SEA AND LAND AREA

Kenji UEHIRA[1], Hiroshi SHIMIZU[1], Norimichi MATSUWO[1], Minoru NISHINO[2], Ryota HINO[2], Kimihiro MOCHIZUKI[3], Kodo UMAKOSHI[4], Hiroshi YAKIWARA[5], Hiroki MIYAMACHI[5] ([1]Kyushu University, [2]Tohoku University, [3]University of Tokyo, [4]Nagasaki University, [5]Kagoshima University)

Seismic activity of the Philippine Sea plate differs notably Hyuga-nada and near Shikoku. Although usual microearthquake activity is active in Hyuga-nada, it is inactive near Shikoku. On the other hand, although the great earthquake (M >8) has occurred repeatedly in near Shikoku at intervals of about 100 years, in Hyuga-nada, smaller earthquakes (M7 class) has occurred at intervals of about dozens of years. Moreover, it was discovered that aseismic slip has occurred from GPS data in Bungo channel, between Hyuga-nada and near Shikoku (Hirose et. al, 1999). Thus, styles of earthquake occurrence differ notably in the adjoining area. As mentioned above, plate coupling of the Philippine Sea plate change from near Shikoku to Hyuga-nada, but this reason is not yet known well.. As one method of know the reason, it is important to investigate the details of the seismic activity in Hyuga-nada. So, we performed extraordinary observation in east coast of Kyushu and Hyuga-nada for two months in April, 2002 to June. 23 OBSs were deployed above hypocentral region of Hyuga-nada and 4 data loggers were deployed in east coast of Kyushu in order to compensate a regular seismic network on land. We calculated the highly precise focus distribution and the earthquake mechanism solution. Consequently, we found that reverse fault type earthquake and normal fault type earthquake have occurred by the almost same frequency, and that normal fault type earthquake has occurred so that a reversed fault type earthquake may be inserted up and down. It is suggested that normal fault type earthquake has occurred both side of plate boundary; we acquired important information about what determine the intensity of coupling between plates.

INFLUENCE OF SEISMIC CYCLES IN KURILE-KAMCHATKA AND JAPAN SUBDUCTION ZONES ON CRUSTAL STRESS CHANGES AND SEISMIC ACTIVITY IN THE BAIKAL LAKE REGION (SIBERIA)

Pyotr G. DJADKOV (Institute of geophysics SB RAS)

Very interesting connections between seismic processes in intracontinental region (the Baikal rift which located in Central Asia at western border of the Amur plate) and the Kuril-Kamchatka and Japan subduction zones were found. The distance between the Baikal region and the West-Pacific subduction zones is 2500-3500 km. As rule the rise of seismic activity in the Baikal region took place 2 – 5 years before the seismic active period with very strong earthquakes, M >7.5 – 8, in the subduction zones near the eastern border of the Amur plate. Similar scenarios took place in 1949-1953, 1957-1962, 1966-1973, 1989-1995. Sometimes during the period of high seismic activity in subduction zones the second stage of seismic activity rise in the Baikal region happened (for example, 1994-1995). During seismic active period (1989-1995) in the Baikal rift zone we observed very unusual phenomenon in results of geophysical monitoring and data of focal mechanisms namely the compression episode (1992-1993) (Djadkov et al., 2000). We consider this episode as evidence of significant accumulation of potential elastic energy in this period in the earth crust of the Amur plate near the West-Pacific subduction zone. This could cause the essential change of crustal stress field in the Baikal region. The end of this episode was a beginning of energy release by means of the strong seismic events with M = 7.5-8.1 in 1993 – 1995 near islands Hokkaido, Shikotan, Honshu, Sakhalin. Thus seismic active periods and regional changes of crustal stress fields in the Baikal region can be indicators of quantity of crustal elastic energy accumulated at the eastern border of the Amur plate near the Kuril- Kamchatka and the Japan subduction zones. Possibly these seismic active periods and crustal stress changes in the Baikal region can be long- and middle-time prognostic criteria for prediction of seismic process development in the West-Pacific subduction zones. Research is supported by RFBR, grant 03-05-65418, and Programmes of Integration Research of SB RAS.

THE 1971 SOUTH YAKUT EVENT AND ITS EFFECTS   Imaev Valery S. 1, Imaeva Lyudmila P. 1, Koz´min Boris M. 1. 1. Institute of diamond and precions metal Geology, Siberian Branch, Russian Academy of Sciences, Lenin pr., 39, Yakutsk, 677891, Republic Sacha (Yakutia), Russia. Instrumental observations mode in the 20 th century revealed the existance along the southern boundary of the Siberian platform of the Baikal-Stanovoy seismic belt stretching from lake Baikal toward the sea of Okhotsk, in which over 300 thousand seismic events have been recorded. The belt forms the boundary between the Eurasian and Chinese (Amur) lithospheric plates. It inchudes the Baikal rift and the Stanovoy fold area. Within the Stanovoy fold area (South Yakutia), , the strongest over the last 20 years the South Yakutian earthquake occurred on the 20 th of April, 1989.The magnitude of the event (Ms) is 6.5 and the depth of focus is 27 km. The intensity of the event in the epicenter is 8 or the modernozed Mercalli scale. The event was belt within radius of 800 km from the epicenter. For example, in Yakutsk and Blagovescensk its intensity attained 3 on the Mercalli scale. Macroeffects of magnitude 3 to 7 were observed over an area of 1.4 million sq. km in Yakutia, Buryatia, as well as the Irkutsk, Chita and Amur regions The distribution of earthquake epicenters in South Yakutia until 1989 showed that within a radius of 200 km from the city of the future focus a seismically silent zone was observed where only solitary small events with M=1-3 were recorded, while large ones were absent. Analysis of the modern topography showed distinctly that features of the local drainage system tend to be confined to active faults in this area. For example, the Tungurcha river has a characteristic slep-like bend, coinciding with the northern and southern benches of the Tungurcha left-lateral strike-slip fault. The territory between the benches, acts as a compression duplex devided, by a system of sublongitudinal local faults. All the blocks have the same southnorthward topographic gradient as evidenced by the watercourtes of Tungurcha tributaries. It may be assumed that the topographical ˝anomalous˝ Usmun block was a large ˝concentrator˝ of tectonic stress originated under the influence of northeastward compression, the removal of whith produced the South Yakut earthquake. It seams that compressive stress field, that formed before the main shock, led to a sharp increase in the rate of defore mation of the earth´s crust, which caused ionization state of atmosphere above the epicentral zone and the appearance of geodetic and geophysical precursors.

TOMOGRAPHIC IMAGING OF VP AND VP/VS IN EASTERN TAWIAN: CONSTRAINS ON EARTHQUAKE NUCLEATION?

Win-Bin CHENG (General Education Center, Jin-Wen Institute of Technology)

AbstractTomographic inversion of P- and S-wave arrival times from eventsoccurred in eastern Taiwan is used to produce three-dimensional imagesof subsurface Vp and Vp/Vs structures. The target area consisted of a130 x 148 x 50 km^3 volume divided into 15 x 25 x 14 grids. 2459 eventsrecorded by the CWBSN during 1991 to 1999 providing 26350 P- and 15089 S-arrivals for inversion. As the preliminary results indicated a large volume of high velocity zone is observed in the middle- to lower-crust between the Central Range and Luzon arc in eastern Taiwan. This highvelocity zone extends northwards to at least 24´N and can be interpreted asthe oceanic crust of the Philippine Sea plate. The plate boundary between the Philippine Sea and Eurasian plates is generally outlined by a sharp across fault velocity variation, which is a primary feature in the 3-D Vpstructure.This study also presents one of the first Vp/Vs tomography for eastern Taiwan. It is well known that Vp/Vs serves as an efficient indicatorfor a particular set of properties, e.g. temperature, pressure, saturation, porosity, crack geometry and lithology. Significant Vp/Vs perturbations appearto correlate with rupture properties of great earthquakes. Preliminary studyshowed a feature that the forearc high Vp body is almost coincident witha less seismic area delineated by two sub-parallel seismic zones.However, this study indicates the high Vp/Vs anomalies occur at or nearnucleation sites of at least five main shocks with magnitude greater than 6.5. Those locations of high moment release events appear to correlate well with the low Vp, high Vp/Vs volume, which may be due to fractured rock matrix, fluid-filled, over-pressurized near the bottom of theseismogenic zone. The existence of over-pressurized fluids beneath the seismogenic zone may affect the long-term structural and compositionalevolution of the Longitudinal Valley fault, change the strength of the fault zone.

AFTERSHOCKS AND SEISMOTECTONIC IMPLICATIONS OF THE SEPTEMBER 13, 2002 EARTHQUAKE (MW 6.5) IN THE ANDAMAN SEA BASIN

Jnana Ranjan KAYAL, S.G. GAONKAR, Gautam1Kumar CHAKRABOR, Om Prakash SINGH (Geological Survey of India)

A medium size earthquake, main shock (MW 6.5), occurred on September 13, 2002 (22h 28m 31s GMT) in the Andaman sea, about 20 km off shore Diglipur, north Andaman Island. The epicentre at 13.0870N and 93.1120E and centroid depth at 31 km were estimated (USGS). The main shock occurred by a reverse faulting. Four digital seismograph stations were established in the Andaman Islands to monitor aftershocks. About 200 aftershocks (Md > 1.0) were recorded during a period from September 19 to October 7, 2002. The epicenter map shows a NW-SE trending aftershock cluster in an area of about 140 x 70 km2, which reflects the rupture area of the main shock. The aftershocks occurred mostly at a depth range 5-20 km, except one at 38 km.The moment tensor solutions (USGS) of the main shock and the largest aftershock (MW 5.8), which occurred 22 hrs after the main shock, revealed consistent reverse faulting. The NE dipping NW-SE trending nodal plane, which is comparable with the aftershock trend, is inferred as the fault plane. The NE-SW compressional stress (P- axis), obtained by the fault-plane solutions, is conformable with the NNE movement of the Indian plate. The main shock and the two well located largest aftershocks, located by the USGS, occurred within the subducted plate. One composite fault-plane solution is obtained for the shallower aftershocks recorded by the temporary network. The solution shows a normal faulting with a NE-SW tensional (T) axis. These aftershocks occurred off the subducted plate at a much shallower depth (<10 km), and are caused due to local tension in the overriding plate.

THE MOST RECENT PERIOD OF SEISMIC ACTIVITY IN DINAVAR SEGMENT OF MAIN RECENT FAULT,ZAGROS MOUNTAINS OF WESTERN IRAN

Noorbakhsh MIRZAEI

Following a period of relative quiescence after September 1958, a seri of violent shocks on 24 April 2002 strongly affected the district of Dinavar in Kermanshah province of western Iran. The shocks completely destroyed 10 villages and damaged another 60. The largest event was a moderate earthquake of mb=5.2, Ms=5.2 (USGS). The earthquake was associated with considerable surface rupture that runs for at least 15 kilometers. The surface rupture follows the trend of Dinavar segment of the Main Recent Fault. Pattern of developed shear fractures confirms right-lateral strike-slip movement in this event. The main shock proceeded by a foreshock of mb=4.8 just five minute before, and was followed by many aftershocks. In the firs week after the main shock seven aftershocks was recorded teleseismically and in a seismographic station in Kermanshah, about 60 kilometers far from the epicenter, fifty aftershocks was recorded in the same time period. The number of aftershocks decreased gradually but continued to December 2002, when another damaging earthquake of mb=5.0 (USGS), on 24 December 2002, strongly affected the same region causing more property damages. It seems a new period of seismic activity is started in an area that has a well known history of devastating earthquakes, with magnitudes as large as Ms=7.0.

SEISMOLOGICAL CONSTRAINTS ON THE STRUCTURE AND COMPOSITION OF THE WESTERN DECCAN VOLCANIC PROVINCE FROM CONVERTED PHASES

Mohan GOLLAPALLY[1], Ravi Kumar MANGALAMPALLY[2] ([1]Department of Earth Sciences, Indian Institute of Technology Bombay, Mumbai, India, [2]National Geophysical Research Institute, Hyderabad, India)

Receiver function analysis (RF) of teleseismic data recorded during the period 1998-2002 by a ten station seismic network comprising of one broadband (BB) and nine short period (SP) stations, deployed in a 50 km x 100 km area near Mumbai, in the western part of the Deccan Volcanic Province (DVP) of India, reveals a crust with thickness varying from 35.5 km to 38.8 km. Comparable results obtained from BB and SP data recorded at a common site enabled the application of the RF technique to SP data recorded by the network, with reliable results. The crustal thickness was effectively constrained by using the Poisson's ratio determined from the crustal multiples recorded by the BB station. Strong conversions were observed from the base of the traps and the Moho and a weak conversion from an intracrustal layer observed at eight stations which exhibit a relatively thick crust. The Poisson's ratio is determined to be 0.26 which indicates the felsic nature of the crust. Neglecting the traps, the crustal thickness, Poisson's ratio and the average shear velocity (3.7 km/s) are all similar to those observed for the Archean shield, implying that the crust in this region does not appear to carry any significant imprints of the basic volcanism.

THE TOPOGRAPHY OF THE MOHO-DISCONTINUITY AND TECTONIC PROCESSES IN THE AREA OF THE REPUBLIC OF MACEDONIA

Todor B. DELIPETROV, Deljo P. KARAKASEV (Department of geology and geophysics, Faculty of Mining and Geology, Stip, University "Sts. Ciryl and Methodius" Skopje, Republic of Macedonia)

Tectonic processes in an area depend on the forces surrounding the area as well as those causing effects on local level. The local forces influencing the Earth's crust in the territory of the Republic of Macedonia are related to the complex topography of the Moho-discontinuity. According to the tectonic regional setting and the geophysical investigations carried out by the present authors the area under investigation can be divided into three zones: the Western Macedonian, the Vardar and Eastern Macedonian zones. In an area of 25 000 km2 and a distance of less than 100 km the Moho-discontinuity shows a variation of 17 km.The fairly complex structure of the boundary M is directly influenced by block displacement comprising the three zones. Depending on the shape of the Moho-discontinuity two structural models are possible: a horizontal and inclined boundary.If the depth of the Moho-discontinuity beneath the block is constant then its topography does not generate tangent forces (thus the plates are stable). An analysis of the map of the Moho-discontinuity for the Republic of Macedonia and investigations carried out made it possible to draw the conclusions as follows:- the Moho boundary in the area of the Western Macedonian zone buries to the west that causes the blocks in the zone to be affected by tangent forces of the east - west general strike.- The tangent force generated in the Vardar zone by the boundary M is either the lowest or absent,- The Moho-boundary in Eastern Macedonia buries to the east generating tangent force that affects the blocks with a general strike to the east.Vertical tectonic movements are caused by gravitation forces. With regard to the M boundary, vertical movements are possible if the blocks do not affect the boundary or if their relationship is not in consolidated state.Vertical displacements take place within the Earth's crust during the processes of subsidence and reconsolidation of the material which is not related to the M boundary.

MOHO DEPTH VARIATION IN SOUTH IBERIAN PENINSULA

Inmaculada SERRANO[1], Jose Benito MARTIN[1], Jose MORALES[1], Federico TORCAL[2] ([1]Andalusian Institute of Geophysics, Granada University, Spain, [2]Pablo Olavide University, Sevilla, Spain)

The steep transition in the Moho depth between the Betic Cordilleras (southern Spain) and Alborán Sea (the western termination of the Mediterranean Sea), has been the focus of widespread debate in the last decades. Numerous authors have studied this interesting region, attempting to relate the continental collision, the late extension and the relationships between these two processes with the intermediate and deep seismicity. In recent years several hypothesis have been proposed to explain its origin, evolution and present-day structure. Crustal thickness variations are of essential importance to comprehend the tectonic evolution of a region. Because of the large seismic velocity contrast between the lower crust and upper mantle, seismology provides the most direct measurement of crustal thickness. The main available information concerning to the crustal thickness in southern Iberian Peninsula includes some early works of seismic profiles during the 70 decade. However, although seismic surveys can provide very detailed pictures of crustal structure along linear profiles, they are expensive and do not always succeed in penetring to Moho depths. Results from gravimetry, magnetic, magnetoteluric and heat flow have provided additional and valuable information, suggesting, for this region, that the petrologic Moho discontinuity differs from the seismic Moho.In this work the Moho depth variation is investigated in southern Iberian Peninsula by applying methods of refraction and reflection to the local earthquakes of the region. Although recent studies have obtained low Pn velocities in the western Mediterranean region, we try to improve resolution by using the new broad-band stations installed recently by the Granada University, Spain. The crustal thickness and upper mantle velocities results from Pn phases are compared with those obtained from Moho-reflected phases, PmP. The results are correlate with major tectonic features and previous geophysical observations.On the other hand, mantle seismic anisotropy is a direct indicator of mantle strain history, and it constitutes an important tool in the study of the tectonic of any region. The first contrasts of the anisotropy beneath the different crustal domain of the Iberian Peninsula have been established from the analysis of teleseismic shear-wave splitting observed. The result inferred for a seismic station located in south Iberian domain is clearly different from those observed in the Alboran domain; the origin of which has to be related to the different geodynamic evolution. However, these results do not agree with those obtained from others authors, presumably owing to their low resolution because of the absence of broad-band seismic stations. In this work new shear-wave splitting observations are made possible by the deployment of the recent broadband seismic network in southern Spain.

SIGNIFICANT EARTHQUAKES IN THE UK OVER THE PAST 25 YEARS

Lars OTTEMOLLER, Alice WALKER, Brian BAPTIE (British Geological Survey)

The UK is an area of low to moderate seismicity with around 200 earthquakes detected each year and a recurrence rate for events of magnitude 5 of approximately 10 years. Historically, the largest earthquake to affect the United Kingdom occurred in 1931 and had a magnitude of 6.1 ML. It was located on the Dogger Bank, in the North Sea, and caused minor damage on the east coast of England. The diffuse temporal and spatial pattern of seismicity observed is consistent with other examples of intraplate continental deformation. However, no historical or instrumentally recorded earthquake has produced a surface rupture, therefore, it is difficult to relate a given earthquake to displacement along a specific fault on land. In the North Sea, however, broad correlations can be seen between the graben structures and offshore seismicity. Over the past 25 years, 11 earthquakes with magnitudes $>$ 4.0 ML have been recorded instrumentally in the UK. In this study, we use data from the UK seismograph network to determine source parameters for these earthquakes and their aftershocks, which include: Carlisle, 1979 (4.7 ML); Lleyn Peninsula, 1984 (5.4 ML); Bishop´s Castle, 1990 (5.1 ML); and Dudley, 2002 (4.8 ML). The network has evolved over the past 35 years and currently consists of 146 stations with an average spacing of 50 km, allowing the detection and location of all seismic events greater than 2.0 ML. Hypocentral depths for these earthquakes are typically in the upper crust and are rarely deeper than 15-20km. However, in some cases the depth constraint is poor. For these, we constrain depth using waveform modelling for simple crustal models. Focal mechanisms for individual earthquakes show a variety of source mechanisms but are generally compatible with the regional stress regime for northwestern Europe due to compression from the Mid-Atlantic ridge. Source parameters are determined from the observed displacement spectra, after correction for geometric spreading and attenuation, to examine the relationship between earthquake size and stress drop for these events.

THE STRESS FIELDS DUE TO RECENT SEISMIC EVENTS IN THE CENTRAL APENNINES, ITALY

Michele DRAGONI[1], Antonello PIOMBO[1], Stefano SANTINI[2], Andrea TALLARICO[3] ([1]Dipartimento di Fisica - Universita' di Bologna, [2]Istituto di Fisica - Universita' di Urbino, [3]Dipartimento di Geologia e Geofisica - Universita' di Bari)

The Central Apennines, Italy, are characterized by moderate seismic activity on normal faults, oriented in directions parallel to the Apenninic chain. The subject of this study is the Umbria-Marche Apennine, a segment approximately 200 km long, where three main seismic events occurred in the last three decades. The 1979 Norcia earthquake was a M = 5.8 event, taking place at the south end of the considered segment. The 1984 Gubbio earthquake was a M = 5.3 event which took place at the north end. The 1997-98 Colfiorito sequence was made of 8 main shocks with magnitudes between 5 and 6 and epicenters comprised between the Gubbio and the Norcia earthquake areas. A model made of an elastic half-space is considered, where the seismic sources are represented byrectangular dislocations having the appropriate values of source parameters, and the stress field produced by each event is calculated. The superposition of the different stress fields and of an assumed regional tensile stress gives the time evolution of the stress field in the area. The analysis of Coulomb failure stress as a function of time gives information as to the role played by coseismic stress transfer and fault interaction during the past three decades in the region.

BOHEMIAN MASSIF ANISOTROPY AND HETEROGENEITY: - BOHEMA EXPERIMENT

Michael KORN, BOHEMA WORKING GROUP (Dept. of Geophysics and Geology, University of Leipzig)

A passive seismic experiment is currently carried out in the western part of the Bohemian Massif close to the border between Germanyand the Czech Republic. A network of 90 temporary stations in addition to 60 permanent stations in the region has been set up in a jointeffort by Czech, French and German institutions and is expected to run until June 2003. The network is concentrated around the crossingof the Eger Graben and the Marianske Lazne fault zone, an area which is characterized by the periodic occurence of earthquake swarms aswell as CO_2 and He gas emanations in mineral springs and mofettes. The scientific aim is to use all available techniquessuch as high-resolution tomography, receiver function analysis, 3D anisotropy studies and investigation of xenoliths to image the crust andupper mantle to depths of about 250 km. Results of the experiment will shed light on the causes of the swarm earthquakes and the role of fluidsin triggering them, as well as on the location of a hypothetical deep seated source of the gas emanations. Preliminary results will be presented with respect to Moho depth variations from receiver function analysis, resolution studies of local traveltimetomography and the development of regional 1D velocity models

WAVEFORM MODELING TO ESTIMATE THE SEISMIC WAVE ATTENUATION IN THE CRUST, IN THE VRANCEA (ROMANIA) SEISMIC AREA

Luminita Angela ARDELEANU (National Institute for Earth Physics, P.O. Box MG-2, 76900 Bucharest, Romania, email: ardel@infp.ro)

Due to its tectonic setting, the Vrancea region (Romania) is an area with a complex structure, which should be described by a 3-D inhomogeneous model. Although the construction of such a complex model is still in early stages, 1-D crustal models designed for various seismic stations are already available; they were constructed as realistically as possible, on the basis of geologic and seismic data, and approximate the local structure for an area of a few km2 around the recording stations. Since we have no local evaluations of the quality factor, in the present paper we propose average models for Q, suitable for the area located at the major bend of the Eastern Carpathians. For each station a pair of extreme, reasonable Q models (one corresponding to high Q-values, the other to low values) is considered. The most appropriate Q model, for various azimuths, is selected by comparing the local, short period records of a set of crustal low magnitude earthquakes with the synthetic waveforms computed for pairs of structures, which differ by the quality factor only. Two zones - one with high attenuation, the other with low attenuation - are evidenced, which determine decisively the optimum Q model for the rays crossing them.

SEISMIC AMPLITUDE VARIATIONS DUE TO SITE AND AZIMUTHAL EFFECTS IN THE LOS ANGELES BASIN

Allen LeRoy HUSKER, Monica KOHLER, Shirley BAHER, Paul DAVIS (Department of Earth and Space Science, University of California, Los Angeles)

Seismic amplitude variations are examined for the 1994 Northridge Earthquake and a first order model for wave propagation through the Los Angeles Basin is presented. The Northridge Earthquake caused greater damage and more violent shaking in Santa Monica than areas closer to the epicenter. An aftershock and Vibroseis study of amplitudes and travel times suggest a deep structure causes higher-frequency seismic energy from a northerly back-azimuth to focus in Santa Monica. We develop an empirical model for amplitude variations throughout the LA and San Gabriel Basins. The model incorporates geometrical spreading, magnitude, soil effects at the surface, and azimuthal effects. The model is compared to data from the LA Basin Passive Seismic Experiment (LABPSE). LABPSE involved running a passive seismic experiment of 18 seismic stations along a line crossing LA and San Gabriel basins for a period of 9 months during which local, regional and teleseismic earthquakes were recorded. The data consist of spectral amplitudes from 37 events for P waves and 39 events for S waves. The parameters of the model are fit to the data using a non-linear least-squares inversion. The spectral amplitudes are broken into frequency bands to determine frequency dependence of model parameters. Focusing by geological sub-structure is expected to be frequency and azimuth dependent. The results indicate that our model is a good first order approximation to the amplitude variation. We resolve statistically significant azimuthal amplitude variation, which we relate to the geologic sub-structure.

ASPERITY DISTRIBUTION OF THE 1964 GREAT ALASKA EARTHQUAKE AND ITS RELATIONTO SUBSEQUENT SEISMICITY IN THE REGION

Stefano SANTINI[1], Michele DRAGON[2], Giorgio SPADA[1] ([1]Istituto di Fisica - Universita' di Urbino, [2]Dipartimento di Fisica - Universita' di Bologna)

S

The 1964 Alaska earthquake was one of the largest seismic events in the 20th century. We study the slip distribution on the fault plane on the basis of surface coseismic deformation. To this aim we decompose the fault plane in a large number of small square asperity units with a side of 25 km. In the first stage, each asperity unit is allowed to slip or to remain locked, providing the geometry of the dislocation surface that best reproduces the observed displacements. To this purpose a large number of slip distributions has been tried by the use of a Montecarlo method. The slip amplitude is the same for all the asperities and is equal to the average fault slip inferred from the seismic moment. In the second stage, we evaluate the slip distribution in the dislocation area determined by the Montecarlo inversion: in this case we allow unit cells to undergo different values of slip in order to refine the initial dislocation model. The results confirm the previous finding that the slip distribution of the great Alaska earthquake was essentially made of two dislocation areas with a higher slip, the Prince William Sound and the Kodiak asperities. Analysis of the post-1964 seismicity in the rupture region shows a strong correlation between the larger earthquakes (M > 6) and the distribution of locked asperities following the 1964 event, which can be considered as an independent test of the validity of the model. Our model confirms the results of recent studies by a different methodology defining the distribution of asperities on the fault plane, using only the fault geometry, the geodetic data and the seismic moment of the 1964 Alaska earthquake.

SEISMOGENIC ZONE STRUCTURE ALONG THE MIDDLE AMERICA TRENCH: RESULTS FROMTHE COSTA RICA SEISMOGENIC ZONE EXPERIMENT

Heather R. DESHON[1], Susan Y. SCHWARTZ[1], Susan L. BILEK[2], Andrew V. NEWMAN[3], LeRoy M. DORMAN[4], J. Marino PROTTI[5] ([1]Department of Earth Sciences, University of California-Santa Cruz, [2]Department of Geological Sciences, University of Michigan, [3]Los Alamos National Laboratory, [4]Scripps, University of California-San Diego, [5]OVSICORI-UNA)

Large or great subduction zone thrust earthquakes commonly nucleate withinthe seismogenic zone, a region of unstable slip along the converging plateinterface. A better understanding of the mechanical, thermal andhydrothermal processes controlling seismic behavior in these regionsrequires accurate earthquake locations and focal mechanismdeterminations. The Costa Rica seismogenic zone experiment(CRSEIZE), a collaborative effort between UCSC, OVSICORI-UNA,UCSD/Scripps, Univ. of Miami, and GEOMAR, combined broadband andshort-period land and ocean bottom (OBS) arrays, oceanic fluid fluxmeters, and GPS measurements in order to better understand the geometry and mechanicalbehavior of the seismogenic portion of the plate interface. Subduction ofthe Cocos Plate beneath Caribbean plate beneath western Costa Ricagenerates large earthquakes (to around Mw 7.6), but the nature ofseismicity is highly variable along strike. We focus on results from twoseismic experiments, deployed on and offshore the southern Osa Peninsulaand the northern Nicoya Peninsula from Sept.-Dec. 1999 and Dec. 1999 - June 2001 respectively. On August 20, 1999 an Mw 6.9 underthrusting interplate earthquake occurredoffshore central Costa Rica. The magnitude was consistent with thehighest magnitudes (Mw 7.0) recorded on the central Costa Rica margin, andthe aftershock sequence was predicted to rupture much of the seismogeniczone. We record and locate interplate aftershocks, intraplate oceanic andcontinental activity, and outer rise events. The aftershock rupture areaencompasses 400 km[2] and illuminates the seismogenic zone from 10 km depth,30-35 km from the trench to 30 km depth, 95 km from the trench. Therupture area spatially correlates with the downdip extension of theoceanic Quepos Plateau, suggesting the morphology of the incoming Cocosplate heavily influences seismicity patterns offshore central Costa Rica. The 1999 earthquake possibly represents rupture of a seamount or basementhigh at depth, and aftershocks reflect complexities caused byasperities in the region. Current results identify a significant deepening in updipseismicity (from 10 - 20 km) occurring along a transition in subductingplate origin, Cocos-Nazca Spreading Center versus East Pacific Rise(EPR) origin. This change in updip seismicity may be partially controlled by thermaldifferences in the downgoing crusts; significant crustal hydrothermalcirculation in the EPR cools the crust and deepens the updip limit. Further evidence for crustal hydrothermal circulation comes from fluidflux meters located on OBS as part of the CRSEIZE experiment. Flux metersrecorded a number of fluid flow excursions on both the toe of the forearcwedge and on the incoming Cocos plate. Initial comparisons to local andregional seismicity rate suggests a causal link. We present a moredetailed analysis of local and regional seismicity, focusing oncomparisons of the datasets.

SEISMOTECTONIC AND SEISMIC ANOMALIES IN NORTH WESTERN OF SOUTH AMERICA

Carlos A. VARGAS-JIMENEZ[1], Lluis G. PUJADES[2], Arantza UGALDE[3], Jose A. CANAS[2] ([1]Departamento de Geociencias, Universidad Nacional de Colombia, [2]Universitat Politécnica de Catalunya, [3]Observatoru de lÉbre, Roquetes, Spain)

Stress inversion from focal mechanisms Mw > 5.5 (NEIC, 1992-2000) correlated with geodetic data of several campaigns (CASA project, 1993-1999) and shear wave splitting analysis with data from Seismological Network of Colombia (1992-1999), suggests the presence of a cortical anomaly that causes a change of convergence direction of the Nazca Plate against South American Plate near to 77°W - 4°N. In this sector lateral variations of Vp are detected and they are agree with Qc, gravimetric and thermal flow anomalies that are product of local distribution of compressives NNW-SSE stress generated by the micro-plate ChocAEagainst the Andean Block of Colombia and that it generates permanent destructive seismicity in this sector along transpressive righ-lateral faults. The presence of predominantly intrinsic attenuation towards south of 77°W - 4°N and scattering atenuation towards north, allow to deduce greater angles in the subduction processes towards the north.

SS03/08A/D-034 Poster **0830-193**

A FIRST STEP TOWARD INTEGRATED GEOPHYSICAL AND GEOLOGICAL STUDIES IN URBAN AREAS: PRELIMINARY RESULTS ON NEOTECTONICS IN THE SOUTHERN KYOTO BASIN

Takanobu YOKOKURA[1], Naomi KANO[1], Kazuo YAMAGUCHI[1], Akiko TANAKA[1], Toshiki OHTAKI[1], Shinobu ITO[1], Masao KOMAZAWA[1], Yoshinori MIYACHI[1], Tomio INAZAKI[2] ([1]Institute of Geoscience, Geological Survey of Japan, AIST, [2] Construction Technology Research Department, Public Works Research Institute)

We started integrated geophysical and geological studies on urban areas in order to provide precise and integrated geoscientific information that leads to mitigation of disasters and suitable public and industrial utilization of land. We have selected the southern Kyoto basin as a model field for the study. Large earthquakes have frequently attacked Kyoto historically. However the area has been very and abnormally quiet since 1830, except small damages by the 1995 Hyogo-ken Nanbu earthquake. Immediate collection and accumulation of geoscientific information is needed in this area. For the first step to do so, we have started to conduct deep and shallow seismic reflection surveys, detailed gravity survey, collection and

---

digitization of boring data, and so on. Shallow high-resolution reflection surveys, compared with some shallow boring data, revealed distribution of a gravel layer that has N-value of about 30-40 and corresponds to a bearing layer for construction in this area. Deep reflection surveys have revealed that the pre-Neogene basement is relatively flat and lies at about 700-800m in depth at the basin side, and becomes rapidly shallow toward the hill (called Yawata hill or Tanabe hill) side. There is a fault between the basin and the hill. Gravity data analysis, combined with the basement depth controlled by reflection seismic sections, has provided detailed basement structure of the southern Kyoto basin. The vertical slip rate of the fault between the basin and the hill can be estimated using precisely dated marine clay beds in the Plio-Pleistocene Osaka Group: indicating about 0.1m/ky during 0.4 to 0.9Ma and negligibly small before 0.9Ma. In the neighboring areas, some kinds of tectonic changes also occurred around 1Ma, such as uplift of Shikoku coastal mountains, unconformity beneath the Kii channel, activation or reactivation of faults, and so on. The activity change of this small fault may also reflect a drastic tectonic event around 1Ma in this region, which may be related to the change of subduction direction of the Philippine Sea Plate.

SHALLOW FAULT GEOMETRY AND SLIP PARTITIONING ASSOCIATED WITH THE IWATE-KEN NAIRIKU-HOKUBU EARTHQUAKE OF 1998 (M6.1), NORTHERN HONSHU, JAPAN

Shin KOSHIYA[1], Tomonori KAWAMURA[2], Hiroshi SATO[2], Masaru NODA[1] ([1]Department of Civil and Environmental Engineering, Iwate University, [2]Earthquake Research Institute, University of Tokyo)

It is important to estimate slip partitioning on each segment of fault system, when the possibility of earthquake in active faults is evaluated based on paleoseismic events. The Iwate-ken Nairiku-Hokubu earthquake (M6.1) of September 3, 1998, northern Honshu, Japan, caused some parallel surface ruptures and flexures, suggesting the contemporaneous motion of main fault and its branched faults. These faults, generally with north to south strike, comprise Nishine Fault System. This study is aimed at revealing the geometrical relationship between these faults and estimating displacement on each fault, by high-resolution shallow seismic profiling and geological survey. Seismic exploration experiment was carried out across the southern extension of Nishine Fault System. The seismic source of our experiment was Mini-vibrator (T-15000, IVI Inc.), and digital telemetry seismic recording system (GDAPS-4, JGI Inc.) was used for collecting seismic data. The geological structure around the experimental line is characterized by four faults, called F4, F3, F2 and F1 faults from west to east, and folds associated with these faults. F4, F2 and F1 faults are thrusts dipping to west, and F3 is a thrust dipping to east. F4 fault is a major fault, and F1, F2 and F3 faults are branches of F4 fault. F3 fault is a back thrust. The formations are strongly folded as an anticline in the western part of F4 fault, while small syncline and anticline folds develop between F4 and F1 faults. The shallow seismic profiling shows the large vertical displacement of remarkable reflectors on F1 faults and small ones on F2 and F3 faults. Particularly the displacement on F2 fault appears to be very small. Preliminary simplified balanced cross section, including F1, F3 and F4 faults, suggests that the total slip on F4 fault accumulated through geologic time is the largest and more than several times of the total slip on F1 fault. According to the section, these faults are presumed to be active together, because F4 and F1 faults have a common low-angle detachment fault plane in the section. Leveling survey reveals that the vertical displacement on F4 fault is almost the same as that on F2 and F3 faults at the earthquake. This implies that F1, F2 and F3 are still younger than F4, though they are all active.

ACTIVE FAULT DRILLING RESEARCH ON STRESS, ELECTRICAL AND BASE ROCK STRUCTURE - FAULT ZONE STRUCTURE OF GOFUKUJI FAULT, CENTRAL JAPAN -

Kentaro OMURA[1], Ryuji IKEDA[2], Tatuo MATSUDA[2], Yukihiro MIZUOCHI[3] ([1]Solid Earth Res. Gr., National Research Institute for Earth Science and Disaster Prevention, [2]Division of Earth and Planetary Sciences, Hokkaido University, [3]Sumiko Consul. Co., Ltd.)

˝Active fault d indicative rilling˝ is an effective method to investigate the physical and chemical state in and around an active fault zone, such as, stress and strength distribution, geological structure and materials properties. In a present study, we did down hole measurement, geophysical prospect and core recovery at a Gofukuji Fault, central Japan, that is considered to have activated about 1200 years ago. Longer duration has passed since the last earthquake occurred as compared with other active faults we have already drilled: Nojima fault which appeared on the surface by the 1995 Great Kobe earthquake (M=7.2), the Neodani fault which appeared by the 1891 Nobi earth-quake (M=8.0), the Atera fault, of which some parts have seemed to be dislocated by the 1586 Tensyo earthquake (M=7.9). A 400m depth borehole was drilled at a distance of about 350 m west from the surface trace of the fault. Recovered cores show the lithology beneath the surface is conglomerate from an alluvial fan and sand/mud stone as a bed rock including aeolian deposit in spots. Logging data show that the apparent resistivity is about 100 ohm-m, density is about 2.5g/cm3 in conglomerates but by 0.1 g/cm3 denser in sand/mud stones. P wave velocity is approximately 3.0 to 3.5 km/sec. By the BHTV logging, the vertical fractures were detected which fractured by hydraulically due to the mud pressure in the borehole. The vertical fractures indicate the orientation of maximum horizontal stress is N45°W. Its shear stress component seems to act on the fault plane. The situation is contrast to the case of Nojima fault where the maximum horizontal stress was nearly perpendicular to the fault plane. We suggested the Nojima fault is ˝weak˝. The Gofukuji fault may be recovered in strength and not weak after long duration since the last earthquake. Electrical prospecting and CSAMT survey were performed with transects normal to the fault surface trace. The measuring line of electrical prospecting was about 1 km. Electrodes were set in the borehole as well as at ground surface and tomographic analysis was applied. CSAMT survey had two measuring lines which were about 3 km length. The electrical conductivity structure at the Gofukuji fault indicates the high conductive region is obscure associated with a fault fracture zone. This is not the case for the Atera fault where a broad fault fracture zone was estimated by an electrical image. The electrical image beside the Gofukuji strike slip fault is guggestive of the existence of vertical displacement in a bed rock . Considering other drilling data, such as well logging and core observation, the reverse fault may exist in the vicinity of the Gofukuji fault. We claim that the drilling method is effective to investigate physical and chemical features of active faults and compare with each other.

FAULTING AND CREEP BEHAVIOR OF COMPLICATED STRIKE-SLIP FAULT SYSTEM- A CASE OF THE ATOTSUGAWA FAULT SYSTEM, CENTRAL JAPAN

Bateer HASI, Akira TAKEUCHI, Yuki MATSUURA (Department of earth sciences, Toyama University)

In this study, we focused on the Atotsugawa fault system (AFS), a main strike-slip structure of central Japan. The AFS is composed of three NE-ENE striking faults, characterized by high seismicity of micro-earthquakes along the fault traces, is the most active zone of right-

lateral strike-slip faults in north-central Japan. To reveal the faulting history and present motional behavior, we carried out comprehensive studies on the fault system, and achieved some interesting features of the faults of AFS. Geological and geomorphological studies clarified detailed geometry of the AFS: The two main faults, Atotsugawa fault (AGF) and Ushikubi fault (UKF) parallel with each other and formed a rectangular block between the two faults. On the surface, the AGF extends continuously whereas the UKF shows right step ＜len echelon/＞. And the another member of the AFS, the Mozumi-Sukenobe (MSF) fault branches from the eastern end of the AGF and towards the UKF, so the activity of the Mozumi-Sukenobe fault is subordinate to the AGF. This geometric feature may indicate reorganization of local stress field near the fault system. We carried out seismo-geological studies on the fault system in three sites. One is in the central western part of the master AGF, one is at the end, and another is on the branching MSF. Trenching surveys on the eastern portion of the AGF revealed the faulting history of the AGF within recent 22,000 years. The results demonstrated a maximum recurrence interval of 3,000 years of the fault, which is similar to that of the central portion of the AGF, an interval of about 2,500 years that calculated by previous studies. This might indicate a uniform behavior in the seismogenic zone of the main AGF, despite the apparent segmentation by seismicity and creep motion in the shallower AGF. Another geo-slicing survey at MSF depicted a scarce interval of 13,500 years. Two simultaneous events on both the AGF and the MSF occurred in 1858 A.D. (Ansei Earthquake), and at about 17,300 years ago, suggesting an intermittent cooperation between the master and branch faults of the AFS. Geodetic data by dense GPS array across the fault system revealed a possible creep movement of the AGF and UKF, across a broad zone between those two faults. It shows that the creep is possibly occurring on the central eastern portion of the AGF and UKF. The creep behavior of the AFS suggests unique crustal phenomena beneath the AFS, such as presence of fluid chamber. Some future studies are necessary to reveal the mechanism of the strain partitioning concerning creep and strong earthquakes along each single fault, AGF and UKF.

SS03/08A/D-038   Poster   0830-197

GEOPHYSICAL AND GEOLOGICAL STRUCTURE OF THE ATERA ACTIVE FAULT, CENTRAL JAPAN

Tatsuo MATSUDA[1], Kentaro OMURA[1], Ryuji IKEDA[2] ([1]National Research Institute for Earth Science and Disaster Prevention, [2]Division of Earth and Planetary Sciences, Hokkaido University)

The Atera fault system runs NW-SE for about 70 km in central Japan. The fault system mainly consists of left-lateral strike-slip faults with NE-side-up reverse component. The Atera fault is one of the main faults of them. Its total lateral displacement is about 8 km and the average slip rate is estimated as 3-5 m per 1000 years. Its activity is very high. In some previous studies, the Atera fault had been regarded as one of the precaution faults for the lack of the evidence for the most recent paleoseismicity. But some other studies show that it is in the period of dormancy during a seismic cycle. In either case, we need more information about its various aspects. So we have conducted integrated investigations by surface geophysical surveys and drilling in and around the Atera fault. Six boreholes have been drilled from the depth of 400 m to 630 m. Four of these boreholes (HATAJIRI, FUKUOKA, UENO, KAWAUE) are located on a line crossing in a direction perpendicular to the Atera fault. The Atera fault runs along the boundary between the Nohi rhyolite and the Naegi-Agematsu granite formations on the surface. In the Kawaue well, mostly fractured and alternating granitic rock continued from the surface to the bottom at 630 m. We did coring and investigated the mineral assemblages of the core using by X-ray power diffraction (XRD). We detected quartz, feldspar, biotite in the parent rock (granitic rock), but also kaolinite, smectite, calcite and chlorite, which are related to hydrothermal alteration. This fracture zone is also characterized by the logging data such as low resistivity, low P-wave velocity, low density and high neutron porosity. Gravity measurements have been conducted at 242 points using the Lacoste G-260 gravity meter. A two-layer model was assumed in this study. The linear arrangement of the gravity low shows "S" geometry. These fabrics are similar to the strain field in the shear zone. A controlled source magnetotelluric (CSMT) survey has been carried out. Sixty measurement points were lined on two lines, A and B, of approximately 10 km length in direction perpendicular to the Atera fault. The high resistivity zone in the deeper part corresponds to mainly granite and a wide fractured zone like a flower-like structure was found out in some parts. In-situ stress measurements by the hydraulic fracturing method were conducted within selected intervals by the well logs, a borehole televiewer and rock core in four test holes (HATAJIRI, FUKUOKA, UENO, KAWAUE). Measurement results suggest that the stress magnitude increase with depth in each hole, however the stress gradient and the differential stress value are different from each other. And the stress magnitude decreases in the area closer to the center of the fracture zone. We are now under consideration to integrate of all these results to understand the activity of the Atera fault more clearly.

SS03/08A/D-039   Poster   0830-198

DEVELOPING PROCESS OF ACTIVE FAULT SYSTEM IN THE INNER ZONE OF WEST-CENTRAL JAPAN: A CASE OF THE ATERA FAULT BELT

Ken-ichi YASUE[1], Akira TAKEUCHI[2] ([1]Graduate School of Science and Engineering, Toyama University, [2]Department of Earth Science, Toyama University)

This study clarified a developing process of active fault systems in the inner zone of west-central Japan (IWCJ) from the both viewpoints of geomorphology and geology. In the IWCJ, many active faults with a strike-slip and a reverse dip-slip are observed. In particular, the Atera fault belt, which limits the southwestern border of the Northern Japan Alps, is one of the most prominent strike-slip faults in Japan. This study clarified a time-space vicissitude of Quaternary faulting in the Atera fault belt as a case study, and then discussed it comparatively with the fault history in IWCJ. Quaternary development of the Atera fault belt was divided into three time-space systems; ˝initial system˝ (an initiation stage of a present faulting style), ˝decline system˝ (a slowed up stage of fault activity partly), and ˝growth system˝ (an extending stage of faulting). The initial system had been situated not only in the southeastern half of current Atera fault belt but also in the southeastern prolongation. Then a southeastern domain of the Early Pleistocene system, that is the initial system, became inactive as a decline system and has not been reactivated as a part of the same fault belt at all. While, a growth system occurred on the northwestern prolongation of the Middle Pleistocene system. An activating process of faulting in the Late Quaternary period might have worked in the fault segment ranging from the north-central part to the central of Atera faults. In short, the northwestward shift of three systems in the Atera fault belt demonstrates a style in evolution of the Quaternary fault province. In the wider area of the IWCJ, activated fault-domain also shifts northwestward in the individual fault belt as well as the Atera fault belt throughout the Quaternary period. The ˝initial IWCJ system˝ has dated in the Early Pleistocene from about 1.5 Ma in the southeastern district and 0.8 Ma in the almost whole area, and then has been changed as the present in the middle to northwestern district. The time-space vicissitude of Quaternary faulting in the IWCJ also evidences northwestward shift of fault activation. The phases of the initial IWCJ system are synchronous with those of volcanism in the eastern margin of west-central Japan. The process will be of great value in interpreting changes in relative motion among the concerning plates. Based on the time-space distribution and characteristics of neotectonics, we attribute such critical ages as 1.5 Ma and 0.8 Ma to the change in subducting direction of the Philippine Sea plate and a jump of the

eastern boundary of Eurasian plate into the eastern margin of the Japan Sea, respectively.

BLIND THRUST FAULTS BENEATH METROPOLITAN OSAKA, SOUTHWEST JAPAN, CONSTRAINED BY TECTONIC GEOMORPHOLOGY AND SEISMIC REFLECTION PROFILES

Tatsuya ISHIYAMA[1], Yuichi SUGIYAMA[1], Karl J. MUELLER[2], Masaki SUEHIRO[3], Hiroshi YOKOTA[3] ([1]Active Fault Research Center, Geological Survay of Japan, [2]University of Colorado, [3]Hanshin Consultants, Co. Ltd)

We present structural models constrained by tectonic geomorphology, surface geologic mapping and high-resolution seismic reflection profiles to define the kinematic evolution and geometry of active fault-related folds along the Uemachi fault zone (UFZ) and Ikoma fault zone (IFZ) beneath Osaka metropolitan area. The UFZ and IFZ are active intraplate fault systems in southwest Japan, and are defined by 45-km-long arrays of active, west-verging reverse faults. We focus on the northern half of the UFZ and IFZ where we use the kinematic evolution of active fault-related folds to constrain rates of slip on underlying blind thrusts since early Quaternary time. Rocks uplifted in the hangingwall of the IFZ are composed of late Cretaceous granitic rocks that form the stripped cores of basement-involved folds which override a thick sequence of Neogene sediments in the Osaka basin. Numerous secondary, bedding-parallel thrusts also deform the Neogene sediments and late Quaternary fluvial terraces and are interpreted to form by flexural-slip folding that acts to consume slip on the primary blind thrusts across synclinal axial surfaces. The best-fitting trishear model for the forelimb geometry above the IFZ imaged on the seismic section requires a 56° east-dipping thrust fault with a 38° apical angle. This solution provides a 0.7 mm/yr of slip rate on the IFZ based on an age of shallow marine deposits folded across the forelimb identified in the borehole. Very subtle, Holocene fold scarps that deform alluvial fan deposits marked by changes in drainage channel networks coincide with the projected surface trace of the thrust tip. Fluvial terraces folded across the west-dipping forelimb, and east-dipping backlimb of the frontal UFZ suggest that it grows above an active, east-dipping thrust. The seismic sections across the northern UFZ and nearby borehole profiles show that the core of the basement-involved fold also overrides onto the lower portion of the thick Neogene sediments in the Osaka basin. Trishear solution for the northern UFZ suggests that the forelimb geometry has formed above the propagating tip of a 40° east-dipping thrust. A 458 m of slip for the retrodeformed horizon (shallow marine sediments Ma-1) provides a slip rate of 0.38 mm/yr, which corresponds well with a rate of vertical separation estimated on numerous, dated shallow marine horizons across the UFZ.

LATE HOLOCENE EARTHQUAKE EVENT ON AN 80-KM-LONG BLIND THRUST FAULT SYSTEM BENEATH GREATER METROPOLITAN TOKYO

Kiyohide MIZUNO[1], Yuichi SUGIYAMA[1], Yuichiro FUSEJIMA[1], Toshihiko SUGAI[2], Takashi HOSOYA[3], Haruo YAMAZAKI[4] ([1]Active Fault Research Center, GSJ, AIST, [2]Graduate School of Frontier Sciences, University of Tokyo, [3]Chuo Kaihatsu Corporation, [4]Graduate School of Science, Tokyo Metropolitan University)

Trenching and continuously-cored boring surveys identified a late Holocene earthquake event on an 80-km-long blind active fault system in the greater Tokyo metropolitan area. The NW-striking Fukaya fault system is located along the northwestern margin of the Kanto plain where greater metropolitan Tokyo is expanding. The fault system consists of an 80-km-long array of four left-stepping west-side-up reverse faults, and several subsidiary east-side-up back thrusts on the west. The west-side-up reverse faults appear as monoclines or fault-related folds on the ground surface. They are widely concealed beneath thin young Holocene fluvial deposits, and partly modified into steeper scarps by fluvial erosion. The maximum long-term uplift rate of the monoclines is estimated to be more than 0.3 mm/y based on tectonic geomorphology, seismic reflection profiles and boring data. For clarifying recent activity of the Fukaya fault system, we dug 14 continuously-cored boreholes across a monocline above the 35-km-long central (third from the north) west-side-up blind thrust, and excavated two trenches on its east-side-up back thrust about 4 km long. The boring survey showed that the most recent growth of the monocline took place after deposition of silt-sand beds dated 5500-6100 yBP. The excavation exposed a sharp north-dipping reverse fault that displaces 5300-5600 yBP soils by about 1 m along the fault plane. A radiocarbon age of 1700 ± 50 yBP was obtained from soils overlying the reverse fault. These data suggest that the most recent earthquake event with major surficial deformations occurred between 5.3 and 1.7 ka on the central geometrical segment of the Fukaya fault system. Historical documents and archaeological evidence indicate that a large (M ≥7.5) earthquake occurred in AD 818 and caused strong shaking in the area adjacent to the Fukaya fault system. However, no archaeological evidence of a large earthquake in the early Jomon to Yayoi Period (about 6 to 1.7 ka) is known in the adjoining area. In order to solve this discrepancy, we reinvestigate the timing of this geologically-identified late Holocene earthquake event.

ACTIVE TECTONICS ON THE MIDDLE PART OF TOKACHI-PLAIN FAULT ZONE, HOKKAIDO, WESTERN EDGE OF KURILE FORE-ARC SLIVER, JAPAN

Wataru HIROSE, Sunao OHTSU, Jun TAJIKA, Masazo TAKAMI (Geological Survey of Hokkaido)

Tokachi-Plain Active Fault Zone exists at the eastern side of Tokachi Plain, and consists of westernmost edge of Kurile fore-arc sliver. They would be appearred at least from Neogene and still active until now. Detailed survey of these faults has started by Hokkaido Local Government until 2001. At the middle part of Tokachi-Plain Active Fault Zone, reverse fault uplifted onto the western side. Pliocene AEPleistocene sedimentary rocks had been steepen by the fault. Al least two liner flexure scarps appeared at the river terrace. Their slip rate could be estimated 0.2 m / ka or smaller. Shallow seismic reflection survey have dune to investigate the subsurface structure of the middle part of Tokachi Active Fault Zone. Obvious flexure zone exist at the eastern side of the survey line. This flexure is 500 m wide and uprise at eastern side. This subsurface flexure agree with the bouguer anomaly survey, that increase at the eastern side on the flexure. On the other hands, reflection data indicates that the weak westward tilting exists at western edge of the survey line. This tilting may correspond to the western frontal deformation zone of the faults.

SS03/08A/D-043   Poster   0830-202

SOUTHERN EXTENSION OF SUMATRAN FAULT AND ITS TECTONIC SIGNIFICANCE, OFF SUNDA STRAIT

Wonn SOH[1], Yusuf S. DJAJADIHARDJA[4], Christoph GAEDICKE[3], Saneatsu SAITO[1], Yasutaka IKEDA[2] ([1]Japan Marine Science and Technology Center, [2]University of Tokyo, [3]Federal Institute for Geosciences and Natural Resources (BGR, [4]Agency for the Assessment and Application of Technology, BPPT)

Slip partitioning between closer-to-trench normal thrusting and trench-parallel strike-slip faulting has been postulated mainly from the study of earthquake slip. Offshore of Sunda Strait is one of the most appropriate areas in the world to examine the strain partition recorded in overlying fore arc. However there is no dependable geomorphic data yet although an attention for offshore of the Sunda Strait has been paid for a long time to the junction of the regimes between normal subduction off Java and oblique subduction off Sumatra. A single channel and bathymetric data were obtained by R/V Yokosuka, YK01-02/YK02-07 cruises provide quite different geomorphologic view to the expected previously. Namely we can identify the southern extension of Great Sumatran Fault as an active fault. Shinkai 6500 dive enables to shows a few meter vertical topographic displacement along the fault associated with a significant shear zone. The junction area is occupied by a bundle of tectonic blocks, well demarcated by SSE- and east-trending lineaments. A few amount of mud diapir mounds are recognized along the east-trending thrust that propagates from the southern extension of the GSF, where corresponds to significant negative Bouguer anomaly zone (*approx. -150 mgal*). Of course the morphologic feature is different to the transtensional graven in the Sunda Strait, it tells us that the strain partition in a fore arc does not uniformly stretched in the entire fore arc but localized (or concentrated) in specific area such as this area.

SUBSURFACE STRUCTURE BENEATH SUNDA STRAIT INFERED FROM MARINE SEISMIC REFLECTION SURVEY

Nugroho Dwi HANANTO[1], Hariadi PERMANA[1], Wahyu TRIYOSO[2], Sonny WINARDHIE[2] ([1]Research Center for Geotechnology, Indonesian Insitute of Sciences, [2]Department of Geophysics and Meteorology, Institut Teknologi Bandung)

Sunda strait is a unique area located at transition between frontal subduction of Indian-Australian plate and Eurasia plate to the south of Java and oblique subduction to the west of Sumatra. The Sunda strait has been developed since last 15My (Later Cenozoic) caused by clock wise rotation of Sumatra relative to Java and displacement to the north-northwest of southern block of Sumatra along Semangka fault. The Sunda strait supposed as the axis during the rotation. The peak of this geological event occurred at 5My. This was characterized by extension and subsidence that builds Sunda strait. Upper part of the subducted plate is 21 km depth whilst the moho is 28km depth and bordered by volcanic products of different ages. Most of the islands within this strait consist of volcanic products covered by recent coral reefs in their flanks.Fault line pattern develops at Sunda strait that controlled Krakatau complex is supposed to NW-SE direction, parallel to Sumatra fault system and interpreted as normal fault with dip direction to SW, but gravity data shows no indication of continuation to the east of Sumatran fault across the Sunda strait. Along NW-SE trending, there are situated some volcanic centers and islands that are supposed to be volcanic centers. These include Rajabasa volcano, Sebuku Island, Sebesi Island, Islands of Krakatau Complex, Panaitan Island and Payung volcanic center in Ujung Kulon Peninsula. Around the southern tip of Sumatra Island and Sebuku Island can be found outcrops of andesite lava that mostly presenting sheeting joints. These rocks are supposed to be Pliocene in age. The Rajabasa volcano and Sebesi volcano (that construct the Sebesi Island) are also situated in the same areas with the former ones. The latter are constituted of lavas, breccias and tuffs of andesitic to basaltic compositions, and they are classified as Young Volcanic Deposits of Quaternary ages. The Krakatau Complex consists of Panjang, Anak-Rakata, Rakata, Sertung and Ombudsmen islands. The rock of this complex consists of lava, lava breccias and pumiceous tuffs having of dacitic, andesitic and basaltic composition. Oldest volcanic products are andesitic in composition and then followed by those of basaltic ones.We have conducted shallow marine seismic survey on northern part of Krakatau Complex and in the front of Semangka Bay. This survey was aimed to study the subsurface structure beneath the Krakatau Complex and to delineate the continuation of Sumatran Faults Zone to Sunda Strait. The seismic images revealed from this research shows, layered sediment and fault structures that indicate the lineament of Sumatra Fault Zone to Sunda Strait and subsidence event of this region.

QUANTITATIVE EVALUATION OF INLAND SEISMIC ACTIVITY IN JAPAN BY USING GIS

Satoshi ITABA[1], Kunihiko WATANABE[1], Ryohei NISHIDA[2] ([1]Research Center for Earthquake Prediction, Disaster Prevention Research Institute, Kyoto University, [2]Faculty of Technology, Tottori University)

It is important for quantitative evaluation to estimate the seismic activity; however, this evaluation has been seldom performed. It has been often determined by subjectivity until now. On the other hand, the assessment of active faults is the general public requirement today. We proposed a GIS(Geographic Information System)-method of quantitative evaluation of seismic activity (Nishida et al,1999). By this method, the activity of inland active faults in Japan is estimated. We used in this investigation 2,324 active faults listed in "ACTIVE FAULTS IN JAPN"(University of Tokyo Press). The shallow inland earthquakes of JMA catalogue from Oct.1997 to May 2002 are analyzed. By applying GIS to these fault traces, a buffered zone can be made, which is the zone within a distance between Ri and Ri+1 from the fault. The earthquakes included in each buffered zone can be chosen. The seismic activity of the zone is expressed by using three parameters, namely, number of events, accumulated fault surfaces and released energy. Dividing total amount of these quantities by the area of the corresponding zone, the density of seismic activity can be obtained for each buffered zone. Considering the relation between those activity density and the distance from the fault trace, the effective distance can be estimated, in which the seismic activity is influenced by the existence of the fault. By adopting the effective distance obtained above, we can examine the seismic activity of each fault. For some faults, the seismic activity decreases in proportion to distance from the fault, but not for others. Generally speaking, the correlation between seismic activity and the distance from the fault is not so high. Inland seismic activity of southwest Japan is generally higher than that of northeast Japan. There may be two reasons. First, the main pattern of fault movement in Northeast Japan is dip-slip, and that in Southwest Japan is strike slip. Dip slip type fault needs much tectonic energy to move than strike slip ones. Second, it may be caused by the difference of coupling factors.

A COMPREHENSIVE SIMULATION OF LITHOSPHERE DEFORMATION WITH FAULT SLIP USING A COUPLED METHOD OF FINITE ELEMENT METHOD WITH SPRING-BLOCK MODEL

Hanjing HONG, Yong YU, Xiuzhen ZHENG, Peixun LIU, Wei TAO (Institute of Geology, China Seismological Bureau)

A numerical method of finite element method (FEM) coupled with spring-block model (SBM) is developed to simulate the system of lithosphere with faults. The slip of intra-plate fault was studied using a spring-block system sandwiched in between two lithosphere blocks. Stress

and displacement exchange between FEM and SBM is engaged to couple these two methods in every time step. The resulting displacement from FEM was imposed on SBM as the boundary constrain of fault, and resulting stress, getting from SBM, was used as the intra-boundary constrain of FEM. The lithosphere is buildup using a heterogeneous two-layer viscoelastic model with different viscosities. With constant stress and constant velocity boundary conditions ,stress transfers from the ductile layer to the brittle layer, and the heterogeneous rheology of ductile layer also affects the stress distribution in the brittle layer. As a result, the brittle-ductile regime provides an efficiency mechanism of stress transfer in the crust, and the deep-seated heterogeneous ductile layer resulting stress concentration in the brittle layer. The stress evolution of this coupled model can be divided into two stages: accumulation stage and critical stage. During the stage of accumulation, the stress build up in both lithosphere and fault, during the stage of critical, the stress fluctuated in a steady level in both lithosphere and fault, and the amplitude of stress alteration is much less than the steady level. Most earthquake events occur in the critical stage. Earthquake recurrence period, the correlated characteristic magnitude, seismic stress drop, Gutenberg-Richter law can be observed from the results of this coupled simulation. The modeling rupture process can be compared with geophysical inversion of seismic wave. The rupture process initiates from the nucleation node, spreads outward to both two sides. As the initial node, the stress state of this slider-block controls the time and place of the rupture, but it cannot affect the magnitude. Instead of the stress of initial node in the fault, the elastic energy of crust blocks play an important role to affect the magnitude of earthquake. Spatial distribution of major earthquakes in the Chuandian area was studied using this coupled simulation. Fault segments are put into the coupling model of boundary faults, and the simulated earthquake sequence is compared with the historical catalogue in this area.

THE ROLE OF PORE FLUIDS IN THE MECHANISM OF SEISMIC SEQUENCES

Antonello PIOMBO, Michele DRAGONI (Dipartimento di Fisica, University of Bologna)

It is generally agreed that the occurrence of seismic sequences implies a kind of interaction between different fault segments. The coseismic stress transfer produced by each dislocation is the most obvious component of such an interaction. However the time intervals elapsing between subsequent events in a sequence indicate that the coseismic stress is not sufficient to trigger other seismic events by itself. We investigate the possibility that the coseismic stress field may induce flow of pore fluids, altering the pore pressure distribution in the region. The flow velocity depends on the pressure gradient and the permeability of the medium. We consider a porous, elastic medium and study under which conditions the change in pore pressure induced by a fault dislocation may lead to a significant decrease in friction on adjacent fault segments. A gradual decrease of friction on a fault segment, which was already loaded as a consequence of stress transfers by previous dislocations in the seismic sequence, might lead to the failure of the segment itself, after the time required for pore fluid diffusion to take place.

PRECISE SUPERVISION OVER MOTIONS OF THE EARTH SURFACE AND UNDERGROUND SITES

Mstislav N. DUBROV[1], Vladimir A. ALYOSHIN[1], Viktor A. VOLKOV[2], Anna V. KALININA[2], Rostislav F. MATVEEV[1], Sergei A. MOISEENKO[2] ([1]Institute of Radio-engineering and Electronics, Russian Academy of Sciences, [2]Institute of Physics of the Earth of RAS, Moscow, Russia)

The test of natural and artificial geological processes which change thestatics and dynamics of stress-deformed state of medium are in consideration.It is the straight method of an estimation of hazard during both the creatingand the using of an engineering or energetic buildings, plants etc. Thecrustal processes in continental areas as active seismicity and recent faultsmotion make the safety problems being over important. The special place inassociated risk decrease is occupied by real time supervising over system:building - basis - geological medium. The precise geophysical methods of thissystem check are discussed. Horizontal and vertical motions of the earthsurface and parts of underground construction are measured by the highaccuracy laser strainmeters and capacitive seismo-gravimeters. Three types ofload actions on medium were explored: (1) immediate mechanical loading, (2)change of mode of the water wells operation, (3) action of sharp differencesof atmospheric pressure. Laser strainmeter measure the relative displacementsof two points at the earth surface or buildings on which the interferometer isanchored. The accuracy of the order of 10(-3) nm is achieved at basis 1-100 m.Seismo-gravimeters are supplemented by inertial properties high-sensitiveaccelerometers. The devices with resolution of 0,5 uGal to vertical biasesabout 1 um in a seismic frequency band. (1) We test the load affection of theearth surface by measuring the linear deformations of a ground under activityof the traffic motion. It´s accompanied by 3-D spatial strains: vertical andhorizontal tensions from which elastic modules of the medium are defined.(2) Changes of a mode operation of underground water wells cause the velocityof ground strains up to 10-20 um per hour. The absence of instrumental checkfor medium status during a heavy use of underground waters give in a raise ofhazard from such phenomena as the sedimentary of building bases, developmentof landslips etc. (3) The connection of intensive variations of atmosphericpressure and motions of the earth surface are explored on distances betweenobservation sites of 45 km. We obtained the synchronous records of pressure,gravity acceleration and the earth strains. The dynamic perturbations in theatmosphere have undular microstructure and are accompanied by motions of theearth surface as enough complicated superposition of horizontal strains andvertical displacements. These perturbations are precisely delineated overphase structure and are spread along a demarcation the Earth - atmospherewith the velocities of 30-50 km per hour.

TECTONIC DEFORMATIONS DOMINATED BY NONLINEAR VON KÁRMÁN EQUATIONS

Tomoaki CHIBA, Hiroyuki NAGAHAMA (Department of Geoenvironmental Sciences, Graduate School of Science, Tohoku University)

Mechanical behaviour of tectonic deformations under the infinitesimal elastic deformationsis linear behavior and therefore Curie symmetry principle, which is the law of causality for symmetry, is always preserved.On the other hand, breaking of Curie symmetry principle has already observed in several nonlinear phenomena.Such nonlinear systems are mathematically proved to be dissymmetrical by functional analysis and group theoretical bifurcation analysis.Von Kármán equations can describe such nonlinear systems,i.e. bending and buckling of thin elastic plates studied in engineering.We point out a few kinds of tectonic deformations (e.g., laccolith mountaining, multilayer deflection and plate bending) can be also described by von Kármán equations.Von Kármán equations can also explain crack pattern formations (e.g., formations of echelon crack and *c*-surface in S-C mylonites) by using an analysis of the group theoretical bifurcation method.The analysis exhibits that von Kármán equations can allow to break Curie symmetry principle.Hence Curie symmetry principle cannot be used blindly to infer the past events from the rests now on the earth.The

group theoretical bifurcation analysis reveals that the nonlinear system behaves nonlinearly only at singular points on the solution path and that the system behaves linearly at ordinary points consisting most part of the solution path on the other hand.Therefore, Curie symmetry principle is still useful to interpret the history of tectonic deformations.With the new constraint for nonlinear dissymmetrical deformations,we can use Curie symmetry principle properly to consider nonlinear systems in tectonic deformations.

VELOCITY AND STRESSES DURING TECTONIC DEFORMATION; INSIGHTS FROM DISCRETE ELEMENT SIMULATIONS

Yasuhiro YAMADA[1], Atsushi TANAKA[2], Toshi MATSUOKA[2] ([1]JAPEX Research Center, [2]Kyoto University)

Discrete Element Method (DEM) approximates the geologic body as an assembly of particles similar to sandbox experiments, thus can simulate the brittle behaviour of the upper crust appropriately. We have applied the method to a modelled collision process of the Indian sub-continent to the Eurasian Plate, and have extracted velocity vectors and normal/shear stress fields of each particle for every short time interval during deformation. Since the method is a forward modelling technique, progressive development of strain and stress can be examined during the collision process. The results show that the velocity distributions and the stress fields of the particles are quite unstable. This may be due to the brittle behaviour of the particle assembly corresponding to the upper crust, in which localisation of the stress and its release by faulting are clearly observed. In particular, shear stress concentration was commonly generated along a broad shear band and was released by faulting causing a large velocity anomaly in two opposite directions. The velocity distribution and normal stresses of the particles correspond to GPS and in-situ stresses respectively when applied to real geology. The GPS vectors and the directions of in-situ stresses of the eastern Asian region, however, show overall continuous curvature from the Himalayan Mountains. Thus such a large-scale tectonics may be primarily controlled by ductile deformation of the lower crust and its substrates.

COMPARING GEODETIC AND GEOLOGIC DEFORMATION RATES AND PATTERNSIN SOUTHERN CALIFORNIA, U.S.A

Noah P. FAY, Eugene D. HUMPHREYS, Ray J. WELDON (Department of Geological Sciences, University of Oregon)

We present a comparison of geodetic and geologic-based deformation models for southern California, U.S.A. Contemporary surface deformation, which is accommodated by a diffuse zone of predominantly strike slip motion (the San Andreas fault system), is well characterized by a dense array of geodetic stations (mostly those of SCIGN, the Southern California Integrated GPS Network). Geodetic data tend to be spatially averaged and temporally discrete and are commonly used to determine long-term slip rates via simple kinematic models, such as an elastic halfspace. Alternatively, geologic data (e.g., paleoseismic trench studies, offset alluvial fans, etc.), which are spatially discrete and temporally averaged, provide an independent measure of the same long-term slip rates on active faults. In this study we have constructed a kinematic forward model, driven largely by geologically determined slip rates. Model faults creep below seismogenic depths of ~ 13 +/- 3 km and are locked above to simulate interseismic strain. Surface velocity and strain rates are calculated using the linear elastic half-space solutions of Okada (1992). In general the surface deformation observed by GPS and predicted by the geology-based kinematic model agree, to within 95% confidence. In other words, the residuals, or differences between the observed and predicted, are not significantly different from zero. The residual RMS (Root Mean Square) is ~ 5 mm/yr. There are, however, three regions where significant differences exist between the two data sets: along the San Andreas fault at Parkfield, CA; the Mojave Desert, north and east of the "Big-Bend" section of the San Andreas fault; and the greater Salton Trough area, between the San Andreas and San Jacinto faults from ~ 33.5N to the US/Mexico border. We offer some possible solutions to reconcile these differences.

PSINSAR AS A RESOURCE FOR TECTONIC MODELLING IN SUBDUCTION AREAS

Roger M.W. MUSSON[1], Mark HAYNES[2], Julian J. BOMMER[3], Alessandro FERRETTI[4] ([1]British Geological Survey, [2]NPA Group, [3]Dept Civil Engineering, Imperial College, London, [4]TeleRilevamento Europa)

PSInSAR is a new technique for Earth Observation derived land motion measurement which relies on permanent scatterers, and offers the possibility of measurements of ground displacements to a degree of accuracy, and over periods of time, previously unobtainable from conventional interferometry. This technique has been developed by TeleRilevamento Europa of the Politecnico di Milano in Italy. By using at least 30 satellite radar scenes of the same place acquired over many years, a network of highly reflective pre-existing ground features (permanent scatterers) are identified against which sub-mm measurements of motion can be made. These permanent scatterers can be any large, permanent angular object, such as building roofs, metallic structures, and even large boulders. Using these data, very accurate displacement histories can be obtained for the period 1991 to the present. Calibration with GPS data show good agreement, but the PSInSAR data are less noisy. A unique attribute of PSInSAR is that the history of displacements over the last nine years (length of the SAR data archive) can be extracted for any part of the globe with data coverage. We present here the results of a test monitoring study for the Tokai area of Japan. The data are similar to those derived by other means (GPS, levelling) but much denser (291,000 data points between Hamamatsu and Ito). Such data provide a resource for studies such as the modelling of impending subduction earthquakes using the ABIC method. This work results from a European Space Agency (ESA) ´Earth Observation Market Development´ project entitled ´Developing markets for EO-derived land motion measurement products´, involving, NPA (lead), the British Geological Survey (UK), Imperial College (UK), TeleRilevamento Europa (Italy), ImageONE (Japan), the Geographic Survey Institute (Japan), Oyo Corporation (Japan), Fugro (Netherlands) and SARCOM (ESA data distributing entity).

TIDAL COMPONENTS IN GROUNDWATER LEVEL OBSERVED AT OSAKAYAMA OBSERVATORY, KINKI DISTRICT IN JAPAN

Kunihiro SHIGETOMI, Masatake HARADA (Research Center for Earthquake Prediction, Disaster Prevention Research Institute, Kyoto University)

Continuous monitoring of groundwater level has been carried out since December 1976 at Osakayama observatory in order to investigate relations between changes in groundwater level and strain changes and earthquake occurrence.To verify availability of continuous monitoring of groundwater level for geodynamics studies, it is necessary to know fundamental characteristics of observation well in various frequency bands.The response of groundwater level for the earth tide is the most fundamental signal.In 1980´s, as a result of the frequency analysis using the self-registering record by the float adopted as an observation system since the beginning, M2 and O1 tidal components were clearly distinguished.And it was clarified that the daily variation of groundwater level was the tidal variation caused by tidal potential.For the digitizing of the self-registering record, however, there was a limit at the accuracy of amplitude and time resolutions, and it was insufficient for discussing amplitude and phase of the tidal variation precisely.From 2001, we therefore applied the pressure detection type groundwater level indicator together in the same well.From this instrument, the accuracy of amplitude and time resolutions of the record was improved.In this study, we analyzed tidal variation which appears in groundwater level using new type indicator record.And we investigated relation between groundwater level and strains.Furthermore, we checked temporal variations of tidal factors associated with the earthquake (M=5.1, Δ=25km).As a result of tidal analysis, it became clear that groundwater level and strain observed with extensometer corresponded well.Comparing groundwater level with cubic dilatational strain predicted by GOTIC2, which was program to compute the global tidal deformation, we obtained these interaction coefficients about 2.5 mm/E-8strain in M2 constituent and about 2.0 mm/E-8strain in O1 constituent.And temporal variations of tidal factors revealed that the changes of groundwater level were seen to appear before about 10 days of the earthquake.

TECTONIC MOTION OF THE RYUKYU ARC, SOUTHWEST JAPAN INFERRED FROM GPS VELOCITY FIELD AND EARTHQUAKE MECHANISM

Tsuyoshi WATANABE[1], Takao TABEI[2] ([1]Graduate School of Science, Kochi University, [2]Department of Natural Environmental Science, Kochi University)

Ryukyu Arc is a NE-SW trending islands arc connecting Taiwan and Kyushu, southwest Japan. At its southeastern boundary, the Ryukyu Trench, the Philippine Sea plate subducts at a rate of 6-8cm/yr. Japanese nationwide continuous GPS array has illustrated trenchward extrusion of the islands at a rate of 2cm/yr in the northeastern part and larger than 4cm/yr in the southwest. Tectonic movement of the Ryukyu Arc may be characterized by low plate coupling (loose constrain) at the Ryukyu Trench and backarc opening (or rifting) at the Okinawa Trough, the active backarc basin on the northwest. Though the movement of the Ryukyu Arc looks like a block motion rather than an internal elastic deformation, more details are not clear because GPS stations have been deployed nearly parallel to the Ryukyu Trench and the Okinawa Trough. At first we divide the region into several blocks based on spatial variation of earthquake focal mechanism and GPS velocity field, and determine Euler vector of each block. As the first approximation, tectonic movement in this region can be reproduced by the motion of five blocks, with an average discrepancy of about 5mm/yr between the observed and predicted velocities. Second we introduce moment tensor solutions of shallow earthquakes and translate them into strain rates in order to quantify plate coupling at the Ryukyu Trench. Plate coupling estimated is about 30% off Kyushu, then steeply decreases to a few percent in the central (near Okinawa Island), and again increases up to about 50% east off Taiwan. However, velocity discrepancy between observation and prediction still remains even after taking the plate coupling into consideration. Current GPS and earthquake data strongly suggest a trenchward motion of the Ryukyu Arc, divided into several tectonic blocks and probably driven by the backarc opening at the Okinawa Trough, accompanying small internal deformation.

MULTI-DISCIPLINARY STUDY OF EARTHQUAKE SOURCE AREAS AND GAPS ALONG THE EASTERN MARGIN OF JAPAN SEA, OFF HOKKAIDO

Yukinobu OKAMURA[1], Kenji SATAKE[2], Ken IKEHARA[1], Kohsaku ARAI[1], Akira TAKEUCHI[3] ([1]Institute for Marine Resources and Environment, AIST, [2]Active Fault Research Center, AIST, [3]Fuculty of Science, Toyama University)

The eastern margin of the Japan Sea has been a zone of major E-W contraction during the last 2-3 million years. Four large earthquakes (M >7.5) have occurred along this margin during the 20th Century. The largest earthquake is the 1993 Hokkaido-Nansei-oki earthquake (M 7.8) that was caused by rupture of 140 km long fault along the Okushiri Ridge. Abundant seismological, tsunami and geodetic data made it possible to construct the detailed model of source faults of this earthquake. In contrast to the 1993 earthquake, the 1940 Shakotan-oki earthquake (M 7.5) that occurred about 160 km north of the 1993 earthquake has been studied based on insufficient data. Because the location and size of its source area has been controversial, it is not clear if there is a seismic gap between the 1993 and 1940 earthquakes. To confirm the source area of the 1940 earthquake, we have conducted detailed marine surveys in and around the inferred source area of the 1940 earthquake.Seismic and bathymetric surveys have shown that there are two overlapping rows of several structural ridges in the area. The northeastern row is composed of three ridges including the Oshoro seamount which is located just on the epicenter of the earthquake. The southern ridge terminates at about 50 km north of the source area of the 1993 earthquake. The southwestern row of the ridge consists of the Kaiyo seamount and ridges extending to the south, which continues to the Okushiri ridge at the source area of the 1993 earthquake.Dive surveys provided us important data about the recent activities of the active faults. Dives in the source area of the 1993 earthquakes observed wide-spread sea-bottom disruption; open cracks, collapse and debris flow deposits. They indicate that ancient earthquakes have been geologically recorded as the sea-bottom disruptions. Several dive surveys were conducted in the source area of the 1940 earthquake. Fresh disruptions were observed on the Oshoro seamount and ridges to the north and south of the seamount, whereas disruptions were covered with thin muddy sediments in the Kaiyo Seamount. The observations suggest that Oshoro seamount possibly belong to the source area of the 1940 earthquake. The Kaiyo seamount can not be a source area of the earthquake, while it is active and could be a source area older earthquake. These sea-bottom observations and geologic structure also suggest that there is a seismic gap between the 1940 and 1993 earthquakes. The width of the gap is inferred to be longer than 50 km. Tsunami simulation from the 1940 earthquake will be updated based on the geologic structure and compared with the observed tsunamis.

COLLISION STRUCTURE IN THE SOUTH OF HOKKAIDO REGION, JAPAN, DEDUCED FROM OBSERVATIONS WITH OCEAN BOTTOM SEISMOGRAPHS AND DENSE NETWORK OF LAND STATIONS

Yoshio MURAI[1], Satoshi AKIYAMA[1], Kei KATSUMATA[1], Tetsuo TAKANAMI[1], Tadashi YAMASHINA[2], Tomoki WATANABE[3], Ikuo CHO[4], Masayuki TANAKA[5], Asako KUWANO[6], Naoto WADA[1], Hideki SHIMAMURA[1] ([1]Institute of Seismology and Volcanology, Graduate School of Science, Hokkaido University, [2]National Research Institute for Earth Science and Disaster Prevention, [3]Japan Marine Science and Technology Center, [4]Geo-Research Institute, [5]Seismological and Volcanological Department, Japan Meteorological Agency, [6]Research Center for Prediction of

S

Earthquakes and Volcanic Eruptions, Graduate School of Science, Tohoku University, [7]Geodynamics Research Center, Ehime University)

In the south of Hokkaido region, Japan, the Kuril arc is considered to collide with the northeast Japan arc. Arc-arc collisions are important process for the growth from an island-arc crust to a new continental crust. Such a collision is responsible for the uplift of the Hidaka Mountains, high seismic activity and large earthquake occurrence such as the 1982 Urakawa-oki earthquake (*Ms* 6.8) in this region. It is important to image the 3-D structure of crust and uppermost mantle in order to clarify the collision tectonics and understand the mechanism of earthquake occurrence. We conducted observations of microearthquakes with a dense network of land stations and ocean bottom seismographs to reveal the relation between the collision structure and earthquake occurrence. 630 hypocenters were determined during the period from August 7 until September 30, 1999. We determined 3-D *P* wave velocity model using travel time tomography. From the tomographic images, low-velocity anomalies are detected to extend from the western side to the central part of the Hidaka Mountains in the depth from 9 to 25 km. These low-velocity anomalies are running parallel to the Hidaka Mountains from 42°N to 42.8°N. They are considered to be the crust of the northeast Japan arc. High-velocity anomalies are found just beneath the crest of the Hidaka Mountains. They stretch in the NW-SE direction so as to overlie the low-velocity anomalies stated above. They are considered to be the lower crust of the Kuril arc obducted towards the west. In the eastern side of the Hidaka Mountains, we find the lower crust of the Kuril arc is delaminated by the collision and the lower part of it is dipping gently southwestward from east of the Hidaka Mountains to the source area of the Urakawa-oki earthquake in the depth from 35 to 45 km. The faulting mechanism of the Urakawa-oki earthquake shows a thrust type solution with a compressional axis in NE-SW direction and the maximum stress axes estimated by the stress tensor inversion method and focal mechanism solutions of many microearthquakes show NE-SW direction in the western side of the Hidaka Mountains. The direction of the earthquake-generating stress is consistent with our collision model. The delaminated lower crust appears to collide with the upper boundary of the subducting Pacific plate. Our model well explains why the seismicity is high even in such a deep crust in this region. The length of the delaminated lower crust estimated here is consistent with the total crustal shortening length between the two island-arcs evaluated from geological data. Our model suggests the geometry of the delamination structure has a strong effect on earthquake occurrence and the Urakawa-oki earthquake was caused at the front of the delaminated lower crust.

STRAIN PARTITIONING BETWEEN THE SURUGA TROUGH AND THE ZENISU THRUST: NEOGENE TO PRESENT TECTONIC EVOLUTION IN THE ONLAND AND OFFSHORE TOKAI DISTRICT, JAPAN

Tetsuro HIRONO (Deep Sea Research Department, Japan Marine Science and Technology Center)

The Tokai district, central Japan, is located close to the convergent boundary between the Philippine Sea and Eurasian plates. Historical documents show that large interplate earthquakes have repeatedly occurred in this district along the Nankai-Suruga Trough. Recent events in the Tokai district include the 1707 Hoei (M8.4), 1854 Ansei-Tokai (M8.4) and 1944 Tonankai (M8.0) earthquakes. On the basis of the distribution of seismic intensities, coseismic crustal movements and tsunami waves, Ishibashi (1977, 1984) concluded that the faulting areas of the former two events covered the Nankai and Suruga Troughs, whereas that of the last event did not reach the Suruga Trough. Therefore, the area extending from the Cape Omaezaki to the northern end of the Suruga Bay can be regarded as a seismic gap, where tectonic stress has been accumulating since the 1854 Ansei-Tokai earthquake. Since this urgent warning against an impending ´Tokai earthquake´, spatially and temporally dense observations of various kinds, such as seismic activity, crustal movements, electrical resistivity, and hydrological and geochemical changes, have been conducted to detect premonitory phenomena of a future Tokai earthquake, and to improve prediction of its occurrence. In addition to such geophysical methods, comparison of the present tectonic activity with past-movement, and to assess whether the tectonic movements in the Tokai district are now active or inactive, are also important. In this study I reconstruct quantitatively the spatial and temporal tectonic evolution of the eastern Tokai district based on a geological survey, and discuss the past and future degree of activity in this district. The geological survey and some interpretations of seismic profiles in the eastern Tokai reveals the tectonic evolution quantitatively. The horizontal crustal shortening strain and the strain-rate since the Neogene are calculated as 12 % and 2 x 10-6 %/yr, respectively. The present interseismic horizontal crustal strain and strain-rate around the Omaezaki area are approximately 4 x 10-7 % and 4 x 10-9 %/yr. By comparing these rates, the present tectonic horizontal movement in the eastern Tokai has been becomig less active. This imply progressive transition of tectonic activity into low strain field. Since the tectonics around the Izu Peninsula have been strongly related to the collision of Izu to Japan, this phenomenon may result from the strain partitioning between the Suruga Trough and the Zenisu Thrust.

TRANSCURRENT MOTIONS AND DEFORMATION ON THE FORE-ARC OF NORTHEAST JAPAN

Yasuto ITOH[1], Tetsuro TSURU[2] ([1]Dept. of Earth Sci., CIAS, Osaka Prefecture University, [2]Japan Marine Science and Technology Center)

Multi-channel seismic survey gives a new insight for deformation mode along an active margin. Geologic structure on the northern part of the fore-arc of northeast Japan has been understood in relation with late Cenozoic compressional stress regime as a result of subduction of the Pacific Plate and / or collision of the Kuril Arc. Recently acquired seismic data combined with reprocessed sections do not accord with such theory, but prefer NNW-SSE trending deformation zone bounded by large transcurrent faults. Contrast in geophysical properties (density, seismic velocity, magnetic anomaly, etc.) and geologic structure across the western fault strands implies considerable rearrangement of the crust associated with fault motion. Because lateral motions in the same azimuth since the Cretaceous time have been reported from the southern fore-arc of the island arc, deformation observed in the study area is to be linked with regional tectonic events along the eastern Eurasian margin. We also confirmed fault displacements in surface sediments using single-channel seismic profiles, suggesting recent activity on the NNW-SSE faults, on which some epicenters of shallow strike-slip aftershocks of the 1994 Sanriku-oki earthquake are located. Several en echelon topographic bulges are aligned on the fault trends, and interpreted as a growth right-lateral wrench deformation zone, since the bulges consist of deformed late Cenozoic sedimentary units. Untilted characteristic remanent magnetization of the Paleogene core samples in a borehole on the fore-arc shelf shows a significant easterly deflection indicative of a clockwise rotation as a result of dextral wrenching. Thus transcurrent motions and related deformation have been dominant on the fore-arc of northeast Japan. It is noteworthy that some remarkable tectonic events such as back-arc opening of the Japan Sea and subduction erosion on the Japan Trench occurred during the course of the long-standing motions of the fault zone, easternmost strand of which seems to converge into the collision front between northeast Japan and Kuril Arcs to the north. Age determination of activity and quantitative estimate of displacement on the faults are essential

for reconstruction and understanding of tectonic processes going on the convergent plate boundary.

TRANSITION OF NEOTECTONICS IN THE KUROMATSUNAI LOWLAND FAULT ZONE, SOUTHWEST HOKKAIDO, RELATED TO STARTING OF CONVERGENCE ALONG THE EAST MARGIN OF THE SEA OF JAPAN

Takashi AZUMA[1], Koji OKUMURA[2], Koichi SHIMOKAWA[1], Yuichi SUGIYAMA[1], Akira SANGAWA[1], Takuichiro KUWABARA[1] ([1]Active Fault Research Center, AIST, [2]Hiroshima University)

Kuromatsunai lowland, located in the southwestern part of Hokkaido, is N-S-trending narrow basin filled with sediments in Pliocene to Quaternary. This area is one of the fault-and-thrust belts adjoining the convergent boundary between the Eurasian and Okhotsk plates in the Japan Sea. The outline of the lowland topography seems to be the remnant of the Early Pleistocene depression while the structures of the Quaternary sediments indicate that the basin has been uplifted under E-W compression since Middle Pleistocene. This change represents the convergence along the eastern margin of the Japan Sea began to affect this area. In topographical, fluvial terraces have developed well in central part of the basin and marine terraces fringe along the Sea of Japan coast and the Pacific coast. These terraces are divided in five groups and are dated by several volcanic ash markers. Fluvial terraces, formed during Middle to Late Pleistocene, are deformed cumulatively by N-S trending fault scarps and folds. The folds on these terraces are characterized by the short wavelength (1 to 2 km), whereas the structure of Pliocene sedimentary rock has folds with rather long wavelength (5 to 10 km). The reverse faults are observed on the wing of the folds and they are seemed to be related to the growth of the folds. Marine terraces along the Sea of Japan coast and the Pacific coast show different pattern of the crustal movement across the lowland. Along the Sea of Japan, >30 km wide east-dipping monocline concordant with bedrock structure deformed Middle to Late Pleistocene marine terraces, but there is no differential movement across the lowland. On the other hand, along the Pacific, the west side of the lowland has been stably uplifted while the eastern side shows overall subsidence since Middle Pleistocene. We will discuss the neotectonic significance of the active structures in the lowland in terms of shortening tectonics in the convergent plate boundary along the eastern margin of the Japan Sea, as well as seismic potential in this area.

SLAB ABUTMENT: A KEY TO THE ORIGIN OF THE BROAD BEND IN THE TRENCH LINE OF THE PHILIPPINE TRENCH SYSTEM AT 6 N LATITUDE

Bautista Caparas BAUTISTA[1], Maria Leonila Pascual BAUTISTA[2], Ishmael Clarino NARAG[1], Jane Tampoc PUNONGBAYAN[1], Raymundo Santiago PUNONGBAYAN[1] ([1]Philippine Institute of Volcanology and Seismology, [2]Department of Science and Technology - Philippine Institute of Volcanology and Seismology (DOST-PHIVOLCS))

Broad bends along the trench lines of subduction zones are usually caused by collision and partial subduction of buoyant features such as microcontinental plates, island arc chains or seamounts and extinct mid-oceanic-ridges at the trench line. These bends develop as a result of the stoppage or slowing down of the subduction of the slab. The plate, instead of being subducted is just pushed towards the arc causing a broad bend to develop. The Philippine Trench System, a very active subduction system located east of the Philippine archipelago, exhibits a broad bend in its trench line at around 6°N latitude. There is, however, no obvious presence or traces of buoyant features mentioned above that could impede subduction process and form the broad bend in the trench line. The reason for the development of this broad bend is presently not so well known. In this study, we will try to seek an answer to the above problem by characterizing the geometry of the slabs comprising the complex subduction system in southern Mindanao, Philippines using earthquake data. Seismicity and focal mechanism maps at different depth ranges and cross-sections showing vertical distribution of seismicity and focal mechanisms are drawn in order to have a three-dimensional visualization of the geometry and stress regimes of seismogenic zones. A model to explain the said phenomenon is proposed. Southern Mindanao is a geologically and tectonically complicated region. One of the features found in this area is a 250-km wide zone called Molucca Sea Plate collision zone. This zone resulted from the continued westward subduction of the Molucca plate beneath the Sangihe island arc and the eastward subduction of the same plate beneath the Halmahera arc. Earthquake hypocenters beneath this zone show oppositely-dipping Wadati-Benioff zone that defines an inverted U-shape slab. In Mindanao island, collision is believed to be complete. Aside from this collision zone, the presence of two other trenches further complicates the tectonic setting in this area. The subduction of the Philippine Sea Plate along the Philippine Trench and the Celebes Sea Plate along the Cotabato Trench forms a complicated configuration with the subducted slabs of the Molucca plate. In this study, we will use the complex configuration of these subducted slabs to argue for the reason for the development of the broad bend in the trench line of the Philippine Trench. Using earthquake data, we will propose abutment at depth of the Philippine Trench slab and the Halmahera east dipping slab as the reason for the impediment of subduction process and the subsequent formation of the bend. This theory is further supported by steepening of the slab dip of the Philippine trench southward towards the bend.

ZAMBOANGA PENINSULA, PHILIPPINES: COLLISION, OPHIOLITE EMPLACEMENT AND MELANGE FORMATION IN A CONTINENTAL MARGIN SETTING

Graciano P. YUMUL, JR., Rodolfo A. TAMAYO, JR., Carla B. DIMALANTA, Victor B. MAGLAMBAYAN, Herve BELLON, Mireille POLVE, Rene MAURY (IAVCEI)

Field mapping and geological investigations were conducted in the northern,central and southern portions of the Zamboanga Peninsula, Mindanao, Philippinesover a 4-year period. Zamboanga Peninsula is underlain by Cretaceous to Paleogene ophiolite and metamorphic basement rocks, pre-Miocene to middleMiocene melanges, Miocene volcanic and sedimentary rocks with associated intrusive bodies and Pliocene to Quaternary volcanic and sedimentary rocks. Several ophiolite and ophiolitic masses, exhibiting back-arc basin to supra-subduction zone geochemical signatures, were found to be distributed along majorshear zones that trend NW-SE in northeastern Zamboanga and NE-SW in the centraland southwestern portions of the Peninsula. Regionally metamorphosed basementrocks often outcrop in proximity to the ophiolite and ophiolitic complexes.Tectonic and sedimentary melange units mapped are bounded by major strike-slipand thrust faults which represent environments that range from subduction totransform fault settings. New whole rock K-Ar isotopic and paleontological ages constrain the temporal and spatial relationships of the different rock formations. The mostwidely distributed rocks in the Peninsula are the volcanic-plutonic andsedimentary rocks that overlie the basement sequences. Pyroclastic and lavaflows that were dated support the existence of a Middle Miocene volcanic arc inthe Peninsula. The Miocene sedimentary sequences were deposited in a bathyalenvironment (northeast Zamboanga Peninsula) to a shallow marine

environment(southwest Zamboanga Peninsula). This suggests shallowing of the Peninsula fromthe northeast towards the southwest during the Miocene. The Peninsula couldhave either been rifted from China or Borneo.

SS03/08A/D-062	Poster	0830-221

FORMATION OF DOUBLE FOREARC BASINS AT THE INITIAL PHASE OF ARC-CONTINENT COLLISION OFFSHORE SOUTHERN TAIWAN: INSIGHTS FROM PHYSICAL AND NUMERICAL MODELING

Wei-Hau WANG[1], Ruey-Cheng WEN[1], Shu-Hao CHANG[2] ([1]. Institute of Applied Geophysics, National Chung Cheng University, [2]. Institute of Seismology, National Chung Cheng University)

The transition from a subduction phase in Philippines to arc-continent collision phase in Taiwan have been creating a unique bathymetry offshore southern Taiwan, where the North Luzon trough northwardly spits into two parallel forearc basins (the Southern Longitudinal Trough and the Taitung Trough) separated by the Huatung Ridge with folded and faulted strata. We have conducted both physical and numerical models to demonstrate that this characteristic is due to northward increase of strength of the accretionary wedge in front of the Luzon arc by lithification and accretion. The lithified accretionary wedge has been acting as a backstop and deforming the sediments in the forearc basin. As a result, a new outer-arc high and a pair of forearc basins appear at the northward extent of the North Luzon Trough. This deformation and shortening of the forearc basin offshore southern Taiwan resulted in transfer faulting at the place of the forearc-basin split.

A NEW TECTONIC MODEL OF GORONTALO BASIN AND COLO VOLCANO, NORTHERN SULAWESI, INDONESIA

Haryadi PERMANA[1], Nugroho Dwi HANANTO[1], Safri BURHANUDDIN[2], Ray BINNS[3], Joanna PARR[3] ([1]Research Center for Geotechnology, Indonesian Institute of Sciences LIPI, [2]. Marine and Fishery Department, Jakarta-Indonesia, [3]. Exploration and Mining, CSIRO, Sydney-Australia)

A new data on geology (petrology and geochemistry), single beam seismic, gravity and bathymetric were collected during IASSHA 2001 cruise surround Colo volcano and Gorontalo basin, Northern Sulawesi, Indonesia. The Gorontalo basin is dominated by a steep graben-like structure east-west direction. To the north of the graben lies the Sulawesi north arm and to the south lies part of the East Sulawesi Ophiolite Complex and Old Mélange Complex. It is suggested that the Gorontalo basin formed as the result of opening and rotating of northern Sulawesi. Flat-lying, undeformed sediments fill the basin and lack of seismic evidence for the Gorontalo fault suggests that the fault has not been active since prior to the opening and rotation of northern Sulawesi. Una-Una island (gulf of Tomini) where the Colo volcano located is structurally controlled by NE-SW and NW-SE graben like structure that are bounded by hilly morphology features. Normal faults cut recent sediments that indicate the structures are still active. The Colo volcanic product is potasic rocks with negatif anomaly in Nb and enrichment of LILE indicates that Colo is produces in subduction environmental. The present of dunite in Colo volcanic product is explained that the magma source had through an oceanic material that possibly is part of East Sulawesi Ophiolite Complex (ESOC). The seismological data show two different patterns beneath the Colo volcano. The first pattern, at 100 to 200Km depths related to the southeast subduction of Sulawesi Sea Plate and the second, directly beneath the Una Una island at 70 to 100Km depths expected as northwest dipping subduction of Banggai-Sula micro-continent. We proposed a model where the Banggai-Sula micro-continent goingdown beneath oceanic crust that interpretated as part of the ESOC and caused Colo volcano activity. High concentration of K and lower MgO/FeO* of Colo volcanic product explained that the magma source is a micro-continent associated.

SS03/08A/D-064	Poster	0830-223

ANALYSIS OF REGIONAL STRESS TENSOR IN TONGONAN, LEYTE, PHILIPPINES

Jane T. PUNONGBAYAN[1], Louis DORBATH[2], Henri HAESSLER[2], Catherine DORBATH[2] ([1]Philippine Institute of Volcanology and Seismology, C.P. Garcia Avenue, U.P. Diliman, Quezon City 1101, Philippines, [2]Institut de Physique du Globe de Strasbourg, 5 rue RenéDescartes, 67084 Strasbourg, France)

In June and July 1997, an experiment on hydraulic stimulation of faulting in a geothermal exploration well that cuts across the active Philippine Fault in Tongonan, Leyte, Philippines was conducted. Seismicity before, during and after fluid injection was monitored with a temporary seismic network composed of 18 stations. Information on earthquake distribution and seismic tomography of the area were obtained via a simultaneous inversion for the earthquake location and the 3-D velocity structure underneath the network. Using results of these earlier reports as well as the raw data of observed polarities, we proceed in studying the regional tectonic stress regime in the area by performing a simultaneous inversion for the local stress tensor and the fault plane solutions of well-constrained events before and after the fluid injection. Events considered in this inversion had a minimum of eight (8) polarities for both pre-injection and injection periods. Seismicity for all observation periods showed that recorded microearthquakes were well related to hydraulic stimulations in the study site. The microearthquakes had magnitudes lower than 2 with depths ranging from 1000-5000 m. Results for the data before, during and after the hydraulic experiment showed a well-constrained stress tensor explaining 91.2% of the observed polarities with a maximum likelihood of 97.7%. After the injection, the minimum principal stress tensor $\sigma3$ remained quasi-horizontal with a direction of N168°(pre-injection: N179°). The maximum principal stress tensor,$\sigma1$, became more vertical with a dip of 57° (pre-injection: 41°) and showed a slight change in the direction towards N287° (pre-injection: N283°). The direction of $\sigma2$ did not change remarkably before (N74°) and after injection but its dip decreased to 27° from its pre-injection dip of 45°. The stress tensors that we obtained before and after the fluid injection in Tongonan, Leyte are in agreement with the left-lateral strike-slip character of the Philippine Fault and thus comply with the tectonic context of the region. Injection of fluids had the principal effect of increasing the pore pressure, facilitating fault rupture. The isotropic component of the stress tensor can be modified but not the deviatoric component, which was what was accessible to us (shape factor R). It is thus normal that our results for the tensors before and after injection be similar. The slight difference could be attributed to perturbations of thermoelastic stress provoked by the injection of cold fluids.

GENETIC ALGORITHM - FINITE ELEMENT INVERSION OF STRESS FIELD IN CONTINENTAL CHINA

Shoubiao ZHU, Yaolin SHI (Department of Earth Sciences,The Graduate School of the Chinese Academy of Sciences)

We use the observed stress field data in Continental China as constraints, and apply the genetic algorithm - finite element method (GA-FEM) to evaluate the relative contribution of boundary conditions and intraplate stress sources to the stress field by geophysical inversion. Boundary displacement, lower crust drags and topographic forces (represented as equivalent nodal forces) are inversed. Pseudo3-D elastic simplification is made for a thin spherical elastic shell at 15 km depth. The vertical stress is assumed to be the lithostatic pressure at the depth, and the horizontal stresses are calculated by Finite Element computation. The studied area of continental China is divided into 1993 bilinear quadrilateral shell elements. The Young´s modulus is chosen as 70GPa, and Poisson ratio as 0.25. Constraints for the modeling are provided by orientations of the maximum horizontal compressive stress derived mainly from focal mechanism and fault types which are related to the stress regime. The objective function for optimization in the inversion is the square root of the summation of square of the differences between observational orientation of maximum compressive stress and the calculated one. Models of different kinds boundary conditions and nodal forces are tested through a statistical F-test. An optimum model which gives best fit of orientation data is found step by step. Although there are no direct data on the magnitude of stress in the crust, the stresses are limited by the strength of faults by Byerlee´s Law. Therefore, we further use the observation of fault types of normal, inverse or strike-slip, to roughly constrain the magnitude of stress, by linearly adjusting the magnitude of the stresses in the optimum model. Such a procedure does not change the fit of orientation data, but give a better fit to the fault type data. In our final optimum model, 54 parameters in total have been used in inversion, in which 32 boundary displacements and 22 equivalent nodal forces simulating basal drug and topographic forces. The results show that the stresses in Continental China are produced mainly by the collision of India plate, and action of the Philippine plate. Topographic highs and lower crust drag forces also play an important role in Tibetan Plateau of local significance. A very interesting suggestion of the optimum solution is that beneath the Tibetan Plateau, the ductile lower crust seems flow more easily than the brittle upper crust. The direction of the lower crust drag force to the upper crust is NE at the central Tibetan Plateau, and SE in the eastern Tibetan Plateau. We further use the GPS data as an independent observation to check the validity of the inversed optimal model. It is found that the displacement calculated from the model deduced from a long term stress data also fits well with the transient data of GPS velocity.

THE USE OF THE MONTE-CARLO INVERSION METHODS IN THE DISTRIBUTION OF DENSITY MODELS OF THE AFRICAN CONTINENT TO A DEPTH OF THE ASTHENOSPHERE

Adedeji Adegoke ADETOYINBO, Ebun Olufunmilayo ONI (Department of Physics, University of Ibadan , Nigeria.)

In the computation of the earthis gravity field with respect to the African continent lying between Latitude 400N-400S and Longitude 300W-600E, the zonal harmonics to J21 computed by Kozai were used as starting values. Fully normalised coefficients of the spherical harmonic expansion of degree 112 and order 112 were also used in the computation. The results of this computation were applied to a 3-Dimensional model of the Lithosphere and Asthenosphere of the African continent. The technique employed for this interpretation is the Monte-Carlo Inversion Method. This method uses a random generator at any stage. In applying the method, five hundred models were examined out of which only nine passed all tests. As far as we know, this is the first time that the technique is applied to the Lithosphere and Asthenosphere of the African continent. Although, the problem of uniqueness of earth structures obtained by this inversion of geophysical data, is still unsolved, the many models generated from the set of data using the inversion method agree with geological interpretation of the continent. Also, results from the interpretation using the Monte-Carlo inversion technique shows that the density range within the Asthenosphere is in agreement with other authors.

MICROEARTHQUAKE CHARACTERISTICS AT THE SLOW SPREADING REGIONS; CASES OF THE LAASQORAY-SHARMAR SEGMENT OF THE GULF OF ADEN AND THE JOURDANNE SEGMENT OF THE SOUTHWEST INDIAN RIDGE

Tomoaki YAMADA[1], Kensaku TAMAKI[2], Hiromi FUJIMOTO[3], Kimihiro MOCHIZUKI[1], Kazuo NAKAHIGASHI[1], Toshihiko KANAZAWA[1] ([1]Earthquake Research Institute, University of Tokyo, [2]Ocean Research Institute, University of Tokyo, [3]Faculty of Science, Tohoku University)

We present the results of two microearthquake experiments conducted at the along axis of two ultra-slow spreading segments, the Laasqoray - Sharmar segment at 49 degrees E of the Gulf of Aden and the Jourdanne segment at 64 degrees E of the Southwest Indian ridge. The Gulf of Aden is a small ocean basin between Arabia Peninsula and Africa, and the continental rifting occurred around Early Miocene. The full spreading rate is 2.1 cm/year. The morphology of western part is affected by the Afar plume, however the Laasqory - Sharmar segment of eastern Gulf of Aden shows a typical segment structure of slow spreading ridges as Mid-Atlantic ridge. The morphology has the axial valley and the segment center is higher relief with a narrow to axial valley whereas the segment ends are lower relief with wide axial valleys. For the experiment, we selected the Laasqoray - Sharmar segment as a typical young and slow spread rift zone. Otherwise, the Southwest Indian ridge is one of the ultra slow spreading ridges, and the full spreading rate is 1.4 cm/year. The northeastern section, especially, does not resemble any other known mid-ocean ridge in the morphology and geophysical and geochemical data. This section is characterized by a low melt supply, and further, underlain by cold mantle (Cannat et al., 1999). This also characterized by very high-relief segments with very strong mantle Bouguer anomaly lows, spaced every 200 km. The high-relief of these segments is inferred to result from large volcanic constructions (Cannat et al., 1999). The Jourdanne segment is one of the high-relief and highly focused magmatic segment. We selected this rarely segment for the experiment. Microearthquake observations were conducted in 2000 around the Laasqoray - Sharmar segment at 49 degrees E of the Gulf of Aden using 10 ocean bottom seismometers (OBSs) and in 1997 around the Jourdanne segment at 64 degrees E of the Southwest Indian ridge using 10 OBSs. In the Gulf of Aden, we got 20days continuous records, and more than 1400 earthquakes were located using arrival times of both P and S wave. The seismic activities were concentrated at three regions. One was the segment center, the others were fracture zones near the segment ends, westward and eastward the fracture zone. The earthquake focal depths were clearly shallow in the segment center whereas the focal depth of fracture zones were limited to deeper zone. In the Southwest Indian ridge, we got one week continuous records from 6 OBSs , and 814 earthquakes were located using arrival times. The pattern of hypocentral distributions was similar to the Gulf of Aden, and the segment center and non-transform offsets near the segment end were high seismicity regions. The focal depth along the ridge axis seems to decline to segment ends as seen in some segments of the other slow spreading ridges, but the lower limit of focal depths is relatively deep. It is consitent with cool temperature.

PROBABLE EXTENSION OF NARMADA-SON LINEAMENT

Gautam GUPTA, Vinit C. ERRAM, Bhisham Prasad SINGH (Indian Institute of Geomagnetism, Plot

No. 5, Sector-18, Near Victoria Petrol Pump, Kalamboli (Highway), New Panvel (W), Navi Mumbai-410206)

The Narmada-Son Lineament (NSL) is one of the most prominent features in the western-central India, characterized by numerous tectonic structures and complex geophysical signatures. The west of the western Ghats may be a belt of active rifts. The best-developed part of this rift system is observed in the Cambay-Kutch area. Transformation of the ground magnetic data in the Cambay basin in west coast of India delineated the Narmada-Son lineament, which appears to turn around and extend beyond the Gulf of Cambay towards the west. Magnetotelluric studies in central India have shown a high conductivity layer in the deep crust below the Vindhyan region. The total thickness of the Vindhyan sediments is about 5 km. Two crustal conductors with a resistivity of about 30 Ω-m are delineated below the Deccan volcanics. The high conductivity may be due to the presence of crustal fluids. The outburst of the Reunion plume on the western India landmass would have had strong effects on the geothermal state of the deep crust in the Vindhyan region, the Cambay basin, and the adjoining Arabian Sea. This is evident from the high Bouguer anomalies, deep-seated electrical conductivity, high heat flow, seismicity and significant high seismic velocity over the NSL and adjoining regions. This process may have had significant contribution to the wide spread intrusive activity. The conductive features noticed in central India over NSL might be associated with transform fault associated with rifts in this region. These studies suggest that the NSL is a typical rift like structure and is a part of the worldwide rift system joining the Indonesian arc to the east and extending on west coast to Carlsberg ridge and may have a probable extension in the northern Madagascar extending into Africa, Somalia and Ethiopia.

EARTHQUAKE RELOCATION AND THREE-DIMENSIONAL VELOCITY STRUCTURE IN THE NORTHEAST INDIA REGION

Pankaj Mala BHATTACHARYA, J.R. KAYAL, R.K. MAJUMDAR, S.G. MUKHUPADAAYA (Geological Survey of India)

A detailed three-dimensional seismic velocity structure of the crust and upper mantle upto a depth of 60 km beneath the northeast India region is estimated using the local earthquake tomography method . A total number of 4850 seismic phases , 2698 P arrivals and 2152 S arrivals, from 700 selected events recorded by 77 standalone/telemetric stations are used. The tomography images show heterogeneous structures in the crust and upper mantle with a substantial horizontal velocity variations in the region. Seismogenic structures are well reflected in the tomography images . Most of the earthquakes have occurred in the high velocity, high Vp/Vs zones. The lateral heterogeneties have been the source area for stress concentration. The Kopili lineament / fault, is mapped with high Vp , high Vs and low Vp/Vs . Relocation of the earthquakes is very much improved with significant reduction in average rms and errors in horizontal and vertical directions.

STUDIES OF INTRAPLATE DEFORMATION IN THE NORTHERN INDIAN PLATE

Ranjit Kumar MAJUMDAR (Department of Geological Sciences,Jadavpur University)

Seismicity map has been prepared for the period 1963-1999 using epicentre listing of International seismological centre(ISC),U.K;Indian Meteorological Department(IMD) and USGS earthquake data file. It shows a widely dispersed diffuse intraplate seismicity in the Bay of Bengal and adjoing Peninsular India in comparison to the clearly defined higher seismicity at the eastern plate boundary.Several geophysical evidences and observations indicate that the northen Indian plate including the Bay of Bengal and Peninsular India has experienced extensive deformation. From the fault plane solution study it apears that almost all intraplate earthquakes in the Bay of Bengal and coastal areas of Peninsular India exhibit thurst faulting mechanism having consistent north dipping fault plane and more or less N-S directed(range of varaition NNW-SSE to NNE-SSW) pressure or compression axis.Composite plot of pressure and tension axes of focal mechanism solution of intraplate earthquake of this region suggest that this region is also experiencing N-S compression.Small scale seismic profiling in southern Bay of Bengal also suggests N-S compressive deformation apparently by folding of upper sedimentary layer and high angle reverse faulting of acoustic basement of oceanic crust having E-W orientation.Pre-existing zones of weekness like rift valley or fault is rejuvinated in respone to N-S intraplate stress and ultimately leads to seismic activity in Peninsular India.Latur earthquake(1993)in India seems to be one of such example which occurs in a low Bouguer gravity anomaly in rift valley area.

SURFACE GRAVITY SURVEY AND GEOPHYSICAL INTERPRETATION OF GRAVITY FIELD DATA TO STUDY STRUCTURAL AND TECTONIC CHARACTERISTIC OF PARTS OF ARCHEANS, SATPURAS AND CHHATTISGARH BASINS AROUND MANDALA-RAIPUR DISTRICTS, M. P., INDIA

Daya SHANKER[1], V.P. SINGH[2], R. SINGH[3] ([1]Department of Earthquake Engineering, indian Institute of Technology Roorkee, [2]Department of Geophysics, Banaras Hindu University, Varanasi-21005, INDIA, [3]Marine Wing (Geophysics Division), DK-6, Bhu Bigyan Bhavan (9th floor) Salt Lake, Kolkata-64, INDI)

Out of all geophysical investigations have been used to derive the structural and tectonic characteristics of large areas, gravity method play a major role in understanding the problems of the earth crust. Owing to technological development, most gravity surveys currently carried out are designed for reconnaissance of large unexplored areas to delineate faults, structural details, depths of intrusive bodies. The gravity method is best suited for mapping the basement configuration and intrusive bodies in them. Nowadays gravity data are being extensively used for study geological structures, tectonics, depths of Conrad and Moho and detailed structural investigations of the crust. For detail geological mapping and crustal structures dense network of gravity observations are required. A number of intracratonic sedimentary basins are existing in Indian subcontinent. The Cuddapah, Vindhyans, Kaladgi and Chhattisgarh basins are most important one. Detailed surface gravity surveys with the station spacing of 2 to 5km over parts of Archeans, Satpuras and Chhattisgarh basins belonging to different ages around Mandala-Raipur region has been carried out. Detailed investigations provide depth of gravity sources, basement structural trend, nature of intrusive bodies and thickness of sediments in the basins. The basement structural trend along the seven profiles in Archeans (FF´), Satpuras (CC´, DD´, EE´, FF´, and GG´), Chhattisgarh (CC´, DD´, EE´, FF´, and GG´) and Deccan Trap (AA´ and BB´) have been derived which ranges from 2.0 to 3.5 km. In Satpura region a positive anomaly of 12 mgal is observed indicating 2 km thick high density material at a depth of 3 km. Negative gravity anomaly of the order of -13 mgal at one place below the Deccan trap suggests thickness of sediments to be 2.5 km extending towards north-west. Thus the present analysis describes the detailed mapping of the local features of the region which may be useful in formulating evolution model of the various formations across NSL and nearby

areas.

INTRAPLATE SEISMICITY AND GRAVITY FIELD ANOMALIES OF THE CONTINENTAL CRUST

Boris Petrovich RYZHII[1], Nikolay Ivanovich NACHAPKIN[1], Svet Yurievich MILANOVSKY[2] ([1]Geophysical Institute of Ural Branch of RAS, Ekaterinburg, [2]Institute Physics of the Earth RAS, Moscow)

According developed concept the areas heightened intraplate seismicity are connected with the increased silica contents in the rocks, i.e. with patterns of acidic composition and, accordingly, with negative Bouguer gravity anomalies. Done statistical analysis of intraplate allocation of earthquakes on territory of Russia, Africa, Australia, South and North America has confirmed effect of correlation of their position with areas of negative Bouguer anomalies. For Russia analyzed the position of plate seismicity and it's relation with: (1) silica content, obtained from DSS observation with VP and VS waves (Egorkin, 2000); (2) Bouguer gravity field. The analysis shows that zones of higher seismicity are associated with 'acidAEcrustal blocks. The interplate earthquakes with magnitude 4-6 take place 6 times more often in 'acidAEcrustal blocks in comparison with 'basicAEones. The earthquakes with magnitude more than 6 happen only in 'acidAEcrustal blocks. The amount of earthquakes in areas with negative Bouguer field is in seven times more than in areas with positive Bouguer field. The outcomes of a statistical analysis testify that practically all earthquakes in Africa are associated with the areas with negative values of Bouguer gravity field. Thus in areas with values of a field -160 mgal to -100 mgal there was 80 % of all earthquakes. It is necessary to note, that the mean value of the field for the African continent is -70 mgal. For Australia was analyzed, that in areas with negative values of Bouguer field from AE0 mgal up to -20 mgal 73 % of all earthquakes (average level of the field for continent is -17 mgal) is massed. If Bouguer anomalies are mainly related to morphology and composition of structural complexes of Earth crust, the isostatic anomalies, as a rule, are connected with acting tectonic forces and characterize a modern stress of Earth crust. In South America regions with negative values of Bouguer anomalies, smaller than its mean for the Platform (-30 mgal), there occur 70% of all earthquakes. The correlation of a magnitude and depth of a hypocenter of earthquake is supervised depending on the value of Bouguer anomalies in its epicenter. In regions with positive values of isostatic anomaly, larger its mean magnitude for the Platform (1 mgal), there occur 77 % of all earthquakes. For North America, from 383 events 288 (75 %) has taken place in areas with negative values of Bouguer anomalies and 95 (25 %) - with positive values. Thus, the amount of earthquakes recorded in a negative gravitational field, in 4 times exceeds an amount of earthquakes in a positive field. At values of isostatic anomalies close to normal (-10 - 10 mgal) there was 55 % of all earthquakes and 41 % - recorded in isostatically disturbed regions at values of a field from -60 up to -10 mgal. Therefore, the areas of intraplate seismicity are characterized predominantly by negative values of Bouguer anomalies, and also negative or normal values of isostatic anomaly. This work was supported with RFFI grant N 00-05-65067

NEW INTERPRETATIVE GRAVITY FOR LITHOSPHERE

Yury Ya. VASHCHILLOV, Natalia K. GAIDAI, Olga V. SAKHNO (North-East Interdisciplinary Scientific Research Institute FEB RAS)

New interpretative gravity (NIG) is independent and self-sufficient., and at this stage of the geologic-geophysical study of the Earth is better in many situations than other geophysical methods with stable reputation, for example, seismology. Large areas of land, seas and oceans are already covered by the gravimetric survey. The NIG use makes possible to obtain structural-substantial parameters of lithosphere by financing only the interpretation. Earlier many of such parameters could be obtained only by the seismologic study. Two principles form the theoretical and practical basis of NIG. They are as follows: 1) an idea about the essentially block nature of the anomaly sources, and 2) revealed regularities in combination of layers and density heterogeneity in the form of blocks. The latter was experimentally proved that the lower and upper limits of blocks coincide with major quasihorizontal surfaces of lamination. Mathematical interpretive methods of NIG was developed on the basis of 3-dimentional (3D) block sources of the gravity anomaly. Based on this method, NIG study makes possible to determine the depths of the lamination surfaces (boundaries of Moho (M), lamination of lithosphere, crust and sedimentary strata), of roots and penetration upwards of the faults and blocks irrespectively of the other geophysical data. It also enable one to interpret by methods lithosphere density «probing», to make gravity tomography according to the systems of horizontal sections, make 3-dimentional density models and give their geological-petrological interpretation (western and central Siberia, north-east and Far East of Russia, region of studies after the DECORP-2 SOUTH Project, Azov, Black, Norwegian and other seas, etc). The depth of investigations is determined by the lithosphere thickness of 60-20 km. **Necessary** condition of the strict quantitative interpretation of the gravity (and other geophysical) anomalies is the similarity with the given precision of gravity values, obtained by measurements, and calculated (theoretical). For mentioned purposes, gravity map and theoretical (model) gravity maps are compared. The interpretation has the total character. During the interpretation, local anomaly are divided between each other, and also we distinguish between the local and regional anomalies. The determination of velocity of seismic waves and distinguishing of the vertical faults are the serious problem in seismology. The use of NIG decreases a sharpness of mentioned problem. During the interpretation of the gravity anomaly, horizontal density jumps at vertical limits of density heterogeneity-blocks are determined. Their values reach the tenth-hundredth g/cm3 . They also like the absolute density values, obtained at the interpretation, are easily calculated into the jumps and full velocity of seismic waves.

INSTRUMENTAL SEISMICITY AND SEISMOTECTONICS IN CENTRAL ALBORZ

Mohammad ASHTARI JAFARI (Institute of Geophysics - University of Tehran)

Alborz Mountains show structural axes trending approximately NE-SW in its eastern part and NW-SE axes in its western part. Central Alborz is the meeting point of the eastern and western trends. The overall structure is the site of shortening due to the compression against Eurasia and contains a high density of active faults. Most faults are longitudinal and follow the arcuate structure of the Alborz Mountains. Although an important horizontal component exists on the earthquake faults of this region, reverse faulting seems to be the main process of mountain building. I have used Central Alborz earthquakes from 1900 to 2001 to study seismicity patterns and focal mechanisms of the earthquakes in this region. Within several numerical methods to solve the focal mechanism problem based on the polarity of the first motion of P wave, I have used a least squares grid search procedure which minimizes the number of discrepant first motions to compute mechanisms. Focal mechanism results are divided into two groups: I) mechanisms based on the single fault plane solutions II) mechanisms based on the joint fault plane solutions. Well located earthquakes with good coverage around the focal region are within the first group. Where it is not possible to

compute well determined single solutions, joint fault plane solutions are calculated. The mechanisms reflect a range of faulting from strike-slip to reverse.

ACTIVE DEFORMATION IN CENTRAL ALBORZ

Mohammad ASHTARI JAFARI[1], Farokh TAVAKOLI[2], Hamid Reza NANKALI[2], Faramarz NILFOROUSHAN[2] ([1]Institute of Geophysics - University of Tehran, [2]National Cartographic Center of Iran)

Alborz Mountains are northern branch of Alpine-Himalayan orogeny in Iran. This range is characterized by a broad arch of parallel folds, reverse faults and nape forming imbricate structures verging both towards and away from the Caspian Sea. Within northern parts of Alborz faults dip southwardly representing underthrusting of the South Caspian basin and in its southern parts faults dip northwardly. Alborz seems to accommodate to the overall motion between the Eurasia and Central Iran that involve oblique left lateral shortening. Central Alborz is the connecting point of eastern and western parts of Alborz. In this study we have surveyed 18 GPS stations two times during 2000 and 2001. In each survey we have measured GPS stations with dual frequency receivers for at least three consecutive days. These measurements are processed based on the routine GPS processing methods to produce daily solutions. Then daily solutions are suitably combined to provide single session solutions. Single session solutions are stacked to produce multi session solutions as the final solution. The results from final solution are used to calculate horizontal velocities and strain rates in Central Alborz and to resolve regional active deformation. It is also tried to constrain direction and style of strain by using mechanism of medium-small sized earthquakes.

CRUSTAL MOTIONS IN A SLAB-DETACHED AREA (SE-CARPATHIANS)

Victor I. MOCANU[1], Boudewijn C. AMBROSIUS[2], Wim SPAKMAN[3], Andrevd HOEVEN[2], Gunter SCHMITT[4] ([1]University of Bucharest, [2]Technical University Delft, [3]University of Utrecht, [4]University of Karlsruhe)

The Carpathian-Pannonian system has had a long geological history culminating in the past 16 Ma in the subduction of an ocean basin. The subduction process seems nearly completed. There is tomographic evidence, which delineates a localized slab (down to 350 km) below Vrancea. Below the remainder of the Carpathian arc no slab is found in the tomography. However, at large depth (>500 km) a huge ″pan-cake″ of high seismic velocity material is detected which is interpreted as the remnant of detached slab [Wortel and Spakman, Science 2000]. One basic question regarding the Vrancea slab is whether it is still attached to surface lithosphere, or already detached, or in the process of being detached. To answer this question we have embarked on a project to measure the crustal motions in this region using both continuous and campaign style GPS observations. In 2001/2002 four permanent stations have been installed. In addition, a large GPS campaign was carried out in 2002, during which a network of 50 stations was observed including many points which were already occupied in previous campaigns. We present the network design and initial results on the data acquisition and data quality.

GEOPHYSICAL INVESTIGATION OF THE TRANSIT ZONES TECTONOSPHERE ASIA - PACIFIC AND INDIAN OCEANS

Evgenya Lvovna MAZO, Adonis GAINANOV, Andrey BULYCHEV, Sergey BOLDYREV, Dolores GILOD, Vyacheslav MELIKHOV (Moscow State University, Geology faculty)

Geoid heights and gravity anomalies field maps were constructed based on combine altimeter and onboard data. There are several reductions of anomalies in the set of the maps for the investigation areas: transit zone Asia - Pacific and Indian oceanic. By original methodic of the authors we calculated Clenny reduction for the geoid heights field.Anomalies fields were transformed by striped methods with the defferent deep descriptions. Analyze all set gravity maps combine other geology-geophysical data allows to construct tectonic-structural scheme and allocated edge zone, boundary blocks earth crust type, transform zones, trending structures elements. Based on the seismic data and gravity anomaly field 2-D density models of the earth crust, lithosphere and astenosphere (tectonosphere) were calculated for the basic tectonic structures of the transit zone Pacific and Atlantic (Arabian sea) types.The earth crust and lithosphere thickness was calculated by geochronology data. The minimum thickness of the earth crust (10 km) is obtained under the oceanic basin Far East sea. The minimum thickness of the lithosphere (20 km) is obtained under the festoon islands. The lithosphere thickness under the older basins Okhotsk, Japanese, Phillipines seas is up to 70 km. Maximum thickness of the astenosphere is 80-140 km is obtained under the young basins Far East marginal seas. Simultaneous thickness is up, astenosphere density in low by 0,02-0,06 g/cm3 . Earthquakes and seismogenic zones are the indicators of the geodynamic processes. Seismotectonic phenomena are the most effective in the continental - ocean transit zones. The earthquakes upper then 60 km are located in belt width about 250 km. Source earthquakes deeper then 60 km are located in the narrow lay conical form which is loaded under continent to 600-700 km.Boundary zone of these blokes date for shelf and continental slope deepwater trough. Region 150 S - 400N; 900 E-1500 E is very interesting. There are group Festoon island structures on the boundary Pacific and Indian oceans. Curvature of these structures is oriented in the different sides. Complexes are not completed by continental masses. They are appear like a special conglomerate. Deeper processes in it probably control the development lithosphere. There is intersection continuos transform zones Earth system Oceanic Ridge. Level of the seismic activity Zonde ridge chain on the east flank (in triple junction zone festoon island sistems) - Zoned, Philippine, NewGweney , 130 0 E - is one order more then on the north flank, when seismoactivity zone is continued under the continent. Seismofocal zones Zoned and Philippine earthquakes slope toward each other. Seismic activity Philippine and Marian basins is present rare shallow-focus earthquakes with is located to the ridge Kusu-Palau. Research is support by Russian Fond Of Fundamental Investigations, project [1] 01-05-64328, [1] 02-05-64212.

MANIFESTATION OF TIBETAN PLUME STRUCTURE AND SEISMICITY OF HIGH ASIA IN REGIONAL GEOPHYSICAL FIELDS

Valentin POGREBNOY[1], Tamara SABITOVA[2] ([1]Applied Research Center, KRSU, Leading geophysicist, [2]Institute of seismology NAS of Kyrgyz Republic)

This paper represents the results of complex analysis of High Asia geophysical fields in regional scale which show peculiarities of tectonic structure and ongoing in the region geodynamic processes. Based on juxtaposition of maps of following regional fields like geoidal undulations, anomalous magnetic and gravity fields, heat flow, shear wave attenuation, the Raleigh wave group velocities distributions for periods Ò=10-70 s, Pn- wave velocity distribution in upper mantle of High Asia we guess that all of those are caused by

anomaly body which might consist of deconsolidated and hot material and hereafter named by authors as Tibetan plume. There was suggested its structure. According to quantitative and qualitative interpretation of geophysical fields, the Tibetan plume represents a steep ellipsoidal body (horizontal projection) where the longer axis size is approximately 2500 km and the shorter axis is 1000 km with narrow branches on the west side. Its depth extension is traced, as a through column, down to >300km from day surface. Judging by geographical location, a great extent both in spread and depth as well as geophysical fields which display it, the Tibetan plume is an independent formation but not consequence of continental plate collision. From comparison of seismicity and geophysical fields, it was made inference about correct correlation between seismic events and of geophysical field structure. High gradients zones of geophysical fields were found to be indicators of possible strong event zones. This criterion can be used for solution of a problem of revelation of seismogenous zones in seismic zoning of certain High Asia regions. It is noted that the location of such large deconsolidated body in High Asia which formed, most likely, due to ejection of a large amount of hot and deconsolidated substance onto upper layers of the High Asia tectonosphere, has an influence on dynamic processes in this region. Dynamic processes in High Asia region are guided with combination both of collision between Indostan and Eurasia litospheric plates and ongoing development of Tibetan Plume. This investigation was carried out with support by International Science and Technology Center (ISTC), Project KR-214.

COMPRESSIVE DEFORMATION IN THE KACHCHH BASIN, GUJARAT, INDIA

Malay MUKUL, Sridevi JADE, Imtiyaz Ahmed PARVEZ, M.B. ANANDA, P. Dileep KUMAR, Vinod GAUR (CSIR C-MMACS)

The Kachchh Rift Basin (KRB), the site of the 2001 Bhuj earthquake, has been recognized as a rift basin that opened around 150 Ma and was subject to NNE-SSW directed compressive stress around 20 Ma. North-dipping Kathiawar fault and the south-dipping Nagar Parkar fault are extensional faults that form the southern and northern boundaries of the KRB, respectively. The NNE-SSW compression has resulted in the formation of two systems of thrust faults within the KRB. The northern Allah Bund system of thrust faults are NNE-dipping, with transport direction from NNE-SSW, whereas the southern Kachchh Mainland Fault system of faults dip to the SSW and have SSW to NNE transport direction. The zone of transition between the two systems of faults lies almost entirely in the Great Rann. Fault propagation folding dominates the geometry of the sheets carried by the major faults. Palaeoseismic data and the recent seismicity in the KRB indicates that both the systems of thrusts are active. Great Trigonometrical Survey (GTS) points were measured in 1857 and were reoccupied using GPS in 2001 and 2003. GTS (1857)-GPS (2001, 2003) baselines oriented at different angles to the regional transport direction in the thrust systems and the fault propagation structures are examined to work out the translation, vertical axis and horizontal axis rotations and elongation/shortening components of the total displacement vectors associated with the neotectonic deformation in the KRB over the period 1857-2003 and gain an insight into which geological structures are active in the basin and the earthquake hazard associated with it.

CRUSTAL DEFORMATION IN THE CHAMOLI REGION OF HIMALAYA INFERRED FROM GPS MEASUREMENTS

Ponraj MALLAPPAN, Amirtharaj SAMUEL, Sunil P. S. (Indian Institute Of Geomagnetism)

Following the Chamoli earth quake of March 29, 1999 (Magnitude 6.8 on Richter scale), three campaigns of Global Positioning System (GPS) measurements were made in Chamoli region of Garhwal Himalaya during 1999 to 2001 in reoccupation mode to estimate the horizontal crustal deformation rate. The study area (30° 13´ to 30° 31´ N and 78° 12´ to 79°31´E) includes many important thrust zones viz. Main boundary thrust (MBT), Main central Thrust (MCT) and some local upwarps. Estimated horizontal velocity vectors in ITRF 2000 are in the range of 35 to 57 mm/yr. Many Geophysical and strain measurements have suggested that about 14 mm/yr crustal shortening is taking place across this region. This paper presents a study relating to the tectonic interpretation of the crustal strain rate in the region.

NAPPE TECTONICS AND METAMORPHISM OF THE NEPAL HIMALAYA

Kazunori ARITA (Department of Earth and Planetary Sciences, Hokkaido University)

The Himalaya is a fold-and-thrust belt formed in the northern margin of the Indian continent after the India-Eurasia collision around 50 Ma. It is divided into three tectono-lithostratigraphic units by a series of foreland propagating thrust system; from north to south, the Higher Himalayan zone (HH) and the overlying Tethys Himalayan zone (TH), the Lesser Himalayan zone (LH) and the Sub-himalayan zone (SH).The HH consisting of high-grade metamorphic rocks sometimes overlain by the TH is thrust southward along the Main Central Thrust (MCT) zone over the LH which is composed of non- to less metamorphosed rocks. The MCT zone is of most significance in the Himalayan tectonics and is a ductile and brittle shear zone with various thickness in places. Its distribution, nature and tectonic role are still in debate. The HH extends southward for 100 km up to near the Main Boundary Thrust (MBT), by which the LH is thrust over the SH, and forms nappe and klippe in the southern part of the LH. In Nepal Himalaya there are four nappe and klippe structures; Ilam nappe in eastern part, the Kathmandu nappe and the Arkha klippe in central part and the Karnali klippe in western part. The Ilam nappe composed of Ky-Sil gneisses and granitic gneisses with no Tethyan sediments covers widely the LH to extend up to the MBT and makes tectonic bridge and window. The Karnali klippe consists of the Ky-Sil gneisses of over 8 km thickness with the Tethyan sedimentary cover and continues westward to the Almora klippe in Kumaon, India. On the other hand, the Kathmandu nappe consists of a thick pile of the Tethyan sediments in the upper part and garnet-grade metamorophic rocks in the lower part. The metamorphism of the Kathmandu nappe looks to be lower in grade than the rocks of the northern root zone of the nappe which represent Ky and Sil grade. Therefore, it is proposed that the Kathmandu nappe is another thrust sheet which underlies the Higher Himalayan rocks in the northern root zone. But this idea is unacceptable, because the MCT zone occurs along the southern margin of the Kathmandu nappe and underlie the nappe. The MCT zone likely continues northward to that in the northern root zone, althouth the Kathmandu nappe is cut by an out-of-sequence thrust in the northern part and separated from the northern root zone. In the Arkha klippe in central Nepal, the Tethyan sequence rests directly on rocks of the MCT zone without the intervening Higher Himalayan crystallines. This, as well as changing of thickness of the Higher Himalayan crystallines in places, suggests that the MCT zone cuts obliquely the structure of the overlying rocks, therefore the hanging-wall of the MCT zone is different in lithology and metamorphic grade in different localities; deeper Ky-Sil grade rocks of the HH in the root zone of the nappe and shallower Grt grade rocks of the HH and even the TH in the frontal part of the nappe.

SEISMOTECTONIC STUDY OF THE KOYNA-WARNA SEISMIC ZONE BASED ON FAULT SEGMENTATION AND VELOCITY STRUCTURE

Sunil Kumar SINGH[1], Srinagesh DAVULURI[2] ([1]ONGC, Karaikudi, [2]NATIONAL GEOPHYSICAL RESEARCH INDIA, HYDERABAD)

A seismic tomographic experiment with 20 short period 3 component digital stations was mounted in Koyna-Warna region to investigate the tectonics andseismogenic character of the area. 634 events comprising of 4487 P-wave and 3689S-wave arrivals were inverted simultaneously for the hypocentral parameters andthe minimum 1-D P and S wave velocity model. The 1-D P and S wave reference velocity model is continuously increasing with depth. 3-D P wave tomography oflocal and teleseismic travel times reveal presence of lateral velocityvariations. The seismogenic volume is associated with higher velocity anomalies(2% to 4%) that extend into the lower crust. This high velocity is inferred as a region of competent lithology. The seismicity patterns and focal mechanism studies reveal three distinct segmented and intersecting fault systems.The competent lithology together with intersecting geometry of faults could bethe possible cause for the sustenance of seismogenic stress accumulation in theKoyna-Warna region.

ACTIVE TECTONICS AND RECENT GEODYNAMICS OF CAUCASUS-EASTERN ANATOLIA AND NORTHERN IRAN REGION

Mher AVANESYAN[1], Ashot AVANESYAN[2], Levon GYURJYAN[2], Ruben STEPANYAN[2] ([1]Yerevan State University, Department of Geology, [2]Armenian National Survey of Seismic Protection)

The recent structure of the region has a heterogeneous mosaic-bloc nature. Such structure is conditioned by its position in the zone of tectonic collision of the Arabian and Eurasian plate. Non-uniformly scaled active blocks of the Earth crust are distinguished, the borders of which are different oriented active faults of different ranks and morphological types.The recent structure of the Arabian and Eurasian plate collision zone is a result of multistage formation during a long period of geological epochs. Every other period of tectonic activation, inheritance of the main structural units as well as their imposition in space happens, in qualitative and morphological plan. Such appearance of recent structure and active tectonics is confirmed by nature of seismicity, GPS data observation and analyses of vertical motion. The recent geodynamics of the region is determined by the northern drift of the Arabian plate (18+- 2 mm/yr). As a result of the effect of the Arabian plate from the South non-uniformly scaled blocks of the region with different speeds of horizontal displacement move in North-East and North-West direction. And the speed of horizontal is notable lower than that of the Arabian plate. The differences of speeds are indemnified by vertical motions. On the basis of the analysis of the neotectonics and recent geodynamics, the zones of high gradients of vertical and horizontal motions are distinguished. From the point of view of geodynamics they represent zones of compression, of relative extension, right-lateral and left-lateral slip. Rotation of the active blocks is also distinguished, on hour and counter-clockwise. Taking into consideration that the zone of high gradients of horizontal and vertical motion of active blocks represents areas of the greatest concentration fields of tension and at a definite moment can be transformed into zones of destruction and rupture emergence, they can be marked as potential seismically hazardous.

NEOTECTONICAL AND PETROLOGICAL FACTORS OF FORMING OF LANDSLIDE SITUATION WITHIN EAST PONT - MINOR CAUCASUS REGION

Arthur V. BOYNAGRYAN (Faculty of Geology, Yerevan State University)

The observed region unites echelon joint folding systems of East Pont, Adjar-Trialet and Minor Caucasus and makes up a part of Pont-Minor Caucasus-Elbrus belt of meganticlinoriums. It's situated within tectonically active belt, is distinguished by high seismicity, break of Earth crust into the blocks of different sizes and their differentiated vertical displacements. A situation of region by numerous fault infringements, zones of fissuring and breaking of rocks, their hydrothermal change (often till the clay state); the dissected mountain relief; an abundance of springs, concussions of slopes at the earthquakes create the favourable conditions for the landslides' forming. The petrological state of rocks of the region has a great importance, i.e. their chemical and mineralogical peculiarities, structure and texture, conditions of occurrence and others, which have an essential influence on the process of their weathering and preparation to the landslide displacements. The landslides in the sections of spreading of porphyrites, loess loams, clays and etc. are lightly formed. There are a great number of large seismogenic landslides that are formed at the strong earthquakes (7 points and more) in the region. They are clearly marked out in the relief of locality as well as in the aerophotos and maps of large scale (more than 1:100 000). They are distinguished by large horizontal displacements from ordinary landslides.

ABOUT CORRELATION BETWEEN THE EARTH'S STRUCTURE AND GEODYNAMIC PROCESSES IN SOME REGIONS OF ARMENIA

Aram Artavazd GRIGORIAN[1], Stepan B. ABOVIAN[2], Amazasp A. BABADJANIAN[3] ([1]Advanced Research Laboratory, ARSAT Center, [2]Laboratory of Mineralogy, Institute of Geological Sciences NAS, Yerevan, Armenia, [3]Institute of Geophysics and Engineering Seismology NAS, Yerevan, Armenia)

The paper concerns with correlation carried out for the Earth´s structure, changes in properties of rock minerals, affected by high strain and temperature,and global geodynamic process, occurring in Armenia and continuing to other regions of the Lesser Caucasus.The folding and block structure of the territory of Armenia were formed as a result of intensive submeridian horizontal compression, caused by movement of rigid northern wedge of the Arabian plate to the North. The process of deep fault formation as well as formation of the ophiolite zones are considered as a result of consecutive periods of the Earth´s crust spreading and compression. Petrography and mineral analysis of mafic and ultramafic intrusive rocks and their serpentinised variety show high degree of deformation in ophiolites, indicating a process of pressing-out the mantle rocks upward to the Earth´s surface. Rock density distribution is compared with geophysical data. Anomalies in gravitational and magnetic field data are discussed and compared with the data on geological investigations.Seismic activity is discussed in relation with structure of the Earth´s interiorof the region and local tectonic processes. Intrusive rocks of mafic and ultramafic composition are associated with the ophiolites. Simultaneously with the ophiolites, the intrusive rocks were formed in a zone being the Tethys oceanic basin of a riftogene trough type in the Jurassic time. The troughs were formed in result of lifting the mantle diapire and development of deep ruptures under spreading, deepening and thinning of the Earth´s crust

accompanying by formation of rift with new ophiolite (oceanic) crust. Under further compression caused by movement of the Arabian plate in the north direction, mafite and ultramafite intrusives have been involved into folding processes, and then they were protrusively embedded into stratigrafically higher levels in the Cretaceoustime and the Eocene. By the same processes, the intrusives have been deformed, broken in blocks and separated. The deep fault consists of a set of sub-parallelruptures manifested as scraps and fractures within the Cretaceous-Palaeocene rocks. The seismo-gravitation formations in a form of large blocks and stepwise landslides appeared along the old gravitational seismic ruptures. According to known conception of global plates tectonics, earthquakes are related to tectonic processes and often confined the contact zones (deep faults) of lithosphere plates. Regional geodynamical, geological and geophysical situation described above, support the main statements of the mechanism of earthquake origin, suggested earlier.

SEISMOGENIC LANDSLIDES AS ONE OF THE VARIETIES OF GEOLOGICAL DANGERS OF ARMENIA

Vladimir R. BOYNAGRYAN (Faculty of Geography, Yerevan State University)

Armenia is situated within tectonically active Alpine-Himalayas belt and represents the mountain country with the dissected relief, complex geological structure, high seismicity, wide spreading of dangerous geological processes, where the landslides take the special place. More than 3500 landslides of different size, activity and different genesis are fixed by us in Armenia. On the whole they are spread in the basins of the Aghstev, Getik, Vedi, Arpa, Pambak rivers, in the vicinities of Yerevan. Dilijan, Kapan, separate sections of Yerevan, Vokhchaberd village suffer from the landslides very much. For the last years the activization of some old landslides took place and the new ones appeared. Thus, in 1992 Odzun landslide-collapse near the Sanain railway station recovered the railway Yerevan-Tbilisi for some days. In Yerevan the Nubarashen landslide caused the considerable destructions in the territory of the town cemetery; the middle rate of its displacement for 10 years made up 0.07-0.13m a year, and maximum was 1.4m. Near the Haghartsin village (basin of the Aghstev river) the activization of surface parts of the old seismogenic landslide because of slope cutting caused the destruction of railway bed and landslide masses throw off into the Aghstev river bed, creating a threat of cover (displacement of surface parts of this landslide occurs with a rate of 1-1.5m a month). State of anxiety has occurred in Vokhchaberd village, where in nowadays about 80% of houses are in a state of emergency and 44 houses are completely destroyed because of activization of the large seismogenic landslide with a size of 2.5x1.3 km2, frustrated and displaced along the line of reversed fault. The amplitude of vertical displacement of this landslide block is 200-225m and horizontal one is till 500m and more. The first destructions from the landslide motions were fixed here as far back as 1982, but for the last years the landslide "revived" and actively wins over the new lots of village. The motions become stronger after the spring snow-thawing and rain. Among the landslides of Armenia the ancient huge landslide-blocks and landslide-flows are especially marked out, those are complex tectonical-seismogravitational displaced bodies formed during the strong earthquakes. All of them are related to the zones of faults and high fissuring of rocks. The damage from landslides in Armenia makes up tens of thousands of dollars a year.

STRUCTURES AND SEISMOTECTONICS OF SOUTH EASTERN GHANA EARTHQUAKE ZONE

Anang Solomon ANUM (IASPEI)

B> Ghana lies on the southeastern margin of the West African Craton, far from the major earthquake zones of the world that mark the present lithospheric plate boundaries. However, there are historic records (The Accra Earthquake of 22nd June 1939), which show that earthquakes occur in the south of and southeast of Ghana from time to time.Geological, Geophysical and Seismological study in Southeastern Ghana shows that the occurrences of earthquakes in Ghana is due to movements along the Coastal Boundary Fault (CBF) and the Akwapim fault Zone (AKZ). Although studies on these fault zones is still in the elementary stage we believe that the reported seismic activities could be attribute to the crutal instabilities with geodynamic stress along the CBF and AFZ. In the last few decades, earthquake with epicenters located along the intersection of the two faults.

KINEMATICS ENGINE OF THE ONGOING DEFORMATION FIELD AROUND CAIRO, EGYPT

Ahmed BADAWY, Sayed EL-ESSAWY, Gamal HASSAN, Ali TEALEB (Seismology Dept., National Research Institute of Astronomy and Geophysics (NRIAG))

Abstract   Kinematics engine of the ongoing deformation field around Cairo, Egypt have been investigated from earthquakes, repeated GPS and gravity observations. First results provided from this combined strategy are presented, by focusing on both stress field and surface kinematics. The spatio-temporal distribution of earthquakes reveals that Cairo region has suffered not only from interplate earthquakes but also from inland seismic dislocations. Earthquake focal mechanisms indicate that the stress field around Cairo is dominated by a transtensional stress regime (normal faulting with strike-slip component). Repeated gravity measurements around Cairo proved an existence of considerable temporal variations of gravity. These non-tidal changes could be explained by dynamics processes within the upper crust related to the development of local stress conditions. The comparison between the observed GPS and gravity shows a remarkable agreement and provides a convincing explanation for the observed fluctuations with seismic activity. The results of deformation analysis indicate three different deformation zones in the investigated area. The northern part dominates as a compressional area with a magnitude of 0.19 ppm/year. The compressions in this area are generally in NW-SE direction. However, an extensional area with a magnitude of 0.21 ppm/year in the NE-SW direction has been observed in the southern part. The central part of the investigation area seems to be in a state of no significant deformation.

MESOZOIC BASIN DEVELOPMENT IN THE NORTH ATLANTIC AREA AROUND IRELAND: SOME CONSTRAINTS FROM POTENTIAL FIELD STUDIES?

Peter W. READMAN, Brian M. O'REILLY (Dublin Institute for Advanced Studies, 5 Merrion Square, Dublin 2, IRELAND)

Multiphase rifting episodes during the early to late Mesozoic Era associated with the break-up of Pangaea led to the formation of a global assemblage of sedimentary basins distributed across the entire North Atlantic region from eastern North America to the European Platform. The region around and to the west of Ireland lies at the centre of this regional assemblage and in this area tectonic re-activation of a strong NE-SW trending Caledonian basement

fabric partly controlled the siting of the basins. The syn-rift phase of basin development was contemporaneous with continental rupturing and the onset of sea-floor-spreading within the Atlantic south of the Charlie Gibbs and Azores Fracture Zones. In this study a compilation of marine and satellite gravity data is primarily used to produce a regional interpretation of the tectonic fabrics in the region around Ireland and extending westwards and southwards into the Rockall and Porcupine Basins. A series of gravity models across the various sedimentary basins including the Celtic and Irish Sea Basins are used with interpretations of vertical incidence and wide-angle seismic data, where available, to define crustal structure and its relationship with basin geometries. End-member sedimentary basin types are identified and a regional preliminary model for Mesozoic basin development is outlined. The deep-water Rockall and Porcupine Basins overlie North Atlantic lithosphere where large amounts of extensional strain were focused into the upper and mid-crust producing greater amounts of syn-rift subsidence. Within the inboard shallow water shelf sea basin areas of the Celtic and Irish Sea generally smaller strains occur within all levels of the lithosphere and this strain is distributed across wide regions of the lower crust and mantle lithosphere. The model for the regional structuring of sedimentary basins requires that the strain field varies erratically within the upper to mid-crust across the North Atlantic but varies more smoothly in the lower crust and lower mantle lithosphere. The changes in the pattern of strain in the upper to mid crust are accommodated by rotation of continental crustal blocks (about vertical axes) and also by large-scale crustal transfer fault systems that penetrate at least to a lower crustal level. These fault systems may have been important in controlling fluid flow at a lithospheric scale locally hydrating the upper mantle.

GEODYNAMIC ANALYSIS OF THE ROMANIAN TERRITORY BY A SET OF GEOTEMATIC MAPS

Ligia-Narciza E. ATANASIU (INSTITUTE OF GEODYNAMICS, 19-21 Jean-Louis Calderon St., Bucharest-37, Romania, R-70201)

The Romanian territory is a very important part of the alpine-carpato-hymalaian belt. We mention only two specific elements: First the Romanian territory placed at the border of the East European Platform is a region of complex geological structure dominated by the presence of the Vrancea active seismic zone, located in the bending area of Romanian Carpathians. Three tectonic plate/sub-plate seem to joint in this region: East European plate, Meosian sub plate and Intra Alpine plate. During the years, Vrancea active seismic area has been subject to much research trying to better understand the mechanism of its intermediate-depth seismicity. Second, on the Romanian territory we find the contact between Central European Platform (Epi-Paleozoic Platform) and East-European Platform (Precambrian Platform) so called Tornquist-Teisseyre zone, which is reflected by the different kind of geophysical maps. Our work is represented by the visualization and plotting of a set of thematic maps with geophysics, topographic and tectonic information on the Romanian territory, offering the possibility of a quick correlation and analysis of this huge amount of data. We hope that the resulted data set may considerably improve the knowledge on the tectonics and geodynamics of the Romanian territory and contributed to a better understanding of the natural hazards on the regional frame.

GEOPHYSICAL CONSIDERATIONS ON PLATE TECTONICS WITHIN THE ROMANIAN TERRITORY AND INTERMEDIATE DEPTH SEISMICITY

Lucian BESUTIU, Dorel ZUGRAVESCU (Sabba S. Stefanescu Institute of Geodynamics of the Romanian Academy)

During the time various models for plate tectonics on the Romanian territory were constructed mainly based on geological arguments, without taking into account the geophysical behavior of a plate boundary. The paper attempts to outline lithosphere blocks boundaries and their dynamics as inferred from geophysical data interpretation. Gravity, magnetics, geomagnetic soundings, heat flow, deep seismic investigations (DSS), magnetotelluric soundings (MTS), borehole breakouts, etc. were used on purpose. Consequently, a three-plate tectonic model for the Romanian territory was considered: East European Plate (EEP), Moesian micro-plate (MoP), and the Intra-alpine micro-plate (IaP). They are separated by large lithosphere discontinuities: Tornquist-Teisseyre (TTZ) compresional zone, Peceneaga-Camena (PCF), and the Trans-Getica (TGF) transform faults. Past to recent dynamics of the tectonic plates on the Romanian territory is discussed with special emphasize on the consequences of the Black Sea opening. It seems that crust extension related to the W Black Sea basin opening split the MoP into several crustal slivers, which relatively move each to another, thus generating normal earthquakes along their wedges. After the Black Sea ended its evolution, active rifts in SW Arabian Plate seem to offer the necessary driving forces for the present dynamics of these blocks. Back to the Black Sea opening, crust shortening took place in various environments. East Carpathians, crust expelled met the inclined boundary of TTZ and came into an oblique subduction to which the peculiarities of volcanism in the southernmost Harghita Mts. seem to be related. South Carpathians, crustal slivers faced the vertical margin of the IaP and provoked a lithosphere buckling, well reflected in the lowest gravity low on the Romanian territory, which lies in front and not beneath the highest mountains in the country. During the years, numerous attempts, mainly based on the hypothesis of a subduction in the area, have been made to explain the strange peculiarities of the intermediate-depth seismicity within the bending zone of East Carpathians. In the authors opinion, the strictly confined hypocenters location in the Vrancea area seems to be due to the presence of a continental unstable transform-transform-compression triple junction. Thereafter, the lithosphere block squeezed between MoP, EEP and IaP wedges was pushed down by tectonic forces driving the three plates. Statistics of the Vrancea intermediate earthquakes occurred after the major event of November 1940 showed a systematic SW migration of the seismogenic zone, advocating for the triple-junction actual slight displacement under the above-mentioned tectonic forces. The penetration of a colder lithosphere block into the hotter upper mantle led to an obvious thermodynamic disequilibrium. During the temperature accommodation various phenomena such as convective cells, phase transform, and devolatilization add new sources to the intermediate seismicity in the area.

ACCRETION TECTONICS OF NORTH PACIFIC AND FRACTAL DIMENSION OF TERRANES

Vladimir S. ZAKHAROV, Vsevolod N. VADKOVSKY (Moscow Lomonosov State University)

The forming continental crust on active zones has been connected with interaction between oceanic and continental lithosphere in convergent plate-boundaries. Different inhomogenities (fragments) of the oceanic crust such as seamounts, island arcs, oceanic plateaus and fragments of craton, becomes continental margin due to subduction and collision processes (present time and in the past). Other fragments created during these processes such as accretionary complexes and subduction zone terranes.Terrain may be defined as tectonic and stratigraphic unit which distinct from adjacent units separated by faults. The size of terrain is undefined: from some micrometers up to thousand kilometers. We used data from detailed digital geological map (GIS compilation on Geophysical, Geologic and Tectonic data for Circum –North Pacific. Eds.: W.Nokleberg and M.Diggles. Open file report 99-422,version 1.0, 1999) To calculate fractal dimension D set of terranes we take Ln(S)/Ln(P) relation where S-area and P- perimeter of the individual terrane. Fractal dimension D=2/B where B defined as slope of the strait-line approximation (LSQM) these ratio for set of terranes (Mandelbrot, Lovejoy). For set of terrans of the Russian Far East D=1.377, r=0.977 whereas for Northwest of the USA and Canada D= 1.202, r=0.974. The range of variation S and P includes many orders. Set of terranes is self-similarity. We investigate variations of fractal dimension ofterranes sets in geologic time, when terrain had been added to the active continental wedge for two regions. This small variability of D may be connected with terrain rigidity which didn't deformed during accretion process and its geologic life.Recent seismicity and GPS measurements for these regions confirm this point of view.

EVIDENCE OF DEEP SEISMOGENIC DEPTH IN STABLE CONTINENTAL REGIONS

Won-Young KIM (Lamont-Doherty Earth Observatory of Columbia University)

Well-documented recent earthquakes that occurred in Eastern NorthAmerica and in other stable continental regions (SCR) provide anopportunity to appraise the seismicity and hazard in this kind oftectonic environment through new data and analysis methods. Oneimportant question is the occurrence of SCR earthquakes at depth --down to mid- to lower-crust (15 to 30 km depth). Deep crustalearthquakes in old cratonic environments such as, Scandinavia andCanadian shield, have been interpreted as brittle rupture at depth dueto low heat flow coupled with favorable rheology. Another question is,are pre-existing faults in the crust is pertinent to SCRseismogenesis? Recent detailed studies of SCR earthquakes in EasternNorth America indicate that deep seated former rift system acted aspre-existing zone of weakness and some part of those may have beenreactivated. In this paper, I will show evidence of such deepseismogenesis in the Eastern North America using the data from recentearthquakes. Regional and teleseismic waveform data from the June 18, 2002,Evansville, Indiana earthquake (Mw = 4.6) indicate that the mainshockoccurred on a steeply dipping fault at a depth of about 18 km. Thesource mechanism determined from regional waveform inversion ispredominantly strike-slip along near-vertical nodal planes, strikingNNE and WNW. The focal depth is well constrained by regional andteleseismic waveform modeling as well as the accurate location of anaftershock recorded by portable local stations deployed following themainshock in the epicentral distance range 5 to 9 km. This earthquakesequence occurred in the Wabash Valley fault zone in the Illinois Basinin Indiana. A large number of subsurface faults are identified in theWabash Valley fault zone from over 6,000 petroleum test wells in thebasin. The close proximity of the mainshock and aftershock epicentersto the trace of the compound Caborn fault, and a strong correlationbetween the trend and dip of the Caborn fault and source mechanism ofthe June 18, 2002 event, suggest that the earthquake may have occurredon that fault. Downward continuation of the Caborn fault as well asother major faults mapped in the shallow subsurface of the WabashValley fault zone (to at least 7 km depth), and the focal depth of theJune 18, 2002 event suggest that the seismogenic depth in the faultzone extends to at least 18 km depth. Its focal mechanism -- verticalstrike-slip faulting at depth -- may suggest that faults associated with a possible Precambrian rift system are being reactivated by thecontemporary NE-ENE trending regional compressive horizontal stress.

THE CAMPBELL PLATEAU, NEW ZEALAND: ITS CRUSTAL EVOLUTION AND BREAK-UP PROCESS

Karsten GOHL[1], Bryan DAVY[2], Daniel BARKER[2], Fred DAVEY[2], Gabriele UENZELMANN-NEBEN[1] ([1]Alfred Wegener Institute for Polar and Marine Research, Bremerhaven, Germany, [2]Institute of Geological and Nuclear Sciences, Lower Hutt, New Zealand)

The Campbell Plateau is a large submarine continental plateau lying to the southeast of New Zealand and separated from the landmass of New Zealand by a series of deep extensional sedimentary basins and morphological deeps. Prior to about 110 Ma, the region (with New Zealand) formed part of Gondwana, fitting adjacent to eastern Ross Sea and western Marie Byrd Land, and coincident with an active subducting continental margin. At about 110 Ma, subduction at the margin ceased and extension of the region commenced. This extension continued until about 82 Ma when active seafloor spreading commenced forming the Southern Ocean. The Campbell Plateau has probably remained essentially submerged (presently at depths of about 500 m to 1000 m) since that time as extension has continued and little sedimentation has occurred on the Plateau due to the remoteness of sediment supply and ocean currents. The southeast margin of the Plateau, the conjugate margin to the western Marie Byrd Land margin of West Antarctica, has little sediment cover. Although the timing of break-up is relatively well documented, the processes that led to break-up and the subsequent evolution of the continental fragment forming Campbell Plateau are not well understood. The reason for the very steep southeastern margin is not known. Was it fast break-up, oblique break-up or erosion? Is a submarine plateau passive margin different to continental passive margin or just a result of differences in sediment supply? On the basis of potential field data, the Plateau can be divided into a series of crustal segments with varying crustal parameters. The Stokes and Campbell magnetic anomaly systems indicate extensive magmatic crustal provinces. What was the role of magmatism during break-up and subsequently? To answer these questions on the evolution of submarine continental plateaus, a geophysical survey was conducted across the Campbell Plateau in January-February 2003. The survey carried out a seismic (OBS) transect and a series of crustal seismic reflection lines from the South Island to and across the southeast margin of the Campbell Plateau. It crossed the Great South Basin and several poorly known east-west trending inferred extensional basins on the Campbell Plateau and defined the change in structure across the southeast margin of the Plateau. Preliminary results of this project are presented here.

EVOLUTION AND DYNAMICS OF THE PACIFIC MARGIN OF WEST ANTARCTICA

Karsten GOHL[1], Graeme EAGLES[1], Robert D. LARTER[2] ([1]Alfred Wegener Institute for Polar and Marine Research, POB 120161, 27515 Bremerhaven, Germany, [2]British Antarctic Survey, High Cross, Madingley Road, Cambridge CB3 0ET, UK)

The Pacific continental margin of West Antarctica has undergone a diverse evolution from a rifted passive margin in the SW Pacific to a converted active-to-passive regime in the SE Pacific sector. While the western margin developed as a result of rifting between greater New Zealand and Marie Byrd Land, the eastern margin evolved after the collision of the Pacific-Antarctic ridge with the subduction trench. While this general scheme has been known for some time, the detailed evolution of the margin and its adjacent ocean basins has become clearer only for the last few years with the gathering of more geophysical data.A distinct boundary between the two different West Antarctic margin types is marked by a

crustal-scale convergence zone in the western Bellingshausen Sea. This zone extends from oceanic to continental crust perpendicular to the margin and can be interpreted as the former eastern Bellingshausen plate boundary. The margin west of it and north of Thurston Island developed as a classical passive one after break-up from Chatham Rise (NZ). The Pine Island Bay and the NW-extension of its main trough across the shelf seem to form another boundary. The margin west of it evolved after separation from Campbell Plateau (NZ) and shows abundant volcanic structures. Although newest plate-tectonic reconstructions of the South Pacific places Pine Island Bay conjugate to Bounty Trough (NZ), it is still speculative to assume that both systems formed as a continuous rift. The data coverage in this remote area is still somewhat sparse. But by integrating seismic information with satellite altimetry and ship/airborne potential field data, we are able show an improved model for the evolution of the West Antarctic margin.

NUMERICAL AND FUNCTIONAL REPRESENTATIONS OF REGIONAL HEAT FLOW IN SOUTH AMERICA

Valiya M. HAMZA, Fernando J.S. SILVA DIAS (IASPEI)

An updated database incorporating results of recent geothermal investigations has been setup for the purpose of examining regional trends in heat flow in South America. These include recent conventional heat flow measurements at nearly 40 sites in the southeast coastal area of Brazil and new BHT heat flow estimates for nearly 150 sites in the sub-Andean basins in the west-central parts of the continent (in Bolivia, Chile, Colombia, Ecuador and Paraguay). The present continental data base consists of 793 heat flow values, giving an overall data density of 45 per million square kilometers and a representative mean of 63 +/- 36 mW/m2. Comparison with previous compilations indicates that there has been some improvements in data quality. Thus, results obtained by conventional methods constitute a significant part of the data set in the central and eastern parts of the continent. The geographic distribution, however, continue to be non-uniform, there being several areas where data density is low, and some for which heat flow data are not altogether available. The updated database was employed in generating numerical surfaces of regional heat flow pattern in several parts of the South American continent. In addition, polynomial methods were employed for examining regional scale variations in heat flow over the continent. Specifically, a general purpose least square solution was used to determine coefficients of up to sixth order in latitude and longitude. Examination of meansquare residuals indicate that higher order polynomials are unwarranted. Maps of regional trends and residual anomalies reveal the existence of several systematic patterns in regional heat flow. Thus cordilleran regions of the Andes are, in general, characterized by relatively high heat flow (with values > 75 mW/m2), compared with the western coastal regions and the Pre-Cordilleran basins to the east. In the eastern part of the continent, heat flow is low to normal (with values < 60 mW/m2), the exceptions being the Mesozoic rift basins (Potiguar, Recôncavo and TaubatAE, areas of Cenozoic alkaline intrusions and some isolated localities in the Precambrian terrain in the central parts of Brazil. Problems arising from low data density allow only limited insights into the nature of heat flow variations along and across the main tectonic units. Thus only large-scale trends associated with changing tectonic patterns and subduction-related magmatism can be identified in polynomial representations of the regional heat flow field. Prominent among these are east-west trending belts of low heat flow in northern Peru and in central Chile, as well as the high heat flow belts in northern Chile (extending into the Altiplano of Bolivia) and southern Chile (extending into northwestern Argentina). The low heat flow belts are found to coincide approximately with zones of sub-horizontal subduction, while high heat flow belts are situated in regions of high angle subduction. The results also indicate that further improvements in polynomial and numerical representations of regional thermal fields can be achieved only through acquisition of new good quality geothermal data in areas of low data density.

VOLCANIC CENTRE DISTRIBUTION FABRIC AS INDICATOR OF FINITE INCREMENTAL STRAIN IN SOUTHERN CENTRAL ANDES

Guillermo Hector RE[1], Maria Silvia JAPAS[2], Silvia Patricia BARREDO[1] ([1]Dpto. Geologia - Universidad de Buenos Aires, [2]CONICET - Argentina)

The Andes chain is built as a consequence of the subduction of the Nazca plate under the South American plate, without continental collision involvement. This fact has made of the South American Pacific margin a typical example of ocean lithosphere subduction under a continental plate. The Cordillera de los Andes system lies parallel to the Peruvian-Chilean trench, which delineates the meet zone between the subducted oceanic plate and the continental plate; and their evolution is linked to the particular characteristics shown by the Nazca Plate subduction and, associated to it, the subduction of the Nazca, Iquique and Juan Fernández ridges under the South American Plate. The main characteristic of the current Andean orogen, and possibly also of the previous evolutionary stages of the South American convergence system, is a persistent, in terms of space and time, longitudinal segmentation of the tectonic, geodynamic and morphological elements that make up the continental margin. The present work is centered in the study of the segment understood between the 20° and the 33° of south latitude. In this sector the analysis of the volcanic centers distribution fabric has permitted to characterize the incremental strain of the Andean system for Miocene to Recent times. The results of this analysis confirm the existence of two sets of localized non-coaxial regional structures that exerted a structural control on the volcanic emplacements, and in the periods of activity of these volcanic centers. These structures consists in NNE and NNW trending extensional megashears zones which play an important role in the Andean evolution. NW secondary wrench structures locally control volcanic bodies location and would represent transtensional features, en-echelon arranged. In close relationship with the volcanism and the kinematics of the orogen, the salt deposits of borates, geysers and hot springs of the Argentinean Puna would also undergo the tectonic control exercised by these megashears. Beginning with the integrated analysis of the tectonic fabrics, the time interval in which any of these structures was active has been delimited with even more precision; and confirm the importance that the shears extensional of regional character exercice in the control of the evolution Andean tectonics. Therefore, it was possible to determine that the system evolution of progressive deformation (type c/c´), developed in an transpressive tectonic environment, has played a fundamental role in the structuring and kinematics evolution of this section of the central Andes.

LOW-VELOCITY OCEANIC CRUSTAT THE TOP OF SUBDUCTING PLATES RESOLVED BY A TOMOGRAPHIC METHODWITH SPATIAL CORRELATION

Makoto MATSUBARA, Shutaro SEKINE, Kazushige OBARA, Keiji KASAHARA (National Research Institute for Earth Science and Disaster Prevention)

The detailed velocity structure beneath Japan arc is obtained by applying the tomographic method (Zhao *et al.*, 1992) with spatial correlations (Matsubara *etal.*, 2001) to 1,061,936P-wave arrival times from 19,943 earthquakes recorded at NIED Hi-net of 664 stations. The

target region is the crust and the upper mantle beneath Japan arc (29-46°N, 129-146°E,0-200 km depth). The horizontal spacing of the grid nodes is 0.125° in the crust and 0.25° in the mantle. 2.5 km. That in the vertical direction is 2.5-5 km in the crust and 7.5-15 km in the mantle. The corresponding resolution is twice as grid interval, say, 0.25° in the crust and 0.5° in the mantle, horizontally. A low velocity zone exists within depths of 30-50 km beneath the northeastern Japan arc corresponding to the upper boundary of the subductiong Pacific plate. In Kanto region, two low-velocity zones have been found at depths of 40-100 km in the southern part and around 30 km in the western part. The deeper section corresponds to the upper boundary of the Pacific plate and coincides with the S-wave reflector (Obara and Sato, 1988). The shallower one indicates the upper boundary of the subducting Philippine Sea plate and supports the results of Ohmi and Hurukawa (1996). We conclude that these low velocity zones are the oceanic crusts that exist at the top of the subductiong Pacific and Philippine Sea plates. We also found the low velocity zones along the volcanic front beneath the northeastern Japan arc and back-arc side in the upper mantle. These zones are parallel to the subducting Pacific plate. The high velocity zone indicating the subducting Philippine Sea plate beneath the eastern Kyushu district, western edge of Japan arc is also shown clearly.

DEEP CRUSTAL STRUCTURE EXPLORATION IN HYPOCENTAL REGION OF THE 2000 TOTTORI-KEN SEIBU EARTHQUAKE

Shintaro ABE[1], Yasuhira AOYAGI[1], Katsuyoshi MIYAKOSHI[1], Daiei INOUE[3], Yoshiya ODA[2] ([1]Geosphere Environmental Science Department, Central Research Institute of Electric Power Industry, [2]Tokyo Metropolitan University, [3]Central Research Institute of Electric Power Industry)

The Tottori-ken Seibu earthquake of October 6, 2000 was a large earthquake exceeding Mj 7. However, active fault was not pointed out on the existing map in hypocentral region of this earthquake. This fact is very important in order to argue about the validity of predicting the magnitude of great or large earthquakes generated in the target area based on the results of earth scientific investigation.We carried out dense earthquake observation in which we installed 44 points in order to grasp the detailed form of earthquake source fault. Furthermore, we carried out seismic reflection prospecting of 3 observation lines which cross the earthquake source fault of main shock. We clarify the relevance of earthquake source fault and lineamen. Principal Results 1. Low velocity zone detected in the crust by velocity analysis. We interpreted S-P interval of the seismic wave obtained by earthquake observation, and carried out velocity analysis using travel time seismic tomography method. Low velocity zone was detected in the depth of about 2 km of hypocentral region as a result of the analysis. The low velocity zone is distributed on earthquake source fault presumed from aftershock distribution. Generally fall in seismic wave velocity is caused by fall of rigidity. That is, it is thought that the low velocity zone was formed from destruction of the crust by fault activity. 2. Flower structure recognized by seismic reflection prospecting. In the place where lineament and an observation line cross, two faults have been recognized in seismic reflection prospecting line-B. These faults seem to converge toward the depths. This geological structure is called flower structure, and it is characteristic underground structure formed of accumulation of lateral displacement. In this area, we were also carrying out aerial photograph interpretation and trench excavation. As a result, the geological proof that the lineaments were formed of left-lateral fault was acquired. That is, both underground structures and deformations of surface have lateral fault features. 3. Aftershock distribution and region crushed by faults recognized by seismic reflection prospecting. Faults recognized by seismic reflection prospecting and region crushed by the faults are located in the upper part of earthquake source fault presumed from aftershock distribution. However, the scale is too large if this crushed region was formed only by fault activity of the 2000 Tottori-ken Seibu earthquake. That is, it suggests that earthquakes with the same mechanism as the 2000 Tottori-ken Seibu earthquake occurred in this area repeatedly in the past. Reference Shintaro Abe, 2002, Seismic Reflection Survey around the 2000 Tottori-ken Seibu Earthquake area, The Society of Exploration Geophysicists of Japan, Proceedings of the 107th SEGJ Conference (Japanese only).

SEISMIC STRUCTURE OF THE CRUST AND UPPERMOST MANTLE BENEATH KYUSHU, JAPAN AS INFERRED FROM RECEIVER FUNCTION ANALYSIS

Takumi MURAKOSHI[1], Hiroshi TAKENAKA[1], Sadaomi SUZUKI[1], Hiroshi SHIMIZU[2], Kenji UEHIRA[2] ([1]Department of Earth and Planetary Sciences, Faculty of Sciences, Kyushu University, [2]Institute of Seismology and Volcanology, Faculty of Sciences,Kyushu University)

Kyushu is one of the typical active subduction zones where the Philippine Sea plate goes northwestward beneath the Eurasian plate. For understanding its tectonic features we studied seismic structure of the crust and uppermost mantle beneath Kyushu by use of receiver function analysis. The data used for receiver function are three-component broadband records of the teleseismic events occurring in the epicentral distance of 30-100 degree observed by 17 stations in and around Kyushu. We obtained 10-80 high quality receiver functions for each station. And we applied SVD filtering to the receiver functions of multi-channel for each station to emphasize the coherent phases. Most of the filtered functions show the Moho-boundary phase converted from P to S. We also found the phases of negative amplitude which means the existence of low-velocity layers in the crust and uppermost mantle. We applied the receiver function inversion using genetic algorithm (GA) to estimate the detailed velocity structures beneath the stations. For estimating the both of shallow and deep structures with high accuracy we applied a new approach by separately using the high-frequency and low-frequency receiver functions. After calculating the receiver function inversion for each station, we estimated the three-dimensional velocity structures beneath Kyushu by using a migration technique. The results reveal the followings. (1) The depths of the Moho-boundary beneath Kyushu are 25-35 km. The Moho of western Kyushu in backarc tends to be shallower, whereas the Moho of northeastern Kyushu and western Chugoku which locate at the junction of the Southwest Japan Arc and the Ryukyu Arc are deeper. The Moho depths beneath the active volcanoes tends to be slightly deeper. (2) The top of the subducting Philippine Sea plate is imaged clearly in the range of depth from 40 to 70 km beneath eastern Kyushu. (3) Low velocity layers are visible at the crust and uppermost mantle beneath the active volcanoes in Kyushu; for instance, at the upper crust under northern Kuju and eastern Aso volcanos, at the lower crust and uppermost mantle under western Aso volcano, and at the upper crust and uppermost mantle near Sakurajima volcano. (4) A low velocity layer is visible in the uppermost mantle beneath Fukuejima island in the western Kyushu. It may show the partially melting by the mantle upwelling in the backarc of Kyushu.

SEISMIC STRUCTURE OF INTERPLATE SEISMOGENIC ZONE IN THE SOUTHERN JAPAN TRENCH FROM SP CONVERTED PHASES

Minoru NISHINO[1], Ryota HINO[1], Masanao SHINOHARA[2] ([1]AOB, Tohoku University, [2]ERI, University of Tokyo)

Evident later phases often appear about 1-3 second after the P first arrivals on seismograms of the interplate earthquakes occurring in the southern part of the Japan Trench subduction zone recorded by the land seismic network in the NE Japan arc. If these arrivals (X-phase) are converted or reflected waves at an interface in the deeper part of the interplate seismogenic zone, it is important to locate the conversion or reflection points to clarify the seismic structure. The results of preliminary analyses on the particle motions and arrival time differences, X-P times, versus offsets indicate that X-phase is possibly a SP converted wave at an interface located near the hypocenter. For accurate estimation of the point of conversion, it is very important to determine the hypocenters of the earthquakes with the SP arrivals. In this study, we relocate the hypocenters of the offshore interplate earthquakes by using ocean bottom seismographic data. Our data set consists of two groups: 1) nine events occurred in 1997 when a dense OBS array was deployed and 2) earthquakes taking places since 1995 when a permanent offshore seismic station was put into operation. The OBS array in 1997 observation was in operation for over three weeks and detected about 900 microearthquakes. 94 of them were recorded also by the land stations and nine were observed with the evident SP phase. Detailed inspection of the OBS waveform records, the SP phase was also recorded at OBSs. Using a seismic velocity structure model determined by an airgun-OBS seismic experiment (Nishino et al., 1999), we relocated both the hypocenters and the point of SP conversion simultaneously, from P and SP arrival times at the land and OBS stations. The estimated SP conversion points are located just above the cloud of the microseismicity defining the location of the subduction interface. Therefore, the nine earthquakes are not actually the interplate events and the observed X-phase was interpreted as the S to P conversion at the plate interface. We are now analyzing the data set 2) and the conversion points also seem to be located along the plate boundary. If our interpretation that X-phase is the plate boundary SP from the intraplate events is true, X-phase can be a good marker to identify intraplate events. Since it is difficult to distinguish whether an earthquake actually occurs along the plate boundary only from its hypocenter location, our X-phase analyses is important not only to clarify the geometry of the plate boundary but also to understand the ´thickness´ of the interplate seismogenic zone.

CRUSTAL STRUCTURE OF CENTRAL JAPAN OBTAINED FROM SEISMIC SURVEYS - ROLE OF STRUCTURE IN MEGATHRUST EARTHQUATE OCCURRENCE

Yoshiyuki KANEDA[1], Shuichi KODAIRA[1], Jin-Oh PARK[1], Ayako NAKANISHI[1], Takashi IIDAKA[2], Eiji KURASHIMO[2], Hiroshi SATO[2], Takaya IWASAKI[2] ([1]IFREE, JAMSTEC, [2]ERI, Univ. Tokyo)

Among subduction zones, the Nankai subduction zone off southwest Japan isknown as one of the best-suited convergent plate margins for studyingsubduction zone earthquakes. Historic, large subduction thrust earthquakeshave occurred with a recurrence interval of 100-200 years along the NankaiTrough. The last two large earthquakes that occurred off the Kii Peninsulawere the 1944 Tonankai (M 8.1) and 1946 Nankai (M 8.3) events. Seismicimaging of deep structure is a very important seismological method and mayhelp explain the mechanisms that control megathrust earthquake occurrencearound the Nankai Seismogenic Zone.Results of seismic studies from 1997 to present include the presence of asubducting seamount that acted as the barrier in 1946 Nankai earthquake, animaged splay fault which may have controlled the rupture process in 1944Tonankai earthquake and cyclic ridge subduction in Tokai district. Remarkable results are summarized as follows.1) Multichannel seismic (MCS) reflection profiles obtained in 2001 showsplay faults in the rupture area of the 1944 Tonankai earthquake.This splay fault may have experienced slip during the 1944 Tonankai event.2) In 2001, onshore-offshore wide-angle seismic data were acquired along aprofile from the western edge of the Izu arc to the northern coast ofcentral Japan crossing the Tokai district. Results from refractiontomography and pre-stack depth migration of the offshore wide-angle datareveals the structures are immediately outside of the rupture zone duringthe 1944 Tonankai earthquake; i.e. a cyclic ridge subduction in thenon-rupture zone. The model shows the repeated crustal thickening withthickness of 13 - 20 km and wavelength of 35 - 50 km between the westernedge of the Izu arc and the Tokai district. This structure is interpreted asthe cyclic ridge subduction beneath the Tokai district. In recent seismic experiments, we have succeeded imaging high resolutionirregular characteristics of the subducting plate and coseismic slip zone suchas a subducting seamount, subducting ridge, offshore splay faults and strongreflectors onshore. In analyses of historical earthquakes, the high energy asperities obtainedaround the subducting seamount area indicates that the seamount acts as acomplementary asperity in the 1946 and 1707 megathrust earthquakes.These results suggest that irregular structure may control ruptureasperities by acting as a rupture inhibitor or high slip zone during themegathrust earthquake cycle.

SS03/08A/D-103 Poster 0830-262

CRUSTAL STRUCTURE OF THE MID-IZU-OGASAWARA ARC FROM WIDE-ANGLE SEISMIC DATA

Kentaro KANEDA[1], Azusa NISHIZAWA[1], Tsuyoshi YOSHIDA[1], Osamu YOKOO[1], Shin TANI[1], Ayako NAKANISHI[2], Shuichi KODAIRA[2], Narumi TAKAHASHI[2], Wonn SOH[2], Yoshiyuki KANEDA[2], Kiyoshi SUYEHIRO[2] ([1]Hydrographic and Oceanographic Department, Japan Coast Guard, [2]Japan Marine Science and Technology Center)

A wide-angle seismic experiment was conducted as a joint operation between the Hydrographic and Oceanogrphic Department, Japan Coast Guard (HODJ) and the Japan Marine Science and Technology Center (JAMSTEC) in April-May, 2002, to construct a crustal structure model of the Izu-Ogasawara (Bonin) arc, which can be a clue to clarify the evolution process of the intra-oceanic island arc. The Izu-Ogasawara arc is located on the Philippine Sea plate along with the Izu-Ogasawara Trench, and shifts to the Mariana arc at its southern end. In this investigation, we deployed 25 ocean bottom seismographs (OBS) at 20-30 km of intervals along about 800 km track-line at 30-31ºN from the Pacific Basin at its eastern end, through the Shichito-Iwojima Ridge and Kinan Escarpment, to the center of the Shikoku Basin at its western end, except for the Izu-Ogasawara Trench area exceeding 6000 m depth. The deployment and retrieval of OBSs were carried out by *S/V Shoyo*, HODJ. The seismic source is an array of eight, 1500 in³ (24.6 l) air guns (12000 in³ or 196.6 l, total) provided by *R/V Kairei* belonging to JAMSTEC, firing every 90 seconds with an approximate 200 m spacing. The data recorded by each OBS were of high quality and travel time data were modeled by the two-dimensional ray tracing. The acquired crustal model along the track-line shows several structural features. One of the features is a thick oceanic lower crust extending to ~50 km east from the Kinan Escarpment which forms a large vertical displacement of over 600 m in water depth on the Shikoku Basin. The structural model also reveals that the thickness of the Izu-Ogasawara island arc crust is up to 22 km and there exits a thick 7.0-7.2 km/s layer with thickness of > 5 km at the bottom of the crust. These characteristics resemble the result of the northern Izu-Ogasawara arc survey at 32ºN(Suyehiro et al. 1996), though the water depth along the Izu-Ogasawara arc gradually becomes larger from north to south.

ON SOME RESULTS OF THE MONITORING OF CRUSTAL STRAINS IN CENTRAL JAPAN

Vladimir CHURIKOV[1], Hiroshi ISHII[2], Rimma KARMALEEVA[1], Yuri KUZMIN[1] ([1]Institute of Physics of the Earth, Laboratory of Recent Geodynamic, Moscow, Russia, [2]University of Tokyo, Earthquake Research Institute, Japan)

Here, we discuss results of borehole extensometer measurements in two points in Tono, central Japan, during 1998-99. Borehole instruments settled on depth about 170 m where temperature variation is less than 0.001º. Country rocks are Toki granites. Between two points Tsukiyoshi reverse fault is extended with dip angle of about 60º to 70º to the south. Author of borehole instruments is Prof. Ishii, H., from Tokyo University. Obtained results are representative because there are high resolving ability of instruments and almost no breaks in measurements. There are important to use tide analyzing during estimation of the data representativeness. Comparison of observed wave parameters with calculated theoretical for each points allows us to reveal a peculiarity of regional tectonics, because magnitude of tidal amplitude is determined by elastic properties of country rocks. In case of activation of tectonic processes variation of tidal waves in time was observed (L.A.Latynina and R.M.Karmaleeva, 1981, R.M.Karmaleeva, 2000). Pertzev's method of tide analyzing with daily moving average was applied for the whole obtained data. Estimation of a see tide was not calculated because no co-tidal maps. However, its influence on amplitude of M2 (which are maximum) estimated less than 35% on the nearest to Tono stations. For next calculation we used main waves - M2 and O1, which ones have maximum amplitude on all azimuths. Magnitude of amplitude is almost the same accurate within 8-10%. In sub-meridional direction it is in 3.7 times (73%) less of theoretical value, in sub-latitudinal - in 1.2 times exceed. In intermediate azimuth difference between stations was observed. On south part of the fault amplitudes is in 1.6 times less, on north part - in 1.2 times exceed of theoretical value. Apparently, this difference we could explain by influence of system of wells for water pumping located at a distance 300 m in the same direction to south part of the fault (C.-Y King at al., 1999). Since Tsukiyoshi fault is impermeable to water then the influence do not extend to the north part. Similar dependence observed for O1 too. Decreasing of tidal amplitude in sub-meridional direction is possible to explain by strain concentrations within faults system and geodynamic zones along rivers close to latitudinal extension, contiguous to Tono area. Observation points located between two geodynamic zones, which traceable along rivers on the distances of 8 and 3 km. Anomalous amplitude decreasing allow us to suppose that strain condition over observed area depends on a geodynamic activity this area. Some changes in spectrum of deformations were revealed during increasing of seismic activity that possible explain by changes of rheological properties of rocks. Investigations realized of many years on extensometer measurements and supersonic sounding, show changes of period of cycles in stressedly-deformed conditions of country rocks in fissured areas (R.M.Karmaleeva and O.I.Silaeva, 2001).

SS03/08A/D-105 Poster 0830-264

PHYSICAL PROPERTY ESTIMATE AT THE ASEISMIC PLATE BOUNDARY IN THE JAPAN TRENCH REGION BY THE SYNTHTIC SEISMOGRAM APPROACH USING THE FDM METHOD

Peyman POOR MOGHADDAM[1], Junzo KASAHARA[1], Gou FUJIE[2], Kimihiro MOCHIZUKI[1] ([1]Deparment of Earth and Planetary Science, University of Tokyo, [2]Japan Marine Science and Technology Center, Japan)

In 1996, we conducted a seismic refraction-reflection experiment at the Japan Trench region to clarify the relationship between seismicity and crustal structure. A number of seismic reflection and refraction experiments using Ocean Bottom Seismometers (OBSs) have been conducted. Consequently, a velocity structure model was obtained by travel-time inversion (Fujie et al., 2002). Extremely important results were obtained showing a strong correlation between seismic activity and the P-P reflection intensity from the subduction plate boundary. Considering the accuracy of the travel time inversion, possible causes to generate intense reflections were investigated. One of possibilities is the presence of low Vp materials such as water, serpentinites or clay.To obtain more accurate estimate for the physical properties, we carried out the simulations using FDM method developed by Shawn Larsen (E3D code). . It is 4th-order accuracy in space and 2nd-order accuracy in time. It is based on the elastodynamic formulation of the wave equation on a staggered grid. The absorbing boundary due to finite number of grids is also considered. The structure obtained by Fujie et al. (2002) has 140k m long and 30 km deep and is heterogeneous in horizontally and vertically. We added a thin low velocity layer to the above model. The thin layer has various parameters such as Vp= 2km/s -4 km/s, Vp/Vs= 1.7 -3.0, and layer thickness= 50m -400m. Using these models, we computed the waveforms and wave field. The 5Hz and zero phases Ricker wavelet was used as source, and it is a reasonable approximation for control source used in the field experiment. We introduced appropriate Q structure.. Spacing for space is 25m and time grid is 1.7msecond. In the field we used shots more than 4000 airguns and 100 explosives from the sea surface. Shot interval was 25m-50m. Due to limitation of computer resources, we computed 100m spacing traced and simulated the reciprocity of this model which we consider several receivers at the sea surface and one shot at the sea bottom (common source).The synthetic seismograms are compared by observed waveforms obtained by Fujie (1999). The current result shows that the layer with Vp=2km/s-3km/s or Vp=4km/s and Vp/Vs=3.0 can explain the observation of high P-P reflectivity. These materials are quite different from the Vp values surrounding the plate boundary at the depth of 13km from the ocean surface. As the low Vp velocity suggests weak frictional strength, this material can explain the aseimicity in the intense P-P reflection zones.Because the above simulation is limited in parameters, more extensive investigation is necessary.

CRUSTAL STRUCTURES ASSOCIATED WITH ACCRETION AND COLLISION PROCESSES IN HOKKAIDO, JAPAN, FROM REINTERPRETATIONS ON RECENT SEISMIC EXPEDTIONS

Takaya IWASAKI[1], Tanio ITO[2], Hiroshi SATO[1], Takeo MORIYA[3], Research Group of HOKKAITO TRANSECT[4] ([1]ERI., the University of Tokyo, [2]Chiba University, [3]Hokkaido University)

Seismic expeditions in the last decade undertaken in Hokkaido revealed detailed crustal structures associated with accretion and collision processes since the late Jurassic. The Hidaka collision zone, central part of the Hokkaido Island, Japan, is known as an ongoing collision zone between Kuril Forearc(KA) and the Northeast Japan Arc (NJA) since middle Miocene, and has been a main target area for the expeditions. This paper presents compilation of crustal structures in and around this collision zone from reinterpretation of the previous seismic data. The most remarkable feature beneath the collision zone is the crustal delamination of KA. According to a series of seismic reflection studies in the southernmost part of Hidaka Collision Zone, the crustal structure in KA is characterized by two distinct reflective zones. Namely, its upper 23 km part is obducted westward onto NJA, while its lower part is descending down, forming a wedge-like structure. Seismic reflection/refraction experiments in 1998-2000 revealed various scale structural heterogeneity across this

collision zone. The data obtained elucidated a complicated collision structure. In the eastern part of the profile, KA is covered with 0.3-4km thick highly deformed sedimentary layer, beneath which two eastward dipping reflectors are imaged in a depth range of 10-20 km, probably representing obducting a middle or lower curst of KA. Beneath these reflectors, another flat and westward dipping reflectors are situated at 25 and 25-27 km depths respectively. The obtained layer geometry also forms wedge-like (crocodile) patterns, indicating that the crust of KA is delaminated into two or three segments beneath the Hidaka Mountains. The crustal image obtained is much complicated as compared with that in the southernmost part of the collision zone mentioned above, showing a significant regional difference in collision style. The seismic data from 1999-2000 experiments mapped a very thick (more than 5-10 km) sedimentary package including two or more velocity reversals in a fold-and-thrust belt west of the Hidaka Collision Zone. Beneath this package, the crystalline crust of NJA is traced with a slight eastward dip down to 20-25 km. Such a velocity reversal may widely spread because other seismic profiles undertaken in 1984 and 1992 show a significant travel-time jump west of the collision zone, strongly indicating the existence of a low velocity zone at depth. If such a velocity reversal corresponds to the shallow part of previous NJA, our result gives an important constraint not only on the crustal shortening ratio of the NJA but the convergence rate of the Okhotsk (or North America) and Eurasian (or Amurian) plates.

SEGMENTATION OF THE CRUST INFERRED FROM SEISMIC REFLECTION PROFILES IN THE FOREARC REGION OF THE JAPAN TRENCH OFF AOMORI

Tetsuro TSURU[1], Jin-Oh PARK[2], Seiichi MIURA[1], Yukari KIDO[1], Yoshiyuki KANEDA[2] ([1]Center for Data and Sample Analyses, Institute for Frontier Research on Earth Evolution, [2]Research Program for Plate Dynamics, Institute for Frontier Research on Earth Evolution)

Seismic reflection character provides geophysical and geological information about subsurface structures, and is extremely useful for structural interpretation. JAMSTEC has been conducting multi-channel seismic (MCS) reflection experiments in the Japan Trench region since 1996, in order to clarify the detailed tectonic structures near the plate boundary. In April-July 2000, an MCS survey was conducted off Aomori, the northernmost part of the Japan Trench, using a total of 12000 cu. in. airgun array, and a digital streamer cable with 156 channels. Seismic records of 13.5 seconds were obtained using 50 m shot spacing and 25 m group intervals. The maximum source-receiver offset distance was 4100 m. The field data obtained were processed using trace-editing, multiple suppression, deconvolution, and filtering, to enhance the signal-to-noise ratio, at Center for Data and Sample Analyses of IFREE/JAMSTEC. This processing also increased the resolution of the data. Even after applying the deconvolution, air-bubble oscillations still appear on the record sections, approximately 200 ms below the primary reflection, because the air-gun array was not tuned. Previous studies revealed a wedge-shaped sedimentary unit with relatively low velocities (2-3 km/s P-wave velocities) at the seaward end of the continental plate [e.g., von Huene et al., 1994; Tsuru et al., 2000]. This sedimentary unit is demarcated from the more rigid continental framework, characterized by 4-6 km/s P-wave velocities, by the buttress [von Huene et al., 1994] or the backstop interface [Tsuru et al., 2000]. The prominent maker horizon in the island arc crust, representing the unconformity separating the Cretaceous basement from the Neogene rocks above [Nasu et al., 1980], terminates at the backstop interface. The wedge-shaped unit is distributed parallel to the trench in the forearc region of the northern Japan Trench, and reaches a maximum width off Sanriku, in the central part of the northern Japan Trench. The width distribution is concordant with the relief of horst-graben structures developed at the outer slope, except off Aomori, where the unit is as wide as off Sanriku even though little relief is developed. Here, the backstop interface no longer terminates the unconformity. Remarkable differences in the seismic reflection character can be observed between the rigid continental framework and the sedimentary unit. Its boundary can be traced along some MCS lines, revealing an NNW-SSE strike. Furthermore, the unconformity shows a gap in the depth of the boundary on some profiles, suggesting some fault activity and/or segmentation of the crust. Crustal segmentation may cause changes in the coupling at the plate boundary around the boundary. Interestingly, two large interplate earthquakes of greater than M7.5 occurred at locations just landward from the boundary. In this paper, we will demonstrate the differences in seismic character in the MCS profiles, and discuss the kinds of tectonic features that are reflected.

THREE-DIMENSIONAL ATTENTION STRUCTURE BENEATH THE JAPAN ISLANDS DERIVED FROM NIED HI-NET DATA

Shutaro SEKINE, Makoto MATSUBARA, Kazushige OBARA, Keiji KASAHARA (NIED)

The attenuation structure beneath the Japan Islands should hold3-D complexities similar to those in the velocity structure. For example,we often observe abnormal distributions of ground motion amplitudes, whichare very different from a circular distribution. Seismicattenuation implies inelasticity or scattering in the Earth's materials,while seismic velocities imply their elastic properties. We can assumehigh attenuation under the volcanic fronts, and low attenuation along thesubducting Philippine Sea plate similarly to the velocity structure. However,this similarity is not always expected in other parts of the Japan Islands.Information on the seismic attenuation is also important for the simulationof strong ground motions. National Research Institute for Earth Science and Disaster Prevention (NIED) has observed at Hi-net stations distributed in the whole Japan Islands. Inthis study, the vertical components of ground velocity amplitudes reportedfrom August 2000 to September 2002 will be used. The seismic attenuationwill be represented with the indexes called Qp and Qs, and their 3-D structurewill be obtained for frequency bands between 1 Hz and 10 Hz. Amplitudesfrom 3835 earthquakes are used for tomography. The number of stations whereamplitudes were observed is 664. There are three characteristic results in this study. First of all,clear low-Q zones can be found beneath the volcanic front in the northeasternJapan, and the distinct high-Q is recovered in the east of the front. Thishigh-Q area coincides with the strata of 100 Ma or older. Low-Q zones appearonly just below volcanoes in the upper and lower crust, while the low-Qarea extends continuously along the volcanic front at a depth of 40 km.The Qp distribution show similar tendencies zone, but the averaged Qp inthe crust is significantly lower than the averaged Qs, so that correspondinglow-Qp zones are not obvious. The tendencies can also be found along thevolcanic front related to the subduction of the Philippine Seaplate. Secondly, a distinct low-Qp area is found at a depth of 65km in theChubu region, central Japan. However, no low-Qs zone can be found in thearea. This may imply a different attenuation process from that under thevolcanic front in the northeastern Japan. Thirdly, the high-Q area is found along the upper boundary of the Philippine Sea slab, which is determined from seismicity in the southwestern Japan.This area is more distinct in the Qp distribution with an average of 1000 than in the Qs distribution. In the Shikoku region, the low-Qp area doesnot extend beyond latitude of 34.2 N, and the area looks falling down intoa deeper part there. On the other hand, in the Kyushu region, the low-Qparea reaches a depth of 100km or larger coinciding with the slab boundarydetermined by the seismicity.

STRUCTURAL CHARACTERISTICS CONTROLLING THE SEISMICITY AROUND THE JAPAN TRENCH INFERRED FROM WIDE-ANGLE SEISMIC DATA OFF MIYAGI FORE ARC REGION

Seiichi MIURA[1], Narumi TAKAHASHI[2], Tetsuro TSURU[1], Aki ITO[1], Shuichi KODAIRA[1], Ayako NAKANISHI[1], Yoshiyuki KANEDA[1] ([1]IFREE, JAMSTEC, [2]Deep Sea Research Department, JAMSTEC)

The Japan Trench is a subduction zone locating east of NE Japan. The seismicity is not a uniform pattern but a regional variation along the Japan Trench. Many large earthquakes occurred in the northern part off Sanriku and Miyagi regions, whereas few large earthquakes occurred in the southern part, off Fukushima. To investigate the detailed subduction zone structure and to understand the regional variation of seismicity, intensive seismic surveys have been conducted by Japan Marine Science and Technology Center (JAMSTEC) since 1996. In 1999, a seismic experiment was conducted off Miyagi using 36 ocean bottom seismographs (OBS) and a 12000 cu. in. airgun array on R/V Kaiyo of JAMSTEC. The objectives of this paper are to investigate the seismic structure off Miyagi fore arc region, and compare the relation between the structure and seismic activity with those of other regions of Japan Trench. Island arc crust off Miyagi consists of four layers: Tertiary sedimentary Layer (Vp=2 km/s), Cretaceous layer (4-5km/s), island arc upper (6km/s) and lower crusts (6.6-6.8km/s) with the thicknesses of 2 km, 5-7 km, 7 km and 10 km, respectively. The depth of Moho is 21km at 115km from the trench axis (TA) and becomes deeper landward. P-wave velocity of mantle wedge is 7.9 km/s. Subducting oceanic curst consists of two layers: oceanic layer2 (5.2-5.7km/s) and layer3 (6.5-6.7 km/s). Dip angle of oceanic crust between 0-80 km, 80-115 km, 115-150 km and 150-220 km from the TA is 5-6 degree, 8-10 degree, 12 degree and 23 degree, respectively. P-wave velocity of uppermost mantle of oceanic plate is 7.7 km/s, which is meaningfully lower than that of more eastern region (e.g. Shimamura et al., 1983). The structure off Miyagi has common characteristics with that off Sanriku (e.g. Takahashi et al., 2002): 1) layer composition; 2) thickness of island arc crust; 3) P-wave velocity of mantle wedge; 4) dip angle of oceanic crust; and 5) low P-wave velocity oceanic uppermost mantle. The structure off Miyagi, however, is different from that off Fukushima (e.g. Miura et al., 2002), especially P-wave velocity of mantle wedge, dip angle of oceanic crust and the existence of thick interplate layer off Fukushima. Despite of the similar structure off Miyagi with that off Sanriku, seismicity pattern are different. Large earthquake (M >7) occurred near the trench axis off Sanriku, for example the 1896 and 1933 earthquakes. However off Miyagi, the 1938 and 1978 earthquakes occurred near the coastline. One possible explanation of the difference of seismicity pattern is characteristics of oceanic plate, such as horst and graben structure development, which may be associated with the crack of oceanic plate.

SEISMIC REFLECTION PROFILING BETWEEN TSUKUBA CITY AND THE TOKYO BAY, CENTRAL JAPAN

Kazuo YAMAGUCHI[1], Naomi KANO[1], Takanobu YOKOKURA[1], Akiko TANAKA[1], Toshiki OHTAKI[1], Shinobu ITO[1], Toshiyuki YOKOTA[2], Hajime KATO[3] ([1]Institute of Geoscience, Geological Survey of Japan, AIST, [2]Institute for Geo-Resource and Environment, Geological Survey of Japan, AIST, [3]Faculty of Education $ Human Sciences, Yamanashi University)

Deep ground structure down to the basement affects the strong ground motions generated by earthquakes. This had been known before the 1995 Hyogo-ken Nanbu earthquake, but it is after the earthquake that underground surveys have been made in densely populated plains especially for the purpose of earthquake hazard mitigation in Japan. The seismic reflection survey is the main method among them. Chiba Prefecture conducted seismic reflection surveys for this purpose between the Tokyo bay and the Tone river, adjacent to the Tokyo metropolitan area, during 1997 and 2000. We have recently completed 24 kilometers long seismic surveys between the Tone river and Tsukuba city, which correspond to a northward extension of Chiba surveys. Our seismic section reveals basement uplift 200 meters in height which has been observed as a high Bouguer anomaly at Yatabe area. The basement top deepens southward and shows some undulations about 500 meters wide and 100 meters high. The upper sediments fill the undulations and slightly tilt southward. Several kilometers to the south of Yatabe, a dyke was inferred on the basis of magnetic data modeling. Some researchers think that the Median Tectonic Line passes between Yatabe and the inferred dyke. There exists a small gap less than 200 meters high along the basement top in the seismic section, but reflectors are not imaged beneath the basement. Taking a broader view of survey lines, our data may be connected to Chiba data in spite of 2 kilometers gap and differences of survey parameters between them. Then we will get a N-S direction seismic line 60 kilometers long between Tsukuba city and the Tokyo bay and it must cross the Median Tectonic Line somewhere on the way. We will discuss the pre-Tertiary basement structure and its movement around the seismic survey lines.

THREE-DIMENSIONAL VELOCITY STRUCTURE OF THE PINGTUNG AREA

Li-Chuin HU[1], Cheng-Horng LIN[2], Horng-Yuan YEN[1], Chau-Huei CHEN[3] ([1]Institute of Geophysics, National Central University, Taiwan, [2]Institute of Earth Sciences, Academia Sinica, Taiwan, [3]Institute of Seismology, National Chung Cheng University, Taiwan)

The Chaochou fault in the Pingtung area is one of the most important faults in southern Taiwan, and is located between the Pingtung Plain and the Central Range. According to previous studies, the Chaochou fault is considered to be a high-angle fault that dips eastward to the Central Range. From a tectonic point of view, regional stresses in the Pingtung area are controlled by two tectonic forces. The first force is the compressional stress related to the arc-continent collision between the Philippine Sea Plate and the Eurasian Plate; the second is the extensional stress related to the opening of the South China Sea to the South. Under these two mechanisms, the crustal structure beneath the Pingtung area has a complex formation. However, in examining earthquakes greater than magnitude 3 that occurred in the years between 1991 and 2001, we discover that the seismicity in southwestern Taiwan in this period was low. The question as to why this is the case is what first inspired our interest in studying this particular area. This study makes use of data collected by the Institute of Earth Sciences, Academia Sinica between August 2001 and January 2002 at 24 temporary seismic stations located near the Chaochou fault, as well as velocity structures collected through tomography in the foothills of the Pingtung area. We hope that this study will teach us more about crustal structure of this area and will enable us to understand the reasons for low seismicity there.

TWO-DIMENSIONAL DENSITY STRUCTURES OF THE SHIEN-SHE PLATFORM

Hsien-Hsiang HSIEH[1], Horng-Yuan YEN[1], Ming-Tar LU[2], Chien-Ying WANG[1] ([1]Institute of Geophysics, National Central University, Taiwan, ROC, [2]Chinese Petroleum Corporation, Taowan,

ROC)

The Chelungpu fault cut through the western side of the Shien-She platform, curved toward the northeast, and splintered into complex branches. Thus, the platform plays the important role in this region. In this study, we have compiled the gravity data (roughly 18 km x 48 km) of the Shien-She platform and its surrounding area. After gravity reductions, the Bouguer anomaly map was constructed. Negative anomalies cover the whole area. The general trend of the Bouguer values decreases from west to east, in consonance with the geological background. The residual anomaly is obtained by using Griffin method to investigate the shallower structure. We also calculate the derivative anomaly map to analyze some high frequency signal of the Shien-She platform. To illustrate how the gravity data constrain subsurface density structures, a two-dimensional gravity analysis is performed with three gravity profiles across the geological strike taken from the Bouguer anomaly map. Preliminary results of the modeling and their geological significance will be presented.

SEISMIC ANISOTROPY IN THE FOCAL REGION OF THE 2000 TOTTORI-KEN SEIBU EARTHQUAKE

Takeshi NAKAMURA[1], Hiroshi TAKENAKA[1], Sadaomi SUZUKI[1], Yasuto KUWAHARA[2] ([1]Department of Earth and Planetary Sciences, Faculty of Sciences, Kyushu University, [2]Earthquake Process Research Group, Institute of Geoscience, National Institute of Advanced Industrial Science and Tecnology)

Seismic anisotropy, varying velocity with the propagation direction, have developed our understandings for heterogeneous structure, the nature of mineral, and the physical properties around faults. Anisotropy is an inherent feature in the Earth, and the distortion of seismograms and travel time differences due to anisotropy have been reported in many observations. For *S*-waves, a pulse propagating through an anisotropic medium splits into two orthogonally polarized pulses with different propagation speeds each other. This phenomenon is known as *S*-wave splitting. The analysis of *S*-wave splitting is one of approaches to investigate anisotropy along the ray path. In this study, we carry out *S*-wave splitting analysis for the seismograms recorded in and around the focal area of the 2000 Tottori-ken Seibu earthquake. The aftershock data we used was recorded in 2000 and 2002. The 2000 observation was carried out at 3 stations for 56 days using strong motion seismographs, and the 2002 observatioin was at 5 stations and one seismic array for 13days. We employ the cross-correlation method to measure the parameters of the *S*-wave splitting from these aftershock data: the polarized direction of the fast *S*-wave and the delay time between the splitted *S*-waves. The polarized directions measured is WNW--ESE, which is almost identical with the *P*-axis direction of the main shock expected from the focal mechanism. This suggests that this anisotropy may be due to the alignment of cracks induced by the regional stress field in the focal region. The delay time of the *S*-wave splitting ranges from 20 to 100 ms. By applying *Hudson´s* (1981) formula for fluid-filled cracks to the delay time, we estimate the crack density. For the 2000 observation data, we found that the value of the crack density shows a strong spatial variation which depends on the fraction of propagation path inside and outside the focal region. It suggests that the crack densities are different between inside and outside of the focal region. We estimated the mean value of the crack densities inside the focal area and outside one, and obtained that they are 0.02 and 0.004, respectively. To evaluate the crack density inside the focal area in more detail, we analyzed the 2002 observation seismograms of which most of rays are propagating through inside the focal region. Although no obvious dependent on spatial distribution are seen inside the focal area, the value of crack density is 0.01, which is still significant large compared with outside one observed in 2000. These results indicate that the main shock and aftershock activity region corresponds with the high anisotropic region near the fault.

TOMOGRAPHY OF P WAVE VELOCITY STRUCTURE IN THE AFTERSHOCK AREA OF THE 1993 OFF NORTHWEST HOKKAIDO EARTHQUAKE (M7.8)

Tetsuo TAKANAMI[1], Yoshio MURAI[1], Hajime SHIOBARA[2], Shuichi KODAIRA[3], Hideki SHIMAMURA[1], Ryo HINO[4], Toshihiko KANAZAWA[2], Kiyoshi SUYEHIRO[5], Masanao SHINOHARA[2], Toshinori SATO[6], Hiroaki NEGISHI[7] ([1]Institute of Seismology and Volcanology, Hokkaido University, [2]Earthquake Research Institute, The University of Tokyo, [3]Institute of Frontier Research on Earth Evolution, Japan Marine Science and Technology Center, [4]Research Center for Prediction of Earthquakes and Volcanic Eruptions, Tohoku University, [5]Deep Sea Research Department, Japan Marine Science and Technology Center, [6]Faculty of Science, Nishi Chiba Campus, Chiba University, [7]National Research Institute for Earth Science and Disaster Prevention)

The 1993 off northwest Hokkaido earthquake (Hokkaido Nansei Oki Jishin in Japanese) with a magnitude of 7.8 ruptured the entire seismogenic zone in the eastern margin of the Sea of Japan. The event is considered to occur in the plate boundary between the Eurasian and the North American (or the Okhotsk) plates. In recent 30 years, the 1964 off Niigata earthquake (M7.5), the 1983 off Akita earthquake (M7.7), and the 1993 off northwest Hokkaido earthquake have successively occurred along the plate boundary. It is very important to know the present situation of the boundary in terms of large earthquake prediction. In order to determine the accurate locations of aftershocks of the 1993 off northwest Hokkaido earthquake, 23 Ocean Bottom Seismographs (OBSs) were deployed about one week later. The depths of aftershocks calculated by the data from OBSs range within 10km ~ 20km. But the aftershocks decrease rapidly in the depth of 20km and over. The picking data of the aftershocks at OBSs gave us opportunity to image the three-dimensional P wave tomography in the seismogenic zone existing in 10km ~ 20km deep. Here, tomographic inversion method was applied to 6510 P arrival data from the 1031 events occurred in seismogenic zone. The result shows that the strong lateral heterogeneities exist in the aftershock region. Furthermore, it gave us a close relationship between seismic activity and low velocity anomaly. The strong low velocity regions exist in both of particularly high seismicity areas in the northern and southern seismogenic zone. While, the main earthquake is considered to occur near the southern boundary of the northern low velocity area. The problem that we have to consider here is what would control the occurrence of aftershocks. The most important point is to know how such a low velocity area is related to the seismogenic zone. If the chemical and mechanical processes such as dehydration and fluid flow have contributed to the occurrence of aftershocks as apointed by Zhao et al.(2002), the generation of aftershocks is not a pure mechanical process, but it closely related to physical and chemical properties of materials in the crust and upper mantle, such as fluids, magma, etc. The zone rich in such a volatile component should be easily raputured and the aftershocks must occur according to the volume of such materials in the crust and upper mantle. Along the plate boundary, some complex physical and chemical reactions may take place, causing heterogeneities in the material property and stress field, which can be detected with seismic tomography and other geophysical methods. Therefore, we must draw attention to the properties of materials in the seismogenic zone in the plate boundary. A further direction of this study will be provide more evidence for this result.

SS03/08A/D-115   Poster   0830-274

THE SHAPE OF THE PHILIPPINE SEA PLATE BENEATH THE CENTRAL JAPAN

Shoji SEKIGUCHI (National Research Institute for Earth Science and Disaster Prevention)

We obtained the three-dimensional seismic velocity structure of the uppermost mantle beneath the Kanto, Tokai and Chubu regions, central Japan, where the Philippine Sea plate descends, by means of travel time tomography using 18 years of P and S phase data recorded by a regional seismic network of micro-earthquake. This region is tectonically complex, because the Pacific plate descends to the northwest and the Philippine Sea plate also descends to the north overriding the Pacific plate at the eastern edge. Because of complex earthquake distribution and the focal mechanisms, some models of the subducting Philippine Sea plate were proposed. We used about 727,000 manually picked travel time data of about 9,500 events to obtain fine seismic velocity structure of this region. Dividing the area into about 5km blocks and picking one event of the largest observed station numbers in each blocks for each year, we selected the events. The travel time data with picking time error larger than one second were omitted. There were about 120 seismic observation stations. We calculated seismic rays by the pseudo-bending method. Shape functions of the Finite Element Method are used to describe the velocity structure. The velocity is interpolated by the values given to 8 grid points of a simple three dimensional rectangular element. Solving matrix equations by the LSQR method, P and S velocity structures and event origin times and locations were determined, simultaneously. Initial velocity model was NIED (National Research Institute for Earth Science and Disaster Prevention) model used routinely to determine hypocenter locations in this area. A distinct low velocity zone, which was the oceanic crust of the descending Philippine Sea plate, was found beneath the Kanto region. The low velocity zone revealed a new configuration of the Philippine Sea plate different from any models obtained through the analysis of hypocenter distribution and focal mechanisms. There was another low velocity area beneath the active volcanoes. We also found a high velocity area in the deep aseismic region below the volcanic front between the Kanto and Chubu regions. It extends to the Philippine Sea plate in both regions. It was likely to be an aseismic extended section of the Philippine Sea plate. High Poisson's ratio areas were found both beneath the volcanoes and in the low velocity zone of the Philippine Sea plate near the volcanic front under the Kanto region. We also calculated the 'checkerboard resolution checkAEto estimate the resolution of the obtained inversion results.

READING THE CURRENT TREND OF CRUSTAL DEFORMATION FROM ACCELERATION FIELD USING GPS DATA

Yuzo TOYA, Minoru KASAHARA (Institute of Seismology and Volcanology, Hokkaido University, Japan)

Local and regional scale crustal movements in the intraplate Japan were investigated using both velocity and acceleration vector fields derived from continuous GPS Network data of GEONET (GPS Earth Observation Network), maintained by the Geographical Survey Institute of Japan. There are about a thousand stations, approx. 25km apart from each, covering the Japanese Islands. The GPS data used here are rates of horizontal and vertical station position changes during the period from June 25, 1997 to October 31, 2002. We fit first- and second-order polynomials to each time-series, with annual, semi-annual seasonality, and major steps removed, and other irregularities avoided based on the goodness of fit of our approximations, thereby obtaining the commonly used velocity-term and the acceleration-term. Acceleration can be described as a vector comparable to velocity, so we simply depict their spatial distribution in the vector-field format. Mapping acceleration fields of crustal deformation in Japan revealed some coherent trends of local and regional deformation and their rate changes such as (1) concentric (subsiding- / uplifting-) trends associated with recent volcanic activities {e.g. Unzen, Sakurajima}, (2) trends of crustal movement associated with recent slow earthquakes {e.g. deceleration of the 1997 Bungo Channel Slow Earthquake, and more recent development of possibly another Bungo Channel slow event; Tokai, Off-Choshi, and Boso-Penn. slow earthquakes}, or much gradual and larger scale buildup of forces against nearby plate interfaces, (3) back-slip trends of the overriding plate on a subducting plate {e.g. Tokai, Tohoku Region}, (4) trends of local crustal block movements {e.g. East of Abashiri Tectonic Line}, (5) rather weak trends of pre- and post- seismic deformations {e.g., the 2000 Western Tottori earthquake and 2001 Geiyo earthquake}. Acceleration presumably arises from cumulative effects of various short-lived geodynamic processes, where it is also influenced by other factors such as mechanical strength (cf. density, heterogeneity, etc.) of crustal materials, and their distributions. In addition, we illustrated the distribution of strain-rate components by utilizing spatially smoothed velocity fields (smoothed with a median window of R=50km for robust sampling; grid spacing 0.15deg). They effectively highlighted some of the known tectonic features. Most notably, near-parallel banded distributions of maximum shear-strain and shortening were observed (both are generally curving up to NE, connecting some of the known tectonic lines) (data: 6/25/97-10/5/00), and one of the bands matched well with the recently discovered low-frequency tremor distribution of western Japan. For the subsequent time-interval (data: 10/6/00-10/31/02), additional set of prominent bands with SSW-NNE orientation is starting to emerge (one of which is from the inland extension of the Suruga-Trough), while the NE-trended bands from the previous time-interval became discontinuous. By comparisons of the results, we speculate that the changes in strain-rate are due to shifts in the regional stress field generated by irregular intermediate-term subduction processes.

ALTIMETER CALIBRATION USING A RUGGEDIZED GPS-BUOY

Matthias FORBERG, Tilo SCHOENE, Roman GALAS, Christoph REIGBER (GeoForschungsZentrum Potsdam (GFZ), Germany)

With the launch of ENVISAT and JASON-1 the successful series of the radar altimetry missions is extended to a second decade. Various analyses have shown that any altimetry mission is subject to performance degradation, like aging of electronic components, resulting in an apparent sea level rise. Comparisons of RA with in situ measurements of the instantaneous sea level e.g. at Harvest Oil Platform have been used to monitor the absolute sea level measurements of TOPEX/Poseidon, but not for other missions. However, only a combination of different missions gives a sufficient coverage in time and space. For the past and current missions different strategies are used for the calibration and the drift monitoring, e.g. using crossovers or tide gauges as a height reference. The disadvantage of all calibration methods is, that no direct measurement beneath the sub-satellite tracks are available for all missions and, therefore, models have to be used to account for e.g. the sea surface slope or time varying signals. As shown for ERS-1 and TOPEX/Poseidon, a GPS-equipped buoy, anchored beneath a sub-track, can be used as a height reference. Since GPS-derived coordinates are ITRF-referenced, an absolute calibration is possible. In the context of the Helmholtz Association´s strategic project SEAL (Sea Level Change: An Integrated Approach to its Quantification) the GFZ Potsdam has developed a ruggedized offshore GPS-buoy which is able to measure the instantaneous sea level with high accuracy. In May 2002 the buoy has been deployed at an intersection point where the actual RA

S

missions TOPEX, JASON-1, ERS-2, ENVISAT, and GFO-1 intersect. The position is the only point in the German Bight that allows data transmission to a land station via an HF radio link. During the first deployment period till August 2002 in total 26 satellite passes has been acquired. Each data set comprises one hour of multi-sensor measurements centered at the satellite pass time. Differential GPS data is collected at 10Hz sampling rate both on the buoy and a reference station. Tilt angles as well as 3-axis accelerations are monitored by a dynamic motion sensor. Thus, together with the dipping depth which is collected by an underwater pressure sensor, the GPS antenna height can be reduced to the instantaneous sea surface height for every single GPS measurement. Additionally several meteorological sensors provide data every 10 minutes (e.g. air and water temperature, air pressure, wind direction and speed) and three moored tide gauge sensors in the vicinity and a wave tide recorder beneath the GPS-buoy allow to account for the sea surface slope and significant wave height, respectively. The resulting series of coincident measurements is used to derive a range bias for each RA, the envisaged long-term deployment will allow the monitoring of all missions. SEISMIC STRUCTURE OF THE CRUST AND UPPERMOST MANTLE IN THE INCIPIENT STAGE OF BACK-ARC RIFTING -NORTHERNMOST OKINAWA TROUGH

Kazuo NAKAHIGASHI[1], Masanao SHINOHARA[1], Sadaomi SUZUKI[2], Ryota HINO[3], Hajime SHIOBARA[1], Hiroshi TAKENAKA[2], Minoru NISHINO[3], Takeshi SATO[4], Toshihiko KANAZAWA[1] ([1]Earthquake Res. Inst., Univ. of Tokyo, [2]Kyushu Univ., [3]RCPEV, Tohoku Univ., [4]JAMSTEC)

The Okinawa Trough is placed between the Ryukyu Island arc and the China mainland as the back-arc region of the Ryukyu arc. From the previous geophysical and geological studies, the Okinawa Trough is considered to be in an early stage of back-arc spreading. Many seismic experiments have been performed in the Okinawa Trough region, however there is no deep seismic survey using Ocean Bottom Seismometers (OBSs) in the northernmost part of the Okinawa Trough. It is important for understanding tectonics of back-arc spreading to obtain a seismic structure beneath the area of East China, west of Kyushu, which is considered as the northernmost part of the Okinawa Trough. A seismic survey with OBSs was carried out in west of Kyushu in fall of 1999. The profile is 300 km long and 20 OBS were deployed at an interval of 15 km. We used airguns and explosives as controlled sources. On the distance-time sections of OBSs, apparent velocities of first arrivals vary due to the heterogeneities. Seismic velocity models for the shallow structure beneath each of the OBS locations are derived by a tau-p inversion using the indivisual OBS record. Next, a deep structure beneath the profile is estimated by a forward modeling using a two-dimensional ray tracing. Outcrops of the acoustic basement through the sedimentary layers are seen in the obtained structures. Velocities of lower layer in upper crust are varying laterally from 5.7 to 6.2 km/s and thickness of 6.0-km/s layer ranges from 3 to 9 km. The lower crust has uniform thickness of about 15 km. The Pn velocity is 7.7-7.8 km/s and the total crustal thickness is about 25km including sedimentary layers. The distribution of P-wave velocities and the thickness indicate that the crust in the northernmost part of the Okinawa Trough is more similar to that of an island arc than that of an ocean or a continent; however, in detail, the structure has characteristics, which are not usually seen in typical island arcs. Particularly, the upper crust in the study area has a large heterogeneity, which can be explained as a result of crustal thinning. These features are considered to result from thinning of the upper crust due to stretching in an early stage of rifting. In addition, low Pn velocities and the outcrops of the acoustic basement suggest igneous activities in this area. The seismic structure suggests that the northernmost Okinawa Trough is in an incipient stage of back-arc rifting.

A POSSIBLE ORIGIN OF ASYMMETRIC EXTENSION ASSOCIATED WITH REACTIVATION OF RIFTING

Tadashi YAMASAKI (Earthquake Research Institute, University of Tokyo)

Thermal relaxation in postrift phase may be important for localized rheological weakening developed by grain-size reduction as a result of spinel- to plagioclase-lherzolite reaction. Although dry conditions are more favorable for localized rheological weakening than wet conditions (Yamasaki, 2002), the mechanical lithosphere strength under dry condition is more than the magnitude of extensional driving forces in the range of a few TN/m (e.g., Bott, 1991; 1982; Bott et al., 1989), which prevents the lithospheric extension and thinning. On the other hand, for the temperatures more than 800 °C, the ductile yield stress under wet condition becomes to be mostly insensitive to grain-size, and the lower boundary for the localized weak zone diminishes. Because the reaction temperature is mostly greater than 800 °C, it is difficult to create the localized weak zone under wet conditions. Thus the thermal diffusion during inter-rifting period is required for an apparent strength contrast of localized weak zone through the reduction of geothermal gradient. During earlier rifting event grain-size reduction takes place significantly by spinel- to plagioclase-lherzolite reaction, and then the following extensional event occurs after the critical thermal relaxation time, 10 Ma for dry condition and 20 Ma for wet condition. If these two conditions are satisfied the lithosphere may be extended asymmetrically.

SEISMIC STRUCTURE OF THE MIDDLE JAPAN TRENCH SUBDUCTION ZONE BY AIRGUN-OBS EXPERIMENT

Ryota HINO[1], Minoru NISHINO[1], Kimihiro MOCHIZUKI[2], Kenji UEHIRA[3], Toshinori SATO[4], Mikako NAKAMURA[2], Shunichi NAKATA[3], Atsushi SATO[3], Masanao SHINOHARA[2], Junzo KASAHARA[2] ([1]Graduate School of Science, Tohoku University, [2]Earthquake Research Institute, University of Tokyo, [3]Graduate School of Science, Kyushu University, [4]Faculty of Science, Chiba University)

In the middle part of the Japan Trench subduction zone, the off-Miyagi area, large interplate earthquakes with M＞7 is known to regularly recur with about 40 years interval. The most recent event occurred 25 years ago (the 1978 Miyagi-Oki Earthquake M7.4) and the Japanese government evaluated that the next large earthquake may occur within 20 years from now with over 80 % possibility. Most of the past large events in this area, including the 1978 earthquake, did not rupture the shallow (less than 20 km) part of the plate interface, although active background microseismicity is observed in the shallow thrust zone. Analyses of the historical records of the tsunami caused by the 1793 earthquake, one of the off-Miyagi series, suggest that the rupture area of the earthquake extended to the shallow part of the thrust zone and that the size of the event was much larger (M＞8) than the other earthquakes in the series. In the northern part of the Japan Trench subduction zone, we recently found a significant relation between the seismic reflection intensity of the surface of the subducting oceanic plate and the interplate seismicity along the interface; the wide-angle reflection arrivals are observed with remarkably strong amplitudes in the region of low interplate seismicity. This finding suggests that the appearances of the seismic reflections from subduction plate boundary can be a good indicator of the seismic coupling strength. As an application of this idea to the shallow seismogenic zone of the off-Miyagi region, we made

---

an airgun-OBS seismic experiment to observe the wide-angle reflections arrivals from the plate boundary in 2002. The surveyed area was in the trenchward extension of the rupture area of the 1978 earthquake and its size was 150 x 40 km in the strike and dip directions of the trench system, respectively. 39 OBSs were deployed in the area and a 3,400 cu airgun-array was shot along the four survey lines. The spacing of the OBS stations was 10 km and the airgun shot interval was about 150 m. The quality of the OBS record sections is good and we can trace the first arrivals up to at least offsets of 80 km. There are two groups of evident later arrivals on the record sections. Preliminary travel time analysis based on a reference structure model in this region presented by Miura et al. (2002) indicates that these later phases are wide-angle reflections from the subducting oceanic crust, which are of our most significant interest. The appearances of these later arrivals are quite different from a station to another, indicating that there seems to be a spatial variation of the reflection intensity of the plate boundary as we found in the northern part of the Japan trench.

P-WAVE VELOCITY MEASUREMENTS UNDER HIGH PRESSURE AND TEMPERATURE CONDITION IN ULTRABASIC ICHINO-MEGATA XENOLITHS, NE JAPAN

Soushi NISHIMOTO[1], Masahiro ISHIKAWA[1], Makoto ARIMA[1], Takeyoshi YOSHIDA[2] ([1]Geological Institute, Graduate School of Environment & Information Sciences, Yokohama National University, 240-8501, Japan, [2]Research Laboratory of Arc Magmatism, Institute of Mineralogy, Petrology and Economic Geology, Graduate School of Science, Tohoku University, Sendai, 980-8578, Japan)

Xenoliths erupted from the Ichino-megata volcano, NE Japan, contain various lower crustal and upper mantle rocks, which provide important clues for estimating crustal section of the NE Honshu arc (Aoki, 1971; Takahashi, 1978; Zashu et al., 1980; Takahashi, 1986 and Kushiro, 1987). Recent extensive seismic experiments across the NE Honshu arc (Iwasaki et al., 2001) suggest that the arc crust is composed of highly deformed Tertiary sedimentary upper crust layer, a middle crustal layer with relatively lower Vp of 5.75-5.9 km/s, and a 15-km thick lower crust with Vp of 6.6-7.0 km/s. In this study, we developed new experimental technique to measure Vp of Ichino-megata xenoliths at lower crustal P-T conditions (up to 900 °C and 1.2 GPa), and combined the measured Vp of the xenoliths with the velocity structure of the arc. The measured rocks include one hornblende gabbro (41.3 wt% SiO2), two samples of pyroxene-hornblende gabbro (45.6 wt% SiO2 and 43.7 wt% SiO2) and one hornblendite (44.6 wt% SiO2). It is widely accepted that Vp value of the rocks considerably decreases with elevating temperature. At constant pressure of 1.0 GPa, the Vp of hornblende gabbro gradually decreased from 7.21 km/s at 25 °C to 6.91 km/s at 700 °C. Similarly the Vp values of the pyroxene-hornblende gabbros reduces from 7.06 km/s at 25 °C to 6.73 km/s 800 °C. Also the Vp value of the hornblendite lowers from 7.11 km/s (25 °C) to 6.45 km/s (800 °C). The measured Vp values are compared with the seismic profile of NE Honshu arc (Iwasaki et al., 2001). We estimate temperature conditions of the lower crustal layer of the NE Honshu arc crust by the geothermal gradient given by Kushiro (1987). The estimated Vp values of the hornblende gabbro measured at the lower crustal P-T conditions are comparable to Vp values of a upper-lower crustal layer of the seismic profile by Iwasaki et al. (2001).

SS03/08A/D-122 Poster 0830-281

CRUSTAL MODELS OF WESTERN PACIFIC ISLAND ARCS: IMPLICATIONS ON ARC MAGMATISM

Carla B. DIMALANTA, Asahiko TAIRA, Hidekazu TOKUYAMA, Graciano P. YUMUL, JR., Rodolfo A. TAMAYO, JR, Kimihiro MOCHIZUKI. (IAVCEI)

The evolution and growth of continental crust remains to be one of the fundamental problems in geology. Crustal growth is defined as the net gain in the volume of crustal material as a result of various addition and subtractionprocesses. In terms of crustal addition, arc magmatism has been recognized asone of the mechanisms where juvenile crustal material is created along subduction zones. The Western Pacific region is thus a favorable site toinvestigate arc magmatic addition processes. A previous study was done by Reymer and Schubert (1984) to quantify arcmagmatic addition rates. Their results show that material is being produced byarc magmatism at rates ranging from 20 to 40 km³/km/Myr. Therecent seismic and gravity data offer improved images of the structure andthickness of the crust beneath some island arcs in the Western Pacific. Presentdata show that the oceanic island arcs in the Western Pacific region have crustal thicknesses between 20 to 30 km. Relevant crustal volumes arecalculated and the corresponding arc magmatic addition rates are estimated.Based on the results obtained, arc magmatism occurs at rates ranging from 30 to95 km³/km/Myr. The magmatic addition rates presented here are nearlytwice as high as previous estimates of arc magmatic addition.

THREE DIMENSIONAL S-WAVE ATTENUATION MODEL OF THE CRUST AND UPPERMOST MANTLE BENEATH ARC-CONTINENT COLLISION, TAIWAN

Yu-Ju WANG, Kuo-Fong MA (Institute of Geophysics, National Cencial University)

The S-wave attenuation structures (Qs) of Taiwan are imaged with data from the dense deployed strong motion stations of Taiwan. The image of 3-D Qs is essential in Taiwan because Qs is sensitivity to localized permeability and heterogeneity, which are important characters for interpreting active tectonic regions as Taiwan. The attenuation images of S-wave are obtained using t* values measured from S-wave spectra from Taiwan strong motion network for moderate size earthquakes (M4.5-5.5) to avoid the source complexity. The time period used in this study is from 1993-1998. Over 2000 velocity spectra of S wave arrivals from 173 earthquakes were analyzed. A non-linear least square technique is applied to the spectra for t* by assuming a w-2 model for the frequency band of 1-20Hz. A frequency-independent Qs was assumed in this study. Combined the existed three-dimensional S-wave velocity model, the three-dimensional Qs images were obtained. The preliminary results show that a relative low Qs zone beneath the Central Range distributed from the depths of 4 to 18 km. This zone correlated well with the low velocity zone found in the 3D Vp and Vs images. Although the complete study on 3-D Qs images is not final yet, the benefit of 3-D Qs images to 3-D Vp, and Vs is believed to be significant, and will be essential to provide imperative insight to an arc-continent collision region of Taiwan.

TELESEISMIC IMAGING OF UPPER MANTLE STRUCTURES AROUND THE TAIWAN AREA

Pei-Yeng LIN[1], Bor-Shouh HUANG[2], Ling-Yun CHIAO[1] ([1]The Institute of Oceanography National Taiwan University, Taiwan, ROC, [2]The Institute of Earth Science Academia Sinica, Taiwan, ROC)

Teleseismic events that had been clearly recorded across TTSN and CWBSN through the past 7 years has been identified and compiled. Recorded waveforms of those with epicentral distances 30°~90° away from Taiwan are analyzed by the multi-channel cross

correlation algorithm (VanDecar and Crosson, 1990) to yield a set of consistent relative differential travel times across the area covered by the seismic networks. After careful quality control, 145 events that yield relative differential travel times within the range of 1.5 seconds across the area are retained. These events compose about 2500 rays going through the upper mantle around the Taiwan region. Tomographic inversion of these travel-time residuals are undertaken by assuming that the heterogeneities of the velocity structure of the target area, within 20°-26° N, 118°-124°E and with the depth above 400 km, is responsible for causing the relative differential travel times. Preliminary model structures obtained from three different inversion strategies, including the damped least squares, the convolutional quelling regularization and the multiscale parameterization, are cross-analyzed to probe for the possible upper mantle structure. Although the data seems to be noisy and the ray coverage is very likely too sparse, there are still some interesting implications for upper mantle structures underneath the Taiwan area. We will discuss some of these preliminary results as well as proposing for directions of future study.

EXPLORATION RESEARCH CRUSTAL STRUCTURE UNDER THE SOUTH CHINA SEA OF SOUTHWESTERN HAINAN ISLAND WITH LANDSTATIONS ARRAY COMBINING OBH

Saijun LIU (Seismological Bureau of Fujian province, China Seismological Bureau)

In the project obtained deep seismic profiles significant data under the South China Sea (SCS) of southwestern Hainan Island (HNI) with the Landstations Array (LSA) combining Ocean Bottom Hydrophone (OBH), for the first time in 1996-97. Comparing them with Gongdong continent and Xisha Ocean Trough (XST), the follow results were gotten: 1. The Land Area Hainan Island (LAHI) researched belongs to continent, its crust thickness close to northern HNI (about 26 km) is thinner than Guangdong landmass (32 km). Moho depth is 27.6 km. The wave velocity under Moho is 7.8 km/s. The crust thickness is 27 km except Cenozoic. The thickness of lower crust is about 14 km, velocity 6.4_6.7 km/s, the upside approximates to 13 km and was divided into two parts: top 6 km, V 5.7_6.1 km/s, a lower velocity layer lies under the top that thickness is near 7 km, V 5.5_6.0 km/s. 2. LAHI due to continental crust, thickness reach 27 km; However, XST fall into extensional ocean rift zone which thickness thins down 8 km till, in evidence. There is a lower velocity layer at LAHI crust profile but the velocity at XST is increased from shallow (V=5.5 km/s) to deep (V=6.8km/s) continuously. The lower velocity layer was no found. At the middle part of profile Moho swelled up. The crust thickness decreased from the two side of the profiles_ 28 km to middle _8 km rapidly, the velocity jumped from the earth crust bottom_ 6.8 km/s to the top of up mantle_8km/s. So, characters for both of them are different completely. 3. The No.1 fault striking NW, should be NE boundary of Red River Fault (RRF), is a normal fault trending SW. Its least distance to the shore is about 28 km. It was showed in profiles that the bottom faults distance of pre Tertiary is >= 7 km, covered with Cenozoic; According to analyze the data of oil profiles explored the top of fault cutting through Tertiary layers had meet Quaternary system. Evidently, No.1 fault activities can be tracked up to early Quaternary period. The normal fault character shows that RRF is being tensile state according to entire SCS. 4. In Yingerhai Basin(YGHB) locating at western of No.1 Fault Cenozoic deposition thickness is huge that can reach 7_10 km at the deepest basin bottom. There are sediments (0.2_4.6 km) at the profiles upside, V=1.7_4.3 km/s. And about 4 km lower velocity layer lying below it, velocity is 3.0_3.5 km/s, can be track on AAˈ or BBˈ profiles.

CRUSTAL STRUCTURE, RECENT DYNAMICS AND SEISMIC ACTIVITY OF RED RIVER FAULT ZONE (RRFZ)

Cao Dinh TRIEU (Hanoi Institute of Geophysics)

The main characteristics of the Crustal structure, the faults and the manifestation of seismic activities of Red River Fault Zone (RRFZ) were presented in this research work. The results of study have shown that:1/ The depth to the Moho surface of RRFZ is varied from 22-24 km to 30-32 km with northwestward dipping tendency. Vice-versa, crystal surface of the earth's crust has northeastward dipping tendency and its depth reached value of about 8-9 km in the central part of Red River Cenozoic depression.2/ At present, RRFZ is affected by compressor from northeast direction. Clear manifestation appeared here is strong uplift and active seismic activity in the northeast part of the Fault Zone.3/ Earthquake epicenters are mainly distributed within the depths of about 7-20 km, but popularly in the range of 10-16 km. The correlation function between minimal depth of hypocenters (Hmin) and maximum magnitudes (Mmax) of the earthquakes as follow: lg Hmin = 0.25 Ms - 0.304/ The mainly seismogenic faults of RRFZ consist of: Lo River, Vinh Ninh, Chay River, Red River, Fansipan and Binh Luc. Strongest earthquakes occurred within RRFZ may be limited by Mmax = 5.5-6.0 and it seems to be that Chay River and Red River have most strong seismic activity.5/ Highest risk of seismic activity may be caused in RRFZ is in Luc Yen-Yen Bai and Viet Tri-Hanoi areas.

ROCK'S MELTING IN CONDITIONS OF THE CONTINENTAL CRUST

Roland Nikolaevich SOBOLEV (Lomonosov Moscow State University, Geological Faculty)

Usually, by analyzing processes of melts generation in continental earth crust,take in consideration only eutectic and cotectic thermodynamic laws. Thisopinion bases on results of experimental investigations by which use powder ofrocks or gels. In this case at constant PTX conditions exists equilibrium state.In the continental earth crust milting metamorphic rocks consists of mineral's grains with sizes of some mm or even cm. In this case the square of contacts ofdifferent minerals' grains is much less then in experiments with a powder or a gel. The principal points are: 1. melting process is not equilibrium, 2. it hasto be analyzed process of melting from position of kinetic of disequilibrium processes. Minerals of different chemical compositions have different melting'stemperatures: quartz – 1713, garnet – near 800 ÅÅC etc. The process of melt formation is very complex – it consists of many stages: 1. Melting of garnet, 2.Reaction garnet's melt with minerals, 3. Appearance thin films of melts of different chemical composition on contacts of minerals in accordance with eutectic and cotectic lows, 4. These melts are not in equilibrium with minerals.As a result of reactions between melts and minerals they disappear in definite succession: garnet → plagioclase → K-Na feldspar → quartz. During the melting take place separation melts in accordance with their density: garnet's melt accumulate in the bottom of a crucible. In the system are many melts related by gradual transitions. So at any melting's stage the system consists of many melts of different chemical compositions and relicts of grains. Experiments ofmelting grains mixture of quartz, feldspars, garnet (minerals of gneiss bymelting of which acid melts form) of the same (1 mm) and different (1, 5, 10 mm)sizes give evidence that succession of melting in all cases is the same without dependence on their size: garnet → plagioclase → K-Na feldspar → quartz. In mostexperiments part of quartz' grains is relict phase. It disappears only bytemperature >1500 °C or by very long time of experiment. In natural conditions melt raises in the earth crust from the upper part of magmatic chamber and as a consequence a compositions of acid magmatic bodies are more leucocratic in comparison

---

with bulk melt's composition in the place of melts generation. These data give new material for understanding structure of the earth crust.

THERMO-MECHANICAL STRUCTURE OF THE SOUTH INDIAN SHIELD

Om Prakash PANDEY, Ajay MANGLIK (National Geophysical Research Institute)

The Dharwar protocontinent of the southern Indian shield forms one of the most interesting region among the cratonic terrains of the world. It constitutes three Archean-Proterozoic blocks separated by mobile shear zones. They are Western Dharwar Craton (WDC), the Eastern Dharwar Craton (EDC) and the Southern Granulitic Terrain (SGT). These blocks appear to have contrasting evolutionary history exhibiting different geologic, tectonic and geophysical characteristics. Recent geological and geophysical studies indicate episodic remobilisation and large regional variation in the crustal structure and heat flow. Rapid uplift can be seen in several parts of the SGT. In this study, we have computed rheological structure of these blocks using available geophysical and geological inputs and analyzed the results in the light of crustal deformation. Our study indicates presence of a rheologically strong lithosphere in WDC, where rheological thickness of the lithosphere and the total force per unit width is highest at 190 km and 5.8 x 10¹⁴N/m, respectively. This region contains the coldest and undeformed oldest cratonic nucleus. Here,the Moho temperature is about 374ºC. In contrast, SGT appears to be anomalous, which has undergone extensive high-grade regional metamorphism even as late as 550 ± 30 Ma. It is found to contain a ductile middle to lower crust besides a warm and weak lithosphere . In spite of being a part of stable shield region, brittle ductile transition in the northern block of SGT occurs at a depth of 20-25 km. Total force per unit width is also quite low here (2.6 AE2.9 x 10¹⁴ N/m). Earlier studies have reported 1-2 percent lower P-wave subcrustal velocities beneath SGT compared to WDC. Recent deep crustal seismic studies indicate presence of a low velocity layer (6.0 km/s) below the middle crust. Therefore, we infer that the Archean crust of WDC may be underthrusting below SGT possibly along Moyar shear zone, which has lead softer upper crustal layers to become sandwiched between harder layers. In these softer layers, deformation is expected to be concentrated which due to north-south compression consequent to Indian-Eurasia collision appears to decouple and result into the continuous uplifting and erosion of SGT, thereby exposing the deepest part of the granulitic crust at the surface.

DEEP CRUSTAL STRUCTURE OVER THE ARCHAEN SOUTH INDIAN SHIELD

Sanjay G. GOKARN, Chinta K. RAO, Gautam GUPTA (Indian Institute of Geomagnetism, Plot No. 5, Sector-18, Near Victoria Petrol Pump, Kalamboli (Highway), New Panvel (W), Navi Mumbai-410206.)

Magnetotelluric studies over the granite-greenstone province of the Archaen Dharwar shield are indicative of intense Precambrian tectonic activity leading to the east-west compression of the upper crustal block and the subsequent formation of three sub-basinal features filled with the greenschists. The upper crustal thickness to the west of the Closepet granitic intrusives is about 25 km compared to the thickness of 20 km observed to the east of this feature. This is also reflected in the observed lower surface heat flows in the west Dharwar compared to the east. Based on this observation, the Chitradurga Boundary fault is proposed to be located along the western margin of the Closepet granites. There are no significant conductivity associations with the Chitradurga boundary fault, presumably because of the lack of any tectonic activity for a long time since the Precambrian. The lithospheric thickness was inferred to be about 180 km from the observed high conductivity of about 50 Ω-m observed at this depth. An interesting observation is the high conductivity of about 20 Ω-m delineated at depth below 80 km, corresponding to the lithospheric mantle. This feature is about 100 km wide along the EW and seems to be located entirely in the continental lithosphere. The thermal and mechanical fluxes generated by the Reunion hot spot, over which the western part of the Dharwar craton passed during its post-outburst phase, may be causing the high conductivity. The higher seismic velocities observed in the lithospheric mantle corresponding to the high conductivity may be due to the tonalitic character of the west Dharwar crust, as against the granitic composition of the eastern part.

ESTIMATION OF INTRINSIC ABSORPTION AND SCATTERING ATTENUATION IN SOUTHERN INDIA USING A DEPTH DEPENDENT STRUCTURE MODEL

Jayant Nath TRIPATHI[1], Arantza UGALDE[1], Mitsuyuki HOSHIBA[2] ([1]Observatori de l'Ebre, CSIC-URL. 43520 Roquetes. SPAIN, [2]Matsushiro Seismological Observatory, Nishijo 3511, Matsushiro-machi, Nagano-shi, 381-1232 Japan)

1143 vertical-component, short period observations of microearthquake codas from shallow earthquakes recorded by the Gauribidanur seismic array were used to estimate seismic wave attenuation in southern India. The magnitudes of the earthquakes range from 0.7 to 3.7 and only the events occurred at hypocentral distances up to 200 km were considered for the analysis. Four frequency bands between 1 and 10 Hz were analyzed. The separation of intrinsic absorption (Q_i^{-1}) and scattering attenuation (Q_s^{-1}) from total attenuation (Q_t^{-1}) was performed using a multiple lapse time window method which compares time integrated seismic wave energies with synthetic coda wave envelopes for a multiple isotropic scattering model. We first assumed a synthetic model based on spatial uniformity of (Q_i^{-1}), (Q_s^{-1}) and S wave velocity (v). Results show that scattering attenuation is greater than intrinsic absorption for all the frequency bands, and a high value of the seismic albedo (close to 1) is found at short and long hypocentral distances, which indicates very strong scattering.Moreover, the observed energy at 0 to 15 seconds from the S wave arrival time bends significantly downward with decreasing distance and some discrepancies are observed between the theoretical model and the observations. In order to clarify this phenomenon, we computed a synthetic model assuming a vertical varying g (Q_s^{-1}=gv/ω), h (Q_i^{-1}=hv/ω) and v structure. A comparison between the attenuation parameters estimated using both models is presented.

POSSIBLE RESOURCE ESTIMATES OF GAS HYDRATES ON WESTERN CONTINENTAL MARGING OF INDIA

Babita SINHA, S.I REDDY, N.K. THAKUR (1)

Naturally occurring gas hydrates are known as gas clathrates, are ice like compound in which gas molecules (mainly methane) are encased in the interstices of hydrogen bonded water lattices at low temperature and high-pressure conditions. Gas hydrates are detected on seismic sections primarily through an anomalous reflector running parallel to the sea floor known as Bottom Simulating Reflector (BSR). Bottom Simulating Reflector are commonly associated withbase of hydrate stability field and may represent the phase boundary betweenthe hydrate bearing sediments and gas charged or water bearing sedimentsbelow.

S

The rate of sedimentation, pressure temperature conditions, sediment thickness, total organic content and prevailing bathymetry indicates probable presence of gas hydrates in Indian Offshore region.It is also being inferred by the presence of strong bottom simulating reflector revealed by the multichannel seismic data from the western continental margin of India. Analysis of the variation of P-wave reflection coefficient with offset and angle of incidence, commonly termed as AVO analysis, has been recognized as one the direct hydrocarbon indicator. We use this in delineating the possible causes and characteristics of BSR in the data from Indian Offshore region. In the present study, we model and perform AVO analysis on multi-channel seismic data from western continental margin of India to arrive at probable estimates of gas hydrate reserve of this region. We also present the AVO-attribute and cross-plot to arrive at the petro physical characteristics of the region

---

SEISMOTECTONIC MODEL OF THE JANUARY 26, 2001 BHUJ EARTHQUAKE (MW 7.6) IN WESTERN INDIA

J.R. KAYAL, Reena DE (1)

The January 26, 2001 Bhuj earthquake is the second largest SCR (Stable Continental Region) earthquake with Mw 7.5, that occurred about 180 years after the 1819 Kutch earthquake (Mw 7.8) in the Kutch rift basin, northwestern part of the peninsular India shield area. This area falls in the high seismic risk zone in the country. A 12-station close spaced network was established by the Geological Survey of India for monitoring aftershocks. About 3000 aftershocks (M $>$ 1.0) were recorded in two and half months during the period from January 29 to April 15, 2001. The aftershocks attenuated with time following the power law t-p, where p = 0.91. The frequency-magnitude relation of the aftershocks also followed the power law with b-value = 1.21.About 350 events (M $>$ 2.0) are well located with an average RMS $<$ 0.1s and average horizontal and depth error $<$ 2 km by 3-D seismic tomography method (Kayal et al., 2002, GRL, v. 29). The epicenter map shows an aftershock-cluster area, about 60 x 30 km2 between 70.00 -70.60E and 23.30-23.60N, which reflects the source area of the main shock and aftershocks at depth. The epicenters show two major trends; one in the NE direction and the other in the NW direction. Depth-sections of the aftershocks indicate that the events are mostly generated at 15-38 km depth. Some events occurred at depth $<$ 10 km; they follow the NW trend only. A south dipping seismogenic plane is revealed in the depth-section.Composite as well as moment Tensor fault-plane solutions of the best-located and selected events are studied. The deeper (25-38 km) as well as the mid crustal (15-$<$25 km) aftershocks show reverse faulting with a large left-lateral strike-slip component along the NE trending inferred fault, which are comparable with the main-shock solution. Along the NW trending inferred fault, on the other hand, the shallower aftershocks (depth $<$10 km) show reverse faulting with right-lateral strike-slip component, and the mid crustal and deeper aftershocks show almost pure reverse faulting. These solutions with the NW trending inferred fault are not comparable with the main shock solution. A seismotectonic model is suggested, which explains that the deeper (depth 25 km) main shock was nucleated at the base of the paleo-rift basin by reverse faulting at the fault end of a hidden fault. The aftershocks mostly occurred at the mid crust and lower crust at a depth range 15-38. The main shock rupture propagated in the NE direction by left lateral strike slip motion, and a conjugate rupture propagated along NE by right lateral strike slip. Surface evidence of ground motions support this observations.

ELECTRICAL IMAGE OF THE DEEP CRUST NEAR BHUJ EARTHQUAKE EPICENTRAL REGION, INDIA

Harinarayana T., Kareemunnisa Shaik BEGUM, Patro B.P.K., Naganjaneyulu K. (National Geophysical Research Institute)

Kutch region is well known for high seismicity with the reported occurrence of atleast three major earthquakes. Although various geological and geophysical studies have been carried out, the deep crustal structure is poorly understood. In order to understand the physical processes related to seismicity of the Bhuj earthquake, a wide-band magnetotelluric survey has been carried out along three profiles with 21 stations. The profiles cut across the major structural features such as Kutch Main Land Fault (KMF) and Katrol fault. In the present study, deep geoelectric structure along a profile oriented in N-S direction is presented. Results indicated the presence of thick sediments (1-4 km) dipping towards south underlain by high resistive basement. From detailed 2D analysis of the data, it is observed that the resistivity of the basement shows distinct variation for the stations located towards the south compared to the north. It is interesting to observe that the well-known KMF is spatially located near the sharp variation in the basement resistivity. This led to believe that the deep structure has a different nature towards the north as compared towards south and gave an evidence for probable existence of a block structure in the region. Relative movement of these crustal blocks might be the reason for the continuous development of stresses that led to major earthquakes in the region.

INTEGRATED SUBSURFACE IMAGING OF DEEP REFLECTION SEISMIC DATA WITH IRREGULAR ACQUISITION GEOMETRIES IN CRYSTALLINE GEOLOGICAL TERRAIN

Susumu ABE[1], Larry D. BROWN[2] ([1]JAPEX Geoscience Institute, Inc., [2]INTOC, Cornell University)

Seismic imaging of the deep crustal structure is strongly affected by surface-consistent static time shift due to a low-velocity weathered layer, irregular acquisition geometries, low signal-to-noise ratio (S/N) of reflections, and interactions of the backscattered wavefield within the shallow subsurface. We have evaluated the limitations and applicability of standard processing to deal with these problems. Refraction and reflection static corrections are key steps to improving the image of deep seismic reflections with low S/N and discontinuous patterns. Turning-ray tomography is an optimum tool for the construction of the weathered layer model with irregular variations of velocity in crystalline terrains. The global optimization method is required for reflection static corrections to accommodate the high multimodal character of objective function on deep seismic data. In order to estimate accurate statics in the board range of wavelength for deep seismic data, we adopted the combination of global optimization method via genetic algorithm and turning-ray tomography. We have investigated the cascaded method to migrate deep seismic data acquired with irregular geometries. Kirchhoff imaging method, which can account for the crookedness and rugged topography of the shot and receiver lines, was combined with residual finite-difference F-X migration to reduce the artifacts that result from the smearing of deep discontinuous reflections via migration operator with a significant aperture. The seismic data used for this case study consists of a series of 2D seismic profiles from the INDEPTH Project in the Himalayas. We find that precise static corrections and geometry-oriented migration processing significantly improved the image of crustal structure in the upper plate of the Himalayan megathrust. Furthermore, subsequent relative-amplitude-preserved processing provides an AVO attribute profile consistent with granitic magmas derived by partial melting of the tectonically thickened crust.

P WAVE CRUSTAL VELOCITY STRUCTURE IN THE EASTERN MARGIN OF TIBETAN PLATEAU

Chun-Yong WANG, Jian-Ping WU, Hai LOU, Zhi-Ming BAI (Institute of Geophysics, China Seismological Bureau)

A deep seismic sounding profile located in the eastern margin of Tibetan Plateau extends along N30°. It passes through the Songpan-Garze Fold System (western Sichuan plateau) and the Longmenshan Tectonic Belt, and ends in the Yangtze Craton (Sichuan Basin). Based on the travel times of phases on the profile, incorporating information on the relevant amplitudes, we determined 2-D P-wave crustal velocity structure along the profile. The crustal thickness, crustal average velocity and Pn velocity are obviously different between the western Sichuan plateau and Sichuan basin. The Yangtze craton has higher crustal average velocity, so the crustal rock is harder than in western Sichuan plateau. The lower Pn velocity in western Sichuan plateau might be related to the marked thermal process through whole Cenozoic. Beneath the Kangding-Luding area, there might exist a series of listric faults, which is connected to the low-velocity-zone in upper crust and to the Piedmont overthrust fault zone on the surface. The low-velocity and low-resistivity zone in crust may play an important role in the process of detachment and overthrust. Due to the collision between Yangtze Craton and Songpan-Garze block, the vehement deformation appears in the relatively soft block so as to thicken the crust, reduce crustal velocity, and produce a series of thrust fault zones. Such a collision pattern is called as "Crocodile Structure". However, on the seismic records along the profile, there is no obvious evidence that there exist eastward-inclining faults in the lower crust.

THREE DIMENSION DENSITY DISTRIBUTION OF LITHOSPHERE IN QINGHAI-TIBET AND ITS ADJACENT REGIONS

Jian FANG, Houze HSU (Institute of geodesy and geophysics, Chinese Academy of Siences)

The goal of this study is to use gravity data combining seismic tomography data to construct a three-dimension density model of the lithosphere of Qinghai-Tibet plateau and its surroundings and to relate this model to tectonic processes. We have collected three dimension S-wave tomography data with grid of 2o×2o in the 10-100km depth range in the area of Qinghai-Tibet and its adjacent regions. Otherwise the observation gravity data of the grid of 10'×10' and sedimentary depth and density data and crustal thickness data with the grid of 1o×1o have been acquired. The gravity effects of sedimentary bottom interface and Mho interface undulation can be calculated by means of spherical gravity forward formula. The density differences of crust-mantle and sediment-crust are 420kg/km3 and 210kg/km3 respectively. After eliminated gravity effects of interfaces and long wave length ($>$2000km) gravity anomaly, the residual gravity anomaly is mainly cause by density inhomogeneities of the lithosphere. We will use the residual gravity anomaly combine tomography data invert lithosphere density anomaly. We divide the lithosphere of research region into grid of 2o×2o and each grid is divided into six layers. So, the lithosphere of research region can divided into 9×18×6 prisms and we assume the density of every prism is unique. By using the relative formula of between difference of density and difference of S-wave speed, we can establish the preliminary model of density in Qinghai-Tibet and its adjacent regions. Then, we using residual Bouguer gravity anomaly data invert iteratively density anomaly distribution by means of the least square method. Finally, we get density anomalies on six different depths in 10-100km depth ranges. The mean square error between observation gravity anomaly and the gravity anomaly of density model forward calculation is less than 5mgal. The density anomalies of Qinghai-Tibet are obviously relative to the tectonic features. High-density region corresponds to old terrain, and low-density corresponds to plateau and mountain region. There are density anomaly gradients along the boundaries of differential tectonic bodies. The density distribution of upper mantle is different to the distribution of crustal density. The variation of crustal density is 15%, while upper mantle density variation is 5%.Key Words: Tomography, gravity anomaly, Inversion, Lithosphere density structure.

P WAVE VELOCITY STRUCTURE OF THE CRUST FROM ZHAYU, XIZANG TO GONGHE, QINGHAI IN THE SOUTHEASTERN TIBET

Zhongjie ZHANG, Guangjie WANG, Ruomei SUN, Jiwen TENG, Liqiang YANG, Yilong QIN, Yun CHEN, Yafeng YAN, Jingyi CHEN, Chaoying ZHANG, Haishan ZHENG (Institute of Geology and Geophysics, Chinese Academy of Sciences)

A wide-angle seismic profile was taken with a total length of about 1000 km, from Zhayu, Xizang to Gonghe, Qinghai, in the southeastern Tibet, in 2001. The wide-angle seismic profile crosses the 4 tectonic blocks: Lahsa block, Qiangtang block, Songpan Ganzhi block and the eastern Kunlun block. 3 sutures such as the Banggoin, Jinshajiang and the eastern Kunlun are cut by the profile. It's implemented to study the crustal structure under the studied area, search for the seismic evidence of crustal material escaping eastwards and possibility of crustal deformation in the southeastern Tibet. In this experiment, 16 shots are triggered, and 200 three component digital seismographers are deployed to record seismic reflection and refraction from the crust. With the analyses of P-wave seismic features of this experiment, we recognized several events such as Pg from the crystalline basement, PmP from the Moho and other 3 phases from the discontinuities in the crust. With the traveltime fitting and velocity inversion of these observations, we obtain the final interpreting model of P-wave velocity in the crust. The results demonstrate the crustal thickness varies abruptly for different blocks. The average crustal thickness varies within 55 and 74km, and thins from the southwestern to the northeastern of the profile. The crust could be divided into upper, middle and lower crust. The average P wave velocity is about 6.2-6.25km/s for the profile. The obvious feature is there is strange lower velocity body under the area centered at the eastern Kunlun fault.

STUDY OF REGIONAL TECTONIC DEFORMATION BEFORE MS8.1 EARTHQUAKE IN THE WEST OF KUNLUN MOUNTAIN PASS

Zai sen JIANG[1], Xi ZHANG[2], Bing CHEN[2], Xi liang ZHANG[2], Shuang xu WANG[2] ([1]Center For Analysis And Prediction,China Seismological Bureau, [2]The Second Center For Crustal Deformation Monitoring,China Seismological Bureau)

The background of regional tectonic deformation, before Ms8.1 earthquake in the west of Kunlun Mountain Pass, is preliminarily studied by using horizontal crustal velocity field data during 1991-2000 observed by GPS in Qinghai-Tibet block and its adjacent area, and from gravity repetition measurement in 1998 and 2000. The analysis shows that, the development and occurrence of this earthquake related to larger regional horizontal motion and deformation background, which might be acted by larger-scale block. Inside the Qinghai-Tibet block, large-range sinistral shear deformation region existed, this earthquake just

happened in the highest region of sinistral shear strain rate in accordance with fault strike, and tensional region of superficial expansion strain and the margin of abnormality region of negative gravity variation. The background of regional tectonic deformation was helpful to develop huge sinistral strike-slip rupture. Conclusion and Comprehension: (1)The development and occurrence of this Ms8.1 earthquake related to larger regional horizontal motion and deformation background. Relative movement produced much big range sinistral shear deformation, this earthquake just took place in the highest region, whose strike was consistent with the fault strike, of sinistral shear strain rate. (2)This earthquake was not only driven by NE principal compressive stress action, but also caused by the total movement of Kunlun block and nearby blocks. Due to resistance of local boundary, in the epicenter area, the lag of movement led to quick accumulation of elastic strain, the total block motion wanted to pull this local region moving eastward, so as to make the movement harmonious, thus brought about huge-type sinistral strike-slip rupture. (3)In the middle and east of Qinghai-Tibet block, on the sinistral fault, 7 earthquakes over 7 magnitude occurred one after another since 1937, 5 of them are over 7.5 magnitude. This group of earthquakes formed a huge arc sinistral shear zone, and acted by stress field of large regional horizontal movement, the activity of this huge sinistral shear zone certainly caused accumulation of elastic strain energy on the segment where no large earthquake has taken place yet. This is the fact indicated by DDA simulation. (4)In the epicenter area, NW principal tensional strain of horizontal strain rate was a little bigger than NE principal compressive strain. Just due to such regional tectonic deformation background, it was favorable to produce large-scale development of sinistral rupture dislocation, and to make the shear strain accumulated before the earthquake fully release. So it was also helpful to understand those questions why this Ms8.1 earthquake had longer rupture length and lower magnitude of aftershocks.

TECTONIC DEFORMATION BACKGROUND AND FAULT ABNORMAL ACTIVITY IN NORTHEAST MARGIN OF QINGHAI-TIBET BLOCK BEFORE THE KUNLUN MS8.1 EARTHQUAKE

Shuang xu WANG[1], Zai sen JIANG[2], Xi ZHANG[1], Xi liang ZHANG[1], Fu ping XUE[1] ([1]The Second Center For Crustal Deformation Monitoring,China Seismological Bureau, [2]Center For Analysis And Prediction,China Seismological Bureau)

By using up-to-data crustal deformation observational data that contain results observed by GPS in 1993,1999 and 2001, together with mobile deformation results crossing main faults during 1980-2002, combined with monitoring and research results of regional vertical deformation nets for nearly 30 years, the time-spatial evolution background of regional tectonic deformation and fault abnormal activity features in northeast margin of Qinghai-Tibet block before the Kunlun Ms8.1 earthquake occurred on Nov. 14 , 2001 are preliminarily studied. The results show that: before the earthquake, regional horizontal movement and deformation intensity decreased, the trend of vertical motion changed, and abnormality of fault deformation developed. In addition, combined with block and structure, further analysis indicates that, occurrence and development of this Ms8.1 earthquake inside Qinghai-Tibet block were acted by larger-scale block activity, that had remarkable effect on the tectonic region of block boundary, and probably promoted accelerating of stress-strain of some tectonic positions or releasing of rupture in this area.

SEISMIC EVIDENCE OF MASS EASTERN EXTRUSION FROM SURFACE WAVE TOMOGRAPHY OF TIBET

Ruomei SUN[1], Zhang ZONGJIE[1], Zhu JIESHOU[2] ([1]Institute of Geology & Geophysics, Chinese Academy of Sciences, [2]University of Science & Technology of Chengdu)

Tibet plateau with uniform height 5km is surround by stable sedimentary basins, Tarim to the northwest Chaidamu to the north, Sichuan to the east. It´s a natural lab to study continental collision. Le Pichon (1992) estimated the surface loss due to collision between India and Asia and pointed out that about 1/2 to 1/3 crust mass can not be accounted by the thickening of the crust. These crust mass disappeared either by lateral escape or lower crusts transfer to the mantle. Our S velocity images from Rayleigh wave dispersion tomography directly show mass eastern extrusion evidence from depth of 24km to 50km. Then more lower crust mass transfers to the mantle. The low S wave velocity anomaly area of depth 85km has similar pattern as the famous paper giving a zone of inefficient Sn propagation. Profiles along 76E, 86E and 90E suggest that India thosphere mantle subducts and meet the Asia's at 41N (76E), at 36N (86E) and 34N (90E); north of Bangong-Nujiang. QT has a thick crust, thick asthenosphere. Geologists found Cenozoic lava with rich kalium element there.

VELOCITY STRUCTURE FEATURES OF NORTHERN TIEN-SHAN CRUST

Tamara Mikhailovna SABITOVA, Albina Alexandrovna ADAMOVA, Zarema Arslanovna MEDJITOVA, Nailya Hannanovna BAGMANOVA (Institute of Seismology, National Academy of Science, Kyrgyz Republic, Bishkek, Kyrgyzstan)

We analyzed velocity sections of Northern Tien-Shan crust, that were plotted on new 3D velocity model of Tien-Shan crust and uppermost mantle (38°,5-43°,5 N; 68°,0-80°,0 E), computed by seismic tomography method (Adamova A.A., Sabitova T.M, 2001). This model makes previous 3D model (Roecker S.W., Sabitova T.M., Vinnik L.P. et al, 1993) more precise. It was also computed with the Roecker S.W. program. Area of study lies within 42°,0-43°,5 N and 73°,5-79°,0 E. It includes Chu and Issyk-Kul depressions, part of Ili depression and their mountain frame - Kyrgyz Range, Terskey, Kungey and Zaili Ala-Tau. For most part of study area P-wave velocity structure is well resolved in depth interval 0-80 km, while solution quality for S-wave velocity structure is good for interval 0-25 km. 10 P-wave velocity cross sections have been reviewed. These were constructed for study area in longitudinal and latitudinal directions and across source zones of known big earthquakes (M >6). To estimate a reliability of velocity structure along those profiles we compare them with sections made by other researchers, as well as with wave field, observed from regional earthquakes and Semipalatinsk nuclear explosions. Found features of velocity structure beneath Northern Tien-Shan are reflected in observed geophysical fields: electromagnetic, gravity, heat flow and S-wave coda attenuation. The following most interesting observations are described below. 1. Velocity structure of crust and uppermost mantle beneath Northern Tien-Shan is rather heterogeneous. In particular, there are specific zones with reverse velocity pattern, which might be attributed to some abnormal high velocity   (Vp=6,3-7,0 km/s) volumes in upper crust (5-25 km), low velocity blocks (Vp=5,4-5,7 km/s) in middle crust (25-35 km) as well as to bodies with strong velocity variations (Vp=6,2-8,3 km/s) in lower crust and uppermost mantle (35-65 km). 2. Velocity structure of crust and uppermost mantle beneath mountain depressions and their mountain frame differs: beneath depressions an alternation of high and low velocities is found, while beneath mountain frame P-wave velocities change gradually – in most cases these remain to be rather low, at least, to depth of 35-50 km. Low velocity roots beneath mountains most likely extend to a mantle at some areas. 3. Hypocenters of big earthquakes (M >6) within study area are located in high P-wave velocity gradient zones. Lateral velocity gradient is usually due to contact between high

---

and low velocity zones, that at the surface corresponds to known fault, separating depression from mountain buildings. Vertical velocity gradient is related to horizontal boundaries, separating high velocity volumes in upper (5-25 km) and lower (35-50 km) crust from zones with low velocities in middle crust (25-35 km). Stress release during earthquakes may take place along above boundaries, separating blocks with different physical properties.

A METHOD FOR PRECISE ESTIMATION OF THE VOLUME OF OIL RESOURCE VIA APPLICATION OF FIRST AND SECOND DERIVATION OF WAVELET TRANSFORMATION.CASE STUDY: DETERMINATION OF VOLUME OF OIL RESERVOIRS IN THE SOUTHERN PART OF IRAN

Manoochehr SHIRZAII, Alireza A. ARDALAN, Roohallah KARIMI (Department of Surveying and Geomatics Engineering, University of tehran)

Using the welcomed property of the first and second order derivation of wavelet transformation for signal detection a new method for estimation of oil reservoirs based on gravity observation on the surface of the earth has be devised.This method has been first examined for simulated data and then having assured of its capabilities it has been adapted to estimate the volume of the oil reservoir in the southern part of Iran. Details of mathematical formulation of the problem and the results of case studies will be presented.

CRUSTAL VELOCITY MODEL IN IRANIAN PLATEAU, REVEALED FROM LOCAL SEISMIC NETWORKS

Azadeh NADERINEZHAD FARD, Mohammad Reza GHEITANCHI (miss)

Using a two station method, which is independent of mislocation errors, P and S velocities are determined along several paths in Iranian plateau. Assuming a simplified two-layered model with a horizontal layer of isotropicmedia and using the obtained velocity model, an attempt was made to determine the thickness of crustal layers. The best fit suggests a 44 km crustal thickness. Similarly, theoretical time-distance curves for S arrivals were produced by using several Vp/Vs ratios and the best fit suggests a value of 1.73. In producing time-distance curves reduced travel time plots, in which on the time axis the distance divided by a constant velocity has been subtracted from the true time, was used. This reduced the size of the plot and made arrivals coming in at the reducing velocity appear as a line parallel to the distance axis. The corresponding S-waves were also later arrivals that follow travel time curves like those P-waves. The waveforms recorded by seismic stations contained several clear and strong later phases both in P and S groups. To identify these phases, the crustal model and the obtained Vp/Vs ratio were used and the theoretical travel time curves for several later arrivals were constructed. In addition to the direct, reflected and refracted P- and S-waves,several combinations of the converted P- and S-waves at the first and second interfaces were computed. Comparison of the observed and the theoretical curves indicated that there are significant reflected phases both in P and S groups. This suggests that the later phases also support the consistency of the crustal model obtained in this study. Strong later arrivals on the records of array stations indicate that the Moho and Conrad discontinuities in this region are significant. For more details such as the dip and topography of layers and local heterogeneity, detailed data as well as additional seismic measurements would be needed.

THE ROLE OF DEEP PROCESSES IN THE CRUSTAL STRUCTURES FORMATION

Alexander Georgievich RODNIKOV (17937)

The studies were carried out within the frame of the International Geotraverse Project along three deep cross-sections of the tectonosphere, which included the lithosphere and the asthenosphere. The cross-sections are: (1) the Okhotsk Sea Geotraverse, (2) the Japan Sea Geotraverse, and (3) the Philippine Sea Geotraverse.The major tasks of the work are the study of the deep structure of the lithosphere under the seismically dangerous regions, sedimentary basins with hydrocarbons, and areas of mineralization. The length of the geotraverses reaches several thousands of kilometers at 100 km depths. The data on the cross-sections are supplemented by bathymetric, magnetic, gravity and geology maps. The model calculations were carried out of deep temperatures. The depths of asthenospheric roof, distinguished by seismic and magnetotelluric data, correlate with the depths of the calculated 1000oC isotherm. The peculiar feature of the transition zone structure is the distribution in the upper mantle of the asthenospheric layer, the processes in which determine the tectonic structure of the region. Under Pliocene-Quaternary deep basins the asthenosphereeaches the crust, under Neogene basins asthenosphere is a depth of 30 km, beneath ancient Paleogene basins the asthenosphere is a depth of 50-70 km. The diapirs of the anomalous mantle are confined to the tectonic active regions.On the surface, the upwelling of the asthenospheric diapirs corresponds with the rift structures and the eruption of tholeiitic magma. Apparently, the asthenosphericdiapirs with partial melting of the matter are a channel though which the hot mantle fluids rise from the asthenosphere and penetrate into the crust. At the Geophysical Center a Data Base was compiled, which included, besides the geological--geophysical deep cross-sections of the lithosphere and the accompanying geological, gravimetric, bathymetric and magnetic charts, also the primary geological and geophysical data, the results of bathymetric measurements and of gravimetric and magnetic surveys, the results on heat flow, deep seismic sounding and tomographic research, the information on earthquakes and the results of studiesof the fine structure of the seismofocal zone, certain data on the chemical composition of rocks and on their age, and the results of deep-water driling and dragging. This work was supported by the Russian Foundation for Basic Research, project 01-05-64400.

THE STRUCTURE OF THE LEINSTER GRANITE, SOUTHEAST IRELAND, FROM WIDE-ANGLE SEISMIC STUDIES: IMPLICATIONS FOR ITS EMPLACEMENT MECHANISM

James A. HODGSON[1], Peter W. READMAN[1], Brian M. O'REILLY[1], Padhraig S. KENNAN[2] ([1]Dublin Institute for Advanced Studies, 5 Merrion Square, Dublin 2, IRELAND, [2]Department of Geology, University College Dublin, Dublin 4, IRELAND)

The Leinster Granite is situated in southeast Ireland and is one of the largest granite bodies within the Caledonian/Appalachian orogen. Its mode of formation during the later stages of the Caledonian orogeny in the late Silurian/early Devonian is not well understood. A wide-angle seismic experiment using 300 Reftek Texan instruments from the University of Texas at El Paso, U.S.A. and the University of Copenhagen, Denmark was carried out to investigate the seismic velocity structure of the granite and its sub-surface extent, and its relationship with the overall crustal structure of southeast Ireland. The results indicate that the granite has a layered/sheeted geometry extending to a maximum depth of 5 km in the south, much less than previous estimates from gravity studies. To the north, the granite

S

exhibits a variable thickness between 1 and 3 km, and thickens towards the west. The results show a subsurface extension of the granite at depth towards the southwest, consistent with the Bouguer gravity field. The average Moho depth is about 30 km and within the mid-crust a series of deep-seated faults are interpreted from the seismic model which may have been active during the formation of the granite. Beneath the main granite body the Moho shallows, from a maximum depth of 32 km, to 28 km and this may be related to to the presence of thickened granite. The sheeted geometry of the granite suggests a stratigraphic control and this is consistent with geochemical evidence indicating that the source of the granite melt may have been Phanerozoic sediments. The resolved geometry of the granite, together with isotopic data which reveals a cryptic internal stratigraphy implies that the granite did not homogenize during emplacement, and further suggests that it did not move very far as a melt. Emplacement of the granite is likely to have involved limited movement from its source.

SEISMIC REFLECTION AND WIDE-ANGLE STUDIES ACROSS THE HIKURANGI SUBDUCTION ZONE OFFSHORE NEW ZEALAND

S.A. HENRYS[1], I.A PECHER[1], S. BANNISTER[1], F.J. DAVEY[1], Y. NISHIMURA[2], A. YAMADA[2], H. SHIMAMURA[2], NIGHTWORKINGGROUP[3] ([1]Institute of Geological and Nuclear Sciences, Lower Hutt, New Zealand, [2]Hokkaido University, Sapporo, Japan)

The North Island GeopHysical Transect (NIGHT) was conducted in 2001 to study the Hikurangi subduction zone. The study included a multichannel seismic (MCS) reflection and a wide-angle seismic survey with ocean bottom seismometers (OBS) and onshore-offshore (o-o) stations. We will present stacked and time-migrated images of the MCS. We used velocity information form the wide-angle experiment to stretch theses images to depth.. A subducted seamount is displayed about 40 km landward of the trench. A small accretionary prism is forming seaward of this seamount. An up to 10-km-thick sedimentary basin seems to be present landward of the seamount. The margin is underlain by oceanic crust of the Hikurangi Plateau, a large igneous province. We estimate its thickness at 10-12 km based on wide-angle arrivals in the OBS records. The Hikurangi Plateau is being subducted at a dip of 2-3 degrees close to the trench. A pronounced increase of subduction dip about 120 km away from the trench is displayed in MCS sections. The change of dip of the subducted plate appears to coincide with the eastern termination of the sedimentary basin as well as a stratigraphic high; the Lachlan Ridge. From the o-o data, we infer the presence of a low velocity zone above the subducted plate at this location. We speculate that the increase of subduction dip may be linked to a major tectonic process shaping the East Coast of New Zealand's North Island, perhaps normal faulting of the Hikurangi Plateau caused by loading from the overriding plate. The low velocity layer may mark sediments entering the subduction zone.

MODES OF CRUSTAL EXTENSION DETERMINED BY RHEOLOGICAL LAYERING

Chris WIJNS[1], Roberto WEINBERG[3], Klaus GESSNER[2], Louis MORESI[3] ([1] School of Earth and Geographical Sciences, University of Western Australia, Crawley, WA 6009, Australia, [2]CSIRO Exploration and Mining, PO Box 1130, Bentley, WA 6102, Australia, [3]School of Geosciences, Monash University, VIC 3800, Australia)

Metamorphic core complexes form during continental extension when stretching is strongly localised onto relatively few normal faults.Each fault accomodates large displacements, eventually dissecting the upper crust and resulting in exhumation of the lower crust. In ournumerical models, the extending crust is mechanically stratified through the temperature gradient, which dictates the transition from astrong, brittle, upper crust to a weaker, ductile, lower crust. We use a two-dimensional Lagrangian Integration Point finite element codewhich allows simulations to develop very large strains comparable to those found in analogue models, while still tracking strain historyaccurately for the constitutive laws. The viscoplastic formulation, with strain and/or strain-rate weakening behaviour, gives rise to thelocalisation of deformation and necking of layers. Results show two distinct extension modes which depend upon vertical rheologicalcontrasts: the distributed faulting mode and the metamorphic core complex mode. In the absence of pre-existing weaknesses, the ratio ofthe integrated strength of the upper to lower crust is an indicator of the resulting mode of extension. When the strength of the lowercrust approaches that of the upper crust (small ratio), the result is distributed, densely spaced faulting, with limited slip on each fault,and no exposure of lower crustal rocks. An example could be faulting in the North Sea. Metamorphic core complexes develop when thelower crust is much weaker (large strength ratio) and flows easily. Significant block rotation, and consequent large displacements alongfaults, leads to the complete dissection of the upper crust, as may be the case for core complexes of the Western U.S.A. and theAegean. Numerical temperature-time paths for our metamorphic core complex models are comparable to field data from apatitefission-track thermochronology for the Central Menderes in western Turkey. The actual critical strength ratio for the transition betweenmodes will depend upon such factors as the relative thickness of the lower crust with respect to the upper crust, and the degree of faultweakening.

THE CENTRAL MEXICO INTERMEDIATE-DEPTH EARTHQUAKES AND THEIR RELATIONSHIP TO THE REGIONAL LITHOSPHERIC STRUCTURE

Jaime YAMAMOTO, Luis QUINTANAR (Instituto de Geofisica, Universidad Nacional Autonoma de Mexico)

Moderate magnitude but damaging earthquakes occur frequently in the central part (18° N) of Mexico along a limited east-west (96°-99° W) narrow belt. From 1928 through 2002 this region of western Guerrero and Puebla-Oaxaca has been the site of twelve intermediate depth earthquakes of similar characteristics, focal depth (~70-100 km), normal faulting mechanism and an strong energy release directivity toward the northwest of the epicenter. Understanding the genesis of earthquakes in this region of Mexico is not only important from the theoretical point of view but also from practical reasons, intermediate-depth earthquakes occur inland, in very populated areas, and their ground motion accelerations seems to be higher than accelerations produced by shallow thrust earthquakes of similar magnitude. Besides, they are frequently used in the discussion of the feasibility of the seismic cycle hypothesis, an important tool for prediction purposes. In the present paper we carry out an overall analysis of the earthquakes to find out common features in an attempt to characterize them and to correlate their occurrence to peculiarities in the regional lithosphere structure. Special emphasis is placed on recent earthquakes since they are best documented. Our analysis indicates that the observed spatial distribution of intermediate-depth focus earthquakes suggests the possible existence of a fracture of the subducted plate in central Mexico. Moreover, we speculate that oceanic plate segments at both sides of the fracture descend into the mantle with slightly different strike and dip. Some observed geotectonic features of southern Mexico as the Balsas Depression is probably related to this particular subduction process. The uniformity of focal mechanism solutions of earthquakes in the region suggests that they occur along a pre-existing complex deep-seated normal fault

system, probably in the upper part of the subducting plate.

CRUSTAL MODELING FROM GRAVITY AND TOPOGRAPHY CORRELATIONS TO CONSTRAIN VERTICAL MOTION IN THE NORTHERN US AND CANADA

Laramie Vance POTTS[1], A. BRAUN[2], C.K. SHUM[1] ([1]Laboratory for Space Geodesy and Remote Sensing Research, The Ohio State University, [2]Byrd Polar Research Center, The Ohio State University)

To assess the tectonically-induced vertical motion of the crust in the northern US and Canada, we investigate the present compensation state of the crust and lithosphere from spectral correlation analysis of topography, bathymetry, and free-air gravity anomalies. Top loading scenarios on regional vertical crustal motions from GIA models, consisting of ice loading histories, upper and lower mantle viscosity and ice thickness data, are limited by model assumptions applicable only on a global scale. In general, GIA models do not well represent regional deformation patters such as over the Great Lakes region where tectonic processes have additional influence. These effects have to be removed before constraining GIA parameters. We focus on isolating tectonically driven vertical motion, compressive stress regimes and mass imbalances of the crust from gravity and topography correlations. We use free-air and terrain gravity correlations to differentiate regional variations in crustal isostatic mass variations. Topography and bathymetry data are extracted from Shuttle Radar Topography Mission (SRTM), GTOPO30 and ETOPO5, respectively, and free-air anomaly components from available gravity (terrestrial, altimetry, GRACE, CHAMP) models. We separate the free-air gravity anomalies into terrain-correlated and terrain-decorrelated component using the spectral properties of the free-air and computed terrain gravity effects. Adjusting the terrain effects for terrain-correlated anomalies yields compensated terrain gravity effects that we evaluate for crustal thickness variations. Terrain-correlated anomalies are interpreted for uncompensated elements of the crustal thickness variations differentiate regional variations in crustal rheologies. A validation of this approach was carried out on studies of impact basins on the Moon, Mars, and Venus where we were able to unmask gravity effects of subsurface mass concentrations. These results provide insight on the mechanical attributes of planetary lithospheres from impact basin ring attributes. We extend our approach over North America to isolate regions in the crust where stresses may dominate and influence crustal motion. Crustal thickness variations in addition to uncompensated mass anomalies may provide additional constraints on modeling tectonic evolution and constraining GIA parameters which in turn are important to estimate mass balance and ice history of former and present ice sheets and their contribution to sea level change.

A SEISMIC STUDY OF THE CRUST IN A CENTRAL SECTOR OF THE NEUQUEN BASIN, ARGENTINA (38 DEG SL)

Alberto H. COMINGUEZ[1], Juan R. FRANZESE[2] ([1]CONICET - Departamento de Geofisica Aplicada, Universidad Nacional de La Plata, [2]Centro de Investigaciones Geologicas, Universidad Nacional de La Plata - CONICET)

Deep seismic sections were obtained by mathematical reprocessing of conventionalvibroseis data recorded in the central sector of the Neuquen Basin. The linesinvolved linear upsweeps with frequency band of 12-65 Hz and time-length of 8sec. The field records were characterized by time-lengths of 13 sec and asampling period of 4 msec . The Self-Truncating Extended Correlation algorithmwas used to compute cross-correlation between the sweep and the records. Theoriginal frequency-band of 12-65 Hz was preserved for the first 5 sec of trace. However, this band was affected by an upper-frequency decreasing from 5 sec on,at a predicted linear-rate of 6.625 Hz/sec. Hence, correlated deep-records witha time-length of 11 sec and a final trace-band of 12-25 Hz were calculated.Depth-migration was implemented on the extended traces. Consequently,progressive models of crust velocity were iteratively matched with thecorresponding migrated log. The iterative process was considered concluded when it was observed acceptable coincidence between the model and thedepth-migrated horizons. The basin stratigraphy in the area consists of acontinental sequence of initial sinrift (Precuyano) deposited on halfgrabens,followed by strong cycles of marine and continental postrift units (Cuyo,Lotena, and Mendoza groups). In addition, continental sedimentites are presentcovering the before sequences (Rayoso and Neuquén groups). The initialstructuration is considered of Superior Triassic-Liasic age. While, the postrifphase would have extended until Early Cretaceous. The analysis in the area ofLas Carceles reveals the following: (1)The lower-crust top is placed at about23-24 km; (2)An oblique reflector horizon between 16 and 18 km depth, isconsidered as a master shear that controlled the extensional system; (3)Asubmaster fault, between 8.5 and 12 km depth, is partially recognized in seismicsections; (4)The top of the rift basemen is characterized by irregular depthsthat, from W to E, fluctuates from 9 to 5 km; (5)Evident features of tectonicinversion, including sinrift as well as part of postrift sequences (i.e. Cuyoand Lotena groups) are observed to the W of Los Chihuidos dorsal (thisinversion episode was possibly initiated in the Bathonian-Callovian). In Bajadade Anelo, the study demonstrated that: (1)The top of the pre-liasic basemen islocated at about 5 km depth, showing a smooth topographic relief; (2)In thecentral-western sector are detected features of bipolar inversion (thisinversion episode dated Pliensbachian-Torcian is previous to the Bathonian-Callovian inversion, and is not reported in previous papers); (3)Themiddle level of the Cuyo group is characterized by oblique reflections relatedwith a strong sedimentary progradation toward the west.

SS03/08A/D-151	Poster	0830-310

SEISMICITY, KINEMATICS AND CRUSTAL STRUCTURE OF CUBA

Bladimir MORENO (Centro Nacional de Investigaciones Sismologicas)

Earthquake data from the new Cuban Seismograph Network has been used to obtain basic results that are necessary for other research applications. The locations of the earthquakes were greatly improved with a new P-wave velocity model, which was obtained combining the Cuban and Jamaican catalogs. The model has seven layers with a crust-mantle interface at 20 km and average velocity of 7.6 km/sec.Moho depth at Cuban seismic stations was estimated using Receiver Function Technique indicating both continental and oceanic crust in Cuba. A new attenuation relation for the quality factor Q as well as a new local and coda magnitude scales were calculated, suggesting strong attenuation for eastern Cuba. Base on these results, a seismicity and kinematic analysis in eastern Cuba was performed. Relatively deep seismicity observed in Santiago Deformed Belt (SDB) supported by earthquake focal mechanisms suggest that the Gonave Microplate is underthrusting the Cuban block in this area. Principal stress axes determined from stress-inversion of focal mechanisms indicate a thrust faulting regime along the southern Cuban margin in agreement with the dominant structural trend associated with the SDB. The orientation of the principal stress axes seems to be induced by the oblique motion of two blocks involves in strike-slip deformation.

THE BLOCK STRUCTURE MODEL OF THE SUBDUCTION ZONE AND CLASS FREQUENCY LOW OF THE EARTHQUAKES

Alexander N. KROLEVETS (Kamchatka State Pedagogical University)

The elastic energy is considered to accumulate by the hierarchically organized geometrically similar geoblocks. The distinctive feature of the model is the giving up the idea of block nesting. The blocks are not overlapped, and altogether formed the outlying part of a wedged shape continental plate. The sizes of the blocks decrease towards axis of a seismic active zone. The sizes L of the largest blocks are first hundreds of kilometers. The number dB of blocks on the sizes L distribution have the form: $dB \sim dL/L\delta$. The power δ is on a unit bigger than the number of the block dimensions counting - height, width and length, which is divided while the transition from blocks of one hierarchical level to the next one. The earthquakes take place at the very instants when the block accumulated energy releases. The maximum energy accumulated by the blocks, is the power function of their sizes with the power of a. The mean duration of the energy accumulation-release cycle is also the power function of the block size and β is the power. The slope γ of the earthquakes frequency - class diagram is connected with δ, γ, a by the formula $\gamma=(\delta+\beta-1)/a$ and does not depend on the similarity factor of the blocks. For the system of blocks concerned (type I) forming a wedge, $\delta=2$, and $a=3$. Accepting $\beta=1$ (the average duration of the seismic cycle of a block is proportional to its size) we shall receive $\gamma=2/3$ for the strongest Kuril-Kamchatka earthquakes (class above 12.7), and the value is in good agreement with the observed value 0.72. The gaps between the blocks and the faults not dissecting blocks completely are in turn filled with hierarchies of rectangular shaped blocks of much smaller sizes. The blocks of such hierarchies engender earthquakes of class below 12.7. Suitable are the hierarchies with $\delta=2$, and $a=2$ (hierarchy type II) and with $\delta=3$, and $a=3$ (type III). The structures will give the value $\gamma=1/2$ typical for weak Kamchatka earthquakes, if is taken into account for structures II $\beta=0$ (duration of a seismic cycle of the blocks does not depend on the sizes of the blocks) or for structures III to accept $\beta=-1/2$ (the duration of a block cycle is an decreasing function of its dimensions). The latter means that the block structure in sites consisting of the smallest blocks is stronger. The structure rearrangement becomes possible in zones of maturing of the powerful earthquakes from one type of hierarchy (type III: $\delta=3$, $\beta=-1/2$, and $a=3$) to another (type II: $\delta=2$, $\beta=0$, and $a=2$). Thus the media gets an opportunity to tune the phase of the internal processes to external influence. After the earthquake the opportunity disappears. It, probably, explains the occurrences of earthquakes precursors of periodicity types before strong earthquakes while observing weak seismicity, high-frequency seismic noise, pulse electromagnetic emission, which disappear after earthquakes.

DZIRULA BASEMENT-CORED TECTONIC WEDGE: STRUCTURE AND KINEMATIC EVOLUTION, GEORGIA

Victor Michael ALANIA (Department of Tectonics, Institute of geology, Georgian academy of sciences)

Georgia as a part of the Caucasus region is situated within the Alpine-Mediterranean belt and consists of two major thrust and fold belts: the Greater Caucasus and Achara-Trialeti, separated by Georgian foreland basin. Between Greater Caucasus and Achara-Trialeti thrust and fold belts, Paleozoic basement outcrops in the Dzirula massif separates the Georgian foreland basin into the Rioni and The Kartli. We present of N-S crustal scale balanced cross-section across Greater Caucasus, Dzirula massif and Achara-Trialeti thrust and fold belt based on geological and geophysical data in order to better understand of structure and late Alpine kinematic evolution of the Georgian thrust and fold belt. Section balancing, together with forward modeling, was used to develop a new tectonic model for the central Georgian thrust and fold belt. Balanced sections suggest that formation of Dzirula basement-cored tectonic wedge structure is related to the southward thrusting of Greater Caucasus accretionary wedge and the presence of "Alpain - style" basement-cored nappes. These structures were formed during late Alpain time, probably late Miocene-Pliocene and characterized by a thick-skinned style of shortening. The amount of displacement of the Dzirula tectonic wedge indicating large horizontal crustal shortening and is accommodated by backthrusting of the Jurassic and Cretaceous strata of the overlying above Paleozoic basement rock. Thrust front of tectonic wedge is linked by backthrust and is structural boundary between Achara-Trialeti and Greater Caucasus thrust and fold belts.

S-WAVE VELOCITY STRUCTURE AT EURO-SEISTEST, VOLVI, GREECE DETERMINED BY ARRAY OBSERVATION OF MICROTREMORS

Kazuyoshi KUDO[1], Tatsuo KANNO[2], Hiroshi OKADA[3], Tsutomu SASATANI[3], Pashalis APOSTOLIDIS[4], Dimitrios RAPTAKIS[4], Kyriazis PITILAKIS ([1]Earthquake Research Institute, University of Tokyo, [2]National Research Institute for Earth Science and Disaster Prevention, [3]Graduate School of Science, Hokkaido University, [4]Department of Civil Engineering, Aristotle University of Thessaloniki)

S-wave velocity structures crossing the Volvi basin along the EURO-SEISTEST, were estimated by the phase velocity dispersion of Rayleigh waves included in microtremors using the Spatial-Autocorrelation (SPAC) method. The Volvi basin is a 5km-wide and 200-m-deep sedimentary valley extending to east and west between the Lagada and Volvi lakes in the Mygdonian graben. The two-dimensional underground structure crossing the valley was well determined by borehole data of geology, down-hole and cross-hole surveys, seismic refraction surveys, surface-wave inversions using explosion records, 2-D and/or 3-D earthquake observations, and simulation works. Our primary objective is to compare our results with those determined by the other methods and to understand an applicability of the array observation of microtremors for site characterization.The existing S-wave velocity models were mostly determined by surface wave inversion using explosion records. The phase velocity dispersion obtained near the center of the valley by the SPAC method is in reasonable agreement with that of explosion data. However, the depths of bedrock at other sites have some disagreements between the present study and the existing model. The

difficulty to determine the S-wave velocity of bedrock exists not only in the methods using microtremors but also other methods of seismic prospecting. Boldly speaking, array measurements of microtremors are superior to the other methods to determine S-wave velocity structure, if we could use microtremors in a wide frequency range. The power of microtremors at low frequency range is significantly low in the Volvi basin compared with Japan, however, the array observations of microtremors is very promising method for determining S-wave velocity structures from shallow to intermediate with less restriction in urbanized areas. The SPAC method, used in this study, generally provides an equivalent result to that of surface waves from artificial source with smaller array size; therefore, it is very useful for applying to site characterization in sedimentary basins. Surface wave inversion techniques are obliged to assume a flat layering structure, while the Volvi basin is roughly two- dimensional structure with variations of bedrock depth and/or thickness of surface layers. The phase velocity of microtremors is more or less affected by some laterally heterogeneous structures; hence the inverted S-wave velocity structure should have some uncertainties. To verify this issue, a reflection survey crossing the valley for determining bedrock shape using P-wave and a simulation analysis for giving theoretical basis are suggested as our future study.

SS04/07A/A03-002 — 0945

3-D STRUCTURE OF THE KANTO BASIN, JAPAN FROM JOINT INVERSION OF REFRACTION AND GRAVITY DATA

Afnimar AFNIMAR[1], Kazuki KOKETSU[1], Masao KOMAZAWA[2] ([1]Earthquake Research Institute, University of Tokyo, [2]Geological Survey of Japan)

The underground structure of Kanto Basin has been revealed from various kinds of data such as seismic refraction/reflection, borehole, microtremor, gravity etc. Unfortunately, the data distribution of refraction, refraction, borehole and microtremor is sparse and/or irregular. In the refraction or reflection traveltime inversion, this case leads the low-resolution problems for complicated and fine spacing model, although this inversion has better resolution than that gravity data, especially in the deep target. In the other hand, the gravity observation was carried out densely and homogeneously but its data inversion hold the inherent non-uniqueness and cannot measure seismic velocity directly. We propose a joint inversion of refraction and gravity data to reveal a more detail structure of Kanto Basin. According to the geological feature, the basin is parameterized by one-fix interface, two-variable interfaces with constant sediment slownesses and laterally heterogeneous basement slowness. The interfaces and basement slowness are defined by a set of knot points with the Lagrange interpolation. Densities for gravity calculation are related to the slownesses through experimental formulae. Model regularization is introduced to avoid oscillatory artifacts and non-uniqueness in a solution. The result of the joint inversion recovers more detail than that inversion of traveltimes only. The distribution of the basement slowness is in good agreement with a geological interpretation in this area.We also conduct a ground motion simulation in Kanto Basin using these results. The synthetic waveforms simulate observed seismograms quite well.

THE DETERMINISTIC ESTIMATION OF SITE EFFECTS AND SEISMIC HAZARD MAP IN BEIJING AREA

Zhifeng DING[1], Yuntai CHEN[1], Guliano F. PANZA[2] ([1]Institute of Geophysics, China Seismological Bureau, [2] Department of Earth Science, Trieste University, Trieste, Italy)

For the realistic modeling of the seismic ground motion in lateral heterogeneous anelastic media, the database of 3-D geophysical structures for Beijing City has been built up to model the seismic ground motion in the City, caused by the 1976 Tangshan and the 1998 Zhangbei earthquakes. The hybrid method, that combines the modal summation and the finite difference algorithms, is used in the simulation. The modeling of the seismic ground motion, for both the Tangshan and the Zhangbei earthquakes shows that the thick Quaternary sedimentary cover amplifies the peak values and increases the duration of the seismic ground motion in the northwest part of the City. Therefore the thickness of the Quaternary sediments in Beijing City is the key factor that controls the local ground effects. Four zones are defined on the base of the different thickness of the Quaternary sediments. The response spectra for each zone are computed, indicating that peak spectral values as high as 0.1g are compatible with past seismicity and can be well exceeded if an event similar to the 1697 Sanhe-Pinggu occurs. The seismic hazard map in North China is assessed using a deterministic approach method. The seismic sources are represented at a set of grid points located at distances of 0.2° from each other. The main inputs for this computation are earthquake catalogue, source mechanisms, the level of seismic activity and the structural models. Synthetic seismograms are generated by different sources, and are used to obtain the distribution map of the maximum ground motion and design ground acceleration (DGA).

SS04/07A/A03-004 — 1015

SITE EFFECTS IN URBAN AREAS : RECENT RESULTS ON SITE CITY INTERACTION

Pierre-Yves BARD[1], Jean-Louis CHAZELAS[3], Philippe GUGUEN[1], Marc KHAM[2], Jean-François SEMBLAT[2] ([1]LGIT/LCPC, Grenoble Observatory, [2]LCPC, Paris, France, [3]LCPC, Nantes, France)

Several observations raised the concern about a possible modification of the seismic wave field in densely urbanized areas, due to interactions between soil-structure interaction and site conditions. While the previous studies were mainly considering the simple superposition of many islated singly-interacting systems (as in single scattering), this presentation will focus on recent results on multiple interaction (analog to multiple scattering) obtained with both centrifuge tests and BEM modelling for 2D structures. Two model buildings have been designed and installed within a centrifuge filled with carefully deposited sand. Centrifuge rotation allows to reach an acceleration of 100 g, and therefore to dilate the space scale by a factor 100. The excitation of one of the model building with a shock, induces a shaking also in the second building; the recordings show that the interaction is increasing when the building to building distance is decreasing, and is maximum when the two buildings have identical frequencies: in that case, beating signals are clearly observed, showing a strong interaction, and similar in some way to strong motion recordings actually observed in some buildings or within densely urbanized areas such as Mexico City. On the other hand, a 2D BEM code has been used for investigating the seismic response of a set of buildings with variable number, size and position, overlying a layered half-space with variable thickness, for incident SH, SV and P waves. In addition to a clear evidence of the interaction effects both within and outside the built area, the parametric study allows to draw conclusions on the main controlling parameters: the most efficient interaction is obtained when building and soil frequencies coincide. In that latter case, the energy of the building induced perturbations with respect to the free field situation may reach 50 to 100 % within the built area, and from 10 to 20% several hundred meters apart.

A STUDY ON SITE EFFECTS IN ADAPAZARI, TURKEY, FROM STRONG- AND WEAK MOTION RECORDS

Oguz Asim OZEL, Tsutomu SASATANI (Graduate Scool of Science, Hokkaido University, Kita-ku N10 W8, Sapporo, 060-0810, Japan)

Approximately 7000 people were killed due to collapse of buildings in Adapazari City during the 17 August 1999 Izmit, Turkey earthquake (Mw=7.4). Most of the fatalities and damage occurred in the city center. Adapazari City is located on a deep sedimentary basin; the thickness of the alluvial deposits is more than 300 m. A strong-motion observation array was deployed in and around Adapazari City after the earthquake by the University of Bogazici to study the site response that caused considerable damage in the city. The temporary array consisted of nine stations, four of which were located in the heavily part of the city center, and was operated from August 29, 1999 to October 10,1999. In this study we use records from the four stations in the city center and the adjacent rock site. Eleven aftershocks are selected in our analysis based on the signal-to-noise ratio; these events have a magnitude range of 3.2 to 5.8. We estimate S-wave spectral ratios of the basin site records to the reference site. These spectral ratios show that the basin S waves are amplified by 2 to 5 times compared to the reference site in the frequency range of 0.5 to about 5 Hz but are strongly de-amplified at frequencies higher than 5 Hz. The apparent de-amplification at the basin sites at high frequencies can be attributed to the site amplification at the reference rock site at these frequencies. We confirm the rock site amplification based on the S-wave H/V (horizontal to vertical) ratios; the average H/V ratio shows about unity with weak frequency-dependency in the frequency range of 0.5 to 5 Hz, but it increases from unity at 5 Hz to about 4 around 10 Hz. We also compare the empirical site amplifications (spectral ratios) with the theoretical ones calculated based on S-wave velocity structures; an agreement between them is generally good. In addition to strong S-wave amplifications, the basin site records show strong excitation of long-period (about 2 sec) surface waves after S-wave arrival during the aftershocks with magnitudes greater than 5; these surface waves produce the long duration of shaking (longer than 30 sec). We conclude that severe damage in Adapazari City during the 1999 Izmit earthquake was caused by not only strong S-wave amplifications but long duration of shaking due to basin-induced surface waves, as well.

SS04/07A/A03-006   1100

USING MICROTREMORS FOR CHARACTERIZING SITE RESPONSE IN GREATER CAIRO AREA AND GENERATION OF MICROSEISMIC ZONATION MAPS

Mohamed Ahmed GAMAL, Yehia Elsaid ABDELHADY (Geophysics)

We have used portable velocity seismometers and accelerometers to record ambient noise arising from cultural disturbances and long- period microtremors at the Nile value cut through Cairo City to define site response within Cairo. The valley is filled with Quaternary deposits mainly of alluvium, silt and graded sand and lime powder. River Nile valley is surrounded by densely populated urban environment. Microtremors were recorded using point-by-point technique in a 5 profiles covering almost the whole area of Cairo. While the Nile valley including its islands of Roda and Zamalek show some fixed peaks at 2.5-3 and 8-9 HZ at the center of the basin, The next surrounding area to the Nile shows disappearance of the fundamental peak leaving 2nd resonance peak. Other sites at Greater Cairo show different peaks depending on their own soils. Resonant frequencies predicted by one-dimensional modeling of the Nile valley center show excellent agreement with observations. The 2.5-3-Hz spectral ratio peak is interpreted as the fundamental resonance mode related to the soft unconsolidated alluvium and sand while 8-9 Hz is interpreted as the resonance peak coming from the older competent underlying rock. The unrealistic amplification factors implied by old microtremor methods is recovered by using spectral ratio between site raw spectra and fixed value flat spectra. This gives more realistic peak amplification and a frequency resembles the traditional site to reference site spectral ratio method but in a more realistic amplification. A microseismic zonation maps based on soil response is generated to help in studying earthquahe hazards in one of the most populated areas in Egypt, which is its capital.

SS04/07A/A03-007   1115

SITE RESPONSE EVALUATION USING H/V AND SPECTRAL RATIOS IN THE TAIPEI BASIN

Huey-Chu HUANG, Yi-Xiang CHIU (Institute of Seismology, National Chung Cheng University)

The relationships between the spectral characteristics of earthquake ground motions are investigated using the observed data from a dense strong-motion network consisting of 69 stations in the Taipei basin. Many high-quality recordings, including those of the 921 Chi-Chi earthquake (M_w=7.6), the 331 Hualien earthquake (M_L=6.8), the 921 aftershocks (M_L>6.5), as well as some weak motion events are selected to evaluate site responses. The stations TAP051 and TAP086 are chosen as the reference stations. The predominant frequencies obtained from H/V ratios are consistent with those from spectral ratios. On the basis of the spectral ratios and H/V ratios of weak-motion events, it is concluded that the lower predominant frequencies ($<$1.5Hz) appear in the basin area, while the higher values are near the mountainous region (around the Taipei basin). The site characteristics between the strong and weak events are different, however. This implies that a nonlinear effect probably occurred with the strong-motion events.

SS04/07A/A03-008   1130

THE NON-LINEAR SITE RESPONSE AT DAHAN DOWNHOLE ARRAY SITE DURING 1999 CHI-CHI TAIWAN EARTHQUAKE

Hung-Chie CHIU (Institute of Earth Sciences, Academia Sinica)

We develop a new algorithm to correct the orientation errors of the downhole seismometers. Then, we study the site response at Dahan downhole array site based the data recorded in the Chi-Chi, Taiwan Earthquake sequence. This proposed algorithm consists of three stages: (1) rotating two horizontal ground motions on the free surface to the SH Vdirection and considering the SH axis as a reference direction, (2) computing the synthetic downhole SH waves at downhole station, and (3) searching a optimized orientation correction that results in a best waveform match between the synthetic and observed downhole seismograms. Then, the rotated angle corresponding to the best waveform match can be considered as the orientation error. We selected five earthquakes that have a good data quality for analyses. Results show that this algorithm gives a more stable estimation than a conventional method because it allows selecting data from a wide time window for analyses. The estimated orientation error of the accelerometers at the Dahan Downhole Array after the 1999 reinstallation are 40, 114 and 285 degrees at depths of 50, 100 and 200 m, respectively. After orientation correction, the waveforms of this vertical array become consistent and can be used to measure the small amount of the velocity change in the shallow layers. A preliminary result shows that, the non-linear effects can be effective when the peak ground acceleration over 100cm/s/s.

SS04/07A/A03-009   1145

ATTENUATION RELATION FOR EUROPE DETERMINED WITH EUROPEAN DATA AND RECENT NEAR FAULT RECORDS FROM CALIFORNIA, JAPAN AND TURKEY

Yoshimitsu FUKUSHIMA[1], Catherine BERGE-THIERRY[2], Philippe VOLANT[2], DaphneAnne GRIOT-POMMERA[3], Fabrice COTTON[4] ([1]Izumi Res. Inst., Shimizu Corp., [2]Institut de RdioProtection et de Sûrete Nucléaire, [3]Hémisphères, [4]Laboratoire de Géophysique Interne et Techtonophysique, Univ. Joseph Fourier)

Strong ground motion close to a fault is expected to be very large, therefore, it's estimation is essential for human safety. Although a few strong motion data exist in European region, we proposed in a previous work [Berge-Thierry et al., 2002] an attenuation relation for spectral acceleration using strong motion data recorded in Europe and some in U.S.: this relationship was derived for the French Safety Rule which is applied for Nuclear Power Plants seismic hazard assessment. In this present study, we propose to constrain the amplitude saturation term related to the proximity of the fault, adding an amplitude saturation term in the regression model. We added to the data-set previously used to derive the European attenuation relationship recent large earthquakes strong motions recorded during the 1995 Hyogo-ken Nanbu (Kobe) Japanese and the 1999 Kocaeli (Izmit) Turkish events. The regression analysis adapted from Fukushima and Tanaka [1990] is non-linear, therefore an iterative procedure was applied. The determined regression coefficients lead to predict peak ground acceleration of about 0.7 g for soil at a fault distance of 0.5 km. The Q coefficient deduced from the distance coefficient is in agreement with the scattering Q model. The introduction of the saturation term leads to predict average spectral accelerations significantly lower at short distances than using the Berge-Thierry et al. [2002] law.

SS04/07A/A03-010   1200

NONLINEAR SEISMIC RESPONSES IN 1D AND 2D MEDIA

Avadh RAM, Arun K. GUPTA (Department of Geophysics, Banaras Hindu University)

During the past two decades, considerable effort has been devoted to develop modelling technique of seismic wave propagation in media to study the effect of the geological site conditions on the ground motions. The propagation of seismic waves plays an important role in seismic risk and hazard analysis. So far, the scientists have developed the models based on linear characteristics of the earth's medium. It is, therefore, necessary to incorporate the effect of lateral heterogeneities in the direct modelling of the wavefield in order to retrieve a correct image of the heterogeneity itself and consequently to understand the geodynamics of the studied portion of the earth. A large nonlinear response in the earth may be responsible for the significant spectral estimation of seismic waves at amplitude and distances, which may be considered within the linear elastic regime. The effect of nonlinear elasticity on the seismic wave propagation may be large and should be considered in the modelling. In the present study, we have solved the linear and nonlinear seismic wave equations for 1D and 2D and tried to see the effect of nonlinearity with the linear response using 2nd and 4th order finite difference technique. The nonlinear effect is mainly associated for soil deposits. The responses in hard rock area for linear and nonlinear case is more or less the same. Some of these results will be discussed.

FINITE-DIFFERENCE SIMULATION OF SEISMIC NOISE IN SURFACE GEOLOGIC STRUCTURES

Peter MOCZO[1], Jozef KRISTEK[2], Cecile CORNOU[3], Sylvette BONNEFOY-CLAUDET[4], Pierre-Yves BARD[5] ([1]Department of Geophysics, Faculty of Mathematics, Physics and Informatics, Comenius University, Mlynska dolina F1, 842 48 Bratislava, Slovak Republic, [2]Geophysical Institute, Slovak Academy of Sciences, Dubravska cesta 9, 845 28 Bratislava 45, Slovak Republic, [3]Institute of Geophysics, ETH Hoenggerberg, HPP P1.1, CH-8093 Zurich, Switzerland, [4]LGIT, Grenoble Observatory, Maison des géosciences, BP 53 X, 38041 Grenoble Cedex, France, [5]LGIT/LCPC, Grenoble Observatory, Maison des géosciences, BP 53 X, 38041 Grenoble Cedex, France)

The SESAME project, funded by the European Commission, has been undertaken as a partnership between various European teams in order to better assess the actual capabilities of microtremor-based site-effect investigation methods (H/V technique and array techniques). One part of this project is dedicated to the development of a numerical simulation technique, and its application to a series of representative ˝canonical models˝ and a few real sites. The presentation will focus on the description of the program package and on the preliminary results obtained for some representative models. The program package ˝NOISE˝ consists of two codes - RANSOURCE and FDSIM. RANSOURCE is designed for random space-time generation of point sources controlled by several parameters (minimum source-source distance, minimum and maximum source-receiver distances, minimum and maximum numbers of sources acting at the same time, ratio between the numbers of delta-like and pseudo-monochromatic signals, maximum-amplitude distribution). RANSOURCE output files serve as input files for FDSIM. FDSIM is designed for simulation of seismic ground motion in a viscoelastic half-space with 3D surface heterogeneities. It is based on the heterogeneous 4th-order displacement-velocity-stress staggered-grid finite-difference (FD) scheme. A realistic attenuation is included based on rheology of the generalized Maxwell body, and new definitions of anelastic functions and their memory-efficient spatial distribution. The adjusted FD approximation technique is used to model planar free surface. The effects of the parameters controlling the random space-time generation of noise sources for a homogeneous halfspace and single layer over halfspace will be shown and discussed. The source depth in particular is of crucial importance in case of 1D structures, for the composition of noise wavefield and the resulting H/V spectral ratio. Then, the effects of geometrical and mechanical parameters (velocity contrast, Poisson´s ratio, sediment thickness, sediment/basement interface geometry) will be discussed for a few selected canonical models of surface sedimentary structures.

GROUND MOTION MODELLING AND DAMAGE EARTHQUAKE SCENARIOS: A POSSIBLE BRIDGE BETWEEN SEISMOLOGISTS AND SEISMIC ENGINEERS

Giuliano Francesco PANZA[1], Luis DECANINI[3], Fabrizio MOLLAIOLI[3], Fabio ROMANELLI[2], Franco VACCARI[1] ([1]Department of Earth Sciences, University of Trieste and The Abdus Salam International Center for Theoretical Physics, SAND Group, [2]Department of Earth Sciences, University of Trieste, [3]Dipartimento di Ingegneria Strutturale e Geotecnica, University of Rome)

The input for the seismic risk analysis can be expressed with a description of ˝groundshaking scenarios˝, or with probabilistic maps of perhaps relevant parameters. The probabilistic approach, unavoidably based upon rough assumptions and models (e.g.

recurrence and attenuation laws), can be misleading, as it cannot take into account, with satisfactory accuracy, some of the most important aspects like rupture process, directivity and site effects. This is evidenced by the comparison of recent recordings with the values predicted by the probabilistic methods. We prefer a scenario-based, deterministic approach in view of the limited seismological data, of the local irregularity of the occurrence of strong earthquakes, and of the multiscale seismicity model, that is capable to reconcile two apparently conflicting ideas: the Characteristic Earthquake concept and the Self Organized Criticality paradigm. Where the numerical modeling is successfully compared with records, the synthetic seismograms permit the microzoning, based upon a set of possible scenario earthquakes. Where no recordings are available the synthetic signals can be used to estimate the ground motion without having to wait for a strong earthquake to occur (pre-disaster microzonation). In both cases the use of modeling is necessary since the so-called local site effects can be strongly dependent upon the properties of the seismic source and can be properly defined only by means of envelopes. The joint use of reliable synthetic signals and observations permits the computation of advanced hazard indicators (e.g. damaging potential) that take into account local soil properties. The envelope of synthetic elastic energy spectra reproduces the distribution of the energy demand in the most relevant frequency range for seismic engineering. The synthetic accelerograms can be fruitfully used for design and strengthening of structures, also when innovative techniques, like seismic isolation, are employed. For these reasons the skill of seismology to estimate realistic ground motions at a particular site should be fully exploited by seismic engineers. In fact, even if recently strong motion records in near-fault, soft soil, or basin conditions have been obtained, their number is still very limited to be statistically significant for seismic engineering applications.

SS04/07P/A03-002   1430
STRONG GROUND MOTIONS FOR SCENARIO EARTHQUAKES IN THE SAN BERNARDINO BASIN REGION, CALIFORNIA

Robert W. GRAVES (URS Group Inc.)

Due to its large population base, extensive built environmentand close proximity to active faults, the region in and aroundthe San Bernardino basin represents onethe highest levels of seismic risk in southern California.This basin is formed by the intersection ofthe San Andreas and San Jacinto faults, both of which are capableof generatingM$_w$ 7+ earthquakes, stressing the need for timely assessmentof the ground shaking hazard for future scenario earthquakes.Ground motion estimation is further complicatedby the highly variable nature of the subsurface geology.Sediment accumulations are relatively thin in the northernportion of the basin, and then steadily increase in thicknesstoward the south. The maximum sediment thickness is about 1.5km just north of the San Jacinto fault, with an abrupt step-upand shallowing of the basement surface across fault.Existing observations from both large (1999 M$_w$ 7.1 HectorMine) and small (2001 M$_w$ 4.7 Big Bear Lake) earthquakes showsignificant amplification and extended durations of shaking atrecording sites within the basin. Recent studies using 3Dnumerical simulation methods have modeled these recorded groundmotions in order to develop and constrain the 3D velocitystructure of the basin region. The current 3D velocity modelsdo reasonably well at matching the recorded waveforms at periodsof about 2 seconds and longer.To estimate the expected levels of ground shaking for futureevents in this region, I have performed 3D finite differenceground motion simulations for hypothetical M$_w$ 7 earthquakeson the San Andreas and San Jacinto faults. The simulationsuse the existing 3D structural models of the region andincorporate a suite of variable slip finite-fault rupture models.Preliminary results indicate that the largest longperiod motions occur when the ruptures propagate from thesoutheast (on either fault) toward and into the basin. Obviously,these rupture scenarios create strong forward directivity effectsin the basin region; however, these effects are further amplifiedby the trapping of energy within the basin sediments. It ispossible that this effect may be maximal for the M$_w$ 7 scenariosconsidered here due to the coincidence of directivity amplificationat 2-3 sec period with the strong basin response in this samebandwidth.

SCENARIO BASED STRONG GROUND MOTION MODELING IN ISTANBUL AND THE ADJACENT REGIONS

Nelson PULIDO[1], Anibal OJEDA[2], Kuvvet ATAKAN[3] ([1]Earthquake Disaster Mitigation Center (NIED, EDM), Miki, Japan, [2]INGEOMINAS, Bogota, Colombia, [3]Department of Earth Science, University of Bergen, Norway)

Following the disastrous earthquakes in Izmit and DAEce along the North Anatolian Fault in 1999, the earthquake hazard in the Istanbul area became a great concern. In this study we simulated the strong-ground motion in the Marmara Sea region with special emphasis in Istanbul. Simulations were based on an earthquake scenario in the Marmara Sea. Three fault rupture models were considered, including the Northern Boundary fault and the Central Marmara fault segments rupturing individually, in addition to a combined rupture of both. The input model was based on the geometry of the fault segments, size and location of the asperities along the fault plane, rupture initiation and propagation, rupture velocity and asperity rise-time. The available seismic reflection profiles in the Marmara Sea were used as a basis for constraining the geometry of the faults. We further considered the recently published stress-transfer element modelling results to constrain the location of the rupture initiation. The wave propagation was modelled through a flat-layered crustal velocity structure and regional attenuation function. The required fault rupture parameters were determined from empirical scaling to the seismic moment. We calculated the ground motion time series and spectra at Istanbul city and evaluated the variability of the predicted ground motion arising from different scenario earthquakes and fault rupture parameters. We identified the most critical scenario earthquake for the Istanbul region. In the simulation of the strong-ground motion, we have used a hybrid model combining a deterministic simulation of the low frequencies (0.1-1.0 Hz), together with a semi-stochastic simulation (i.e. empirical Green's function which uses stochastic element seismogram) of the high frequencies (1.0-10.0 Hz). We applied a high-frequency radiation model which uses a smooth transition between non-spherical to spherical wave radiation as the frequency increases. Computation at each frequency range was performed separately and the total ground-motion was combined in the time-domain. The estimated strong-ground motion is largely affected by the fault rupture parameters, such as the location of the rupture initiation, the rise-time and rupture velocity. The preliminary results give an insight of the complexity of the seismic hazard in Istanbul area. Our simulated ground motion shows large values of acceleration response spectra at long periods that could be critical to the building damage at Istanbul during an actual earthquake.

SCENARIO EARTHQUAKES FOR EMERGENCY RESPONSE AND PREPAREDNESS IN BEIJING URBAN REGION

Mengtan GAO, Yanxiang YU (Institute of Geophysics,China Seismological Bureau)

Scenario earthquake is a very important concept in earthquake disaster mitigation, especially

for the risk evaluation, hazard preparedness, and emergency response. In Megacities, which located in the earthquake prone region, the preparedness and emergency response of the event in the key of the countermeasures of earthquake disaster. Based on this understanding, the selection of the scenario earthquakes must consider the following factors: 1)The distribution of the potential sources surrounded the megacity; 2)The distribution of the active faults in and surrounded the megacity; 3)The historical earthquakes in and around the megacity; 4)The return period of the maximum magnitude of the potential sources; 5)The results of earthquake prediction for large earthquakes; 6)The basin effect of the strong ground motion. 7)The seismic design code used for construction. Beijing is a megacity, which located in the earthquake prone region. There were some strong events in the history. According to the above factors and the data of historical earthquake, the distribution of active faults, the delineation of potential source, the study of seismicity of the region, four scenario earthquakes were selected for the hazard preparedness and emergency response. The first scenario earthquke is Xiadian earthquake with magnitude 8, which locates in the east of the city, only 70 kilometers to the downtown; the second scenario earthquake is the fengtai earthquake with magnitude 7; the third scenario earthquake is the Summer Palace earthquake with magnitude 7; and the fourth earthquake is the Sunhe earthquake with magnitude 7.5. These three earthquakes are located in urban region of the Beijing cities. These scenarioearthquakes are critical for emergency response and preparedness of Beijing.

ACTIVE FAULTING AND GROUND SHAKING SCENARIOS ESTIMATES USING EXTENDED SEISMIC SOURCES AT THE ALPS-DINARIDES JUNCTION

Francesca FITZKO[1], Abdelkrim AOUDIA[2], Angela SARAO'[1], Peter SUHADOLC[1], Giovanni COSTA[1] ([1]Department of Earth Sciences, University of Trieste, [2]The Abdus Salam International Centre for Theoretical Physics, Trieste)

The identification and characterization of active faults as earthquake sources are essential parts of seismic hazard assessment studies. The area of the Alps-Dinarides Junction (NE Italy-Western Slovenia) is characterized by a very complex active deformation pattern and it has been struck in the past decades by the 1976 Friuli thrust-faulting earthquake (M 6.5) and by the 1998, Bovec-Krn Mountain strike-slip event (M 5.7). Active faulting data are used to define input fault models for computing realistic ground shaking scenarios, in the extended source approximation and for frequencies up to 1 Hz. For each fault model, we consider different nucleation points along the fault and both a uniform and a non-uniform seismic moment distribution. In this latter case, the seismic moment distribution is computed according with the K2 Model. We calculate ground motion parameters for a set of equally spaced receivers and we obtain contour maps. We validate our approach using the fault model proposed by Aoudia et al. (2000) for the 1976 Friuli earthquake, showing that our modeling and estimation of the seismic input at a specific site, when applied to different earthquake scenarios in its surroundings, can be a powerful, economically valid and easily applicable scientific tool for assessing its seismic hazard.

SS04/07P/A03-006   1530
SIMULATION OF STRONG GROUND MOTION IN METROPOLITAN MANILA, PHILIPPINES

Hiroaki YAMANAKA[1], Nobuyuki YAMADA[1], Chihoko KUMADA[1], Motoi TAKEZONO[1], Janila R. BAUL-DEOCAMPO[2], Robert B. TIGLAO[2], Bartlome C. BAUTISTA[2] ([1]Dept. of Environmental Sci. and Tech., Tokyo Institute of Technology, [2]Philippine Institute of Volcanology and Seismology)

Metro Manila is located in one of the high seismicity areas of the Philippines. It is needed prediction of strong ground motion for seismic disaster mitigation. The surface geology is characterized by three different topographical units, namely, coastal lowland, Marikina valley, and central plateau. The former two areas are covered with Quaternary low-velocity sediments, while the central plateau belongs to good soil area. For seismic risk mitigation, effects of site amplification factors should be taken into accounts. In this study, we conducted various geophysical explorations in the area for construction of a 3D geological model and strong motion simulation due to an anticipated near-by fault. First, borehole investigation and microtremor array exploration were conducted at several sites in Metro Manila, the Philippines. Thickness of soils and clays with SPT N-values less than 20 is about 20 meters at soft soil sites in Marikina plain and coastal lowland. Rock site was covered with basalt over thin weathered layer. Deep S-wave profiles were estimated from microtremor exploration. The thickness of deep sediments is about 2 km in the coastal lowland, while it reduces thickness in the Marikina plain. The amplification factors calculated from these data agree with the observed amplification estimated from strong motion data observed in strong motion network developed by our group (Kurita et al, 2000). Using these data with existing data, we constructed a 3D underground model for seismic simulations. Then, we estimate strong ground motion using FD method for some assumed earthquakes which have simple rupture source models. The results of simulations show large velocity over 100cm/s in the low-velocity area around the Manila city caused by directivity and site effect for the case of rupture start point from northern edge Western Valley Fault. We also simulate ground motion using rupture pattern of the 1995 Hyogo-ken Nanbu Earthquake, Japan.

SS04/07P/A03-007   1545
SIMULATION ANALYSIS OF GROUND MOTIONS IN KOBE CITY DURING THE 2000 TOTTORI-KEN SEIBU EARTHQUAKE USING 3D FINITE-DIFFERENCE METHOD COMBINING NONUNIFORM AND DISCONTINUOUS GRIDS

Masayuki NAGANO (Kobori Research Complex, Kajima Corporation)

This study describes 3D simulation analyses of strong ground motions in Kobe City during the 2000 Tottori-ken Seibu earthquake. Kobe is more than 300km from the epicenter, located near the edge of the sedimentary area of the Osaka plains. Modeling of large-scale soil is required to realize wave propagation from the epicenter to the Kobe area. A numerically efficient finite-difference technique combining nonuniform and discontinuous grids is applied for the 3D wave propagation analysis. The entire soil region is divided at particular depth into two regions modeled by different nonuniform grids. Grids in the bottom region for bedrock are coarser than the top region including sediments, which largely cut down on the number of grids. Calculating steps can also be reduced by introducing the longer time increments than the top region. The top and bottom regions have two overlapping grid layers to synchronize particle velocity by interpolating velocity in space and time with each other. Accuracy of the proposed technique is validated in several test cases. Length of modeling region is 216km, 324km and 101km for NS, EW and depth direction, respectively. The entire region is divided at the 3km depth into two different grid sizes. In the top region, a small area of the Osaka plains (minimum S-wave velocity is 0.5km/s) has grid spacing of 150m. The other top region and the whole bottom region have 900m grid spacing, 6 times that of the finer grids. Time step in each region is varied according to the minimum grid spacing, 0.009s and 0.054s for the top and bottom region, respectively. The bedrock structure in the Kobe area is realistically modeled considering the inversely inclined fault configuration inferred from the geological surveys. Total number of nonuniform and

S

discontinuous grids is about 20M, approximately one-third of only the nonuniform grids. The computational steps for calculation can be reduced to one-fifth by the coupling effects of the grid reduction and variable time steps, which allows us tolerable use of the moderate-class workstation. Three-dimensional analysis simulates well the velocity seismograms recorded in both mountain and sedimentary sites in the Kobe area. The snapshots of the velocity wave indicate that the wave front starting from the seismic fault impinges at the left Osaka plains and travels into the Kobe area as is largely amplified. The PGVs in sediments gradually amplify from the basin edge to Osaka bay, which can be commonly seen in both observed and synthetic motions. Special amplification did not occur in the ″heavily damaged belt zone″ during the 1995 Kobe earthquake. The source process during the 2000 Tottori-ken Seibu earthquake generated velocity pulses with a predominant period of 6s, which results in the different PGV pattern in Kobe City.

SS04/07P/A03-008   1615

STRONG MOTION PREDICTION FOR INLAND EARTHQUAKES IN FUKUOKA CITY AND KUMAMOTO CITY, JAPAN AND THEIR DAMAGE IMPACT

Hiroshi KAWASE, Arichika MASUDA (Dept. of Human-Environment Studies, Kyushu University)

First we extract statistical characteristics of seismic ground motions from K-Net records observed in the Kyushu region. We select ground motions for earthquakes with shallow depths (<60km) and moderate magnitudes (>4.5), observed within 200km from hypocenters. For the envelope characteristics first we express them by Boore's envelope function (Boore, 1983) and identify its model parameters. Then we express them as a function of the magnitude M and the hypocentral distance X using two step regression analysis. For the spectral characteristics we separate source, path, and site effects from the observed Fourier spectra and express them also as a function of M and X. We use them to predict strong motions for future large earthquakes through the so-called hybrid method, in which we combine the statistical Green's function method for high frequency range with the three-dimensional finite difference method (Graves, 1996) for low frequency range. Before to predict ground motions for a hypothesized earthquake we must test our method against the ground motions observed during a previous large earthquake. We apply the method to the Hyogo-ken Nanbu earthquake and show that our synthetic waveforms match well with the observed. Note that we use 1.75 Hz as a matching frequency since we use a source model that can represent very distinctive velocity pulses (Matsushima and Kawase, 1998). Then, we apply this method to hypothesized Fukuoka and Kumamoto earthquakes. In thess practical applications strong motions at the bedrock level are predicted first and then the strong motions at the ground surface are obtained by the 1-D wave propagation theory. We assume similar source scenarios as in Kobe. In case of Fukuoka City the maximum peak ground velocity (PGV) estimated reaches 130 cm/s at most, which is less than the PGV observed in Kobe. In case of Kumamoto City the maximum PGV reaches to 200 cm/s at the edge of the shallow Yatsushiro basin. From these simulations we emphasize the importance of both a detailed source rupture process and a three-dimensional basin structure for quantitative strong motion prediction.

SS04/07P/A03-009   1630

SYNTHESIS OF STRONG MOTION, ATTENUATION CHARACTERISTICS (CODA) AND ISOSEISMALS IN INDIAN REGION

Brijesh Kumar BANSAL[1], Hari Narayana SRIVASTAVA[2] ([1]Department of science and Technology, [2]India Meteorological Department)

Strong motion arrays and other strong motion instruments have brought out significant differences in the attenuation characteristics of peak ground acceleration in north-west and central Himalaya vis-a-vis north-east India and in the Koyna region. A few accelerogrpahs were also triggered due to the great Bhuj earthquake of 2001. These results have been interpreted in the light of coda attenuation characteristics based on digital seismographs and isoseismal patterns. The paper also discusses the methods used to synthesize expected ground motion parameters by random summation of the Green's function and the stochastic methods for different site conditions in Delhi due to a 'hypothetical' great earthquake (magnitude 8.0) in the central Himalayas. The results have been compared with the result derived from broad band digital data due to the great Bhuj earthquake, 2001. The divergent results due to simulation and other studies, however, could be attributed to the mechanism of earthquakes, the size and geometry of the source, the rupture velocity and the local site conditions. For more realistic earthquake hazard analysis, therefore, dense network of stations in the plains of northern India is required where several populated cities (with sky rise buildings) are located. Meanwhile, the usual methodology based on isoseismal patterns still appears to provide the simplest approach for this purpose due to the similarity in the isoseismal patterns of moderate and great earthquakes. Case examples of the Bihar Nepal earthquake 1988 (Magnitude 6.0) vis-à-vis great Bihar Nepal earthquake 1934 (Magnitude 8.0) and others support these inferences.

SS04/07P/A03-010   1645

LARGE SCALE PARALLEL 3D SIMULATION OF SEISMIC WAVE PROPAGATION AND STRONG GROUND MOTIONS USING THE EARTH SIMULATOR

Takashi FURUMURA (Earthquake Research Institute, University of Tokyo)

Recent development of high-performance computer in Japan, The Earth Simulator (5120CPUs, 40Tflops) at JAMSTEC Yokohama Institute, realizes realistic 3D simulation of seismic waves at relatively higher frequencies. We developed a hybrid parallel code for the large-scale parallel simulation of seismic wave propagation. The simulation model uses accurate Fourier spectral method (PSM) or higher-order staggered-grid FDM in horizontal coordinate system and a conventional 4th order FDM is used in vertical direction in order for parallel computing. The 3D model is divided into a number of subregions to assign to many processors, and each processor calculates the wave propagation in each region. The MPI inter-processor communications are done at each time step to exchange data between neighbor regions. In order to include the low-velocity superficial layer in the large-scale modeling, we combine a smaller grid model embedded over a large grid model. The wavefield in each model is connected accurately by an interpolation using the FFT. We implemented the multigrid, parallel, hybrid PSM/FDM code for strong motion simulations of large earthquakes in Japan, such as the 1944 Tonankai (M8), the 1946 Nankai (M8), the 1993 Kushiro (Mj7.8), and the 2000 Tottori-ken Seibu (Mj7.3) events. The scale of the simulation model varies from 260 million to 3.3 billion grid-points. The simulation took computer memory of about 64 to 365 GB, and CPU time of about 1 to 2 hours by parallel computing using 16 to 1024 processor of the Earth Simulator. A volume rendering technique is used to visualize the simulated wavefield, and the snapshots of ground motion at each time step are combined into a MPEG movie. The simulated wavefield are compared with the observation, in terms of the waveforms and the distribution of intensity patterns. The simulation results for the 2000 Tottori-ken Seibu earthquake can be also compared with the dense array recordings from the K-net and KiK-net, NIED, Japan, which are recently installed in Japanese island at almost uniform interval of about 15 to 20 km. We found a fairly good match between the simulation results and observation from dense array, which

indicates that it is now possible to estimate the rough pattern of ground motions expected for future earthquake scenarios.

SS04/07P/A03-011   1700

3D FINITE-DIFFERENCE SEISMIC MODELING - COMBINED EFFECTS BY HYBRID METHODS

Ivo OPRSAL[1], Johana BROKESOVA[2], Jiri ZAHRADNIK[2], Domenico GIARDINI[3] ([1]Swiss Seismological Service, ETH Zurich, Switzerland, on leave from Faculty of Mathematics and Physics, Charles University in Prague, Czech Republic, [2]Faculty of Mathematics and Physics, Charles University in Prague, Czech Republic, [3]Swiss Seismological Service, ETH Zurich, Switzerland)

Complex interactions resulting in the earthquake ground motions can be, inmany cases, efficiently modelled by hybrid methods. Our two-step hybridmethod combines an arbitrary 3D method evaluating the source and patheffects, and the 3D finite differences (FD) to incorporate the sitefeatures. In the 1st step we use ray, discrete wavenumber(DWN), or FD method to simulate the source and path effects in abackground regional structure. The regional model is considerably simplerthan the local structure which is absent in the 1st-step model.The complex local structure is enveloped in a formal box of receiverscalled ´excitation box´ (EB). The wavefield, due to the source and path,is recorded at EB and stored on a disk as so-called excitation. In the2nd step, the wavefield in a relatively small model containingonly the EB and its vicinity is computed. At this step, the local sitestructure is included inside the EB. The wavefield from the 1st step is injected at the EB into the 2nd-step model. The2nd step is based on 3D FD performing on irregular rectangulargrid. The FD approximation is of a second-order accuracy, the boundaryconditions at the material interfaces are approximated via treatment ofeffective (geometrically averaged) material parameters. The EB is fullypermeable in both steps and the result comprises all effects of thesource, path, and site. The computational cost and memory requirements aresignificantly reduced compared to the case of all-in-one FD method. In ourexamples, the 1st-step crustal structure is 1D and the sourceis represented by a point double couple. The free surface is non-planar,the example of a local structure is a modified Volvi-Lake site with Vp/Vs~ 4 and maximum ratio of the velocities Vp_{max}/Vs_{min}~ 10. The maximum frequency of the synthetics is 5Hz and the distance ofthe site from the source is ~ 10km. The comparison of the results for theray-FD, DWN-FD, and FD-FD hybrid solutions shows a very good agreement, inspite of the fact that the ray excitation contains less complete wavefieldthan the DWN and FD excitations. The whole 2nd-step FD modelingneeds only 6 hours on P3 1Ghz, and this makes the hybrid method aneffective and competitive tool for the earthquake ground motioncomputations.

SS04/07P/A03-012   1715

A THEORETICAL METHOD FOR COMPUTING NEAR-FAULT GROUND MOTIONSIN LAYERED HALF-SPACES CONSIDERING STATIC OFFSET DUE TO SURFACE FAULTING- WITH PHYSICAL INTERPRETATION OF FLING STEP AND RUPTURE DIRECTIVITY -

Yoshiaki HISADA[1], Jacobo BIELAK[2] ([1]Dept. of Architecture, Kogakuin University, [2]Department of Civil & Environmental Engineering, Carnegie Mellon University)

An efficient mathematical method is presented for computing the near-fault strong ground motions in a layered half-space, giving explicit consideration to the static offset due to surface faulting. The combined effects of ″fling step″ and ″rupture directivity″ on the near-fault ground motions are also investigated. When an observation point is close to the fault plane, Green´s functions exhibit near-singularities, which consist of extremely sharp peaks in a narrow band close to the observation point. Therefore, direct numerical integration becomes quite onerous for computing near-fault ground motions, because the dynamic Green´s functions must then be distributed very densely in order to evaluate accurately the effects of the near-singularities. Instead, a new form of the representation theorem is introduced, which exploits the property that the dynamic Green's functions can be approximated by the corresponding static Green's functions in the vicinity of the singularities. The modified theorem is the sum of two fault integrations. The first integration involves the difference of the dynamic and the corresponding static Green's functions, while the second contains only the static Green's functions. This formulation requires much less CPU time than the original one when near-fault ground motions are considered, because the near-singularities of the dynamic Green's functions in the first integration are completely eliminated by subtracting the static Green's functions. While the second integration does require a densely distributed set of points to capture the near-singular behavior of the static Green's function, it needs to be performed only once, as it is valid for all frequencies. Subtraction of the static Green's functions from the dynamic functions has the added benefit of making the integration over the wavenumber in the determination of the Green's functions much more efficient, especially for considering surface faulting. The proposed methodology is used to investigate the physics of the fling step and rupture directivity. The fling effects stem mainly from the second integral in the modified representation theorem, which involves the static Green´s function. The fling effects are dominant in the slip direction only in the vicinity of the surface fault, and are negligible for buried faults, because the static Green's function attenuates rapidly with distance from the fault, r, as O (1/r2). Also, more importantly, when an observation point is located above a buried fault, the medium has to remain continuous, and thus cannot ″fling″. By contrast, the directivity effects stem mainly from the first integral, which involves the dynamic Green´s function, and attenuate much more slowly than the fling, on the order from 1/r to 1/squared r . The directivity effects are dominant in the fault normal direction, especially in the forward rupture direction, not only for the surface fault, but also for the buried fault. When softer surface layers are added to the medium, the directivity effects become more significant than the fling effects, because the dynamic Green´s functions are more pronounced than the static ones.

SS04/07P/A03-013   1730

3-D MODELING OF SEISMIC GROUND MOTION PROPAGATION IN THE KANTO BASIN, JAPAN

Kazuki KOKETSU, Kazuki KOKETSU, Afnimar, Takashi FURUMURA (Earthquake Research Institute, University of Tokyo)

The pattern of ground motion for a magnitude 5.7 earthquake near Tokyo, Japan was captured by 384 strong ground motion instruments across the Kanto sedimentary basin and its surroundings. Koketsu and Kikuchi (2000) visualized the propagation of long-period ground motion in the basin using the records, and show the refraction of surface waves at the basin edge.We construct a 3-D model of the Kanto basin based on the result of Afnimar et al. (2003) and simulate seismic ground motion propagation using a hyibd PSM/FDM method. We then compare resultant seismograms and propagation images to the above observations. The 3-D model is repeatedly revised to improve the agreement between the simulations and observations.

SS04/07P/A03-014 1745

THREE-DIMENSIONAL SIMULATION OF SEISMIC MOTIONS IN THE NORTHWESTERN CHIBA PREFECTURE, JAPAN

Sadanori HIGASHI, Hiroaki SATO (Geotechnical & Earthquake Engineering Department, Central Research Institute of Electric Power Industry)

Three-dimensional seismic simulation was carried out in the northwestern Chiba Prefecture, Japan, based on the results of geophysical survey conducted by Chiba Prefecture. The calculated waveforms were compared with the observed records derived from the seismometers installed by Chiba Prefecture. The model, which is 29.4km(NS) by 24km(EW) in dimensions, consists of three sedimentary layers (Shimohsa, Kazusa, and Miura formations) and a seismic basement. P-wave velocities are 1.7, 2.2, 2.9, and 5.7 km/s, while S-wave velocities are 0.45, 0.9, 1.5, and 3.0 km/s, respectively. The upper boundary of the seismic basement tends to deeper in the southern area. The deeper part beneath the seismic basement (Vs3.0km/s) was modeled based on Sato et al.(1998). A hybrid pseudo-spectral method / finite difference method parallel simulation with discontinuous grid spacing was used for the seismic simulation. The model was divided into four in the vertical direction. The grid spacing in the horizontal direction was 160m, while that in the vertical direction was 80, 80, 160, and 320m, at each subdomain. Data exchange between the adjoining subdomains are carried out by using MPI (message passing interface) library. The maximum frequency was 1.25Hz and the time increment is 0.005s. Firstly, we simulated an earthquake occurred in the calculated region (M4.6, depth=71km). We used a point source with the source mechanism derived from F-NET (National Research Institute for Earth Science and Disaster Prevention, NIED) and the Herrmann´s pseudo-delta function with a time width of 1.0s as a source time function (moment rate function). The velocity amplitude of calculated waveforms were in good agreement with that of observed records in the northern area, while those in the southern area were underestimated in the simulation. The calculated peak ground velocity in the southern part was smaller than that in the northern part. Secondly, a case of plane wave incidence was calculated for an earthquake of M5.1 (depth=67km). The incident wave at the upper boundary of the seismic basement was derived from the borehole data that located in the seismic basement in the area (Shimohsa deep borehole observation station by NIED). Qs in the sedimentary layers were determined as Qs=Vs/42 by fitting the spectral ratio of surface to borehole data. The results showed that the simulated peak ground acceleration was in good agreement with observed one in the northern part, while that simulated was underestimated in the southern part. As the earthquakes used in this study were deep and small, it is probable that seismic motion at a rather long-period (2-10s) did not predominate and the effects of 3-D irregularity of the interfaces was not so obvious in the simulation.

THE CHARACTERISTICS OF STRONG GROUND MOTIONS IN NEAR SOURCE

Guoxin WANG, Hongnan LI (Earthquake Engineering Research Institute, Department of Civil Engineering, Dalian University of Technology)

Strong ground motion in near source is a very complex problem and has been paid more attention by engineers and seismologists around the world. The most important problem is how to predict the ground motions accurately for the future events. To solve this problem, the successful simulation to the motions of the past events is the essential step, which can verify the validities of different predicting methods proposed by some researchers. The characteristics of near source strong ground motions are analyzed in this paper. First, we propose an improved finite source stochastic method based on seismology and ground motion database to simulate the strong ground motions of past events in near source, and certify the efficiency of this method by comparing the predicted ground motion parameters with recorded ones by trail and error, and then we utilize the predicted results to analyze the ground motion characteristics in near source to understand the so-called saturation phenomenon and attenuation rate in near source, especially the affections of fault plane parameters, such as fault size, orientation, slip distribution, to the motions. The results of this paper prove that the suggested method is valid for not only moderate events but also strong earthquakes, and the ground motion characteristics in different orientations of fault plane can be indicated fully.

SS04/08A/A03-002 0845

THE ATTENUATION OF STRONG GROUND MOTION IN TERMS OF INPUT ENERGY

Mao-Sheng GONG, Li-Li XIE (Institute of Engineering Mechanics China Seismological Bureau)

The disaggregation and probabilistic seismic hazard calculations based on input energy may prove useful for the identification of scenario event because input energy is a convenient single-parameter descriptor of strong ground motion duration and amplitude. Based on 266 strong ground motion records (two horizontal components and a vertical component are included in each record) from 15 significant earthquakes in California of America, an attenuation relationship was developed for ground motion input energy spectra with earthquake magnitude, source-to-site distance, and site class. All the records are examined and classified into three site categories. For each horizontal component of one record, two kinds of input energy equivalent velocity, absolute input energy equivalent velocity ($V_a=(2E_a/m)^{1/2}$, where E_a=absolute input energy, m=mass) and relative input energy equivalent velocity ($V_r=(2E_r/m)^{1/2}$, where E_r=relative input energy, m=mass), were calculated for 4 ductility levels (μ=1,2,4 and 6) and one damping ratio (ξ=5%), in the period range 0.1 to 3.0 second. The geometric mean of the two horizontal components for each kind of input energy was used in a two-stage non-linear regression method. The effect of parameters such as magnitude, site class and ductility factor on the input energy spectra constructed from the attenuation relationship was discussed. It is found that the site class has a significantly effect on both absolute and relative input energy, the input energy (including both absolute and relative input energy) for soft site class is much higher than that for stiff site class. The two kinds of input energy spectral increase rapidly with the increasing of earthquake magnitude and attenuate quickly with the increasing of distance, so, larger magnitude earthquakes contribute more to seismic hazard if V_a or V_r is used. The effect of the ductility is very different for the input energy spectra constructed from the attenuation relationship with the change of periods. When the period of single-degree-of-freedom (SDOF) oscillator is less than 0.5 second, the input energy increases with the increasing of ductility factor, on the contrary, the input energy decreases with the increasing of ductility factor when its period is larger than 0.5 second. Moreover, the effect of ductility on the relative energy spectra in the short period range (say, less than 0.5 second) is much larger than that on the absolute energy spectra. After comparison of the two kinds of energy spectra constructed from the attenuation relationship, it is found that the absolute energy is some larger than relative energy in the short period range and some less than relative energy in long period range, and they are almost equivalent at the period about 0.5 second. Finally, it

is shown that the attenuation relationship developed in this paper would underestimate the input energy demand produced by a near-field strong ground motion because little number of near-field ground motion records data were used in the paper.

STUDY ON THE SEVEREST REAL GROUND MOTION FOR SEISMIC DESIGN AND ANALYSIS

Chang-Hai ZHAI[1], Li-Li XIE[2] ([1]School of Civil Engineering, Harbin Institute of Technology, [2]Institute of Engineering Mechanics, China Seismological Bureau)

In the seismic analysis and design, the real strong ground motions are usually selected as the seismic inputs to structure. How to select the adequate real strong earthquake ground motion for seismic analysis and design of structures is logically an essential problem in earthquake engineering research and practice. For the seismic design and structure analysis, especially for the huge complex structure, one of the most important tasks is selecting the proper real ground motion for design. The idea of selecting the severest design ground motion is presented in this paper. The severest design ground motion should be selected from the existing strong earthquake ground motion that can drive the structure to its critical response and thereby result in the highest damage potential. At present, the EL CENTRO record (NS) of 1940 and TAFT record of 1952 are in the first place to be considered in the seismic design and structure analysis. However the rationality of such selection is not sufficient. For example, the study (Naeim and Anderson, 1993) has shown that the EL CENTRO record (NS) of 1940 is far from severest ones, and its peak acceleration (PA), peak velocity (PV), peak displacement (PD), effect peak acceleration (EPA), effect peak velocity (EPV) and duration are 338cm/s/s, 45cm/s, 10.88cm, 290cm/s/s, 30.77cm/s and 9.3s respectively, which only rank as the 81, 87, 49, 99, 62 and 58 place in a database that consists of more than five thousand significant strong ground motion records collected over the world. Evidently, whether the records should be considered as the severest design ground motion is a problem that ought to be further thought over. The concept of the severest design ground motion is presented in the paper. A comprehensive method for estimating damage potential of ground motions is developed in this paper and it has been used in selecting the severest design ground motion. The severest design ground motions corresponding to four different classes of site condition and three different period ranges of structure are attained. The three period ranges of structure are long period range (1.5-5.5s), middle period range (0.5-1.5s) and short period range (0.0-1.5s). At the end, the validity and reliability of the severest deign ground motions are verified preliminary by several numerical calculations.

SS04/08A/A03-004 0915

3D FINITE DIFFERENCE SIMULATION WITH IRREGULAR TOPOGRAPHIC SURFACE

Wei ZHANG, Xiaofei CHEN (Department of Geophysics, Peking University)

3D staggered-grid finite difference method is the most popular method in simulation of seismic wave propagation in complex media, in which the treatment of free surface boundary condition plays an important role to numerical computational stability and result accuracy. It's easy to implement a planar free surface boundary in two ways: the first is vacuum method, which can be easily implemented but only stable for second order in space. The second is zero-stress formulation, which explicitly satisfies the zero-stress condition in both stress and velocity components at the free surface and can get perfect result. For irregular topographic surface, there are also two widely used methods: Firstly, the vacuum method in which 3D topography is discretized in a staircase grid, then vacuum free surface with second order finite difference scheme is applied (Ohminato, 1997). However, in this method the free-surface condition in corners cannot be exactly satisfied, is only approximated (Robertsson, 1996; Hayashi, 2001). Secondly, the coordinate mapping method (Tessmer, et al. 1992; Hestholm & Ruud, 1994,1998), in which only curved grids in vertical direction are transformed to planar grids. In this method, velocity components can satisfy the free surface condition, but stress components not. In this study, we use adaptive grid generation method to generate the grids satisfying following conditions: (1) in the area of the free surface, all vertical grids are normal to the free surface, the horizontal grids are coincide with the free surface; (2) in the inner area, we try to keep the grids' smoothness and orthogonality. In such discretized grids scheme, we can implement explicit zero-stress free surface boundary condition to the irregular topographic surface, thus guarantee an accurate free surface condition is satisfied. Using this improved 3D staggered-grid finite difference method, we simulate the seismic wave propagation in a complex basin structure.

SS04/08A/A03-005 0930

NUMERICAL SIMULATION OF STRONG MOTION AROUND ADAPAZARI BASIN DURING THE1999 KOCAERI EARTHQUAKE, TURKEY

Hiroyuki GOTO[1], Sumio SAWADA[1] ([1]Disaster Prevention Research Institute, Kyoto University,Gokasho, Uji, Kyoto 611-0011, JAPAN, [2]Department of Civil and Architectural Engineering, College ofEngineering, Drexel University 3141 Chestnut Street, Philadelphia, 19104, [3]Department of Civil Engineering, Kanto-Gakuin University1-50-1 Mutsuura-Higashi, Kanazawa-ku, Yokohama 236-8501 JAPAN)

The Kocaeli Earthquake of August 17, 1999 (Mw 7.4) brought destructive damage to Adapazari, Turkey. The area most severely damaged was downtown Adapazari and located 8-10km away from the ruptured fault; whereas, the damage was only moderate or even light near the sourcefault. This implies that the deep ground structure may affect thedistribution of strong ground motions, as we have already observed on1995 Hyogoken-nanbu (Kobe) Earthquake, Japan. Several surveys have been performed to obtain information of subsurface structure around Adapazari. The 3-dimensional shape of the bedrock around this area has been reported, based on gravity anomaly data, and verified by the analysis for array and single-site observations of microseisms. We, however, did not obtain the detailed velocity structures which were necessary to simulate strong ground motions inthe basin. The seismic refraction and reflection survey were carried out to determine the velocity structure of the basin. Two seismic shots were detonated at northern and southern edges of the Adapazari Basinon June 14 and 16, 2002. The artificial seismic waves werecollected at 80 sites along a 16km-long profile, which traversed thebasin in approximately a N-S direction; although almost half of the instruments failed to record the ground motions due to several reasons. A model was made for the subsurface structure of the basin. The velocity structure at the seismic profile was estimated through a gravity anomaly analysis and refraction and reflection waves generatedby the seismic shots. The estimated 2D model consists of three soiland two rock layers. The 2D model was then extended to a 3D model which is represented by a cubic B-spline function, which is based on the gravity data. The modeled structure shows narrow depressions of bedrock with very steep edges around the downtown of Adapazari. Thedepression runs in a E-W direction along the North Anatolia faults,and the depth to the bedrock reaches more than 1000m. Finally, the strong ground motions, simulated numerically for the main shock, were demonstrated to be in the frequency range of up to 0.4 Hz using the 3D finite-difference methods. The source model proposed by Sekiguchi and Iwata (2002) was used for thenumerical simulation. The calculaion

successfully simulated thewaveform observed at SKR (Sakarya) during the main shock. The results of the simulation show that the ground motions were significantlygreater at downtown Adapazari in comparison to the region between thedowntown and the seismic fault. Furthermore, it was observed that the maximum velocity may be reduced to one-third the value obtained through our model of ground structure, if horizontal layered mediums are modeled around the downtown Adapazari.

MICROZONATION AND SITE-SPECIFIC GROUND MOTION MODELLING FOR DELHI CITY

Imtiyaz Ahmed PARVEZ[1], Franco VACCARI[2], Giuliano Francesco PANZA[3] ([1]CSIR Centre for Mathematical Modelling and Computer Simulation (C-MMACS), [2]Department of Earth Sciences, University of Trieste, Via E. Weiss 4, 34127 Trieste, Italy AND INGV, Instituto Nazionale di Geofisica e Vulcanologia, Naples, Italy, [3]Department of Earth Sciences, University of Trieste, Via E. Weiss 4, 34127 Trieste, Italy AND The Abdus Salam International Centre for Theoretical Physics, SAND group, Trieste, Italy)

Delhi, the capital of India lies on a severe earthquake hazard threats not only from the local earthquakes but also from Himalayan events just 200-250 km apart. The seismic ground motion in a part of Delhi City is computed with a hybrid technique based on the modal summation and the finite difference scheme for site-specific strong ground motion modelling. Complete realistic SH and P-SV wave seismograms are computed along two geological cross-sections, (1) North-South, from Inter State Bus Terminal (ISBT) to Sewanagar and (2) East-West, from Tilak Bridge to Punjabi Bagh. Two real earthquake sources of July 15, 1720 (MMI=IX, M=7.4) and August 27, 1960 (M=6.0) have been used in modelling. The response spectra ratio (RSR), ie the response spectra computed from the signals synthesized along the laterally varying section normalized by the response spectra computed for the bedrock reference regional model, have been determined. As expected, the sedimentary cover causes an increase of the signal amplitude particularly in the radial and transverse components. To further check the site-effects, we reversed the source location to the other side of the cross-section and re-computed the site amplifications. There are only a few sites where a large amplification is invariant with respect to the two source locations considered. The RSR ranges between 5 to 10 in the frequency range from 2.8 to 3.7 Hz, for the radial and transverse components of motion along the NS cross-section. Along the EW cross-section RSR varies between 3.5 to 7.5 in the frequency range from 3.5 to 4.1 Hz. The amplification of the vertical component is large at high frequency (> 4 Hz.) whereas it is negligible in lower frequency range.

SS04/08A/A03-007   1000

ON PRECISION OF S-WAVE VELOCITY STRUCTURE DETERMINED BY THE SPATIAL AUTO-CORRELATION METHOD USING MICROTREMORS

Seiji TSUNO[1], Kazuyoshi KUDO[1], Tatsuo KANNO[2] ([1]Earthquake Research Institute, The University of Tokyo, [2]National Research Institute for Earth Science and Disaster Prevention)

Conventional methods for determining shear wave velocity structure generally require active control sources, such as in PS logging, reflection/ refraction surveys, and surface wave inversion using shot-records. These methods are costly in general and sometimes meet difficulties in urban area for practical uses. The array observation of microtremors provides a good estimate of the S-wave velocity structure with relatively low cost. The efficiency of the Spatial Auto-Correlation method applied to microtremors has mostly been verified for deep underground structures. However, the precision and guideline of the SPAC method are not sufficient to extend and apply in the field of engineering seismology and earthquake engineering. The primary object of us is to understand the precision and/or limitation of the SPAC method for practical use. We carried out array observations of microtremors at 7 sites, where the underground structures have already been determined by the other methods. The S-wave velocity structures determined by this method gave good agreements with the geological interfaces determined by PS logging, reflection survey and the inversion results for spectral ratios of downhole array records. We postulated that the S-wave velocity increases gradually with depth in the inversion procedures from Rayleigh wave dispersion to S-wave velocity structures, for simplicity. This approximation is certainly difficult to estimate details of the interface of layer and its velocity, however, the site amplification and dominant period of earthquake ground motion are well assessed by the structure model. The reason will be that the approximation gives an equivalent S-wave velocity structure with sufficient fitting of the observed dispersion to that of Rayleigh waves, even if we neglect high and/or low velocity layers interposed between a surface layer and a half-space. We compared the optimized S-wave velocity structure model that was determined by spectral ratios of downhole array strong motion data with the initial model determined by the SPAC method. A good agreement of the site amplification in the lower frequency than 5 Hz was also obtained without any exceptions. The differences of a velocity and a thickness of layer between initial and optimized models were mostly less than 10% from the optimized. Therefore, we may conclude that the SPAC method using microtremors has sufficient precision for applying to site characterization purposes. The level of the precision is not inferior to that of PS logging data. In addition, we also examined that the SPAC method works well for determining deep underground structure using microtremors of longer period than 1 sec. rather than shallow structure using higher frequency than 1 Hz. We found that observable wavelengths by this method were larger than 3.5 times of array radius (R) and smaller than 11R in average.

SS04/08A/A03-008   1015

BOOTSTRAP RESAMPLING FOR IMPROVEMENT IN THE NONPARAMETRIC SEISMIC HAZARD ESTIMATION

Beata ORLECKA-SIKORA (Department of Geophysics, Faculty of Geology, Geophysics and Environmental Protection, University of Mining and Metallurgy)

The cumulative distribution function (cdf) of magnitude is essential for the probabilistic seismic hazard analysis. The magnitude distributions are usually drawn from the Gutenberg-Richter relation or its smooth modifications. Such distributions are log-linear or at most smoothly non-linear. In practice, however, the observed frequency-magnitude relations can exhibit a multi-component structure. In non-linear cases the assumption of a simple Gutenberg-Richter based distribution is frequently inadequate and can generate unpredictable hazard errors. In order to remedy the problem a model-free, non-parametric approach to characterise the source size has been postulated. The approach proved to be effective in the mean value for both simple and complex magnitude distributions. In practical studies one has in hand only one data sample. Thus in place of the mean cdf estimate only one sample estimate is obtained. Inevitable differences between the actual cdf and its one-sample estimate result in hazard errors of unknown percentage. In order to improve the non-parametric estimation of the magnitude cdf the use of the bootstrap resampling method is proposed. A bootstrap sample is a set of items drawn uniformly from the original data sample with replacement, such that its size equals the size of the data sample. The resampling procedure performed on the real sample provides a number of data samples that have asymptotically the same properties as the real data. The bootstrap samples are then used to

reconstruct the distribution of error of the magnitude cdf estimate. This distribution is used to correct the cdf estimate for the bias and to evaluate the cdf confidence intervals. The approach has been tried on Monte Carlo generated data of given population distributions, namely mixtures of the Gutenberg-Richter born and normal distributions, which imitate non-linear magnitude distributions that can be met in practice.

SS04/08A/A03-009   1045

DYNAMIC SOURCE PARAMETERS AND CHARACTERIZED SOURCE MODEL

Tomotaka IWATA[1], Haruko SEKIGUCHI[2], Hiroe MIYAKE[1], Wenbo ZHANG[1], Ken MIYAKOSHI[3] ([1]DPRI, Kyoto University, [2]AIST, GSJ, [3]Geo. Res. Inst.)

Somerville et al. (1999) characterized source slip models inverted from strong motion records for mainly California events. They introduced a criterion to extract rectangular-shaped asperities that an asperity consists of fault elements with final slips larger than 1.5 times of the average over an entire fault. They found that total area of asperities follows a scaling relation to seismic moment. Recent events such as the 2000 Tottori-ken Seibu (Mw6.6), Japan, the 1999 Chichi (Mw7.6), Taiwan, and Kocaeli (Mw7.4), Turkey, and some moderate-size crustal earthquakes in Japan were shown to follow the relation (Miyakoshi et al., 2000, Miyake et al., 2001). Irikura and Miyake (2001) proposed characterized source model based on this scaling relation in a RECIPE for strong motion prediction. The availability of the characterized source models has been proved through the strong motion simulation in near-source area in the broadband frequency band (BB) for the 1995 Kobe (Kamae and Irikura, 1997) and for the 1997 Kagoshima-ken Hokuseibu (Miyake et al., 1999) earthquakes. However, in those simulations, they estimated stress parameters only for the asperities by forward simulation of the high frequency contents of the records. When constructing a characterized source model for BB strong motion, we need rules to set stress parameters. Bouchon (1997) proposed a mapping method of a spatio-temporal shear-stress distribution on the fault plane from a spatio-temporal slip distribution. We examined dynamic source parameters such as stress drops, Dc (critical distance), and Gc (surface fracture energy), by his method for the 1999 Chichi, and the 2000 Tottori-ken Seibu earthquakes (e.g. Zhang et al., 2001). Dynamic parameters averaged over on- and off-asperity areas are estimated from a viewpoint of characterized source model. For the both events, average effective stress values of on-asperity areas, that were estimated to about 20MPa and 10MPa, respectively, which coincide with the ones that were used for forward ground motion modeling (e.g. Ikeda et al., 2002, Kamae and Irikura, 2001). Average effective stress value in off-asperity area was estimated about 1-5MPa. Those values both on- and off - asperity area obtained here can constrain the characterized source model parameters.

SS04/08A/A03-010   1100

BROADBAND SOURCE ASPERITY MODEL OF THE 2000 TOTTORI EARTHQUAKE (JAPAN) FROM A NONLINEAR INVERSION OF NEAR-FAULT GROUND MOTION

Nelson Edilberto PULIDO[1], Tetsuo KUBO[2] ([1]Earthquake Disaster Mitigation Research Center EDM, NIED, [2]Dept. Architecture, Nagoya Institute of Technology, Nagoya, Japan)

The large amount of near-fault strong motion data recorded during the 2000 Tottori earthquake, provides a unique opportunity for investigating a source asperity model of the Tottori earthquake that combined with a hybrid strong motion simulation technique, are able to reproduce the observed broadband frequency near-fault ground motion.We investigated the optimum source asperity and high frequency attenuation parameters of the Tottori earthquake, by applying a Genetic Algorithm (GA) inversion scheme to optimise the fitting between simulated and observed acceleration response spectra and PGA values of near-fault ground motion. We constrained the initial model of our inversion by using the heterogeneous slip distribution obtained from a kinematic inversion of the source of previous studies. We used all the observed near-fault ground motions (-100m) from the borehole strong motion network of Japan (KiK-Net). The calculation of broadband frequency strong ground motion (0.1 to 10Hz) is achieved by applying a hybrid technique that combines a deterministic simulation of the wave propagation for the low frequencies and a semi-stochastic modelling approach for the high frequencies. For the simulation of the high frequencies we introduce a frequency dependent radiation pattern model that efficiently removes the dependence of the pattern coefficient on the azimuth and take-off angle as the frequency increases. The good agreement between the observed and simulated broadband ground motions shows that our inversion procedure is successful in estimating the optimum asperity parameters of the Tottori earthquake, and provides a good test for the strong ground motion simulation technique.The ratio of background stress drop to average asperity stress drop from our inversion is nearly 50%, in agreement with the theoretical asperity model of Das and Kostrov (1986), and an empirical ratio of asperities to rupture area (Somerville et. al 1999). We obtained an attenuation value for the Tottori earthquake near-fault region of $Q(f) = 146f^{0.67}$. Our results suggest that the effect of downgoing S-waves completely disappears at the borehole depth.A forward ground motion simulation from the optimum asperity model shows that the strong motion radiation towards the North-West of the epicenter is larger than the radiation towards the South-East, despite most of the seismic moment within asperities was released towards the South-East. A possible explanation is that in the vicinity of the fault, S-wave radiation from the shallow slip North of the epicenter is more efficient than the radiation from the deeper slip South of the epicenter, as inferred from the radiation pattern coefficient distribution within asperities. The simulated PGA values have a weaker dependence on the radiation pattern compared with the PGV values, in the near-fault region. The simulated radiation pattern at 1 Hz is very complex for epicentral distances within half the fault length but it approaches the radiation of a double-couple point source for larger distances.The rupture velocity and rise time have a significant influence on the PGV distribution around the fault. An increase in rupture velocity produces a similar effect on the ground motion as a reduction in rise time.

SS04/08A/A03-011   1115

EARTHQUAKE SOURCE AND GROUND MOTION CHARACTERISTICS OF THE JUNE 23, 2001 MW 8.4 AREQUIPA, PERU EARTHQUAKE

Paul Graham SOMERVILLE, Hong Kie THIO, Gene ICHINOSE, Nancy COLLINS, Arben PITARKA, Robert GRAVES (URS Corporation)

The June 23, 2001 Mw 8.4 Arequipa, Peru Earthquake ruptured a 400 km length of the interface between the Nazca and South American plates, extending from Atico to Ilo. This is the largest earthquake for which strong motion recordings have been obtained. We derived a rupture model of the earthquake from the inversion of teleseismic and regional body waves and surface waves. Most of the slip occurred in the offshore region, with a large asperity offshore from Mollendo. This rupture model is compatible with geodetic measurements in Arequipa, the slight sea level rise at Matarani, and tsunami waveforms recorded in Peru and Chile. Strong motion recordings were obtained in Moquegua, Peru and at seven stations in northern Chile, including three in Arica. The response spectra of the strong motion recordings lie between the median and 84th percentile level of empirical ground motion models. We attribute these unusually large ground motions to the effect of southwesterly rupture propagation from the epicenter near Arica toward southern Peru and northern Chile.

The ground motions recorded on soil sites in northern Chile exceeded the elastic design spectrum of the 1996 Chile building code for soil type II, although these sites are 90 km or more from the southeastern end of the earthquake rupture zone. Broadband ground motion simulations using our rupture model of the earthquake produced a good fit to the recorded ground motions, with no significant bias and a standard error of a factor of about 1.5.

SS04/08A/A03-012   1130

SEISMIC ENERGY DISTRIBUTION ON THE FAULT PLANES OF GREAT INTERPLATE EARTHQUAKES OCCURRED ALONG THE NANKAI TROUGH REPEATEDLY DURING 300 YEARS

Katsuhisa KANDA[1], Masayuki TAKEMURA[1], Tatsuo USAMI[2] ([1]Kajima Corporation, [2]non)

Three great earthquakes (the Showa in 1944 and 1946, the Ansei in 1854, and the Hoei in 1707) have occurred since about 300 years ago in the both of the Tokai and Nankai areas along the Nankai trough in southwestern Japan, where the Philippine Sea plate is subducting beneath the Eurasian plate. The Showa and Ansei earthquakes consisted of two events occurring separately in the both areas of Tokai (Tonankai) and Nankai at a short interval. The fault rapture of the Hoei earthquake took place in the both area at the almost same time. The next occurrence of the Tokai and Nankai earthquakes are predicted early in the 21st century. It is quite important for the estimation of future earthquakes to investigate the fault mechanisms of historical earthquakes. However, there is no geodetic, tsunami, and strong motion data for waveform inversion analysis except in case of most recent events, the Showa earthquakes. On the contrary, there is much seismic intensity data evaluated from seismic damage records for old earthquakes. The inversion analysis has been developed to evaluate the distribution of seismic energy radiated from an earthquake fault plane using the seismic intensity data and applied to the great interplate earthquakes occurring along the Nankai trough. The result of the inversion shows that large energy sub-faults, which generated short period seismic waves related to the seismic intensity data, are located as to avoid the large slip of sub-faults obtained from the tsunami waveform inversion for the Showa earthquake. Though the locations of sub-faults radiating large energy in case of the Hoei earthquake are similar to those of the Showa earthquake in Tonankai area, there is some discrepancy in Nankai area between the Hoei and Showa earthquakes. A portion of the large energy sub-faults of Hoei earthquake locates on a subducted seamount off Cape Muroto, where there is little energy radiation at the Showa and Ansei earthquakes. Kodaira et al. suggested that the subducted seamount might play a role of the barrier to the propagation of fault rapture at the Showa earthquake. We suggest that the similar rupture process might occur at the Ansei earthquakes, but the accumulated stress at the subducted seamount might be released at the Hoei earthquake. It is deduced from this result that the intensity of radiated short period seismic waves was very high in case of the Hoei earthquake. It can be also suggested that ground motions during the next earthquake may be hazardous, if the fault rapture propagates through the subducted seamount like the Hoei earthquake. Reference: Kodaira et al., 2002, Structural factors controlling the rupture process of a magathrust earthquake at the Nankai trough seismogenic zone, *Geophys. J. Int.* **149**, 815-835

SS04/08A/A03-013   1145

SOURCE MODEL OF THE 1979 IMPERIAL VALLEY EARTHQUAKE ESTIMATED FROM STRONG-MOTION WAVEFORMS, WITH NEW GEOTECHNICAL DATA

Ken MIYAKOSHI[1], Kazuyoshi KUDO[2], Tomotaka IWATA[3], Rikiro KIKUCHI[4], Yasuhiro OHTSUKA[5], Susumu OHNO[5] ([1]Geo-Research Institute, JAPAN, [2]Earthquake Research Institute, University of Tokyo, JAPAN, [3]Disaster Prevention Research Institute, University of Kyoto, JAPAN, [4]Nuclear Power Engineering Corporation, JAPAN, [5]Kajima Corporation, JAPAN)

It is one of a key issue to use appropriate velocity structures or to give a well-tuned Green´s function for estimating source model in the shorter period than the previous researches. Simultaneous array microtremor measurements to estimate an S-wave velocity structure up to about several km depth are well developed (e.g. Horike, 1985; Okada et al, 1990) and the obtained velocity structures were validated through comparing the transfer function from the structure with the one from observed seismic waves (e.g. Tsuno et al, 2002). The target event in this study is the Imperial Valley (Mw6.4) earthquake of 1979. First, array observations of microtremors were conducted at two sites of both west and east sides of the Imperial fault near El Centro, southern California. Each array consists of 7 vertical seismometers with several radii of less than 3.0km. The spatial autocorrelation (SPAC) method (Aki, 1957) was applied to microtremor data to obtain frequency-dependent phase velocity. S-wave velocity models were then derived from modeling of phase velocity assuming the fundamental-mode of Rayleigh waves by the genetic algorithm (GA). The observed phase velocities are dispersive from 2 to 6s at east side, from 0.3 to 5s at west side. The obtained model at the west side of the fault shows the basement with an S-wave velocity of 3.2 km/s at about 5.0 km deep, whereas about 6.0 km deep at the east side. The shallow velocity structures of 0.2 to 0.3km depth at 11 strong-motion observation sites were also estimated by the well-logging. Using these new geotechnical data we modeled 1D-velocity structures for each strong motion sites. Next, we conducted source inversion of the 1979 Imperial Valley earthquake using strong-motion data whose underground structures are obtained above. We applied the multiple time-window linear waveform inversion method (Hartzell and Heaton, 1983) for the analysis. The recorded acceleration data were integrated into velocity and band-pass-filtered between 1.0 and 10.0s. Because of the lack of absolute time on observations, we set to shift the synthetics to match the S-wave onset of observation and synthetics. The source time function in each subfault is represented by a series of four-smoothed ramp function with a 1.0s rise time with 0.5s apart. We assumed a single fault plane with referring to Archuleta (1984) who assumed one main fault with a branching fault. We have searched for the first time-window front propagation velocity (propagation velocity of triggering front of the first time-window at each subfault) by performing several inversions, changing the first time-window front propagation velocity. The model with the first time-window propagation velocity of 2.8 km/s has given the best-fit model. The total seismic moment is estimated as 8.8*10**18Nm. An area of large slip over 1m was mainly distributed at depths between 4 and 11 km, about 18 km north of the hypocenter. We will examine the effect of rupture propagation and Green´s function on the obtained source model in detail and compare with Archuleta´s model.

AN ANALYSIS OF LOCALLY RECORDED BROADBAND WAVEFORMS OFTHE 10 AUGUST, 1997 (MW 6.3) COLLIER BAY EARTHQUAKE, NW AUSTRALIA

Phil R. CUMMINS (Minerals & Geohazards Div., Geoscience Australia)

The 1997 Collier Bay earthquake, which occurred on 10 August, 1997,was the largest event (Mw=6.3) to have occurred within continental Australia since the 1988 Tennant Creek earthquakes. Although feltover a wide area, it occurred in a sparsely populated region and so caused only minor damage. Its occurrence in the riftedcontinental margin of NW Australia, however, suggests that study of this earthquake may have important implications for seismic hazard in Australia. Global studies of earthquakes in stable continental regions indicate that

the largest such earthquakes occur in this environment, and if an event of similar size had occurred in the rifted margin of a densely populated part of Australia the damage could have been much more severe. Although the earthquake was well recorded teleseismically, regional observations are sparse and no local observations have been reported in the literature. Here I will present a study utilizing data from a temporary network ofbroadband seismometers in the Kimberley region of NW Australia,which were fortuitously deployed by the Australian National University prior to the Collier Bay event. The nearest station was just over 100 km from the epicenter, and although much of the 24-bit data recording the event were clipped, I will show that substantial information about the earthquake source can be extracted from the unclipped portion of the waveforms. Although only 2 aftershocks appear in the earthquake catalogs (both Australian and worldwide), the temporary network recorded a large number of aftershocks, andan analysis of these will also be presented.

AN ASSESSMENT OF TECTONIC STRESS FIELD AND SEISMIC HAZARD IN THE NEPAL HIMALAYA

Kedar Nath KHANAL, Avadh RAM (Central Department of Physics, Tribhuvan University)

The 2500 km long chain of the Himalaya is one of the seismically active regions of the world. The northwest (72˚ E- 80˚ E) parts are more active as compared to the central part (80˚ E- 88˚ E). Almost the whole of the central part of the Himalaya lies in Nepal. The earthquake epicentral data of the region shows that at least an earthquake of magnitude mb=5 or greater occurs every year and the magnitude mb =6 or greater generally occur in 10 to 15 years. In general, an earthquake of magnitude mb = 6 or greater has been found destructive. In 20th century, thousands of people have been killed and a loss of property of millions of dollars have been made as a result of such earthquakes in Nepal and the adjoining region. Although, Nepal is one of the least developed countries it has got tremendous amount of water resources. In the process of development of the country, the water resources can be utilized for hydroelectric power generation as well as irrigation etc. which ultimately requires the construction of the large dams, tunnels and multistory buildings with a large investment of money. So precaution should be taken for their safety. Since the present technology is not enough for reliable earthquake predictions, emphasis should be put on the evaluation of seismic hazard and risk in the region. In the present investigation, the tectonic stress field and the seismic hazard in the Nepal Himalaya have been estimated from the idea of fault plane solutions of the earthquakes occurred in the region and constructing the hazard map using earthquake data of the time interval from 1901 to 2001 AD. From the idea of fault plane solutions, it has been observed that the pressure axis lies in the north direction. Some of the events have shown the pressure axis lying in the east west direction which we consider as the effect of residual field caused by the inhomogenities prevailing in the region Moreover, the hazard map has helped to distinguish comparatively least or highly active areas and this distinction can be used in developing the earthquake resistant design. In this investigation such maps have been drawn and these results would be highlighted.

TIME DEPENDENT SEISMIC HAZARD ASSESSMENT FOR THE TAIWAN REGION ON THE BASIS OF PROGNOSTIC ZONATION OF FUTURE EARTHQUAKES AND RECENT STRONG-MOTION DATA

Vladimir Yu. SOKOLOV[1], Arkady OVCHARENKO[2], Chin-Hsiung LOH[3], Kuo-Liang WEN[4] ([1]Geophysical Institute, Karlsruhe University, [2]2. Institute of Geophysics Russian Academy of Science, Urals Division, RUSSIA, [3]3. National Center for Research on Earthquake Engineering, TAIWAN, [4]4. Institute of Applied Geology, National Central University, TAIWAN)

We describe an integrated approach to seismic hazard assessment, which was recently (1999-2002) applied for the Taiwan region. **First**, empirical models for ground motion estimation in the Taipei region were obtained on the basis of records from recent (1993-1999) earthquakes. The database includes strong-motion data collected during the recent Chi-Chi earthquake (M=7.6, 21 September 1999) and large (M=6.8) aftershocks. The ground-motion database was used for evaluation of generalized site response functions for typical soil classes (B, C and D) in the region, as well as for analysis of local site response in the Taipei basin (northern Taiwan). **Second**, the 4D-model (x, y, z - coordinates, time) for dynamic deformation of the Earth´ crust and 5D-model x, y, z - coordinates, time, magnitude) for seismicity were developed on the basis of observed geophysical data (GPS and PSWL observation, seismic catalogue, etc.). The models were applied for calculation of theoretical seismic catalogue (2001-2050) for the Taiwan region. The theoretical catalogue was compared with observed seismicity (July 2001-August 2002). The comparison shows that the theoretical catalogue adequately describes real seismicity for this time period. The averaged difference (absolute error) between parameters of observed earthquakes (M > 5.0, 66 earthquakes) and predicted events does not exceed 15-18 km for location, 1 year for time of occurrence and 0.1 unit for magnitude. **Third**, the region & site & time-dependent seismic analysis, which is based on schemes of probable earthquake zones evaluated from the theoretical catalogue, regional source scaling and attenuation models, and information on local site response on seismic motion, has been performed. The seismic hazard zonation maps are compiled in terms of Peak Ground Acceleration (PGA) and Response Spectra (RS) amplitudes (5% damping). The maps show distribution of amplitudes that will not be exceeded with certain probability (50%, 84% and 97%) in condition of generalized soil classes (B, C and D) during all possible earthquakes that may occur in the region during time period of 2003-2025. The approach allows us to introduce a new parameter that describes dependency of seismic hazard on time, so-called ″period of maximum hazard″ or PMH that is of particular interest of seismic risk management and insurance business. The parameter shows the period, during which every considered site will be subjected by the maximum value of ground motion characteristic (PGA or RS). The above mentioned stages may be considered as the parts of unified approach to seismic hazard assessments: from evaluation of characteristics of future earthquakes to site-dependent design input ground motion parameters. By the other words, we introduce a concept of so-called ″Real Seismic Hazard″ - the hazard, which is based on parameters of *future* earthquakes and, at the same time, which utilize information obtained during earthquakes that did occur.

SS04/08P/A03-002   1415

EVALUATION OF SEISMIC HAZARD AND STRONG GROUND MOTIONS FOR TASHKENT CITY

Bakhtiar S. NURTAEV, Lylya PLOTNIKOVA (Institute of geology and geophysics)

arthquake hazard assessments, conducted in connection with risk analysis in urban centers has been traditionally linked to scenario earthquakes in a deterministic manner, easily characterized to address a wide range of concerns. Proper design of earthquake resistant

S

structures and facilities requires estimation of the level of ground shaking to which they will be subjected. Seismic hazard assessment for the territory of Tashkent city has been carried out based on selection of earthquake generating zones within the limits of surrounding region, estimation of the maximal probable magnitude event in limits of every selected zone and the selection of earthquake sources, which may be the most dangerous for the city. Thorough seismological, geological and geotechnical studies have been carried out in and around Tashkent in order to determine the seismic hazard level. Seismic source zones are determined and seismicity parameters such as magnitude - frequency relationships and maximum magnitude are determined using past occurrence of earthquakes and expert judgment. For the Radius case study scenario for Tashkent city we recommended to adopt probable earthquake with the magnitude M = 6.1 within Tashkent focal zone and an intensity of 8 ball (MSK intensity units) on average soils. After we have made attempt to improve reference strong ground motions for Tashkent city, using all available geological and geotechnical information, prior observations and available records. It is known that intensity distribution in city depends on geometry and properties of the subsurface materials, ground water level, site topography and the characteristics of input source motion. 32 records of main shock and aftershocks of Tashkent 1966 earthquake with $2 < M < 5.3$ registered at different site conditions were used for analysis of soil effects on ground motions. Spectral earthquake source parameters for Tashkent source zone have been estimated. Using geological data, reached Paleozoic basement and geophysical sounding results, the spectral transfer functions of soil profiles have been calculated. Time history of bedrock motion that is consistent with the predicted parameters of probable scenario earthquake M=6.1 have been generated on the base of deconvolution techniques. A conventional ground response analysis is then performed to predict the motion at the surface of the soil profile of interest. This motion, which is consistent with the results of seismic hazard analysis and also with the local site conditions, may be taken as design strong ground motion.

SS04/08P/A03-003   **1430**

PROBABILISTIC SEISMIC HAZARD ASSESSMENT IN NORTHERN ALGERIA, USING SPATIALLY-SMOOTHED SEISMICITY. PART I :SEISMIC HAZARD MAPS IN TERMS OF PGA

Mohamed HAMDACHE[1], Jose Antonnio PELAEZ MONTILLA[2], Carlos LOPEZ CASADO[3] ([1]Seismological Survey Department - CRAAG - Algiers - Algeria, [2]High Polytechnic School. University of Jaen. Spain, [3]Theoritical Physics department . University of Granada. Spain)

Seismic hazard in terms of peak ground acceleration (PGA) has been evaluated in northern Algeria using spatially-smoothed seismicity data, after introducing different modifications to the initial approach developed by Frankel (1995). We present here a preliminary seismic zonation in northern Algeria as derived from the obtained results. Initially, we have compiled an earthquake catalog of the region taking data from several agencies. Afterwards, we delimited seismic areas where the b and mmax parameters are different. Finally, by applying the modified methodology proposed by Frankel (1995), and using four complete and Poissonian seismicity models, we are able to compute the seismic hazard maps in terms of PGA with 39.3% and 10% probability of exceedance in 50 years. A significant result of this work is the observation of mean PGA values of the order of 0.20g and 0.45g, for return periods of 100 and 475 years, respectively, in the central area of the Tell Atlas. Seismic hazard curves in terms of PGA have been derived in great details at the twelve selected cities, located at the most industrial and populated areas in northern Algeria.

SS04/08P/A03-004   **1445**

SEISMIC HAZARD ASSESSMENT IN THE KUTCH REGION, INDIA

Bal Krishna RASTOGI[1], Prantik MANDAL[1], Mark PETERSEN[2] ([1]Seismology Group, National Geophysical Research Institute, Hyderabad, India, [2]USGS, DENVER FEDERAL CENTER, MS966, Box. 25046, DENVER, CO 80225)

Occurrences of two M7 earthquakes during last 200 years makes the Kutch region of Gujarat state, Western India a unique site for the devastating intra-plate earthquakes in the Globe. The region has a high frequency of damaging earthquakes e.g. Kutch earthquake of 1819 (Mw 7.8), MMI VIII Lakhpat earthquake of 1845, Mw 6 Anjar earthquake of 1956. During last 155 years, the region has witnessed nine earthquakes of M5-6 indicating a repeatability of 17 years for M5-6 events. Hence, the region is prone for the occurrences of large and moderate earthquakes in the future. Thus, it is essential to assess the hazard to assist engineers and public officials in making informed planning decisions that will influence economic and life-safety policies for the region.On 26 January 2001, a devastating lower crustal intra-plate earthquake of Mw7.7 took place with an epicentral location of (23.4oN, 70.23oE) and a focal depth of 23 km. The aftershock activity has been very intensive. Till date, 11 aftershocks of magnitude exceeding M5, over 180 earthquakes of magnitude exceeding M4 and about 1000 aftershocks of magnitude exceeding M3 have occurred in the area. The last aftershock of magnitude exceeding M5 occurred on March 4, 2001. The well-located hypocenters of aftershocks delineate a hidden EW- trending causative fault plane, which dips at 45o towards south. We name this south dipping hidden fault as north Wagad fault (NWF). Trends of isoseismals, damage patterns, ground deformations, decay of intensity with distance, liquefaction, site amplifications and accelerations due to the main earthquake and aftershocks have been studied. The earthquake was assigned a MM intensity of X+. A catalog of earthquakes of Kutch region has been prepared. We have derived preliminary probabilistic and deterministic ground motion models for Kutch. This new hazard analysis includes updated sources and recurrence rates, incorporates two crustal intraplate ground motion prediction relations, and applies new hazard methodologies that were used to produce the U.S. National Seismic Hazard maps (Frankel et al., 1996). NEHRP criteria have been assumed for the soil characteristics. The probabilistic hazard is calculated for the two hazard levels used in producing current building codes: 2% and 10% probability of exceedance in 50 years. The deterministic hazard is calculated using the median ground motion from published ground motion prediction equations. We construct maps for peak horizontal ground acceleration and 0.2 s and 1.0 s spectral acceleration with 5% damping using two different scenarios for return times of large earthquakes. The coda-Qc has been studied using 200 aftershocks of M³3.0, which suggests a frequency dependent coda Qc relation as Q=(102±0.8) f0.98±0.17. The decay of acceleration estimated using Qo=102 suggests a good correlation with the attenuation relations obtained for northeastern US and the observed peak ground acceleration caused by the 2001 Bhuj mainshock. Based on this decay of amplitude and recorded accelerations, the acceleration at epicenter of mainshock is estimated to be 1g.

SS04/08P/A03-005   **1500**

A NEW SEISMIC HAZARD MAP FOR IRAN

Mehdi ZARE[1], Mehdi ZARE[1], Paivi MANTYNIEMI[2], Andrzej KIJKO[3], Mayshree BEJAICHUND[3] ([1]Seismology Research Center, IIEES, Tehran Iran, [2]Inst. Seismology, Univ. Helsinki, Helsinki, Finland, [3]Council for Geoscience, Pretoria, South Africa)

A parametric-historic procedure for mapping of seismic hazard in Iran and the surrounding region has been applied. The procedure does not require any specification of seismic source zones and allows for the use of the whole seismological record, comprising both historical and instrumental data, available for the region of interest. The new seismic hazard map prepared for Iran and its vicinity specifies a 10% probability of exceedance of the given peak ground acceleration (PGA) values for an exposure time of 50 years. When preparing the map, the new PGA attenuation relationship for Iran was employed. The new map shows a spatial distribution of the seismic hazard that corresponds well with the features of seismicity within the examined region. It depicts the level of seismic hazard in which the exceedance of the PGA value of 0.30g may be expected to occur within limited areas. The highest estimated levels of seismic hazard inside the territory of Iran are in excess of 0.50g at individual sites.

SS04/08P/A03-006   **1515**

GIS BASED SEISMIC HAZARD ZONATION IN THE SIKKIM HIMALAYA

Sankar Kumar NATH[1], Probal SENGUPTA[1], Indrajit PAL[1], Debasis ROY[2], Jnana RKAYAL[3] ([1]Department of Geology & Geophysics, Indian Institute of Technology, Kharagpur - 721 302, INDIA, [2]Department of Civil Engineering, Indian Institute of Technology, Kharagpur - 721 302, INDIA, [3]Geological Survey of India, Kolkata- 700 016, INDIA)

The Himalayan region, about 2500 km long belt from Kashmir in the west to Arunachal Pradesh in the east, can be divided into several seismotectonic blocks, the Darjeeling-Sikkim constituting one of those, where a good number of moderate magnitude earthquakes (M 5.0) had been recorded in the past. The recent damaging earthquake of 1988 (M 6.7) was distinctly felt in the Darjeeling-Sikkim Himalaya, and the isoseismal VII passed through Darjeeling and Gangtok towns. The Geological Survey of India (GSI) conducted a few microearthquake surveys deploying close-spaced temporary networks in the Darjeeling-Sikkim region. The strong motion network of the Indian Institute of Technology (IIT), Kharagpur sponsored by the Department of Science and Technology (DST) had been in operation in the Sikkim Himalaya since 1998. The Fault-plane solutions of the weak motion and strong-motion events indicate dominantly thrust faulting mechanism, with a north dipping fault plane. A N-S depth-section shows that the earthquakes occurred down to a depth of 45 km. The seismic activity is very high below the plane of detachment and the Main Boundary Thrust (MBT) is a mantle reaching active fault, earlier indicated by gravity survey. With this well constrained tectonic model, the strong-motion data had been of immense use in the proposed hazard zonation. The IIT Kharagpur strong motion network in Sikkim comprising of 9 digital accelerographs recorded more than 100 events during 1998-2002, of which 71 events have been selected with signal-to-noise ratio Sankar 3 for the estimation of site amplification (SA), peak ground acceleration (PGA) and resonance frequency (RF) at all stations. The geological themes with inputs from IRS–1C LISS III digital data, topo-sheets, geographical boundary of the State of Sikkim, surface geological maps, soil taxonomy map in 1:50,000 scale and seismic refraction profiles, are united and integrated to form the basic site condition coverage of the region. The seismological themes, namely, SA, PGA, RF are assigned normalized weights and feature ranks following a pair-wise comparison hierarchical approach and later integrated to evolve the seismic hazard map. The overall SA, PGA and RF show an increasing trend in the NW-SE direction peaking at Singtam in the lesser Himalaya. Six seismic hazard zones with percent probability index $<22\%$, 22-37%, 37-52%, 52-67%, 67-82%, $>82\%$ coupled with the geological integrated coverage exhibit no-hazard ($<22\%$) to maximum hazard ($>82\%$) probability. The effect of undulating topography on site amplification is also assessed using an explicit finite difference computer code for two earthquakes. The hypocenter of one of the events with a magnitude of 5 was in close proximity to the Singtam recording station. The hypocenter of the second event with a magnitude of 3.2 was very near the Gangtok recording station. These results agree well with the inference on topographic site amplification based on GIS integration.

SS04/08P/A03-007   **1530**

A SEISMIC HAZARD AND RISK ASSESSMENT FOR THE TULBAGH AREA IN SOUTH AFRICA: APPLICATION OF THE PARAMETRIC-HISTORIC PROCEDURE

Andrzej KIJKO, Gerhard GRAHAM, Mayshree BEJAICHUND (Council for Geoscience)

The strongest and most damaging earthquake recorded in the earthquake history of South Africa took place on 29 September 1969 in the Tulbagh valley, some 90 km from Cape Town, South Africa. Nine deaths resulted from the earthquake and damage to buildings in the epicentral area was estimated at US$ 24 000 000. This study is aimed at applying a probabilistic seismic hazard assessment to the Tulbagh area, and to quantify the risk the town will be exposed to in the event of a large earthquake. The applied technique for the assessment of seismic hazard is known as the "Parametric-Historic" procedure. This method permits the combination of both historical and instrumental data. The historical part of the catalogue contains only the strongest events, whereas the complete part can be divided into several sub-catalogues, each assumed complete above a specified threshold of magnitude. In the analysis, the uncertainty in the determination of the earthquake magnitude was taken into account by incorporating the concept of "apparent magnitude". A significant effort was also required in the calculation of a reliable maximum earthquake magnitude. Since the Parametric- Historic procedure is parametric in nature, it consists essentially of two steps. The first step is applicable to the *area* in the vicinity of Tulbagh and requires an estimation of the area-specific parameters. These parameters include the mean seismic activity rate, the Gutenberg-Richter parameter, and the maximum regional magnitude. The second step is applicable to the Tulbagh *site,* and consists of parameters characteristic of the site. These are the parameters that give the distribution of the amplitude of peak ground acceleration (PGA). The results of the hazard assessment are expressed as probabilities that specified values of PGA will be exceeded during the chosen time intervals. A worst case scenario sketches the possibility of a maximum PGA of 0.30 g. The second part of the study concentrates on the probabilistic seismic risk analysis. The results from the seismic hazard assessment were used as part of a process to translate probabilistic estimates of ground motion into a damage factor through certain ground motion-damage relationships. Three classes of buildings, typical to the Tulbagh area were considered in the analyses. It indicates that (as example) for low rise, unreinforced masonry buildings, there is a 1% annual probability of suffering a mean value of damage around 20%. This type of information can be further reduced to provide values of expected annual damage, as required by many insurance agencies.

SS04/08P/A03-008   **1545**

EVALUATION OF SEISMIC RISK FOR HYDROPOWER DAM DESIGNS IN VIETNAM

Trinh Trong PHAN (Institute of Geological Sciences)

Hydropower take very important role for the development of economics in Vietnam. Some large dams like Hoa Binh, Tri an, Thac ba Dams were built in Vietnam. Some other will be built in near future like Son la dam of 250 meter high, a largest dam in south east Asia. The estimation of seismic risk for hydropower dam design in Vietnam is carried out in following successive stages : A seismic hazard assessment carried out through both the connections, at various scales, of the structural geology with seismicity. The estimate of the seismogenic capability of the active faults identified through satellite image, topographic and geological

map, field survey and earthquake catalogue. A seismic risk assessment of the regional seismic hazard on the site corresponding to the occurrence of design earthquake magnitude such as: maximum credible earthquake (MCE), maximum design earthquake (MDE) consisting of an earthquake having 10% risk of occurrence during the service-life of dam (100 years), the operating basis earthquake (OBE) consisting of an earthquake having a 50% risk of occurrence during the service life of dam and peak ground acceleration (PGA) corresponding to MCE, MDE and OBE,. Maximum credible Earthquake is estimated from combination of various methods : fault segment, fault surface, seismic moment and fault slip rate. Many arguments of remote sensing, geomorphology, geology, geodesy, state of stress attest the intensive actual tectonic activity in Vietnam. However, the poorness of the seismological network prevents accurate localization of moderate seismicity. For this region, using pure probabilistic model or historical approaches to select a seismic risk in structure design will be quite random. The combination of the deterministic and probabilistic analysis was performed in several stages. The application of the seismic risk assessment for many hydropower sites in Vietnam such as: Song Ca , Hoa Binh and Son La hydropower dams is presented in detail. MDE is 6.3 - 6.5 for Song Ca fault, 6.9 - 7.0 for Nam Chou fault. OBE is 5.6 - 6.1 for Song Ca fault, 6.3 - 6.5 for Nam Chou fault. Various attenuation laws based on world wide data recorded in near field and by Xiang based on Yunnan data (next to Vietnam) are used to calculate PGA. The above-mentioned MDE magnitude should induce at the dam site a PGA of about 0.35 - 0.39 g. The OBE magnitude should induce at the dam site a PGA of about 0.24 - 0.31 g.

SS04/08P/A03-009 — 1615

A NEW APPROACH FOR RAPID SEISMIC RISK ASSESSMENT

Serguei BALASSANIAN, Yuri BALASNYAN (Department of Geophysics, Yerevan State University)

In the presentation the author shows that the rapid seismic risk assessment is a particular task which should be considered at least for three events: 1) rapid seismic risk evaluation immediately after the strong earthquake in urban areas for prompt response; 2) rapid seismic risk assessment for developing countries with usually limited input data available; 3) rapid seismic risk assessment for Global risk mapping. Analyzing all the factors that contribute to seismic risk (geological, engineering, economic, social, political, and cultural), the author has developed the rapid seismic risk assessment (RSRA) approach. This method is based on three main factors that contributed to the magnitude of risk: earthquake hazard, vulnerability of built environment, and density of population. In the presentation the author has shown examples of application of the RSRA method for all the three above listed events: 1) scenario of the rapid seismic risk assessment after the devastating Spitak earthquake (Armenia, 1988, M=7.0); 2) seismic risk assessment in Armenia as an example for developing country and 3) the Global seismic risk mapping.

SS04/08P/A03-010 — 1630

SOME PROBLEMS OF SEISMIC ZONING OF THE NORTHEASTERN SAKHALIN ISLAND, RUSSIA AND ADJACENT SHELF

Alexey I. IVASHCHENKO, Kim Choon OUN, Tatiana NAGORNYKH, Michael STRELTSOV (Institute of Marine Geology and Geophysics, Far East Branch of Russian Academy of Sciences)

Problems of seismic zoning and accurate seismic hazard assessment of the northeastern Sakhalin Island and adjacent shelf areas became of the great interest 10-15 years ago due to rapidly growing activity related to industrial exploration of the oil-and-gas resources on Sakhalin shelf. That time, the seismic potential and seismic activity of the coastal and adjacent shelf areas were considered to be higher as compared with the inner parts of the Island. However, the new seismological and geophysical data obtained during the last years force to reconsider many of the existing representations on seismicity and seismic zoning of the northeastern Sakhalin Island and adjacent shelf. These new data include the results of: a) detailed active fault studies performed in zones of main regional faults after occurring the destructive Neftegorsk earthquake of 27 May 1995 (M_w 7.1) accompanied by the first time observed within Sakhalin Island surface faulting; b) comparative tectonic analysis of Cenozoic structures onshore and offshore the north Sakhalin Island; c) accurate re-evaluation of earthquake source parameters for the largest seismic events (M_w 4.5-5.8) occurred here during the period of 1932-1964 years; d) thorough analysis of available instrumental and macroseismic data aimed to develop the proper models of earthquake frequency rates and ground motion attenuation relationships; e) analysis of the available seismic reflection and geodetic data, and others. As a result of this comprehensive studies, many new features of regional tectonics and crustal structure related to the earthquake source locations, style of l crustal faulting and deformation and seismic wave attenuation within the northeastern Sakhalin Island and adjacent shelf were revealed. In particular, based on the above results one can conclude that the present-day seismic activity of the coastal and adjacent shelf areas is lower comparing with the inner parts of the northeastern Sakhalin Island, because the main earthquake generating structures here are situated within a broad zone of the active regional right-lateral shear faulting located on land, between two major regional fault systems. Incorporation of the mentioned data into the well-known procedures of seismic hazard assessment leads to a noticeable change of the seismic hazard estimates obtained earlier including those presented on the official general seismic zoning map of Russian Federation (GSZ-97).

SS04/08P/A03-011 — 1645

GPS APPLICATION FOR SEISMIC ZONING

Mikhail T. PRILEPIN (Institute of Physics of the Earth)

Till now seismic zoning is founded practically only on seismic statistics and geological data of the region under study. Using GPS technology can greatly help on seismic zoning by study the real picture of the stress of the seismically dangerous regions lithosphere and check its changing in time. That allows to update maps of seismic zoning permanently. As suppressing number of intra-plate earthquakes is a seismic moving on the faults, the most informative feature for seismic zoning will be the shear deformations. Modern GPS technologies allow to provide accuracy of shear deformation at the level of $1\text{-}2\times10^{-7}$ when the distances between observational points are 5-30 km. Since critical shear deformations, on which occurs the slip of locked fault flanks as a rule on 2 orders more, monitoring of shear deformations on seismically dangerous territory not only provides improvement of maps of seismic zoning, but also is an important forecasting feature. The study of the possibilities of applying GPS for the seismic zoning is carried out for Caucasus where the detailed map of seismic zoning [Ulomov, 2001] is available. Besides, there is GPS network including about 50 points. This network was established [Prilepin, Reilinger, 1991AE002] after the most strong Racha earthquake (Racha, 7.0, April, 1991) with the purpose of the general study of regional geodynamics of the Caucasus. On 5 sites of the network, outlining epicentral zone of Racha earthquake, observations repeated each two years since 1991, and the data of GPS study of post-seismic deformations will briefly presented in this report. The present Caucasian GPS network has insufficient density (the distances between points 50AE50 km) for solving the problems of seismic zoning and its further densification is needed. Two

approaches for the densification network are discussed. In the first case the technology of the using of GPS is developed for revision of the available maps of seismic zoning. In the second case the problem of the creation GPS network for ˝seismic protection˝ of the populous region or large engineering buildings is considered. For Caucasus the region of North-Eastern Dagestan is chosen as there is possible to consolidate both approaches considered above. As ˝safe-protection˝ objects we chose zones of Chirkey Water-Power Plant and city of Makhachkala with population more than 500 thousand. On the modern maps of seismic zoning this region is classified as 9-ball zone. Considering the fault tectonics of this region the densing GPS network is designed. Density of the GPS sites allows to determine the position of the shear deformation isolines with errors no more than 5×10^{-7}.

SHAKE MAP PREDICTION BASED ON EMPIRICAL SITE CORRECTION MODEL

Kuo-Liang WEN[1], Wen-Yu JEAN[2], Yu-Wen CHANG[2], Chih-Kuo WANG[1] ([1]Institute of Applied Geology, National Central University, [2]National Center for Research on Earthquake Engineering, Taiwan)

The seismic hazard analysis is usually to develop rock outcrop or hard soil site ground motion for seismic design. One of the main factors that affect the seismic risk is the existence of site effects on the attenuation relations, which are probabilistic descriptions of the level of ground motion as a function of the earthquake and site parameters. In order to make a good estimate of ground motion, many parameters are taken into consideration for attenuation relations. Researchers proposed several attenuation relations for different source region and site classification. There are several site classification schemes used in different attenuation relations. However, the information for site classification may be not widely available for strong motion station sites. An effective site-dependent attenuation model should be provided for better estimate of ground motions. Taiwan government supported an extensive seismic instrumentation program for the urban areas with densest digital strong-motion network of the world. This strong-motion network collects a large amount of high quality earthquake data since 1990. These data provide useful information for us to set up empirical site correction model. In this study we use the site correction model to predict shake map. If this model can connect to earthquake report system, then the source correction also can be done. It will give us a better shake map result.

NONLINEAR SEISMOLOGY:THE QUANTITATIVE DATA

Gheorghe MARMUREANU, Carmen Ortansa CIOFLAN, Florin Stefan BALAN, Bogdan Felix APOSTOL, Alexandru MARMUREANU (Engineering Seismology, National Institute for Earth Physics)

The model of linear elastic response of the Earth has been almost universally used by seismolgists to model teleseismic, weak and also strong earthquakes. Forteleseismic and weak ground motions, there is no reason to doubt that this modelis acceptable, but for strong ground motions, particularly when recorded on softsoils, the consequences of nonlinear soil behavior have to be seriously considered. Ground motion characteristics, particularly the duration of strong shaking, can be affected by seismic energy being trapped in large sedimentary basins. Nonlinear effects in ground motion during large earthquakes have long been a contraversial issue between seismologists and geotechnical engineers. Laboratory tests made by using resonant columns consistently show the reduction in shear modulus G and increase in damping ratio D with increasing shear strain (γ), therefore nonlinear viscoelastic constitutive laws are required. More than that, the seismological detection of the nonlinear site effects requires a simultaneous understanding of the effects of earthquake source, propagation path and local geological site conditions. The difficulty in demonstrating the nonlinear site effects may be due to fact that they are overshadowed by the overall patterns of shock generation and propagation. In order to make evidence of large nonlinear effects, the authors introduced the spectral amplification factor (SAF) as the ratio of the maximum spectral absolute acceleration (Sa), relative velocity (Sv), relative displacement (Sd)to peak values of acceleration (a-max), velocity (v-max) and displacement (d-max),respectively, from processed strong motion records. The SAF coefficient is usefullto describe the nonlinearity fenomena at a given site, being indirectly dependent on the frequency content of the earthquake record. The analisys of our strong motion records reveals the decreasing of the SAFs as the earthquake magnitude increases. The median SAF values of the recent strong Vrancea earthquakes for damping 5% are: 4.16; 3.63 and 3.26 corresponding to the May 31,1990 Vrancea earthquake (M_s=6.1), May 30,1990 Vrancea earthquake (M_s=6.7), respectively, August 30,1986(M_s=7.0.At the same seismic station, for example Bacau, for 5% damping, SAF for accelerationsis 3.94 for August 30,1986 earthquake (M_s=7.0); 4.32 for May 30,1990earthquake (M_s=6.7) and 5.22 for May 31,1990 (Ms=6.1). The evidence of nonlinearity at least for thick Romanian Plain Quaternary sediments is a systematic decrease in the variability of peak ground acceleration for increasing earhquake magnitude. As the excitation level increases, the response spectrum is larger for the linear case in comparison with the nonlinear one. For the Vrancea earthquakes there is a difference in the frequency-dependent site effect between weaker motion (May 31, 1990) and strong motion (March 4, 1977).

THE CANADIAN URBAN SEISMOLOGY PROGRAM DEMONSTRATION STRONG MOTION SEISMOGRAPH NETWORK IN VANCOUVER, BRITISH COLUMBIA

Garry ROGERS, Andreas ROSENBERGER, Tuna ONUR, John CASSIDY (Geological Survey of Canada)

The Canadian Urban Seismology Program (CUSP) has been initially funded as a two year pilot project. The centrepiece of the project is the installation of a densely-spaced demonstration urban strong ground motion network in a section of Vancouver, British Columbia, a city with a metropolitan population of about two million people. One hundred strong motion seismographs of Geological Survey of Canada design are being deployed. Sixty of them are in a 6km x 8km array that straddles the edge of the Fraser River delta, ranging from bedrock in Vancouver to 300m deepsoft sediments of the delta. This is a region where we have seen large variations in shaking response recorded on the existing widely spaced network of stand-alone strong motion instruments.The relatively low amplitude recordings (all less than 0.04g) from several nearby earthquakes show frequency-dependent amplification, with factors of up to 12 times (relative to bedrock) near the edge of the delta. The new network will use the public Internet for communication, delivering peak values of acceleration, velocity and displacement in near real time, available for rapid display as ground motion shaking maps or other purposes. Full wave-form data can be retrieved using standard Internet protocols like FTP and SSH/SFTP. Twenty-five instruments have been installed to date. Most of the deployments so far are in small elementary school buildings. We hope to have the demonstration network fully in operation by the end of 2003.

SELF-CENTRING ASEISMIC SYSTEM WITH DOUBLE NATURAL FREQUENCY

Federico /BARTOLOZZI (Civil Engineer & Independent Researcher)

The proposed system is based on the following operations: 1. interruption of the solidarity between the building and the foundation-soil complex; 2.laying of multidirectional movable bearings with sliding or rolling friction.This application confers the building with the main properties of centring after an earthquake and of doubling the natural frequency of vibration during an earthquake. The centring is automatic and it takes place due to the presence of a sliding spherical bowl in each bearing.In the presence of an earthquake, this bowl also permits the immobility of the building with respect to the horizontal translation of the foundation-soil complex, because its thickness variation is perfectly balanced by the corresponding elastic deformation of the main springs at every instant and for any value of the horizontal displacement. The horizontal inertial force in the building does not modify its static equilibrium, because it is minor when using bearings with sliding friction and negligible when using bearings with rolling friction. The variation of the natural frequency of the building takes place during the vertical motion of the soil only during an emergency, characterised by an interval seismic frequencies including the resonance one. In fact, the presence in each bearing of a system of auxiliary springs, automatically started in this situation, permits the action of the main springs to be strengthened with a consequent increase in the natural frequency of the building and a drastic decrease in the vertical displacements of the building to values compatible with its safety characteristics.

STRESS SIMULATION AND OCCURRENCE OF QUATERNARY THRUSTING IN HIMALAYAS

Daya SHANKER[1], V.P. SINGH[2], Nipun KAPUR[3], A.I. GORSHKOV[4], Olga V. NOVIKOVA[5], V.G. KOSSOBOKOV[6] ([1]Department of Earthquake Engineering, Indian Institute of Technology Roorkee, Roorkee-247667, India, Email:dayasfeq@iitr.ernet.in / pateel2k1@yahoo.co.in, [2]Department of Geophysics, Banaras Hindu University, Varanasi-221005, India, [3]GE Capital International services, Race Course Road, Bangalore-560 001, India,, [4]International Institute of Earthquake Prediction Theory and Mathematical Geophysics, Russian Academy of Sciences, Moscow, Russia, Email:gorshkov@mitp.ru, [5]International Institute of Earthquake Prediction Theory and Mathematical Geophysics, Russian Academy of Sciences, Moscow, Russia, Email:onovikov@mitp.ru, [6]International Institute of Earthquake Prediction Theory and Mathematical Geophysics, Russian Academy of Sciences, Moscow, Russia, Email:volodya@mitp.ru)

Thrust dominated southern Tibet during the Cretaceous and Paleocene, resulting in the formation of the Gangdese and renbu Zedong Thrust system. This thrust activity culminated in north dipping shallow normal-faulting (South Tibetan Detachment –STD) in the Higher Himalayas during the Miocene. Activities on the STD are coeval with that on the Main Central Thrust (MCT). Thrusting activity virtually ceased around 8 Ma after which there is no evidence for major Quaternary shortening in Southern Tibet. Although, thrusting continued in the Himalayas during recent times. The occurrence of Quaternary thrusting in Himalayas and its geodynamics constraints in southern Tibet is modelled using stress simulation analysis. 2-D non-linear elastic and homogeneous wedge models, representing cross-sections of the Himalayas and Tibet are used. Varying the strength of the base in the model and corresponding stress distribution and failure patterns in the wedge is analyzed. Simulated stresses for a set of boundary conditions, representing building up of Himalayas and southern Tibet, reveals the region of thrust failure gradually recedes away from the wedge towards the base (lower boundary) with a decrease in the strength of the base. Thus, the result favours the preposition that a strong and a weak basal (Main Himalayan Thrust; MHT) respectively, below Himalayas and Southern Tibet is responsible for presence and restricting the extension of Quaternary thrusting in these regions. A decrease in strength of MHT from the Himalayas to Tibet is also supported by observational evidence and thermal modelling, imply partial melting along MHT.

THE INFLUENCE OF LOCAL TOPOGRAPHIC RELIEF ON REGIONAL STRESS: AN EXAMPLE FROM THE RUKWA RIFT, TANZANIA

Richard Wambura FERDINAND (Deparment of Geology, University of Dar es Salaam)

The seismo-tectonic structure of the Rukwa rift is interpreted using fault plane solutions for earthquakes within the rift. Fault plane solution for micro-earthquakes were obtained by moment tensor inversion of the full waveform using high frequency local data, while for large earthquakes the low frequency body wave inversion solutions from previous large earthquakes were adopted. The combined results indicated there is a difference in T (tension) axes orientation between the western side located beneath the rift in Ufipa plateau end the eastern side along the Songwe basin. Within the Ufipa plateau the orientation is NE-SW to NNE-SSW, orthogonal to the rift, while along the Songwe basin it is NW-SE, parallel to the rift. This difference is attributed to differences in local topographies. The Ufipa plateau is about 1 km higher than the Songwe basin which is almost level with the East African plateau where the extension trends NW-SE.

SEISMICITY OF THE QAENAT KHORASAN REGION IN EASTERN IRAN

Shayesteh MEHRABIAN, Goodarz HAMIDI (Department of Earth Sciences, University of Tehran)

In this study seismicity of Qaenat Khorasan, which is one of the most seismically active regions in eastern Iran by using all effective seismological and geological factors, has been investigated. The earthquake catalogue is provided by using available references which concerning the earthquake data in Iran and special attention has been paid to the destructive Zirkuh-Qaenat earthquake of 1997 May 10. The procedures of, aftershocks deletion, the principle of region selection, the upper and lower limit magnitude and verification of the historical catalogue are applied. For some representative regions the Gutenberg-Richter relation curves according to their seismicity characteristics, by using the earthquake data greater than or equal to magnitude 3.0 (1974-1998) and higher magnitudes (1900-1998) are obtained. According to these results the annual occurrence rate of events of each magnitude can be inferred from the G-R relation and it seems that both results are almost the same. Therefore using the obtained relations at the first stage as the proper region is selected with respect to the seismicity system and the duration of time can make estimation of the recurrence period of large earthquakes. It should be noted that this region shows irregular seismic activity pattern, which is discussed.

SS04/09A/A03-004   0945

A HOMOGENEOUS EARTHQUAKE DATA BANK IN WESTERN MEDITERRANEAN COUNTRIES –ALGERIA, MOROCCO, TUNISIA – FROM THE RECORD SOURCES OF PAST SEISMIC EVENTS

Djillali BENOUAR (Department of Civil Engineering, University of Science and Technology Houari Boumediene (USTHB))

The main purpose of this work is to give a comprehensive overview of the establishment of the catalogue of all earthquakes reported in the western Mediterranean countries (Algeria, Morocco, Tunisia), and from which were derived from this basic data set the general laws governing the space and time distribution of earthquake occurrences in the seismic source zones. This region is called hereafter the Maghreb region. In recent history, strong earthquakes have occurred in northern Algeria in Algiers (1716), Oran (1790) and Cheliff (1867, 1873, 1922, 1934, 1954 and 1980). A detailed study and analysis of the seismicity of Algeria and adjacent regions during the twentieth century is presented in Benouar (1993). This research work presents the present situation of the earthquake catalogues in the Maghreb region and the methodology being used in the assessment of the seismicity. It illustrates the historical background of the catalogues, their completeness and the types of archives used in their compilations. It also presents the problems encountered in their establishment as language, calendars, place-names, scatter of documents, low density of population, censure and poor economic conditions in the Maghreb region. For the Maghreb region, earthquake hazard constitutes a constant threat to human life and property, sometimes causing major economic losses and disruption. The rapid urbanization, development of critical engineering works such as dams, nuclear power plants, industrialization of cities with modern types of buildings and the concentration of populations living or settling in hazardous areas are matters of growing concern, as they contribute to heavier loss of life and increase considerably the cost of disaster damage. In order to assess the seismic hazard with a certain degree of reliability, an earthquake data of the region under survey which are as complete, homogeneous and accurate as possible are needed. For this purpose, and from the point of view of long term prediction and seismic hazard assessment, it is imperative that input data in the catalogues of the Maghreb countries be revised and homogenized. Actually, it is of interest to mention that earthquake catalogues in the Maghreb region could be separated in two types: a parametric one which includes most of the events that occurred in the twentieth century and a descriptive catalogue for seismic events that occurred in the early years of the twentieth century and earlier. A methodology has been developed by Benouar (1993) to assess the seismicity of the Maghreb region; this methodology has been used for the period 1900 onwards and resulted in a homogeneous earthquake catalogue. It is obvious that more research work is needed for a reliable earthquake catalogue in the region including the pre-instrumental and the instrumental periods.

PROBABILISTIC EARTHQUAKE POTENTIAL MODELS TESTED AGAINST A HISTORICAL CATALOG OF JAPANESE INLAND EARTHQUAKES

Kunihiko SHIMAZAKI[1], Wahyu TRIYOSO[2] ([1]Earthquake Research Institute, University of Tokyo, [2]Department of Geophysics and Meteorology , Bandung Institute of Technology)

Several methods have been proposed to estimate earthquake potential in addition to the classic regionalization method to estimate seismic hazard. They include a spatial smoothing technique proposed by Frankel in 1995, utilization of information on strain accumulation attempted by Ward in 1994, and a method based on estimated slip rate and other parameters of active faults (e.g. Wesnousky et al. in 1984). All these models appear to be reliable because they are based on sound ground of seismology, i.e. the Gutenberg-Richter magnitude-frequency relationship, Kostrov´s formula on seismic moment and strain, and characteristic earthquake model. However, if they are tested against a 400-year Japanese historical earthquake catalog, we find that they do not necessarily reproduce the observed seismicity. In some cases they are worse than a no-information model which assumes that the earthquake potential is uniform all over the Japanese islands. Dividing the data set into different time-periods, we find that the present-day spatial distributions of small earthquakes and surface horizontal strains are much affected by large earthquakes which took place in the past 100 years. In general, we find that three sources of information are effective. They are regionalized seismicity of small earthquakes, smoothed distribution of seismicity obtained by Frankel´s method of combining small and moderate-size earthquakes, and active fault data. We classified historical earthquakes according to whether or not they are correlated with active faults and find that models based on the three sources are relatively robust. In this testing, we assume that the b-value is constant all over the Japanese islands. We declustered JMA (Japan Meteorological Agency) catalog of small earthquakes for a period of 1980-1997 and that of moderate-size earthquakes for a period of 1926-1997. The spatial variation of the likelihood of large earthquakes is tested. An adjusting factor which is multiplied to the rate of occurrence is introduced for the model comparison and AIC (Akaike Information Criterion) is calculated. For the real evaluation of various models we need the world-wide testing proposed by David Jackson, or we have to wait for many decades until enough number of large earthquakes take place. However, our study would shed some lights on the effectiveness of the proposed probabilistic models of earthquake potential and seismic hazard

SS04/09A/A03-006   1015

STUDY ON STRONG EARTHQUAKE RECURRENCE BEHAVIORS ON ENTIRETIES OF ACTIVE FAULT ZONES IN SICHUAN-YUNNAN REGION, CHINA

Guixi YI[1], Xueze WEN[2], Xiwei XU[3] ([1]Chengdu University of Technology, Chengdu 610059, China; Seismological Bureau of Sichuan Province, Chengdu 610041, China, [2]Seismological Bureau of Sichuan Province, Chengdu 610041, China, [3]Institute of Geology, China Seismological Bureau, Beijing 100029, China)

Basing on data of historical and modern strong earthquakes, we use statistical methods to study the recurrence behaviors of strong earthquakes on entireties of selected 7 active fault zones with different number of independent rupturable segments in Sichuan-Yunnan region, China. The result mainly shows that recurrences of strong earthquakes on the 7 studied fault zones are characterized by near-random, random or clustering behaviors. The variation coefficient σ, the ratio of the standard deviation to the mean of recurrence intervals of strong earthquakes, is proportional to the number of rupturable segments of an individual fault zone. The recurrence processes never display a well quasi-periodic behavior, and exhibit neither strength-time nor time-strength dependence. For the active fault zones, the more the number of the strong-earthquake rupture segments that form a zone is, the more complicated the recurrence process is. The recurrence interval distributions of earthquakes suggest bimodal or tri-modal character, indicating relatively active and quiet periods of earthquake activity occurring alternatively. For the active periods, recurrence interval distribution has relatively large discretion, and can be well-fitted by the Weibull distribution with parameters of α=1.34 and β=1.12. While, for the quiet periods, the duration distribution has relatively small discretion, and can be described approximately by distributions, such as

the normal (N)(μ_N=1.00,σ^2_N=0.24^2), the lognormal (LN)(μ_{LN}=-0.03, σ^2_{LN}=0.23^2), or the Weibull (α=4.99, β=1.53). Both the duration of every active period and the number of strong earthquakes in every active period are obviously variable cycle to cycle, which leads to the relatively active periods having never repeated quasi-periodically. Therefore, it is difficult to make a meaningful probabilistic forecast for middle and long term seismic hazard only based on the recurrence interval distributions of strong earthquakes, due to the complexity of strong earthquake recurrence processes for entireties of active fault zones. However, the efficiency of the probabilistic forecast would be improved if the additional information or evidence can be obtained, from which either an active fault zone is in its seismic active period or in the quiet period can be identified.

AMPLIFICATION CHARACTERIZATION OF K-NET, KIK-NET, AND JMA SITES BASED ON THE SPECTRAL INVERSION TECHNIQUE

Hiroshi KAWASE, Hidenori MATSUO (Dept. of Human-Environment Studies, Kyushu University)

To predict strong ground motions for future scenario earthquakes in a broad-band frequency range, we need to characterize both source spectra and site amplification. For short period we can use statistical method based on the observed records and the wave summation technique (e.g., Kamae and Irikura, 1997). Thanks to the advent of the K-Net, KiK-net, and JMA Seismic Intensity (Shindokei) Network in Japan, we have now plenty of weak motion data, enough to construct statistical Green's functions. On the other hand, in order to represent long- and intermediate period nature of strong ground motions in the near field region, including both the forward rupture directivity effects and the basin effects, we want to use theoretical technique such as three-dimensional finite difference method in which we can take these effects into account. Any theoretical methods need S-wave velocity structures that should reproduce the observed site amplification quantitatively. In this study we perform first the analysis to separate the so-called source spectra, attenuation coefficient, and site amplification factors from K-Net, KiK-Net, and JMA Shindokei records observed throughout Japan. The separation method is the well-established one of Andrews (1980) and the resultant source spectra are modeled as omega-square spectra. As a reference site we use one rock station of KiK-Net in Yamaguchi Prefecture, from which we take the amplification effect of shallow surface deposits. Once we obtain site amplification factors, we try to reproduce them by using one-dimensional S-wave velocity structures below each site. We use Genetic Algorithm to invert the S-wave structures. We succeed to reproduce site amplification factors at about two thirds of the sites very well. For the rest of the sites we may need 2D/3D structures to explain the amplification quantitatively or we must investigate some local topographic effects near the site. Once we obtain S-wave velocity structures at as many sites as we can, we will extrapolate them with the help of the gravity and geology data and construct an initial model of the three-dimensional basin structure of the whole Japanese islands. We would like to emphasize here that frequency characteristics of the inverted amplification factors show very large variations from site to site so that they cannot be characterized by simple soil-type classifications. We also derive site amplification factors for peak values of ground motions.

SS04a/09P/D-002 Poster **1400-251**

EARTHQUAKE OBSERVATION USING HOT SPRING BOREHOLE AND MICROTREMOR ARRAY SURVEY IN SOUTHWEST PART OF NAGOYA CITY

Yoshihiro SAWADA[1], Hideki NAGUMO[1], Kazuaki MASAKI[1], Miyako NORITA[1], Susumu KURAHASHI[2] ([1]Graduate School of Engineering, Nagoya University, Furo-cho, Chikusa-ku, Nagoya 464-8603 JAPAN, [2]Department of Civil Engineering, Aichi Institute of Technology)

Nagoya city located in the eastern part of the Nobi plain is one of the largest cities in Japan. Although the foundation investigation by the seismic reflecting method etc. has been conducted in Nobi plain in recent years, the foundation structure to a base rock is not clear especially in the southwest part area of Nagoya city since data is not fully accumulated yet. We try to clarify the foundation structure of this area by carrying out the earthquake observation at a hot spring borehole (San-no site mostly located at the center of Nagoya city) and microtremor array surveys. It is confirmed that base rock under the San-no site is in a depth of 670m and consists of hard granite of which S wave velocity is about 2.8 km/s. P and S wave velocity in each sediment layer along borehole is also obtained from the PS logging. We observe many earthquake records at base rock and surface ground, including the small earthquakes happened under the Nobi plain. The earthquake amplification characteristics between bottom and surface of borehole are examined, and the optimal physical-properties value of each deposit layer; velocity and Q value, is identified by using these earthquake observation data. We verify the applicability of microtremor array method by comparing the S wave velocity distribution estimated from this method with that obtained by PS logging along the San-no borehole. Then, we carry out the high-density microtremor array survey in the southwest part area of Nagoya city where sudden change of the depth of base rock is expected to be from the bouguer anomaly distribution. Consequently, it was clarified that the basement beneath the southwestern part of Nagoya city inclines from the north-east to the south-west direction. The depth of base rock changes rapidly from 500-600m at a northeast side to1200m-1600m in a southwest side of the San-no site. That is, it is surmised that the seismic basement under the southwest part of Nagoya city has irregular form of the shape of a concave with a depth of about 1600m at the deepest point. At last, we propose the three dimensional structural model for this area based on above examination results and verify the property of model by seismic wave simulation.

SS04a/09P/D-003 Poster **1400-252**

TEMPORAL AND SPECIAL CHARACTERISTICS OF STRONG GROUND MOTION WAVE FIELD IN THE TAIPEI BASIN DURING THE M 7.1 EASTERN TAIWAN OFFSHORE EARTHQUAKE OF 31 MARCH 2002

Yi-Ling HUANG[1], Bor-Shouh HUANG[2], Kuo-Liang WEN[3] ([1]Institute of Geophysics, National Central University, [2]Institute of Earth Sciences, Academia Sinica, [3]Institute of Applied Geology, National Central University)

The ground motion snapshots in the northern Taiwan area during the M7.1 eastern Taiwan offshore earthquake of 31 March 2002 have been reconstructed (Huang et al., 2002). Those snapshots displayed complicated wave propagation and complex direction of ground motion in the Taipei basin. The major shocks during the earthquake of 31 March 2002 were arisen from S-wave later phases and dominate in its radial direction. Those phases could be basin induced surface waves, which converted from body waves through complicated topography of Taipei basin, and made the large shock in the eastern edge and western portion of Taipei basin. The aim of this study try to investigate the characteristics of the converted seismic wave amplitude in different frequency bands with respect to the basin topography and rock site properties. The recorded ground motions from dense seismic network have been analyzed by F-K analysis and beam-forming method. Results of this study showed that the seismic wave phases have strongly bent through it pass the Taipei basin. To rely on the assistance of reconstructed ground motion snapshots and beam-forming method, results of this study could provide the researchers much useful information to constrain the further three-dimensional numerical simulation for the basin response and velocity structure, and to predict ground motions of the further large earthquakes.

SS04a/09P/D-004 Poster **1400-253**

THE DURATION-DISTANCE RELATIONSHIP AND AVERAGE ENVELOPE SHAPES OF SMALL KAMCHATKA EARTHQUAKES

Anatoly G. PETUKHIN[1], Alexander A. GUSEV[2] ([1]Geo-Research Institute, 4-3-2 Itachibori, Nishi-ku, Osaka, 550-0012 JAPAN, [2]Institute of Volcanic Geology and Geochemistry RAS , Petropavlovsk-Kamchatsky, RUSSIA)

Average envelope shapes (mean square amplitude time histories) of small earthquakes represent a convenient basis for the construction of semi-empirical stochastic ″Green's functions″, needed for prediction of future strong ground motion. At the same time, they provide crucial evidence for verification of the theories of scattering of high-frequency seismic waves in the lithosphere. To determine such shapes in the Kamchatka region, Russia, we use the records of near (R=50-200 km) shallow earthquakes located around the broadband station PET. On these records, we select the S-wave group and determine its root-mean-square duration T_{rms} separately for each of the five octave frequency bands. We determine the empirical T_{rms} vs. distance dependence and find it to be very close to a linear one. At the reference distance R=100 km, average T_{rms} decreases from 5.4 sec for the 0.75 Hz band to 3.9 sec for the 12 Hz band. To analyze average envelopes, we assume that the functional form of the envelope shape function is independent of distance, and stretch each of the observed envelopes along the time axis so as to reduce it to a fixed distance. Through averaging of these envelopes we obtain characteristic envelope shape functions. We qualitatively analyze these shapes and find that around the peak they are close to the shapes expected for a medium with power-law inhomogeneity spectrum, with the spectral exponent 3.5-4. From onset-to-peak delay times we derive the values of transport mean free path and of scattering Q for a set of distances. Broadening of envelopes with distance due to random scattering is especially important for simulating high-frequency seismic records of large, relatively distant, interplate, subduction zone earthquakes. To demonstrate the general methodology of stochastic simulation of strong motions using our average band-pass envelopes we developed a simplified algorithm that employs the point-source approximation; extension to an expanded source also is possible. To show it in action we simulated ground motion from two moderate earthquakes recorded by station PET: (1) November 13, 1993 with MW=7.0, R=135km, seismic intensity I=5 in Petropavlovsk-Kamchatsky, and (2) May 7, 1994, MS=5.5, R=107km. Both the envelope shape and the frequency content of the observed and simulated records match quite well. Acknowlegements. We deeply appreciate Kamchatka Experimental and Methodical Seismological Department, GS RAS, for providing data of the IRIS station Petropavlovsk (PET).

SS04a/09P/D-005 Poster **1400-254**

THE FIRST MODEL FOR SCALING OF RESPONSE SPECTRA OF STRONG GROUND MOTION RECORDED ON KAMCHATKA

Anatoly G. PETUKHIN[1], Alexander A. GUSEV[2], Evgeniya M. GUSEVA[2], Evgenii I. GORDEEV[2], Victor N.CHEBROV[2] ([1]Geo-Research Institute, 4-3-2 Itachibori, Nishi-ku, Osaka, 550-0012 JAPAN, [2]Kamchatka Experimental and Methodological Seismological Department, Geophysical Survey, Russian Academy of Science, Petropavlovsk-Kamchatsky, RUSSIA)

To determine the average relationship among response (pseudo-velocity) spectrum of horizontal acceleration $PV(f)$, moment magnitude M_w and hypocentral distance R for Kamchatka earthquakes, we analyzed 140 analog strong motion records obtained during 1969-1998. The records of acceleration and velocity meters were obtained at 19 rock to stiff soil-ground Kamchatkan sites from 77 earthquakes with M_w = 3.9-7.9, at distances R = 10-300 km and depths 0-145 km. Response spectra $PV(f)$ were calculated from digitized, zero-line corrected and instrument corrected records of 255 horizontal components. After smoothing, the values were picked at a set of fixed frequencies. With the scarce amount of data at hand, it was impossible to determine reliably the entire $PV(M_w,R|f)$ average trend surface. Hence we first performed distance equalization, with distance corrections calculated on a theoretical basis, and thus reduced the observed data to the reference distance of R_0 = 100 km. The model of distance attenuation applied included (1) point source decay terms (1/R plus attenuation specified by $Q(f)$ = 250 $f^{0.8}$), (2) finite source correction (using the formula for a disc-shaped incoherent source, its size depending on M_w) and (3) duration correction using stochastic approach formula for calculation of response spectrum. After reduction, we determined the $PV(M_w,R_0|f)$ vs M_w trends. To do this we employed a multiple regression procedure, with ground type and station dummy variables. The M_w dependence was assumed to consist of two linear branches intersecting at M_w=6.5. The result of multiple regression represents the first systematic description of response spectrum properties of destructive ground motion for Kamchatka earthquakes.

EVALUATION OF THE GROUNDS?EPARAMETERS ON THE EXAMPLE OF THE STRONG EARTHQUAKES OF THE CAUCASUS

Levon Garnik SUVARYAN[1], Heghine Vladimir SARGSYAN, Khoren Garnik SUVARYAN ([1]Northern department of National service for seismic protection of RA, [2]Northern department of National service for seismic protection of RA, [3]Politechnical Institute)

The analysis of strong earthquakes, which occured after the Spitak destructive earthquake in 1988, shows the connection of seismic effect with the value of the earthquake's energy and its azimuth of spreading. By results of detailed study of damages it is possible to judge about the necessity of the account of such parameters of tremors, as the constitution of frequncies and its changes during the oscillations, duration of strong oscillations and is probable by the form of oscillations. The listed parameters are confined in time functions (accelerograms), which are the most informative characteristics of the ground's oscillations. The parameters of tremors are depending on parameters of the source of earthquakes AE mechanism, the size and geometry of the source, the magnitude of adjustments, velocity of propagation of a rupture and from the properties of the medium, trough which the waves are spreading. We

S

selected the strong earthquakes for study: the Spitak destructive earthquake of 1988 and the all earthquakes, which occured after the Spitak earthquake, with M ³ 4.0 in this source zone and the Racha-Djava earthquake on the territory of Georgia which occured in April 29 of 1991. By the network of equipment SMACH of the ground's strong motions, which were installed during the last period on the territory of Armenia-Georgia, are registered accelerations of ground’s oscillations. By the records of accelerograms are studied the spectra of oscillations of grounds and arre compared with the macroseismic inspections. By the records of accelerograms is proved about the complexity of the source of the Spitak earthquake and about the strong spreading in the northwest direction. The dominant periods of oscillations of earthquakes in the source zone 'Spitak-88' and the Zangezur earthquake of 1968 are determined.

EXTENDED STOCHASTIC SIMULATION METHOD FOR THE VERTICAL STRONG GROUND MOTIONS

Boming ZHAO[1], Masanori HORIKE[2] ([1]Geo-Research Institute, JAPAN, [2]Osaka Institute of Technology, JAPAN)

We examine the possibility for simulation of high-frequency vertical ground motions by an extended stochastic method using corrected microtremor horizontal-to-vertical spectral ratios (H/V ratios). Comparing earthquake-motion and microtremor H/V ratios we show that, although microtremor H/V are smaller than earthquake ones, their spectral shapes are similar. It was suggested that the difference between two ratios is controlled by local geological conditions, and hence earthquake HV ratios can be obtained from microtremor HV ratios using a correction factor (CF) common for geologically similar sites. At first we show that the CF is almost the same among geologically similar sites in Osaka basin, Japan. Then, we reproduce vertical strong ground motions of the 1995 Kobe earthquake. We also tried to extend our method for simulation of P wave and P coda. 12 observation sites in the Osaka basin were used. The sites are located in different geological conditions: rock (2 sites), hard-sediments (4 sites) and soft alluvial sediments (6 sites). The CF was derived from the difference between the microtremor and the earthquake-motion HV ratios by Least Square Fitting. We used both HV ratios in the frequency range 0.5 Hz to 10 Hz. At all the sites the corrected microtremor HV ratios are similar to the earthquake motion, indicating that the CF are estimated appropriately. However, it should be mentioned that using of these results should be limited within the Osaka basin. Then we simulated vertical ground accelerations for the 1995 Kobe earthquake using the corrected microtremor HV ratios. Strong horizontal ground accelerations were calculated using the stochastic simulation method in conjunction with the ω^2 source spectra (Boore, 1983). Vertical accelerations were computed by the same method except for using modified source spectra where the ω^2 source spectra are divided by the corrected microtremor HV ratios. It should be mentioned that the modified source spectra are required only for the convenience of simulation. We replaced three asperities of the source rupture model of Kamae and Irikura (1998) with three point sources, which are located at the center of the asperities. The radiation coefficient for vertical motions was assumed to be the same as for horizontal motions, 0.64. Subsurface structure models of sediments at the target sites (soft alluvial sediments) were derived from results of the reflection survey and the microtremor array surveys. For the sites on soft alluvial sediments the CF were varying from 1.7 to 2.1, we assumed CF = 2.0 for target sites. Simulated horizontal and vertical peak accelerations and durations of the S wave group were similar to the observed ones. Also, enriched high-frequency content of vertical motions was reproduced well. The non-linear effects at sites are discussed. Our results show that the extended stochastic simulation method may be a useful tool to calculate the high-frequency vertical strong ground motions in the area where the correction factors are the same at geologically similar sites.

GROUND MOTION CHARACTERISTICS IN THE TAIPEI BASIN (NORTHERN TAIWAN) DURING LARGE EARTHQUAKES OF DIFFERENT LOCATION

Vladimir Yu. SOKOLOV[1], Wen-Yu JEAN[2], Chin-Hsiung LOH[2], Kuo-Liang WEN[3] ([1]Karlsruhe University, Geophysical Institute, [2]National Center for Research on Earthquake Engineering, Taiwan, [3]Institute of Applied Geology, National Central University, Taiwan)

The paper compares ground motion characteristics (Peak Ground Acceleration, Fourier and Response Spectra, local site response) observed in the Taipei basin - the triangle-shaped alluvium structure with maximum thickness of sediments up to 400 m, which is located in the northern part of Taiwan Island. The ground motion parameters in the Taipei basin was studied using the records of more than 70 earthquakes located to the South, Southeast and East of the basin and occurred in 1993-2002. The magnitude range is from 2.6 to 7.3 on the local magnitude scale, focal depth is between 1 km and 118 km, and the hypocentral distance range is from 10-15 km to 150-160 km. The database includes the records from the Chi-Chi earthquake of September 21, 1999 (ML = 7.3), two large (ML > 6.5) aftershocks, and the Hualien earthquake of March 31, 2002 (ML = 6.8). The Chi-Chi and Hualien earthquakes, even if occurring more than 80-100 km from the basin, caused severe damage in the Taipei area. The unique set of the TSMIP (Taiwan Strong Motion Instrumentation Program) recordings provides an opportunity to analyse the peculiarities of the basin response with respects the earthquake location. It has been shown that distribution of ground-motion parameters throughout the Taipei basin is determined by the joint influence of propagation path, subsurface structure and local soil properties. The ground motion characteristics depend on location of stations and location of earthquakes. Thus, one single design curve and seismicity coefficient (PGA value) proposed by building code are not adequate for the whole basin area.

THE ATTENUATION OF VERTICAL AND TWO HORIZONTAL GROUND MOTIONS

Guoxin WANG (Earthquake Engineering Research Institute, Department of Civil Engineering, Dalian University of Technology)

It is known that the every component of ground motions has different characteristics in many aspects, such as response spectrum, intensity, frequency and so on, as compared with others, so the structural response problems concerning the multi-dimensional earthquake action have been paid more and more attention. Usually, only the differences between vertical and horizontal components are considered, two horizontal components are treated equally for simplification when multi-dimensional ground motion should be considered in structural design. In fact, this simplified method obliterates the efficiency of multi-dimensional seismic analysis in a limited way, even the differences between two horizontal components may be smaller than that between vertical and horizontal components. The main purpose of this paper is to understand the differences between the vertical and two horizontal components further. First, the strong ground motion database is rechecked and classified depending on the site conditions, and then the acceleration response spectrum of every component is calculated. The response spectra ratios of two horizontal components (response spectra with larger peak acceleration to another one), vertical to each horizontal

---

component and vertical to the average of two horizontal components are analyzed finally in this paper. The results show that there are some correlations between the response spectra of different ground motion components, and the magnitude, distance and site condition can also have some affection on the distributing characteristics of strong ground motions. The more valid methods should be considered further in order to analyze the multi-dimensional structural seismic response.

LONG-PERIOD GROUND MOTION FD SIMULATION DURING 1984 WESTERN PART OF NAGANO PREFECTURE EARTHQUAKE-THE INFLUENCE OF 3D UNDERGROUND STRUCTURE IN KANTO PLAIN-

Nobuyuki YAMADA[1], Hiroaki YAMANAKA[1], Shin KOYAMA[2] ([1]Tokyo Institute of Technology, [2]National Institute for Land and Infrastructure Management)

1984 Western part of Nagano Prefecture Earthquake (MJMA: 6.8) occurred at central Honshu Island in Japan with heavy damaged around the source area. This event was recorded at some JMA observation stations. Koyama et al. (1992a) pointed out one of some records had a distinct later phase with a delay time of 1 minute after arrival of initial S-wave only at Kumagaya JMA station in the northern part of Kanto plain. According to their work, the initial S-wave amplitude has a predominant period at about 6.0 sec and the direction propagation of N50W, which is different from orientation of the epicenter. Furthermore, they point out the generation of the large later phase depending on the location of hypocenter and source mechanism from the analysis of seismic records of the main and after shocks at Kumagaya. From ray tracing simulation Koyama et al. (1992b) qualitatively showed the propagation paths of the Love waves considering the 3D effects of sedimentary basin. We carried out FD simulations of the long-period ground motion during 1984 Western part of Nagano Prefecture Earthquake and the other events which generated similar later phase using the three-dimensional underground structure model proposed by Yamanaka and Yamada (2002). A computed area was 220km (NS) 330km (EW) include from Kanto to Tokai district with a depth of 50km down the upper Moho continuity. Minimum grid spacing was 0.4km and a total grid number was 24 million. A source rupture process of the main shock was referred from result of Yoshida and Koketsu (1984). The simulation technique used three-dimensional finite difference method with 2nd-order time approximation and 4th-order space approximation (Graves, 1996). The synthetic waveforms of the FD simulations showed the distinct later phase only at Kumagaya. The analysis indicated the appropriateness of the Koyama's interpretation. Although, we can simulate qualitative feature of the observed motion at Kumagaya, perfect matching of the synthetics and observation is still difficult task. It is required in future study to improve subsurface structure model near the Kumagaya station.

REDUCTION OF GROUND MOTION VARIABILITY USING THE VARIANCE COMPONENTS TECHNIQUE

Chu-Chuan P. TSAI[1], Yi-Hau CHEN[2] ([1]Inst. of Earth Sciences, Academia Sinica, [2]Inst. of Statistical Science, Academia Sinica)

The 1999 Chi-Chi earthquake created a significant increase of strong-motion data set in Taiwan. Data from the main shock and aftershocks of the Chi-Chi event and those occurred elsewhere around this area offer an opportunity to explore the variability of ground motion estimates in Taiwan. Using the variance components technique, Chen and Tsai (2002) decomposed efficiently the prediction errors of ground motions into three components: the earthquake-to-earthquake, the site-to-site, and the residual. From a data set of over thirty thousand records of various site conditions, the percentages of variances of the prediction errors, partitioned into the earthquake and site components, are dependent on the numbers of earthquake events and stations in the sampled records; however, both the variances are in general smaller than that of the residual. It is apparent that the path-to-path component of the variability of ground motions is embedded in the ˝residual.˝ Empirically based on the estimated variance components, the path component of variance is approximately comparable to those of the earthquake and the site. Thus, the prediction errors of ground motions can be partitioned with one more step into earthquake-to-earthquake, site-to-site, and path-to-path components, and the remaining ˝smaller residual.˝ From the data in Taiwan, the variability of the site and path components is more coherent in space than that of the earthquake. This implies that the site and path components of variability are more feasible to be extracted from the total prediction errors than the earthquake component. The results show that the prediction errors of ground motions reduce dramatically after ground motion estimates have been corrected for the site-to-site and path-to-path components of variability. This reduction of ground motion variability has significant implications for probabilistic seismic hazard analysis.

SIMULATION OF GROUND MOTIONS DURING THE 1993 HOKKAIDO-NANSEI-OKI EARTHQUAKE BY EMPIRICAL GREEN'S FUNCTION METHOD AND STOCHASTIC GREEN'S FUNCTION METHOD - VERIFICATION OF CHARACTERIZING PROCEDURE OF EARTHQUAKE SOURCE MODEL FOR STRONG MOTION PREDICTION -

Akira FUKUKITA[1], Jun'ichi MIYAKOSHI[2], Kazuo DAN[2], Kazuhiko YASIRO[3] ([1]Institute of Technology, Shimizu Corporation, [2]Izumi Research Institute, Shimizu Corporation, [3]Tokyo Electric Power Company)

We simulated strong ground motions during the 1993 Hokkaido-Nansei-Oki, Japan, earthquake (M_{JMA} 7.8) based on its variable-slip rupture model and on its characterized asperity models to verify the characterizing procedure of source models for the strong motion prediction in future earthquakes. The asperity models were characterized by the total seismic moment, the short-period level of the source spectra, and the ratios of the area, the slip amount, and the effective stress on the asperity to those on the entire fault.First, the empirical Green's function method was applied to the simulation of the records at Sapporo JMA and Akita JMA, and the following results were obtained: 1)The asperity model whose asperity was arranged at the shallow position according to the final slip distribution of the variable-slip rupture model reproduced the long-period earthquake motion of 10 seconds, but this model produced a little larger short-period earthquake motion of 0.2 AE0.5 seconds than the records. 2)The asperity model whose asperity was arranged at the deep position according to the seismic moment or short-period level distribution of the variable-slip rupture model reproduced the short-period earthquake motion of 0.2 AE0.5 seconds, but this model produced less long-period earthquake motion of 10 seconds than the records. 3)From the above results, the location of the long-period radiation of 10 seconds was different from that of the short-period radiation of 0.2 AE0.5 seconds. Next, the stochastic Green's function method was applied to the wide area (192,000km²=230,400points) including the epicentral region, and the following results were obtained: 1)The asperity model whose asperity was arranged at the shallow position according to the final slip distribution of the variable-slip rupture model produced a little larger seismic intensity than the variable-slip rupture model did. 2)On the other hand, the asperity model whose asperity was arranged at the deep

position according to the short-period level distribution of the variable-slip rupture model produced the same seismic intensity as the variable-slip rupture model did. This study was jointly funded by eleven electric power companies in Japan.

SIMULATION OF ACCELERATION SPECTRA OF 1986 DHARMSALA EARTHQUAKE USING RANDOM VIBRATION THEORY

Shikha RAJPUT[1], Sanjeev KUMAR[2] ([1]KURUKSHETRA UNIVERSITY,INDIA, [2]NATIONAL GEOPHYSICAL RESEARCH INSTITUTE)

Ground motion of a particular site can be thought of as being influenced bythree main elements: source, travel path, and local site conditions. Thefirst describes how the size and nature of the earthquake source controls the generation of earthquake waves, the second describes the effect of earth onthese waves as they travel (at same path) from the source to a particularlocation,and the third describes the effect of the uppermost several meters of rock and soil and the surface topography at that location on the resultantground motion produced by the emerging or passing earthquake waves. Thenumbers of parameters have been used to describe the characteristics of strong groundmotion time histories. This includes the peck values of ground acceleration,velocity,displacement duration of strong ground motion and the spectral amplitude in terms of Fourier and Response spectra. The earthquake strongground motion are characterized by parameters in time domain such as peck valueof acceleration, duration of strong ground motion as well as by the spectralparameters such as Fourier and Response spectrum in frequency domain. Theearthquake strong ground motion time histories are required to properly evaluatethe seismic hazard of a region. If the recorded time histories are not available than alternate is to simulate the earthquake strong ground motionsusing an effective technique. One of the effective techniques available is ̋Random Vibration Theory˝. The technique states with the windowing of atime sequence of band-limited random white Gaussian noise with zero expected mean and variance. The spectrum of the window time series is multiplied by the model spectrum and transformation back to time domain to get the final timeseries. In the proposed work ̋Random Vibration Theory˝ was applied to simulate the acceleration spectra at nine sites which recorded the 1986Dharmsala, India earthquake. The simulated Fourier spectra are found to bewith good agreement with those of empirical accelerogram of both components(L & T) at Bhawarna and Jawali, T components of N-B, Baron and Sihunta. The match is satisfactory for the L component of Kangra. At Dharmsala and Shahpur the match is poor with simulated Fourier spectra has less energy as compared to the observed accelerogram.

GROUND MOTION CHARACTERISTIC IN THE KAOHSIUNG AREA, TAIWAN

Hsien Jen CHIANG[1], Kuo Liang WEN[1], Tao Ming CHANG[2] ([1]Institute of Geophysics, National Central Universy, [2]Office of the National S&T Program for Hazards Mitigation, National Taiwan University)

Kaohsiung city is the most important harbor in Taiwan. Recently, there are many high-rise buildings and public transportation system are under construction in this area. Therefore, it is very important to know the surface geological conditions for many practical reasons especially after the strikes of 1999 Chi-Chi, Taiwan earthquake. The Central Geological Survey had spent four years to bore more than 50 wells. And now, it is very clear to know the basement depth is changing from 120 to 40 meters for the western and eastern part of the Kaohsiung city. The harbor and commercial area locate at the western part of this area, and the eastern part is small hill area. To serve the purpose of earthquake hazard mitigation, it would be better to understand the soil amplification effect of the Kaohsiung city. We then conducted a research to study the site effects of the Kaohsiung city, which includes analyze the acceleration seismogram data of TSMIP (Taiwan Strong Motion Instrumentation Program) network and two newly installed borehole seismometer arrays, and perform very dense microtremor measurements in the study area. Most microtremor measurements were done during the midnight to reduce artifacts. After carefully selection, we pick 233 records and use the H/V ratio method to get information of soil amplification. From the result, we found it correlated to the basement depth very well. For the purpose of the earthquake resistant design, earthquake engineers must consider the site response at a specific period. For example, the structure period of a ten-flour building is at about 1 second. If the input ground motion is dominate at 1 Hz, then the building will has a resonant effect. Therefore, in this study, we select 10 frequencies (0.3, 0.5, 0.7, 1.0, 1.5, 2.0, 2.5, 3.0, 3.5 and 4.0 Hz) to plot out the contour map for understanding the frequency responses in this area. For the 0.5 Hz, the contours show that main amplification effects occurred at the southern part of Kaohsiung area. With the frequency increasing to 2.0 Hz, the main amplification area move from the harbor and the southern part of Kaohsiung area to the hill area, which locates at the eastern part of Kaohsiung area. For the higher frequency (3.0 Hz), there are no obvious high contour areas. We pick the dominant frequency of each record and plot out the contour map. At the harbor and city area, the dominant frequency is about 0.5 ~ 0.9 Hz, and the northeastern part is about 1.3 ~ 1.7 Hz. We found that the basement structure can explain the contour very well. Yet, the H/V dominated frequency distribution map reveals more detail features.

SS04a/09P/D-015 Poster 1400-264

STRONG MOTION PARAMETERS ESTIMATION IN THE NEAR SOURCE: APPLICATION TO THE 1688 DESTRUCTIVE SOUTHERN APENNINES (ITALY) EARTHQUAKE

Giovanni IANNACCONE[1], Mariateresa BONAGURA[2], Vincenzo NISII[1], Luigi IMPROTA[2], Antonio EMOLO[2] ([1]INGV - Osservatorio Vesuviano, Naples, Italy, [2]Dipartimento di Scienze Fisiche, Universita' degli Studi di Napoli)

We simulated the high-frequency synthetic accelerograms in the near field foran extended source responsible for a strong historical earthquake (M 6.7) occurred in the Sannio region (Southern Apennines, Italy). The study areahas experienced several large earthquakes in historical time and in the last decades is characterized by low magnitude background seismicity. We used a mixed statistical-deterministic procedure in order to simulating theacceleration field. This method is based on the simulation of a large number ofpossible rupture processes, on the same fault, parameterised by differentrupture nucleation points and final slip distributions on the fault plane (obtained according to the k-square model). For each considered ruptureprocess, we computed the seismic wavefield at a grid of receivers around thesource. Due to the large number of synthetic seismograms produced at each receiver, a statistical analysis of results is possible allowing to compute,for example, mean PGA and associated coefficients of statistical variation maps.This method is applied in a double format: to translate by empirical relationships the accelerometric parameters in seismic intensity map to add more constraints to a fault model and to compute the accelerometric records expected at a medium town (Benevento, about 60 km NE of Naples).We considered one of the largest historical earthquake occurred in the region(1688, M 6.7) and integrating seismotectonics evidences and synthetic groundmotion modelling we propose a fault model of the earthquake. For this fault we simulated accelerometric time histories for 100 randomly generated nucleation points and slip distributions at a near source

---

site corresponding to the city of Benevento. The simulation is considered at the bedrock, consequently effects of shallow soils are not included. Finally, the set of accelerometric records are used to yield engineering parameters.

STRONG GROUND MOTION SIMULATION USING DYNAMIC RUPTURE MODEL

Takashi MIYATAKE (Earthquake Research Institure, University of Tokyo)

Computer simulation of the strong ground motion generated from the earthquake rupture process on a shallow strike-slip fault are carried out by using a 3-D finite difference method. The faulting process is modeled using a dynamic crack model with slip-weakening constitutive laws. The near-source ground motion is sensitive to the details of fault rupture processes. So we do not choose the kinematic modelling in which slip-rate time need to be assumed. In dynamic modelling, the slip-rate time function at each fault point is calculated by solving 3D wave equation of motion. We applied the model to several shallow earthquakes. The method is as follows,(1) Initial model of stress drop distribution is estimated using slip distribution inferred from waveform inversion.(2) Initial model of Dc is assumed or estimated using method proposed by Mikumo et. al. (2002). (3) Rupture process is simulated by using quesi dynamic model in which rupture time distribution is assumed to be same as that inferred from waveform inversion. And peak stress distribution is estimated.(4) If the simulated rupture process and slip distribution does not fit the rupture model inferred from waveform inversion, we adjust the parameters and repeat the above process.

STRONG MOTION SIMULATION FOR THE 1999 DUZCE EARTHQUAKE WITH STOCHASTIC GREEN'S FUNCTION METHOD:AMPLITUDE AND PHASE CHARACTERISTICS OF THE DUZCE BASIN

Gulum BIRGOREN, Aaron MOYA, Kojiro IRIKURA (DPRI. Kyoto University)

In most of applications to simulate an earthquake motion with the stochastic Green´s functions, only amplitude characteristics are taken into consideration. Phase characteristics are often disregarded or just assummed to be random. However, when seismic waves take multiple paths from the source, phase information becomes vital to calculate the arrival time of waves. It has been shown by many researchers that the standard deviation of a group delay time, which is basically the first derivation of an unwrapped phase spectrum of an earthquake record, is related to the shape of its envelope in the time domain. Further, the mean value represents the location of the maximum of the envelope. Hence, this suggests the accurate calculation of the duration of a stochastic Green´s function especially at the basin structure region. Based on the assumption stating that the observed ground motion can be represented as the multiplication of source, site and propagation effects, group delay time also can be regarded in a similar manner except for the sourcefactor. The main objective of this study is to investigate the amplitude and phase characteristics of the Duzce Basin using observed strong motion data. We have used the aftershock records of the 1999 Duzce event recorded at 15 stations located in and around the Duzce Basin within the epicentral distances of 50 km. Strong motion records were provided from the temporary array of Earthquake Engineering Department of Bogazici University and Columbia University. We have estimated the amplitude characteristics through a spectral inversion method using several events and stations. Regarding phase information, we have calculated the groupdelay time and mean and standard deviation of each waveform through a wavelet transformation to represent their frequency content variation with time. We have checked the scattering of the group delay time and edge of the basin to check the directivity effect. For further steps, this information will be used to get the precise Green´s function calculation for the stochastic simulation of the strong ground motion. Results can also be the reference to create a sample phase spectrum for this region.

SS04a/09P/D-018 Poster 1400-267

GROUND MOTION PREDICTION IN THE OSAKA BASIN BASED ON DYNAMIC RUPTURE SCENARIOS AND THREE-DIMENSIONAL UNDERGROUND STRUCTURE MODEL

Haruko SEKIGUCHI[1], Yuko KASE[1], Haruo HORIKAWA[1], Tatsuya ISHIYAMA[1], Kenji SATAKE[1], Yuichi SUGIYAMA[1], Arben PITARKA[2] ([1]Active Fault Research Center, GSJ/AIST, [2]URS Corporation)

We compute ground motion in and around the Osaka sedimentary basin, central Japan, from expected future large earthquakes that have high potential to cause considerable damage there. The possible sources of such earthquakes are active faults bordering or lying inside the basin, the plate boundary about 200 km to the south of the basin (the Nankai trough) and inside the subducted Philippine Sea Plate. Looking back the past, the 1995 Hyogo-ken Nanbu, or Kobe, earthquake (M7.2) occurred on the Rokko fault system hemming the northwestern margin of the basin, generated ground motion of up to VII on the JMA scale along the northwestern margin of the basin. The 1707 Hoei-Nankai earthquake (M8.4), the historically recorded largest earthquake on the Nankai trough, is estimated to have brought ground motion of about JMA intensity VI in the Osaka basin and even intensity VII along the eastern edge of the basin. The 1952 Yoshino earthquake (M6.8) occurred at about 10 km to the east, 60 km depth inside the subducted plate, and caused 2 deaths and 9 complete collapses of building in Osaka prefecture. Theoretical calculation of ground motion is from earthquake rupture scenarios in a three-dimensional underground structure model of the Osaka basin. We compiled available geophysical and geological data including the latest ones and constructed a three-dimensional structure model in 100m mesh data in which sharp offsets on faults are realistically expressed. Rupture scenarios on active faults are generated by numerical simulations of dynamic rupture considering friction law on the fault planes. Fault geometry and stress fields surrounding them are assumed from available geological and geophysical information. We made many simulations varying the unknown parameters such as hypocenter location, stress drop at rupture, and separation distance between fault segments to examine the variation of possible scenarios. Simulations of ground motions are carried out using three-dimensional finite difference method. For earthquakes on active faults, the resultant ground motion distribution strongly depends on the location of the causative fault and the rupture process. Hypocenter location and/or segment-gap distance result in different rupture process on the same fault plane and cause forward directivity effect in different directions. On the other hand, ground motion distributions from interplate-type and slab-type earthquakes are more controlled by the subsurface structure of the Osaka basin because of large hypocenter distances.

NEW PEAK GROUND ACCELERATION MAPS FOR EGYPT

Mohamed Ahmed GAMAL, Yehia ELsaid ABDELHADY (Geophysics)

Seismic hazard maps for Egypt are updated using the so-called total probability theory. A

modified and updated earthquake catalogue till 2000, earthquakes occurring in Egypt and surrounding areas is used for the correlation of the seismic activity with the geo-tectonic elements and seismic sources zones in Egypt and surrounding areas. Estimation of recurrence relationships and regression constants, maximum magnitude earthquake was calculated for 72 source zones used in the present study, with two new zones at Gilf EL Kebir and Abu Debab Area. These data were used to generate peak ground acceleration contour maps based on the regionally developed PGA attenuation relation for all shallow seismic sources for respective forecast time periods (exposure times), 50 and 100 years. Hazard maps were calculated using the computer program developed by McGuire (1976).The same data were used to generate iso-acceleration contour maps based on the regionally developed PGA attenuation relation for the intermediate seismic sources of Greece for the same time periods (exposure times), 50, and 100 years. Using the same program developed by McGuire (1976), it includes the effect of 6 intermediate sources separately. These maps were used to interpret the amount of risks reaching the northern coast of Egypt at which fast urban communities and construction work is done.

SHOULD WE CONSIDER SEA IN SIMULATING SEISMIC GROUND MOTION?: SOME NUMERICAL EXPERIMENTS

Ken HATAYAMA (National Research Institute of Fire and Disaster)

I investigated the effects of the sea on seismic ground motion through some numerical experiments and examined the necessity of considering the sea in ground motion simulation. To specify the effects of the sea, I compared the waveforms calculated for the models including the sea with those done for the models ignoring the sea. Japan is prone to oceanic earthquakes with large magnitudes and now four hypothetical earthquakes along the trenches in the Pacific Ocean are considered to be likely in the near future. For these earthquakes, magnitudes over 7 are anticipated. Around these source regions, the depth of the sea is several hundred meters and obviously we have to recognize that the seismic waves come to us after propagating across the sea. It is nevertheless usual to ignore the sea in numerical methods to simulate ground motion. This study aims at examining whether ignoring the sea is valid. The subsurface structure models examined in this study are very simple. The models are composed of a sea part and a land part. Both parts are horizontally stratified layers overlying elastic half-space and as regards the sea part the medium of the uppermost layer is water, which is regarded as the ideal fluid here. For such models, I solved impulse responses of the two-dimensional P-SV wave-field in the frequency domain and velocity waveforms are calculated by convolving the impulse responses for a certain point source with Ricker wavelets. The impulse responses were calculated by the direct boundary element method using the Green function for horizontally layered media, which was originally presented by Fujiwara & Takenaka (1993) to calculate seismic wave-field in sedimentary basins. I first applied this technique to media in which solid and fluid coexist and interestingly found that the hyper-singularity appears in some boundary integrals. The most interesting feature of the numerical technique used here is that we can calculate Rayleigh waves alone as well as the total waves. From the comparison of the waveforms from the models including the sea with those from the models ignoring the sea, I found the effects of the sea with a depth of several hundred meters on seismic ground motion within a period range from 1.5 to 6 s. (1) The Rayleigh waves are strongly affected by the sea; (2) As the sea is deeper, its effects extends to longer-period ground motion; if the depth is 400 m, around-1.5-s-period ground motion is influenced; if the depth is 800 m, 1.5-to-3-s-period ground motion is influenced; (3) Substituting sediments for sea water, which is usual in ground motion simulation, can have bad influence particularly on vertical components and we would sooner replace water sea by vacuum than substitute sediments for water sea. The above findings strongly suggest the necessity of considering the sea in ground motion simulation and the effects of the sea on the three-dimensional wave-field still remain to be evaluated.

VOXEL FINITE ELEMENT METHOD FOR 3-D ELASTODYNAMIC ANALYSIS

Hiroyuki FUJIWARA[1], Tadaomi FUJIEDA[2] ([1]National Research Institute for Earth Science and Disaster Prevention, [2]Fuji Research Institute Corporation)

Quantitative and deterministic evaluation of seismic wave field is essential for strong ground motion evaluation. Modeling wave fields using numerical techniques such as the finite difference method (FDM) and the finite element method (FEM) is important. The basic equation of FDM is differential equation and that of FEM is weak form integral equation. These methods belong to the more general weighted residual method. The difference between FDM and FEM arises from technique of discretization. In this study, we develop a code for the Voxel Finite Element Method (VFEM) for 3-D elastodynamic anaylysis and compare finite-difference and finite-element solutions of the 3-D elastic wave equation. Because conventional finite element method requires much larger size of memory than that of the VFEM, it is difficult to solve large size problems by using the conventional finite element method. The VFEM is numerically economical version of the conventional finite element method. Absorbing boundary conditions, representation of double couple force, and multi voxel domain decomposition technique for the VFEM are studied. Numerical dispersion, numerical stability condition and numerical complexity of the VFEM are investigated both numerically and theoretically. Numerical dispersion of the VFEM is comparable to the second-order conventional finite difference method. The stability condition of VFEM is 1.73 times longer than the second-order staggered grid finite difference method. Numerical complexity of the VFEM is theoretically 17/5 times larger than that of second-order conventional finite difference method. Although numerical complexity of VFEM is larger than that of FDM, flexibility to model complicated structure, such as complicated topography, is larger for VFEM than FDM.

NEAR REAL-TIME MAGNITUDE DETERMINATION FOR LARGE EARTHQUAKES

Yih-Min WU[1], Ta-liang TENG[2] ([1]Seismological Observation Center, Central Weather Bureau, Taiwan, [2]University of Southern California)

We introduce an empirical method of near real-time, near-field magnitude determination for large ($M > 6.5$) earthquakes. Time integration over the strong shaking duration on the absolute values of the acceleration records is carried out for stations surrounding many large earthquake sources in Taiwan. The integrated quantity, called total effective shaking here, is used in a regression process to derive an empirical relationship for a quick Mw determination useful for a reliable real-time operation in earthquake rapid reporting and earthquake early warning systems.

REGRESSION ANALYSIS TO ESTIMATE MAGNITUDES FROM MACROSEISMIC OBSERVATIONS - COMPARISON OF DIFFERENT METHODS AND APPLICATION TO EARTHQUAKES IN EUROPE

Diethelm KAISER[1], Rolf GUTDEUTSCH[2], Guenter LEYDECKER[1] ([1]Federal Institute for Geosciences and Natural Resources, Stilleweg 2, 30655 Hannover, Germany, d.kaiser@bgr.de, guenter.leydecker@bgr.de, [2]Institute of Meteorology and Geophysics, University of Vienna, Althanstrasse 14, 1090 Vienna, Austria, rudolf.gutdeutsch@univie.ac.at)

Magnitudes (Ms or ML) of earthquakes earlier than 1900 only can be derived from macroseismic observations, i.e. parameters as maximum intensity, felt area or isoseismal radii of different intensities, focal depth. The purpose of our study is to compare different regression methods and to apply them to data sets of earthquakes in Europe to derive appropriate empirical relationships. In general, all input parameters are in error. Several least square fit approximations are presented and compared as follows. (1) Standard regression where one parameter is in error and the remaining parameters are error-free. (2) Mean coefficients of standard regressions with different dependent parameters. (3) Orthogonal regression, minimising the normal distance of data points under the assumption that all parameters are in error (Gutdeutsch et al. 2002). (4) Maximum likelihood, minimising the weighted sum of squares of errors. We use carefully selected instrumental parts of two earthquake catalogues: Shebalin et al. (1998) for Central and Eastern Europe and Leydecker (2003) for Germany. Results: (1) represent extreme cases due to the unrealistic presumption of the method. (2) is of importance as it agrees quite well with (4). (3) agrees well with (2) and (4) if the scatter of data is low. The use of high quality data solely as input in the regression analysis provides reliable relationships to estimate magnitudes. The magnitude estimation of a historical earthquake based on epicentral intensity gives reliable results only if the focal depth is known well enough. Relations using isoseismal radii or felt area are of greater practical importance as they allow more reliable magnitude estimations. Regional variations in the relationships between magnitude, epicentral intensity and isoseismal radius have to be considered. References: Gutdeutsch, R., Kaiser, D., Jentzsch, G. STATISTICAL ANALYSIS OF JMA SEISMIC INTENSITY DIFFERENCES USING SEISMOMETER ARRAY RECORDS

Hidenori MOGI[1], Hideji KAWAKAMI[2] ([1]Department of Civil and Environmental Engineering, Saitama University, [2]Geosphere Research Institute of Saitama University)

The JMA (Japan Meteorological Agency) seismic intensity scale has been playing an important role in earthquake engineering such as seismic risk analyses and planning for disaster response. Since 1996, seismic intensity meters have been densely installed by JMA and many local governments for automatic and rapid announcement of seismic intensities in the region. However, it has been pointed out that the variation of the instrumental seismic intensity at neighboring sites is not small. Therefore, the spatial stochastic properties of the instrumental seismic intensity should be examined for proper utilization of the seismic intensity scale as the regional intensity of seismic ground motions.In this study, seismic intensity difference (SID), the difference between instrumental seismic intensity observed at two sites during each earthquake, was introduced and investigated to examine the statistical characteristics of the instrumental seismic intensity. First, the probability distribution of the SIDs was analyzed using mathematical expressions for probability density functions, averages, standard deviations and percentiles that were derived based on the assumption that the instrumental seismic intensities are Gaussian random variables.Second, the instrumental seismic intensities were calculated using the database of the Chiba and SMART-1 seismometer arrays. The intensities were corrected by the site amplification indices estimated from station-wise average of the intensities. In order to eliminate the deterministic differences, the SIDs were calculated from these corrected intensities. Then, the relationships between above-mentioned statistics of the SIDs and the station separations were analyzed. We have found that the averages and standard deviation monotonously increase with increasing logarithm of the station separation distances ranging from about several meters up to six kilometers throughout the two different arrays. The 50th, 80th, and 95th percentiles were also calculated from the standard deviations of the SIDs.Finally, the probability of occurrence of the same/different seismic intensity scale at two sites was considered by using both observed seismic intensity scale and theoretical ones estimated from the standard deviation of the SIDs. This consideration revealed the following: 1) the same intensity scales can be observed with 95 per cent probability at two stations separated by several ten meters, 2) with 75-80 per cent probability for stations separated by several kilometers, and 3) there is less than 0.5 per cent probability to observe intensity scale difference greater than or equal to two for the site pairs with separation distances discussed in this study. It was also confirmed that the theoretical probability estimated from the standard deviation of the SIDs is close to those probabilities.

RADIATION PATTERN OF SEISMIC MOTION IN SHORT PERIOD RANGE-SPECTRAL RATIO OF TWO SAME LOCATION AND MAGNITUDE EARTHQUAKES-

Ryoichi NAKAMURA[1], Kazuhiko YASHIRO[2] ([1]Tokyo Electric Power Services Co.,Ltd, [2]Tokyo Electric Power Company)

Observation amplitude ratio by same stations and near location of pairs of two earthquakes are studied here using the strong motion records of K-NET installed in Japan. First, we selected the earthquakes occurred at same location and obtained 10 pairs. Here, definition of the same pair is within 10km of the distance between two earthquakes. Second, we calculated response spectra ratio (h=5%) of two seismic records observed a same observation station by two earthquakes. Third, we found that spectrum ratios in short period (1Hz<) of a pair are clearly difference in different azimuth from epicenter to station, although it would be expected that the direction dependency in short period by the radiation pattern from mechanism solution had been small [i.e. Liu and Helmberger,1985] . The direction dependency of amplitude ratio has cyclic change. We assumed this phenomena caused by fault rupture. As Koyama(1987) shown the amplitude changes theoretically as $(c/v-\cos\theta)^{-1/2}$ in case of unilateral rupture, we calculate theoretical amplitude direction dependency using this equation (c : S-wave velocity , v : rupture velocity and θ: azimuth between earthquake and observation site). The calculation result correspond to the observation level of amplitude ratio and shows cyclic change similar to observation. Finally, we obtained standard deviation of the variability of amplitude ratio by the observation data as 1σ=0.4-0.5

in natural logarithm. This value of the ratio can be converted to the value of amplitude (not ratio) as 1σ=0.28-0.35. This value is much smaller than the deviation of attenuation empirical relation which is often used in probabilistic seismic hazard analysis.1) Liu and Helmberger (1985) Bull. Seism. Soc. Am, 75, 689-7082) Koyama(1987) zisin, 40, 397-404 (Japanese)

THREE DIMENSIONAL ATTENUATION STRUCTURE ESTIMATED FROM STRONG MOTION DATA AND ITS APPLICATION TO STRONG MOTION PREDICTION

Ryoichi NAKAMURA[1], Tomiichi UETAKE[2] ([1]Tokyo Electric Power Services Co.,Ltd, [2]Tokyo Electric Power Company)

The three-dimensional attenuation structure of the Japanese islands and site amplification factors are obtained by simultaneous inversion of strong motion records recorded by many acceleration seismometers, i.e. JMA87-type seismometers and the Kyoshin-Net (K-NET) seismometers, almost uniformly distributed in Japan.The results shows that the Pacific slab is high-Q and that the frequency dependence of Q values is expressed as f^0.75.We classified all stations into 5 groups by ground conditions mainly on the basis of S-wave logging data and obtained the site amplification factor for each group. The result shows that the frequency band where large amplification factors are obtained by inversion well agrees with the predominant frequency calculated from S-wave velocity data.Finally, we tried to estimate response spectrum using the 3-D attenuation structure and compared with empirical attenuation fomula. The target of evaluation was the 1996 Hyuganada event (M6.6, h=35km). The observed ground motion of this event showed the attenuation with directional dependancy. The method using 3-D attenuation structure well explains the semi-near field records at approximately Δ=100km, much better than the empirical attenuation fomula. This result shows that 3-D attenuation structure affect ground motion in semi-near field depending of place.

STRONG MOTION SIMULATION CONSIDERING FREQUENCY DEPENDENT RADIATION PATTERN

Shinichi MATSUSHIMA, Toshiaki SATO, Toshimi SATOH, Motofumi WATANABE, Takashi HAYAKAWA (Ohsaki Research Institute, Inc.)

Since strong motions around frequency of 1 Hz strongly affect the degree of structural damage, it is a major concern for us to simulate strong motions in this frequency range accurately for use in disaster mitigation. One of the important characteristics that control strong motions in this frequency range is the radiation pattern. However, the fundamental characteristics of radiation patterns of strong motions in this range are complex (Liu & Hemlberger, 1985, Vidale & Bonamassa, 1993). The authors investigated the fundamental characteristics of high frequency strong-motion including 1 Hz using dense strong-motion network data (KiK-net) for an aftershock event (Mj5.5, depth=9km) of the 2000 Tottori-ken Seibu, Japan, earthquake and found that the frequency range of transition from deterministic to random phenomena of radiation patterns is approximately 1~2 to 5 Hz (Matsushima & Sato, 2002). This result was consistent with the radiation pattern model of strong motions derived from statistical analysis by Satoh (2002) using KiK-net data for mainshock and aftershocks of the 2000 Tottori-ken earthquake. In this study, we incorporated the radiation pattern model into strong motion simulation and verify the validity of the model. We simulated recorded data by K-net for a moderate size earthquae (Mj5.4, 1998/4/22) that occurred beneath the Nobi, Aichi prefecture in central Japan, plain using a hybrid method, since we have a well constrained three-dimensional basin structure in this region. We assumed a point source for the simulation. For the low frequency range, we used a three-dimensional finite difference method (Pitarka, 1999). For the high frequency range, we used statistical Green's function method (Satoh, 1994) considering the model of the radiation pattern that has a transition zone from 1 to 5 Hz. In the transition zone, the radiation pattern is assumed to change linearly. The hybrid method is to sum up these results after filtering then with a matching filter at 0.5 Hz. In order to verify the validity of the radiation pattern model, we did the same calculations using the statistical Green's function method considering the radiation pattern for all frequencies and another case without considering the radiation pattern at all. The results showed that the case considering the radiation pattern model proposed by Satoh (2002) matched the data very well, compared to the other two cases. We acknowledge NIED for the use of KiK-net and K-net data. Some figures were made using GMT. This study was supported by the project Study on the master model for strong ground motion prediction toward earthquake disaster preventionAEfunded by Special Coordination Funds for Promoting Science and Technology, from MEXT (2000-2004).

A METHOD FOR EXTRACTING SLIP TIME FUNCTIONS SPATIALLY CONTINUOUS ON A FAULT PLANE FROM RESULTS OF CONVENTIONAL SOURCE INVERSION

Hiroshi TAKENAKA[1], Yushiro FUJII[1], Hiroshi KAWASE[2], Ken MIYAKOSHI[3], Tomotaka IWATA[4] ([1]Department of Earth & Planetary Sciences, Kyushu University, [2]Dept. of Human-Env. Studies, Kyushu Univ., [3]Geo-Research Institute, [4]DPRI, Kyoto Univ.)

Kinematic source inversion techniques such as multi-time window inversion have been widely applied to broadband seismic records including teleseismic and strong-ground motion records to estimate spatio-temporal slip distribution on seismic fault planes of middle to large earthquakes. In the kinematic source inversion the fault plane is conventionally divided into many subfaults to express spatial variation, and each subfault is represented by a single or many point sources placed at constant intervals on the planar surface. Such conventional subfault discretization is convenient for the representation of spatial distribution of slip in kinematic source inversion. However, it is not continuous at the subfault boundaries, and in the case of a single point source at a subfault, the inversion results (e.g., moment release time history) include not only a slip time function but also a rupture propagation effect inside each subfault. Therefore such inversion results may not be directly suitable for fine-scale numerical modeling such as the FDM computation to simulate near-fault strong-ground motion or to calculate stress changes on the fault planes for dynamic source analysis. In this study we propose a new technique for extracting slip time functions continuous spatially from such conventional inversion results. The spatio-temporal distribution of slip rate is expanded with the linear b-spline basis functions in 2D space and time. Each linear b-spline function is an isosceles triangle defined by three knots, and thus this discretization can give a slip distribution continuous everywhere spatially and temporally. This approach is similar to that employed by Ide and Takeo (1997, JGR) for a kinematic source inversion, but slightly different from theirs. In our representation unlike theirs, it is possible to treat even rupture velocity variation of sub-subfault level if we have its information. The expansion coefficients are determined by fitting the spatial integration of slip rate function over each subfault in a least squares sense with some constraints to the contribution of the subfault derived from the conventional kinematic source inversion. Our technique was applied successfully to the 1997 Northwestern Kagoshima, Japan, earthquake (M_{JMA} 6.5) to extract a spatially continuous slip rate function. We adopted the Miyakoshi´s inversion result as the input data. He applied a kinematic source inversion to K-NET strong motion records (NIED) to obtain the moment

---

release function at each point source located at the center of each subfault. We extracted slip rate function from his inversion results and found that it has a peak of 4 m/s.

SOURCE MODELS OF TWO LARGE INTRA-SLAB EARTHQUAKES FOR BROADBAND STRONG GROUND MOTIONS

Nobuyuki MORIKAWA[1], Tsutomu SASATANI[2] ([1]National Research Institute for Earth Science and Disaster Prevention, [2]Graduate School of Science, Hokkaido University)

Two large earthquakes occurred along the southern Kurile-Hokkaido arc in 1993 and 1994. One is the January 15, 1993 Kushiro-oki earthquake (Mw=7.6) and the other is the October 4, 1994 Hokkaido Toho-oki (Shikotan) earthquake (Mw=8.2). Both events are intra-slab earthquakes occurring within the subducting slab, and caused considerable damage around their epicentral regions. These earthquakes have two unique characteristics of observed strong ground motions. The first is the much large peak horizontal accelerations compared with the empirical attenuation relationship. The second is the far more extensive felt area compared with that for plate-boundary events having the same magnitude. In this study, we construct source models of these intra-slab earthquakes that explain broadband strong ground motions. Our source models consist of multiple asperities on a fault plane. The number and location of asperities and their parameters (area and stress drop) are estimated by matching the synthetic waveforms (displacement, velocity and acceleration time histories) and spectra to the observed ones. We apply the empirical Green's function method to syntheses of the broadband strong ground motions. The estimated source models have the following characteristics compared with the source models of in-land and plate-boundary earthquakes having the same magnitude: (1) the total asperity area is much small, and (2) the stress drop is extremely high (about 400 MPa). These indicate that the large intra-slab earthquake source radiates seismic energies from a small area in short time duration. This source process results in extremely strong radiation of short-period seismic waves as observed during the two large intra-slab earthquakes. Finally we confirm a correlation between outer fault parameters (entire fault size, seismic moment and short-period level of the acceleration source spectrum) and inner ones (areas and stress drops of asperities) for the two intra-slab earthquakes.

DIFFERENCES IN GROUND MOTION AND FAULT RUPTURE MODELS BETWEEN SURFACE AND BURIED RUPTURE EARTHQUAKES

Takao KAGAWA[1], Kojiro IRIKURA[2], Paul G. SOMERVILLE[3] ([1]Geo-Research Institute, [2]Disaster Prevention Research Institute, Kyoto University, [3]URS Corporation)

We have studied differences in ground motion and fault rupture characteristics between surface rupture earthquakes and buried rupture earthquakes. We found that the ground motion generated by buried rupture in the period range around 1 sec. is larger than the average empirical relationship for crustal earthquakes (e.g. Abrahamson and Silva, 1997). On the other hand, ground motion from earthquakes that rupture the surface is smaller in the same period range. This phenomenon is considered to be caused by differences in fault rupture process between the two types of earthquakes.We reanalyzed original source slip distribution data, used by Somerville et al. (1999) to construct scaling relations for source parameters of crustal earthquakes, and divided them into two groups of surface rupture and buried rupture earthquakes. It was found that the large slips of surface rupture earthquakes are concentrated in the depth range shallower than about 5 km, i.e. their asperities are shallow. On the contrary, large slips of buried rupture earthquakes are spread over the depth deeper than 5 km, i.e. asperities are deep. We also found that the rupture area of buried rupture earthquakes is clearly smaller than that of surface rupture earthquakes having the same seismic moment [Kagawa et al.(2001)] and deep asperities have several times larger apparent stress drops than shallow asperities. Furthermore, slip velocities of deep asperities are almost twice that of shallow asperities.To test whether these differences in source characteristics can explain the observed differences in ground motions between the two types of earthquakes, we constructed asperity fault rupture models for surface and buried rupture earthquakes and calculated strong ground motion in the near fault region by the stochastic Green's function method [Kamae and Irikura (1992)]. The simulated ground motions in the period range around 1 sec. have similar characteristics as those of the observed ground motions. We conclude that the difference in ground motions between two types of earthquakes is caused by the difference of the rupture area vs. magnitude scaling, depth of asperities, their apparent stress drop and slip velocity.[REFERENCES] Abrahamson and Silva (1997), SRL, 68, 94-127. A STUDY ON DEVELOPING 3-D BASIN STRUCTURE MODEL CORRESPONDING TO INFORMATION AVAILABLE IN THE TARGET AREA

Takao KAGAWA, Boming ZHAO, Ken MIYAKOSHI (Geo-Research Institute)

We propose a practical procedure for construction of 3-D basin structure model for strong motion simulation that combines a simplified layered 3-D deep structure and shallowest fine velocity structure under site. The methods were applied to the Osaka Basin, Japan.Similar to Koketsu and Higashi (1992) we applied the 2-D 3rd-order B-spline function to construct structure model from the available exploration information. Using the spline function, we can produce smoothed model with any accuracy corresponding to information available in the target area. The Osaka Basin is one of the best-investigated sedimentary basins in the world, a lot of geophysical explorations have been conducted here and the results are published. So we can construct detailed structure model that matches geological model and smooth enough for numerical calculations at the same time. On the other hand, for a poorly explored area we can make at least a very rough spline model from a scarce data.Kagawa et al. (1998) constructed a 4-layered velocity structure model for the Osaka Basin that explains well the dispersion of Rayleigh waves, derived from the microtremor array measurements. The velocity in the uppermost layer of the model is estimated as 350 m/s (engineering bedrock). Here, the model was verified by the wave propagation simulation using 3-D FDM. The results agree well with the observed ground motions in frequency range f < 1 Hz.Deep borehole explorations until granite bedrock (depth around 1.6 km) were conducted at the Higashinada site. For this site we added the shallow borehole velocity structure (from surface to the engineering bedrock) to the 4-layered model and compare the site response of such structure with site response of detail 1612-layer model (thickness of each layer 1 m). The responses agree very well in wide frequency range, both f < 1 Hz and f > 1 Hz. This indicates that simplified deep velocity structure plus detail shallow data can be used to simulate realistic site response.Modeling sedimentary basin structure is important for strong motion estimation. Without a good model of structure, any powerful numerical method to calculate wave propagation cannot work well. Our proposed modeling procedure could be a useful tool to get a structure model for strong motion calculation.[ACKNOWLEDGEMENTS] This study was performed through Special Coordination Funds, titled 'Study of the master model for strong motion prediction toward earthquake disaster mitigation' of the Ministry of

CHARACTERIZATION OF SOURCE PARAMETERS OF DYNAMIC FAULTING FOR STRONG GROUND MOTION PREDICTION

Kojiro IRIKURA, Hiroe MIYAKE, Luis A. DALGUER (Research section of strong Motion Seismology, DPRI, Kyoto University)

Strong ground motion prediction based on dynamic rupture models is needed to fill thegap left by the lack of physics of conventional methods. Since dynamic models take intocount the physical conditions of the friction and stress distribution across the fault zone,the characterization of fault parameters can be improved based on more realistic seismicsource properties. The main purpose of the present paper is to derive the ratios of averageslip and seismic moment between the asperity area and total rupture area. First we analyzed and compare consistently analytical solution of classical asperity models by Das and Kostrov (1986), Boatwright (1988) and Madariaga (1979). Then we started our study with dynamic rupture simulation of many theoretical circular asperity models keeping the ratio of 0.22 between the asperity area and total rupture area. This ratio, proposed by Somerville et al. (1999) after studying many kinematic slip models, fits the characteristic slip models of recent large earthquakes. A fixed rupture velocity (80% of S-wave velocity) and the simple slip-weakening model (friction law on the fault) were used for the dynamic shear rupture propagation. The critical slip distance (Dc) between 0 cm to40 cm was assumed. These values of Dc do not affect the ratios. We found that the kinematic characterized slip model proposed by Somerville et al (1999) is equivalent to the dynamic model when the stress drop surrounding the asperity (background area) is equal to around 10% the stress drop of the asperity area. We also confirmed that the background stress drop strongly affects the ratios; however, the asperity and hypocenter locations slightly affect them. We propose the ratios of average slips, maximum slip, and seismic moments between the asperity and total rupture areas for practical application of strong ground motion prediction.

3D GRAVITY BASEMENT STRUCTURE ASSOCIATED WITH ACTIVE FAULTS IN THE MIDDLE PART OF KINKI DISTRICT, WEST JAPAN

Masao KOMAZAWA[1], Kajuro NAKAMURA[2], Keiichi NISHIMURA[3], Junpei AKAMATSU[2], Ryuichi SHICHI[4], Akihiko YAMAMOTO[5] ([1]Geological Survey of Japan, [2]Disaster Prevention Research Institute, Kyoto University, [3]Faculty of Informatics, Okayama University of Science, [4]College of Engineering, Chubu University, [5]Graduate School of Science, Hokkaido University)

3D gravity basement structure of the middle part of Kinki District, west Japan, was estimated with special attention to basement configuration of three major sedimentary basins: Kyoto basin, Nara basin and Osaka plain, and its relation to active faults bordering or crossing the basins. In these basins, large cities are located and there is a great fear, among people, of extensive damages caused by earthquakes like the 1995 Kobe earthquake or great earthquakes presumed to occur in the first half of the 21st century along the Nankai trough south off Kinki District. In this study we use the precise gravity data published by Gravity Research Group in Southwest Japan(2001). The characteristic features observed from obtained structural model are as follows. In Kyoto basin, the basement descends southwards down to a depression of about 700m deep, with an ENE-WSW striking steep slope probably associated with the Ujigawa fault which has been recently revealed by seismic reflection method. The basement of Nara basin descends eastwards down to about 800m deep near the easternmost margin, along which the Sanbyaku fault runs in the N-S direction. As for Osaka plain, the largest of the three, the basement is separated into eastern and western parts by N-S trending uplift called the Uemachi terrace. The basement of the eastern part descends eastwards steeply and reaches the deepest of about 1600m near the easternmost margin, along which the Ikoma fault runs in the N-S direction. This fault branches off in its northern part and brings about the complicated configuration of basement in the northeast part of Osaka plain. The western part of Osaka plain is part of a large basin including the Osaka bay. Although the basement of this part is flattened compared with other basins, the depth to the basement is estimated to be about 1400m near the eastern margin, along which the Uemachi fault runs in the N-S direction. The Arima-Takatsuki Tectonic Line(ATTL) borders the whole northern margin of Osaka plain, along which the basement subsides steeply down to 500m or more forming an E-W striking basin wall. Of particular interest is that, the subsidence of basement associated with ATTL appears to continue eastwards, with some offset to the north, to the newly revealed Ujigawa fault. Accordingly, it seems evident that the configuration of basements of the basins is governed and complicated by faults bordering and crossing the basins. All these features concerning the fault-related configuration of basement of the basins are considered to affect strongly the levels of ground shaking caused by earthquakes, and therefore the 3D structural model obtained in this study is believed to provide a basis for producing a seismic-risk map of the middle part of Kinki district.

SUGGESTION AND FEASIBILITY TESTS OF A NEW METHOD TO EXTRACT PHASE VELOCITIES OF RAYLEIGH WAVES FROM MICROSEISMS

Ikuo CHO[1], Takuya SHIGA[2], Taku TADA[2], Yuzo SHINOZAKI[2] ([1]Geo-Research Institute, [2]Tokyo University of Science)

We suggest an effective method to extract phase velocities of Rayleigh waves from microseisms. The dispersion characteristics extracted from miocroseisms can be used to determine velocity structures because microseisms are considered as ensemble of surface waves. Our method makes it possible to extract dispersion characteristics from waveform data sets of microseisms that are provided by a simple array consisting of three sensors. In this study the formulation of our method is presented first, and then the practical use of seismic arrays consisting of three sensors is examined by both theory and application to real data sets. Our method is formulated using circular arrays. The number of sensors consisting of an array is related to a shorter limit of wavelength ranges to apply our method. Based on theoretical calculations, when an array consists of three sensors, the shorter limit is 3r (r being the array radius). A longer limit of a wavelength range depends upon observational errors. There is no problem even if the intervals of sensors along a circle are uneven, but the permissible level of unevenness exists depending on observational errors. To test the feasibility of three-sensor arrays we deployed small-scale arrays with radiuses less than several tens of meters at three test sites where the velocity structures were well documented. The phase velocities obtained by analyzing data sets of three-sensor arrays were compared with those obtained by analyzing data sets of five-sensor arrays. It revealed that the phase velocities obtained showed good fits with theoretical ones in both cases within almost the same wavelength ranges. The differences in accuracy and variance were very small. Therefore we limited our attention to three-sensor arrays, and examined the relation

between the normalized variance (γ) in the azimuthal intervals between adjacent sensors and the wavelength range over which our method could be applied (analyzable wavelength range). It revealed that when $\gamma < 0.4$, the analyzable wavelength range was from 5r to 10r at the narrowest. For r < 9 m and $\gamma < 0.4$, the analyzable wavelengths range was from 3r-7r to 20r-40r. We also examined the applicability of our method to large-scale, three-sensor arrays with radiuses of several hundreds of meters. The velocity structures to the depth corresponding to the array radius had not been well documented in this case, so that we compared the phase velocities obtained by applying our method with those obtained by applying the spatial autocorrelation method and the frequency-wavenumber spectral method. Although the phase velocities obtained by these methods were not necessarily compared directly because the analyzable wavelength ranges depend on method, the dispersion curves showed natural linking with each other, overlapping in part. This fact suggests the applicability of our method to large-scale, three-sensor arrays.

ESTIMATION OF S-WAVE VELOCITY STRUCTURES BENEATH URBAN AREAS BY USING MICROTREMOR H/V SPECTRA TECHNIQUE BASED ON BOTH RAYLEIGH- AND LOVE- WAVES

Hidekazu YAMAMOTO, Minoru TESHIMA, Tsuyoshi SANO, Tokumi SAITO (Department of Civil and Environmental Engineering, Iwate University)

It is important to clarify basement structures of urban areas from a view point of earthquake engineering. Microtremor H/V spectra techniques had been conventionally used to estimate the basement depth based on medium responses of horizontal to vertical amplitude ratio of Rayleigh wave. It is insufficient to consider only Rayleigh wave because microtremor consists of not only Rayleigh wave but also Love wave. This study tried to estimate the velocity structures from microtremor H/V spectra based on the theory of surface wave H/V spectra [Arai and Tokimatsu, 2000]. This theory needs both Rayleigh and Love waves to explain microtremor H/V spectra. But, the power ratio of Rayleigh and Love waves in microtremors had not been estimated. We apply three-component spatial auto-correlation analysis, which we have developed, to obtain the power ratio of Rayleigh to Love waves in microtremors. By using this analysis we can obtain the power ratio based on tri-axial microtremor array records empirically.We carried out microtremor observations at three sites in Morioka City, the northern Honshu, Japan. We employ a circular seismic array with seven tri-axial sensors. The array observation aims to obtain the dispersion curve of phase velocity of Rayleigh wave and the power ratio of Rayleigh to Love wave, respectively. Estimated power ratios were around 1.0 at all sites. Therefore, we assumed that the ratios were 1.0 in order to calculate surface wave H/V spectra. The microtremor H/V spectra were estimated from the average of spectra at all sensors. We used genetic algorithm inversion technique to determine velocity structures from microtremor H/V spectra because the inversion of structures from microtremor H/V spectra is a non-linear problem. Estimated velocity structures are consistent with bore-hole data and geological information in those areas. They also agree with the structures estimated from the dispersion curves of Rayleigh phase velocity by using a classical array technique. And synthetic H/V spectra calculated from the structure are concordant with observed microtremor H/V spectra. The results suggest that the use of both Rayleigh and Love wave is necessary to estimate velocity structures using microtremor H/V spectra.

THE VELOCITY STRUCTURE ESTIMATION AND THE SHAPE DETERMINATION OF ILAN BASIN, TAIWAN

Tao-Ming CHANG[1], Yeou-Jyh HWANG[2], Kuo-Liang WEN[3] ([1]Office of the National Science & Technology Program for Hazards Mitigation, [2]Institute of Geophysics, National Central University, [3]Institute of Applied Geology, National Central University)

The Ilan basin, which is located in the northeastern of Taiwan Island, is usually considered as the western end opening of Okinawa Trough. Therefore, the basin shape can be though as half of a bowl. The basin shape is very important for the tectonic development and for the strong motion simulations. In this research, we try to determine the shape of Ilan basin. We use two methods. First of all, we conduct a very dense micro-tremor measurements in the basin. From the H/V spectral ratio results, we selected the dominate frequency for each site and made the distribution map. By using the borehole suspension PS velocity logging results and the dominate frequency map, we get the first order basin shape of the Ilan Basin. Second of all, we performed micro-tremor array measurements at 10 different sites to get the velocity structures. From the micro-tremor array measurements, we can get the surface-wave dispersion curve via F-K analysis. And from surface wave inversion technique, we can get the 1-D shear wave velocity structure can be computed

ESTIMATE ENAR SURFACE VELOCITY STRUCTURE USING RECEIVER FUNCTION TECHNIQUE

Tao-Ming CHANG[1], Jer-Ming LIN[2], Kuo-Liang WEN[3] ([1]Office of the National Science & Technology Program for Hazards Mitigation, [2]Institute of Geophysics, National Central University, [3]Institute of Applied Geology, National Central University)

The receiver function technique has been used to study the worldwide crustal velocity structure for many years. It is a well-accepted technique already. In this research, we try to estimate near surface velocity structures beneath the TSMIP (Taiwan Strong Motion Instrumentation Project) stations using the receiver function technique. It is because, for the past decade, more than 600 acceleration seismometers have been installed in the Taiwan Island. Many acceleration seismograms show very simple waveforms for those shallow seismic events (less than 7 km depth) which were virtually beneath the stations. The basic assumption is that most energy has been blocked out due to the strong velocity impedence for the near surface structures. Therefore, only part of the energy with almost vertical incident angle can reach the ground. It implies the signals received between P and S phases are the reverberations of the vertically incident energy. Base on this assumption, we develop and test the receiver function techniques in studying near surface velocity structures.

A MODEL OF THE SUBSURFACE STRUCTURE BENEATH THE OSAKA SEDIMENTARY BASIN, SOUTHWEST JAPAN

Haruo HORIKAWA[1], Kiyohide MIZUNO[1], Tatsuya ISHIYAMA[1], Haruko SEKIGUCHI[1], Yuko KASE[1], Kenji SATAKE[1], Takanobu YOKOKURA[2], Yuichi SUGIYAMA[1], Hiroshi YOKOTA[3], Masaki SUEHIRO[3], Arben PITARKA[4] ([1]Active Fault Research Center, GSJ/AIST, [2]Institute of Geoscience, GSJ/AIST, [3]Hanshin Consultants Co. Ltd., [4]URS Corporation)

A three-dimensional subsurface structure model for the Osaka sedimentary basin is developed for the evaluation of strong-motion in the basin. Our model consists of sediments

and discontinuous basin-floor geometry, on the basis of newly compiled geological and geophysical data. Calibration of the model with a small earthquake indicates that the model needs further improvement, particularly in the southeastern part of the basin. The Osaka sedimentary basin is shaped like an ellipse with the northeast-southwest striking major axis, and is bounded by active fault systems. The fault system running along the northwest margin of the basin caused the 1995 Hyogo-ken Nanbu (Kobe) earthquake. The Uemachi fault system runs below the eastern part of the basin, one of the population centers in southwest Japan. The Osaka-wan fault systems lies in the middle of the basin, the Osaka bay. We first inferred the depth of several key horizons in the sediments (Holocene to Pleistocene series) and depth of the basin floor, boundary between the sediments and pre-Neogene rocks. Time since deposition of each point in the sediments was interpolated from that of the reference horizons. P-wave velocity was determined by application of an empirical rule to the depth and depositional age, and density and S-wave velocity were derived from the P-wave velocity on the basis of the theory of poroelasticity. The sediments are expressed as a volume with spatially variable seismic velocities and density rather than as a stack of several layers of constant seismic velocities and density. The maximum depth of the basin floor was observed in the Osaka bay and was estimated to be over 2500 m. Overhanging structures formed by repeated thrust faulting were realistically expressed in our model while the structures were approximately described as smoothed ramps in previous models. For a calibration of the model, we compared the observed and simulated waveforms from a small (M~4) earthquake near the eastern margin of the basin. The simulation, using a finite-difference method, well reproduced basin-edge-induced waves, which would not appear from a flat-layers velocity model. However, in the southeastern part of the basin, the simulated basin-edge-induced waves arrives faster than the observed with small amplitudes. This suggests underestimation of the basin depth and/or the overestimation of shear wave velocity in the sediments. Simulated arrivals of body waves agree with the observed ones at all the stations except for those near the northeastern edge of the basin, where the simulated arrivals are later than the observed. This discrepancy may result from underestimation of the sediment velocity.

THREE DIMENSIONAL SUBSURFACE STRUCTURE OF THE NOBI PLAIN

Hideki NAGUMO[1], Yoshihiro SAWADA[1], Suqun LING[2] ([1]Department of Civil Engineering, Nagoya University, [2]Nippon Koei Co. LTD.)

The Nobi plain is situated near the center of Japan with an area of 40 km x 30 km and has been repeatedly suffered from the destructive earthquake. Recently earthquake researchers point out the occurrence of Tokai and Tonankai earthquakes in near future. We investigate three-dimensional subsurface structure of the Nobi plain based on geological survey results and seismic data. Recently Aichi Prefecture Government carried out geological survey from the center to the west of the Plain with 3 reflection lines and 12 microtremor observation sites, which provide detail geological information. Especially two reflection profiles across the western boundary of the plain clarify the edge shape. The Yoro fault forms a step-like structure with the vertical discontinuity of 2.0 - 2.5 km there. To get more geological information we carried out microtremor array measurements at 11 sites in the plain. The spatial autocorrelation method was applied to array data for estimating phase velocities in the frequency range from about 0.5 to 3 Hz. S wave velocity structures are inverted to minimize the misfit between observation and theoretical phase velocities. On the other hand, about 60 seismometers are installed by several organizations in the Plain. M5.4 event occurred near the Yoro fault at shallow focal depth and seismic records were obtained at most sites in the plain. In these observation data, Ps and Sp transduced phases are clearly seen, which are considered to generate at the boundary between sediments and bedrock. Ps-P and S-Sp times become shorter from east site to west site. We assume three sedimentary layers and fix S wave velocities based on geological survey results. Then each layer thickness is estimated by comparing observation Ps-P, S-Sp and S-P times with those calculated by 1D theory though a trial and error method. Together with these results, subsurface structure model of the Nobi plain is obtained. Bedrock is deepest near the western edge and gradually become shallower to the east. These trends are consistent with gravity survey results. Finally we perform numerical simulation of M5.4 event using the three-dimensional finite difference method in the frequency range of 0.1 to 0.5 Hz. The observed waveforms are reproduced well at most stations. This agreement suggests the validity of the model in the frequency range from 0.1 to 0.5 Hz.

ESTIMATION OF Q-VALUE IN KINKI REGION, JAPAN, BY ELIMINATION OF ELASTIC ATTENUATION EFFECT USING RAY THEORY APPROXIMATION IN 3-D VELOCITY MODEL

Anatoly G. PETUKHIN[1], Kojiro IRIKURA[2], Takao KAGAWA[1], Shiro OHMI[2] ([1]Geo-Research Institute, 4-3-2 Itachibori, Nishi-ku, Osaka, 550-0012 JAPAN, [2]Disaster Prevention Research Institute, Kyoto University, JAPAN)

We studied seismic waves attenuation in Kinki region, Japan, in high frequency range 1-10Hz. To do this it was assumed that observed amplitude Fourier spectrum is a product of source, elastic path attenuation, inelastic path attenuation and site effects. Inelastic path attenuation is described by the Q-value. Frequently, to estimate path attenuation effect, Q-value is inverted under assumption that geometrical spreading is spherical (true for uniform velocity model). Actually, elastic attenuation is complex effect that includes geometrical spreading in non-uniform velocity model, reflection and conversion on major velocity discontinuities, free-surface effect. In this study, elastic path attenuation was calculated using Complete Ray Tracing method (CRT) of červen et.al, 1988 in 3-D velocity model. Source and Site effects were eliminated using the double spectral ratio scheme. Travel times inside blocks were calculated by the 3-D ray tracing. After this, Q-values in blocked media were inverted using a tomography approach. For this study we developed 3-D velocity model for Kinki area. This model includes: (1) low-velocity layer, (2) seismogenic zone (or upper crust), (3) lower crust, (4) subducted Philippine Sea plate, (5) mantle wedge (between crust and subducted plate) and (6) upper mantle (below subducted plate). It was assumed that velocities inside each layer have gradient of several percent, and that in high frequency range, at a point of crossing with velocity interface there is no reflection/conversion for upward rays. The whole media of the wave propagation were divided into blocks with constant Q-value according to the tectonic structure: upper crust (UC), lower crust (LC), mantle wedge (MW) and subducted plate (SP). UC was subdivided into 6 smaller blocks with boundaries along main fault systems in Kinki region. For inversion we used borehole data of the Hi-net network, and hard rock/stiff soil data of CEORKA networks and so on. Totally, 1453 records were selected for inversion, number of used earthquakes - 128, stations - 91. Analysis of the results of inversion shows that largest Q~150$f^{0.8}$ was in UC block, smallest Q=60$f^{0.64}$ was in LC+MW block; for SP Q=155$f^{0.4}$. In UC, Q-valueis larger in area north from the MTL: Q=160$f^{0.9}$, than in area south from the MTL: Q=86$f^{0.75}$ or in northern part of Kinki region: Q=92$f^{0.8}$. Based on results of inversion we calculated examples of attenuation correction factor: the difference between path attenuation calculated in the developed model and by the uniform model, for a set of sources. <u>Acknowledgements.</u> Many thanks to consortium "Seismic Waves in Complex 3-D Structures", project leader Vlastislav Červen, for providing CRT package. We also deeply appreciate the National Institute of Earth Science

UPPER MANTLE QS STRUCTURE AND ITS EFFECTS ON STRONG GROUND MOTIONS

Takahiro MAEDA, Tsutomu SASATANI (Division of Earth and Planetary Sciences, Graduate School of Science, Hokkaido University)

It is known that the anomalous upper-mantle structure exists beneath island-arc regions; the existence of a high Q, high V zone about 100 km thick, that is, the descending plate (slab). We investigate effects of the upper mantle Q structure on strong ground motions based on numerous data observed at dense strong motion stations in the eastern part of Hokkaido, Japan. First we investigate strong motion records and their S-wave spectra from intermediate-depth earthquakes. The S-wave spectra at stations on the back-arc side of the volcanic front (VF) are extremely different from those at stations on the fore-arc side of the VF; the S-wave spectra at the back-arc side stations severely lack high-frequency contents. Next we estimate the Qs (Q value for S-wave) structure beneath the eastern Hokkaido. The study zone is tentatively divided into three zones bounded by the coastline and the VF; the three zones mainly correspond to the back-arc side mantle wedge, the fore-arc side mantle wedge and the shallow descending plate. We especially use strong motion data obtained by ocean bottom seismometers for the plate Qs estimate. Two different methods, the spectral inversion and the coda normalization method, are applied to Qs estimate for the fore-arc side mantle wedge and the plate. The Qs values for two zones are nearly the same and show strong frequency dependence. The Qs values obtained from two methods are also nearly the same. Finally we try to estimate Qs values for the back-arc side mantle wedge by using the S-wave spectra observed at stations on the back-arc side of the VF and the source spectra obtained from the inversion. Although the data set for the back-arc side mantle wedge is incomplete due to few records and low signal-to-noise ratios of the S-wave spectra, we suggest that the Qs values for the back-arc side mantle wedge have considerably weak frequency-dependence. We conclude that the anomalous upper mantle attenuation structure beneath eastern Hokkaido reflects the difference in the frequency dependence of Qs value at high frequencies (> 1Hz). The laterally heterogeneous Qs structure obtained in this study is useful for predicting strong ground motion from great intra-slab earthquakes such as the 1993 Kushiro-oki earthquake.

INVERSION OF QS OF SEDIMENTS FROM VERTICAL ARRAY SEISMOGRAMS USING SIMULATED ANNEALING METHOD

Toshimi SATOH (Ohsaki Research Institute)

In this study I apply adaptive simulated annealing (ASA) method (Ingber, 1989) to invert frequency-dependent Qs (quality factor for S-waves) of sediments from vertical array data seismograms. ASA is a global optimization algorithm to statistically find the best global fit of a nonlinear cost-function. Frequency-dependent Qs, an incident angle, and S-wave velocities (Vs) are inverted to minimize the misfit between observed surface-to-downhole spectral ratios and those calculated by one-dimensional wave propagation theory considering obliquely incident SH-waves and SV-waves. Transverse, radial, and vertical components are used for the inversion. Based on numerical experiments it is shown that frequency-dependent Qs, an incident angle and S-wave velocities are inverted very well, independent of initial random numbers used in the ASA algorithm. As the first trial, this method is applied to records of four aftershocks (magnitudes of 3.5 to 4.4) of the 2000 Tottori-ken Seibu earthquake observed at a vertical array station (Akasaki : TTRH04) in the Tottori basin. It is confirmed that all the unknown parameters are inverted stably. The incident angle to the downhole at a depth of 207 m is inverted to be 8.4 degree. The inverted Qs for gravel and Quaternary rock is modeled by Vs/43*f**0.41 using Vs in m/s and frequency (f) in Hz. Recently National Research Institute for Earth Science and Disaster Prevention (NIED) has deployed the digital strong-motion seismographs (KiK-net) at several hundreds sites across the all of Japan. At each site two seismographs are installed at the surface and the downhole at depths between 100 m and a few km. TTRH04 station used in this study is also one of KiK-net stations. The inversion method proposed in this study will be useful to invert Qs of sediments using these KiK-net records. I acknowledge NIED for the use of KiK-net data. This study was supported by the project 'Study on the master model for strong ground motion prediction toward earthquake disaster prevention" funded by Special Coordination Funds for Promoting Science and Technology, from the Ministry of Education, Culture, Sports, and Technology.

3D HYBRID SIMULATION OF THE SOURCE AND SITE EFFECTS DURING THE 1999 ATHENS EARTHQUAKE

Ivo OPRSAL[1], Jiri ZAHRADNIK[2], Anna SERPETSIDAKI[3], G-Akis TSELENTIS[3] ([1]Swiss Seismological Service, ETH Zurich, Switzerland, on leave from Faculty of Mathematics and Physics, Charles University in Prague, Czech Republic, [2]Faculty of Mathematics and Physics, Charles University in Prague, Czech Republic, [3]Seismological Laboratory, University of Patras, Greece)

The damaging 1999 Athens earthquake of M_w=5.9 occurred at about 20km from the city center. The intensity distribution in the capital, ranging from V to IX, was quite irregular due to combinationof the source, path and site effects. The 30-stations temporary network, installed in Athens by the University of Patras, recorded and located morethan 400 aftershocks. The horizontal-to-vertical spectral ratios from the 20 selected aftershock recordings provided site classification. The most significant anomaly (H/V exceeding 4 in the frequency range 1-4 Hz) was found at the Ano Liosia site, belonging to the most heavily damaged zones with intensity IX. The site is situated in a shallow basin whose surface extent is about 4x4 km, and the maximum depth is of about 150 m. The basin is filled with basically 3 layers. The topmost layer consists of alluvium and soft soil, the second one consists of stiff soil and alternations of conglomerates, clay and sand, while the third layer is represented by Neogene formations like marl, marly limestone and sandstone. The bedrock of the basin consists of Triassic limestone and schist. Borders of the basin, where the topmost layer directly overlies the bedrock, are locally quite steep. Based on geophysical data (V_p, V_s, Q) measured at the site, the numerical modeling of the seismic site response was carried out. The 2D and 3D finite-difference techniques were used, and significant edge effects were revealed. No recording of the mainshock is available in Ano Liosia. Nevertheless, based on the finite-extent composite source model, validated by the existing strong motion records in Athens, we found that the bedrock motion in Ano Liosia had its PGA ranging from 0.2 to 0.3 g, resulting from the relatively small epicentral distance (~ 10 km) and the forward source directivity. The source and site effects were combined with each other by a hybrid technique (Oprsal and Zahradnik, JGR 2002), allowing fast full-wave 3D calculations up to 10-20 Hz on a standard personal computer, and showing that the combined source and site effect in Ano Liosia might provide the PGA values locally

THREE DIMENSIONAL FINITE-DIFFERENCE MODELING OF STRONG GROUND-MOTIONSITE EFFECTS DUE TO THE FINITE-EXTENT SOURCE - 1356 BASEL EARTHQUAKE,UPPER RHINE GRABEN

Ivo OPRSAL[1], Donat FAEH[2], Domenico GIARDINI[2] ([1]Swiss Seismological Service, ETH Zurich, on leave from Faculty of Mathematics and Physics, Charles University in Prague, Czech Republic, [2]Swiss Seismological Service, ETH Zurich)

The Basel earthquake of October 18, 1356 (I₀=IX, M=6.9) isconsidered to be one of the most disastrous European events. The Baselarea - Upper Rhine Graben - belongs today to seismically modest regions.Reducing the seismic risk by anti-seismic design needs the knowledge ofthe strong ground motion. The lack of the real data may be effectivelyestimated by numerical modeling using the finite differences (FD).The 3D explicit FD method is designed for topography models on irregularrectangular grids. The single-template approximation to the hyperbolicpartial differential equation (PDE) is solved explicitly in the spatialand the time domain. The boundary conditions at the interfaces (includingthe topographic free surface) are satisfied via a treatment of thematerial parameters. The medium is Hooke´s isotropic inhomogeneous body,with a particle-velocity dependent term added to the PDE to approximateviscoelastic behavior of the medium.The 3D FD modeling is computed for the recently established P and S-wavevelocities structure of the Basel area (Kind, 2002), including thetopography. The relatively simple finite-extent source features arecombined with strong site effects. The finite-extent source is adjacent tothe free surface, since the fault has been recognized through trenching onthe Reinach fault. Several rupture histories are tested because the 1356Basel earthquake source features are not possible to be determined. Themacroseismic information of the Basel area as well as recently established2D computations serve as a comparison to the results.

SEISMIC WAVE PROPAGATION IN THE 3D BASIN STRUCTURE OF NOBI PLAIN

Akira KOTANI[1], Takashi FURUMURA[1], Kazuro HIRAHARA[2] ([1]Earthquake Reseach Institute, University of Tokyo, [2]Graduate school of Environmental Studies, Nagoya University)

We carried out numerical 3D simulations of ground motions to see the wave propagation character in the Nobi Plain, which is one of the high population cities in central Japan. In this area, many large earthquakes occurred in the past, such as the 1891 Nobi earthquake (Mj8.0), the 1944 Tonankai earthquake (Mj7.9) and the 1945 Mikawa earthquake (Mj6.8). In order to mitigate the potential disasters for future earthquakes, 3D subsurface structure of Nobi Plain has recently been investigated by Aichi metropolitan government. We referred to this model together with bouguer anomaly data to construct a detail 3D basin structure model for Nobi plain, and conducted computer simulations of ground motions. We first evaluated the ground motions for two small earthquakes (Mj4~5); one occurred just beneath the basin edge at west, and the other occurred at south. The ground motions from these earthquakes were well recorded by the strong motion networks; K-net, Kik-net, and seismic intensity instruments operated by companies, Aichi and Mie metropolitan governments. We compare the observed seismograms with simulations to evaluate the validity of the 3D model. For the 3D simulation we used a 32nd-order staggered-grid FDM to solve the equation of motions in horizontal directions, and a conventional 4th-order FDM is used in vertical direction. The simulation model is 128km by 128km by 40km, which is discritized at variable grid size of 250-500m in horizontal directions and of 125-250m in vertical direction. We assigned a minimum shear wave velocity as Vs=0.5km/s, at the top of the sedimentary basin. The seismic sources for the small events are approximated by double-couple point source, which impart seismic wave at frequency bellow 0.67Hz. We used a cluster of eight Intel Xeon PCs, and conducted the large scale simulation concurrently. The parallel simulation took memory of 2.5GByte and cpu-time of 16hours. The simulated wavefield for the source beneath the basin edge shows clearly the narrow zone of large ground amplification which is called the ˝basin edge effect˝. On the other hand the shallow source that occurred at south of Nobi plain generates large surface waves in the basin. Comparisons between the observed waveforms computer simulations agree well, so that it is indicating the effectiveness of the 3D model. We therefore conducted a large scale numerical simulation to estimate the pattern of strong ground motion for the 1945 Mikawa earthquake. We employ the fault rupture model of Kikuchi et al (2002) which is derived from the inversion of regional records. We used the Earth Simulator to conduct a high-resolution simulation which employ lower velocity (Vs=0.4km/s) superficial layer and high-frequency seismic source at 1Hz. The simulated wavefield from the Mikawa earthquake is dominating in large surface wave at amplitude over 10cm/s in the center of the Nobi plain. We also find directivity effect of the fault rupture from south to north in the PGV distribution and waveforms. This explains the major pattern of seismic intensity and the distribution of strong motion damage during the earthquake.

EFFECTS OF GEOLOGICAL CONDITIONS ON THE GROUND SHAKING IN THE BUCHAREST URBAN AREA

Neculai MANDRESCU[1], Gheorghe MARMUREANU[1], Mircea RADULIAN[1], Cristea CAPRA[2] ([1]National Institute for Earth Physics, [2]Institute of Geodynamics of the Romanian Academy)

This paper outlines some results obtained through review and reevaluation of the old and new data concerning the natural environment in the Bucharest urban area. The geologic, geomorphologic, hydrogeologic, and other physical features were included in three-dimensional digital models. Maps and cross-sections, showing the geometry and the physical properties of the Holocene and Pleistocene sedimentary deposits, emphasize a good correlation between underlying geologic conditions and site effects. The ground motion amplitudes in the long-period range increase with increasing of the Quaternary deposit thickness. The results of ambient noise measurements (Bonjer et al., 1999) are also well correlated with the structural data. The effects of the geological conditions in the Bucharest area upon the ground motion induced by Vrancea strong and moderate earthquakes, and implications for a new seismic microzonation map will be discussed.

SITE AMPLIFICATION STUDY IN ISTANBUL PROVINCE

Nurcan Meral OZEL[1], Tsutomu SASATANI[2], Asim Oguz OZEL[2] ([1]International Seismological Centre, [2]Division of Earth and Planetary Sciences, Graduate School of Science, Hokkaido University, Sapporo 060-0810, Japan, [3]Kandilli Observatory and Earthquake Research Institute of Bogazici University, 81220, Cengelkoy, Istanbul, Turkey)

On 17 August 1999, a destructive earthquake (Mw=7.4) occurred near Kocaeli city in the northwestern Turkey. More than 15,000 people were killed and more than 20,000 people

---

were injured mainly due to collapse of buildings. The best sets of near-field records from the Kocaeli earthquake were extensively used to study characteristics of the strong motions and rupture process of this event. Strong ground motions during the largest aftershock (Mw = 5.8) of the 1999 Kocaeli, Turkey, earthquake (Mw = 7.4) recorded by 19 observation sites and at various hypocentral distances have been investigated by this study. We constructed an attenuation relationship from the PGA values for the region. This relationship shows that there is one order scatter in the PGA values at the epicentral distances of about 100 km. If compared to the attenuation relationship for the main shock PGA values, the PGA values for the main shock are considerably smaller than expected from a Mw = 7.4 earthquake while those for the largest aftershock surround the median prediction. The spectral source parameters are also estimated based on the near-distance, rock-site records. The parameters for this largest aftershock are A=3.7x1025 dyne/cm/s2 and fc=0.4 Hz that normal values for an Mw = 5.8 earthquake. We study the site effects in and around Istanbul province based on the records of 100 km distance from the largest aftershock, using the traditional spectral ratio method. The S-wave spectral ratios to the reference rock site, YKP (Yapi Kredi Plaza), show noticable amplifications depending on the soil types, but it is somewhat difficult to quantitatively predict the amplification only using the simplified classification of the soil types. The highest amplifications were found for the site of FTH (Fatih), KMP (Kocamustafapasa) and ATS (Ambarli) in the relatively low frequency range of 0.6 to about 6 Hz. Considerable amplifications were also found for the site of DHM (Devlet Hava Meydanlari) and CNA (Cekmece Nukleer Arastirma) though they are classified as at stiff-soil sites. Their spectral ratios are greater than factor of 2 over a wide frequency range. The empirical amplifications at a few sites are compared with the theoretical ones calculated based on the S-wave velocity structures. The comparison shows a qualitative agreement between them.

PRELIMINARY RESULTS OF SITE EFFECTS ASSESSMENT IN THE CITY OF TEHRAN (IRAN) USING EARTHQUAKE AND MICROTREMOR RECORDING

Pierre-Yves BARD[1], Ebrahim HAGHSHENAS[2], Mohammad JAFARI[2], Denis HATZFELD[1] ([1]LGIT/LCPC, Grenoble Observatory, [2]IIEES, Tehran, IRAN)

Within the framework of a French-Iranian cooperation, 13 seismological stations were installed in the city of Tehran (Capital of Iran) from February to July 2002 to record earthquakes and ambient noise over areas of different geotechnical characteristics. Ten broad band velocimeters (CMG40 20 s sensors), three shortperiod sensors (L22, 2 Hz) and 13 Accelerometers (CMG5) were coupled to Reftek stations : each station had both a velocimeter and a accelerometer. An accurate, absolute timing was obtained through GPS receivers. Two stations were installed on the rock, north and east of the city. Despite the high noise level within the city, more than 40 local and regional earthquakes were recorded with a good signal to noise ratio in at least three stations. Four of them have a magnitude larger than 5. The most important event was the Avaj earthquake, a Magnitude 6.5 event located 230 km west of Tehran, which killed more 230 person and destroyed or damaged many villages. In addition, microtremor measurements were performed in 100 points throughout the city in order to provide some guidance on the way to interpolate results obtained from these few temporary stations. The presentation will show the preliminary results obtained with those records, focusing on site effects. It will include classical spectral ratio to two reference stations, receiver functions (H/V) for each of the 13 sites, and H/V ratios from noise recording. Amongst the preliminary results, a very important one is the existence of large, low frequency amplification not only in the southern part of the city, but also in the central part. A result which was not expected on the basis of the available geological and geotechnical information.

LOOKING FOR SITE EFFECTS IN THE DAMAGE DISTRIBUTION – APPLICATION TO ANGRA DO HEROISMO (AZORES) USING MICROTREMORS MEASUREMENTS

Paula TEVES-COSTA[1], Luisa SENOS[3] ([1]Centre of Geophysics, University of Lisbon, [2]Faculty of Sciences, Lisbon University, [3]Institute of Meteorology, Lisbon)

On January 1st 1980, the Terceira Island (in the Azores Archipelago, North Atlantic Ocean) was struck by a 7.2 magnitude earthquake, which killed 56 people and produced lot of damage, in particular in Angra do Heroismo, the island capital. The Azores Archipelago, close to the Azores triple junction (meeting the Africa, the Eurasia and the North America plates) is one of the regions that exhibits higher seismic hazard in Portugal. Reports on seismic swarms, volcanic eruptions and damaging seismic events date from the beginning of its settlement (15th century). The Terceira Island is located in the Central Group and suffered several strong earthquakes. Up to 1980, most of these earthquakes attained villages located on the northern and eastern coast and Angra do Heroü mo, located in the southern coast, have been saved. However, due to the importance of this town, the most populated of the island and considered by Unesco as world patrimony (consequently presenting a high level of seismic risk), it would be suitable to understand its seismic response and to identify the possible existence of site effects within the town, in order to prevent similar damages in a future earthquake. A microtremor survey was carried out consisting on about 250 noise measurements, obtained with Marslite seismic stations with 1Hz Lennartz 3D seismic sensors. Some measurements were performed along the streets in order to identify the possible existence of site effects related with the damages observed on the January 1st 1980 earthquake. Besides, measurements were also performed according a grid with 100m intervals, in order to characterize, in a larger scale, the seismic behaviour of the town. The processing methodology was based on the estimation of the H/V ratio, as defined by Nakamura, and using software developed within the SESAME project. We tried to correlate the H/V results with the damage observed during the 1980 earthquake, taking also into account the existing building typologies. A map of the natural frequencies of the soil formations for the whole town was also performed. This work involved 5 teams of the Lisbon University and from the Institute of Meteorology (Azores delegation) and was performed with the knowledge of the local civil authorities. This work was partially done in the aim of the SESAME European project (EVG1–CT–2000–00026).

ASSESSMENT OF SITE EFFECT IN ROMANIA DURING INTERMEDIATE DEPTH VRANCEA EARTHQUAKES USING DIFFERENT TECHNIQUES

Vladimir Yu. SOKOLOV[1], Klaus-Peter BONJER[1], Mihaela RIZESCU[2] ([1]Geophysical Institute, Karlsruhe University, [2]National Institute for Earth Physics, Bucharest-Magurele, Romania)

The soil response on earthquake ground motion was studied using ground-motion database collected in Romania. Almost all of the earthquakes occurred in Vrancea focal zone (SE-Carpathians), which is characterised by a high rate of occurrence of large earthquakes in a narrow focal volume. The epicentral region is confined to about 60 x 20 sq.km and the seismic activity ranges within an almost vertical stripe in depths between 70 and 170 km. The used ground-motion database includes several tens of acceleration records obtained during three large (M 7.5, 7.2 and 6.9) earthquakes and several hundreds records from more

than 120 small magnitude (M 3-5) earthquakes occurred in 1996-2001. The records were obtained at up to 40 stations; the local site conditions vary from metamorphic rock to deep soft soil deposits. The characteristics of the soil responses were evaluated in terms of frequency-dependent amplification using two techniques. One of the technique is a modification of the well-known horizontal-to-vertical Fourier spectral ratio of the S-wave phase, which was proposed for earthquake ground motion by Lermo and Chavez-Garcia (1994). The second one (Sokolov 1998) consists in calculating spectral ratios of spectra of actual earthquake records (horizontal components) and those modelled for a hypothetical ″very hard rock″ (VHR) site. The VHR spectral model may be evaluated using the Vrancea earthquakes ground-motion database. Besides the local site response, the spectral ratios include effects of source rupture peculiarities and inhomogeneous propagation path, too. However, when using a large enough number of events varying by magnitude, source depth and azimuth, the effects of focal mechanism and directivity are expected to be averaged out. The approach was recently applied for the evaluation of characteristics of spectral amplification for generalised site conditions (site classes B, C and D) in the Taiwan region and for particular sites in the Taipei basin (northern Taiwan). In this paper we analysed the ability of the techniques for intermediate-depth earthquakes of various magnitudes.

ASSESMENT OF STANDARD SITE EFFECTS IN ASHIGARA VALLEY, JAPAN USING STRONG MOTION RECORDS FROM LARGE BUT REMOTE EVENTS

Tomiichi UETAKE[1], Kazuyoshi KUDO[2] ([1]R&D Center, Tokyo Electric Power Company, 4-1, Egasaki-cho, Tsurumi-ku, Yokohama, 230-8510 JAPAN, [2]Earthquake Research Institute, Tokyo University)

Ashigara Valley, Japan is a sediment-filled valley of middle-size (12 km x 5 km). A strong motion observation network has been run by Earthquake Research Institute, the University of Tokyo ant it recovered several large but far events, such as the 1993 Kushiro-oki (Mw 7.6), the 1994 Vladivostok (Mw 7.3), the 1994 Hokkaido-toho oki (Mw 8.3), the 1994 Sanriku-oki (Mw 7.8) and the 2000 Torishima (Mw 7.4). The epicentral distances of these events are longer than 700 km; therefore, assumption of a plane-wave incidence to Ashigara Valley will be permitted. That is, the source and path effects will be common with a sufficient approximation for a middle size valley. As a first step, we obtained average spectral ratios with a reference rock site and amplification factors in time domain using a band-pass filtering technique. A spatial distribution of amplification factors is almost common among the events. The amplification factors of all sites at lower frequency than 0.2 Hz is relatively simple and they tend to large at the south of valley, reflecting deep structure inferred from refraction/reflection surveys and gravity data. We have to pay attention that deviations of spectral ratios among the rock sites are factor of 2 in the frequency range of 0.1-10 Hz. While, the ratios or amplification factors exceed more than factor of 10 at some sediment sites, especially at the south of valley. Using the data set from the Torishima event, we found the apparent velocity of the first S-arrival by the semblance analysis to be 8 km/s. This tells us almost vertical incidence of the first S-arrival part. On the other hand, latter arrivals show very low semblance values and it is difficult to identify proper velocities. Semblance analysis using small array of sediment sites shows that the later arrivals propagate from various directions with low velocities. This tendency is much distinct at high frequency range. These results may suggest that the later arrivals were not direct waves from the source but scattered or secondary generated waves. We checked the variation of spectral ratios using many time windows with same length of 40 s and different starting time. The properties of spectral ratios were approximately stable for different time windows. This result means that there is no significant difference between the amplification characteristics of the direct S arrival and the coda parts. The present results will give a standard amplification factor at a site when we study the effects of source, path and site effects using events of near and local distances.

ESTIMATION OF SITE AMPLIFICATIONS IN ADAPAZARI, TURKEY, FROM MICROTREMOR AND EARTHQUAKE OBSERVATIONS

Hiroaki YAMANAKA[1], Masato KATO[1], Nobuyuki YAMADA[1], Umit GULERCE[2], Recep IYISAN[2], Atilla ANSAL[2] ([1]Dept. of Environmental Sci. and Tech., Tokyo Institute of Technology, [2]Istanbul Technical University)

Heavy damage was experienced in many cities in the north-western part of Turkey during the Kocaeli earthquake and the Duzce earthquake in 1999. Although several strong ground motion records were obtained in the area, there are not enough records in the heavy damage area to understand causes of the damage. Furthermore, subsurface structural data that are very important in assessment of ground motion characteristics are not well defined in the heavy damage area. In this study, we conducted single-point measurements and array measurements of microtremors in Adapazari city for estimation of site amplification factors. First, we estimated subsurface structure using microtremor data from the array and single-point measurements. S-wave profiles down to the basement with an S-wave velocity of 3 km/s were revealed at 5 sites in Adapazari from microtremor array explorations. The basement is as deep as 1 km at the sites in the northern part of the city, while it becomes shallow in the southern sites. We also conducted earthquake observation for small earthquakes in the area by installing 4 stations. From travel time analysis of initial P- and S-waves from small events, we validated the subsurface structural models. Site amplification factors from earthquake data were also compared with the theoretical transfer functions calculated from the models. The agreement of these amplification factors again indicated the validity of the models.

SYNERGETIC EFFECTS OF SOURCE AND SITE ON THE NEAR-SOURCE STRONG GROUND MOTION AT DAMAGED AREAS IN SEDIMENTARY BASINS DURING THE KOCAELI, TURKEY EARTHQUAKES OF AUGUST 17, 1999

Tatsuo KANNO[1], Kazuyoshi KUDO[2] ([1]Advanced Technology Reserch Group, National Reserch Institute for Earth Science and Disaster prevention, [2]Earthquake Research Institute, University of Tokyo)

The estimation of strong ground motions during the Kocaeli, Turkey earthquake of 1999 at downtown Adapazari and Golcuk, where heavy damage was observed, is necessary for understanding the relation between ground motion severity and damage to buildings. For this purpose, we estimated the strong ground motion at damaged area during the mainshock based on the empirical Green´s function method, regarding with underground structures estimated by array observations of microtremors and nonlinear behaviors of soft ground by the equivalent linear method. First, we estimated the bedrock motion during the mainshock by the empirical Green´s function method using the largest aftershock records. We selected five asperities referring mostly to the source inversion results by Sekiguchi and Iwata (2002) for synthesizing the ground motion during the mainshock. We, in addition, assumed that the strong motion was generated by only these asperities. The validity of this simulation was confirmed by the comparison of the strong motion records and the synthetics at several stations near the fault (IZT, SKR, YPT). Then, we convolved the effects of surface sediments taking into account of nonlinear behaviors of soil by an equivalent linear method. As results, the ground motion at a period of 1-2 seconds in downtown Adapazari (ADC; heavy damage) during the mainshock is estimated to be similar to that of JMA Kobe from the Hyogoken-Nanbu earthquake of 1995. The estimated strong ground motion at ADU (slight damage) is smaller than that at SKR (slight damage) in shorter period range than 1 second, and this is qualitatively consistent with the damage level. No strong motion records from the largest aftershock was available in Golcuk area, therefore, we have to estimate the largest aftershock motion as a first step. We apply two-step estimation, that is, we first simulate the ground motion in Golcuk area during the largest aftershock using two small aftershock data, and next we estimate the ground motion during the mainshock using the simulated aftershock motion as EGF. The same source model of the mainshock was used. Response spectra of simulated motions in Golcuk area, except at a mountain site (GLS), show very high level in the longer period range than 1.0 seconds, exceeding to that of JMA Kobe from the Hyogoken-Nanbu earthquake of 1995. We cannot go into details, however, ground motion due to synergetic effects of surface soils and source would be very important. Directivity effects were not distinct in the results of Adapazari; however, the ground motion near Golcuk would be influenced by not only site condition but also source process or rupture propagation of a fault. The ground motion in a longer period than 1 second at damaged area in Golcuk during the mainshock is estimated to be larger than that of JMA-Kobe from Hyogoken-Nanbu earthquake of 1995.

3-D UNDERGROUND STRUCTURE MODEL IN KANAZAWA REGION, JAPAN

Tatsuo KANNO[1], Nobuyuki MORIKAWA[1], Shigeki SENNA[2], Akira NARITA[2], Hiroyuki FUJIWARA[1] ([1]Advanced Technology Reserch Group, National Reserch Institute for Earth Science and Disaster prevention, [2]Mitsubishi Space Software Co., Ltd.)

The Earthquake Research Committee, the Headquarters for Earthquake Research Promotion, the Ministry of Education, Culture, Sports, Science and Technology is planning to create a ″Seismic Hazard Map in General View of the whole of Japan″. This includes two kinds of maps, a probabilistic seismic hazard map and a seismic shaking map for a specific seismic source fault. For the seismic shaking map, empirical attenuation relations and/or hybrid simulation procedure that combined the 3-D finite difference method and the stochastic Green´s function method are applied to evaluate strong ground motions. In such evaluation, especially for the hybrid simulation, a detailed 3-D underground structure of the target area is very important information as well as a detailed source model. In the Morimoto-Togashi fault zone, one of the mapping regions in 2002, some surveys of underground structures have carried out with the aim of understanding the shape of bedrock layer and active fault. However, few data on velocity structures are available. In this study, therefore, we first carried out array observations of microtremors. Then we construct 3-D underground structure model for the hybrid simulation of strong ground motions for an earthquake occurred in the Morimoto-Togashi fault zone, compiling results of the observations, gravity data and so on. We carried out the array observations of microtremors at ten sites in and around Kanazawa city near the Morimoto-Togashi fault zone. Phase velocities of the fundamental mode Rayleigh wave were obtained from observed microtremors by using the spatial autocorrelation method and were inverted to the S-wave velocity structures by an inversion technique based on genetic algorithm. We derived a good correlation between the estimated depth of upper boundary of each layer and its corresponding residual gravity anomaly value at the site. Therefore, we converted distribution of the residual gravity anomaly into one of the depth of upper boundary of each velocity layer using these correlations. As results, we showed the bedrock layer under Kanazawa city shaped like a bowl. The bedrock under the center of Kanazawa city was deepest in the target area and its depth was estimated to be about 3400m. The validity of our underground structure model was confirmed by the comparison with other investigations, for example, results of survey using deep-well boreholes.

ESTIMATION OF STRONG GROUND AMPLIFICATION IN METRO MANILA

Janila R. BAUL-DEOCAMPO (Seismological Observation and Earthquake Prediction Division, Philippine Institute of Volcanology and Seismology)

Metro Manila has been growing and developing without regard for its vulnerability to hazards. From the strategically located Manila City it has grown to include five cities and eleven municipalities. With a total population of 8 million that has been rapidly rising since the last two decades, it is the commercial, industrial, administrative and educational center of the country. It is also the host of past large and damaging earthquakes from seismic source zones that include the Valley Fault System, the Philippine Fault Zone, Lubang Fault, Casiguran Fault and the Manila Trench. With future large-magnitude earthquakes being highly probable in this area, strong ground amplification was estimated. Amplification of spectral ratios are compared with one-dimensional theoretical transfer function generally to validate the theoretical model. Strong ground motion was then estimated to a small extent enclosing the strong motion stations and using the Valley Fault System as causative Fault

NONLINEAR BEHAVIOR OF SOILS IN THE 1995 KOBE (JAPAN) EARTHQUAKE IDENTIFIED BY VERTICAL ARRAY RECORDS

Olga V. PAVLENKO[1], Kojiro IRIKURA[2] ([1]Institute of Physics of the Earth, Russian Academy of Sciences, B. Gruzinskaya 10, 123995 Moscow, Russia, [2]Disaster Prevention Research Institute, Kyoto University, Gokasho, Uji, 611-0011, Kyoto, Japan)

To improve our understanding of the behavior of sedimentary basins in the near-source zones in strong earthquakes, a method is proposed of estimation of stress-strain relations of sediments in situ based on vertical array data. As an example, records obtained during the 1995 Kobe earthquake (Japan) were used to estimate the stress-strain relations in the soil profiles at sites Port Island, SGK, TKS, and NKK in the vicinities of the fault planes and the

obtained relations are analysed.For different layers, different types of nonlinear stress-strain relations were selected, according to the profiling data. To account for temporal changes in the soil behavior, consecutive parts of records were examined, and for successive time intervals, the relations were found showing the best-fit approximation to the observed data. Various lengths of the time intervals are analysed, and the range of optimal values is found. The difference between the observed and simulated accelerogramms and their spectra is analyzed, and found to be dependent on the accuracy of our knowledge of the profiling data. The best agreement was achieved for SGK and TKS sites, where repeated thorough measurements of the profiling data were carried out. The discrepancy between the observed and simulated accelerogramms was found to increase with time from the beginning of the strong motion, which probably indicates that the middle and tail parts of the accelerogramms recorded on the surface are determined not only by the imposed motion on the bottom of the system of sedimentary layers, but also, by processes, induced in the sedimentary layers by the strong motion. At the four sites, vertical distributions of stresses (in bars) and strains (in rel. units) are obtained for all depths, from the surface down to the locations of the deepest recording devices, and the contents of nonlinear components in the ground responses are estimated by the nonlinear system identification technique. The obtained stress-strain relations showed systematic changes in the upper 10 - 15 meters, such as, a progressive reduction of the slopes of the stress-strain curves due to liquefaction at Port Island and reduction and recovery of the slopes at other sites. The method can be applied to evaluate the ground response at sites, where the profiling data are available and an imposed motion can be estimated.

IDENTIFICATION OF THE NONLINEAR BEHAVIOR OF SOILS DURING THE 2000 TOTTORI (JAPAN) EARTHQUAKE

Olga V. PAVLENKO (Institute of Physics of the Earth, Russian Academy f Sciences, B. Gruzinskaya 10, 123995 Moscow, Russia)

 The method for estimation of the stress-strain relations in soil layers at different depths based on vertical array records was applied for the analysis of the behavior of soils in the near-source zone of the October, 6, 2000 Tottori (Japan) earthquake (M=7.3, depth is 11 km). Data of the Digital Strong Motion Seismograph Network Kik-Net were used. Though the earthquake was recorded by vertical arrays at 220 sites located at epicentral distances of 7 to 626 km, the nonlinear behavior of soils was identified for only six sites: the closest to the epicenter sites located at 7 km (max. acceleration 927.2 gal) and 8 km (max. acceleration 720.4 gal) and for sites located at distances of 44 to 99 km (max. accelerations 240.3 - 131 gal). For other sites, located in the near-source zone and far from the source, at distances 24, 26, 31, 32, 33, 41, 45, 46, 52, 53 km and more, either the thickness of the soil layer was less than 20-25 m and resonant phenomena were most important, or profiling data were absent, or accelerations were too small for the occurrence of nonlinearity. For six sites, where the nonlinear soil behavior was identified, stresses and strains (changing with time during the strong motion) were estimated in the soil layers at all depths 0 - 100 m from the surface down to the location of the device at depth. The obtained vertical distributions of stresses and strains depend on the profiling data: the better our knowledge of the parameters of the soil layers, the more realistic the obtained vertical distribution of stresses and strains. Since the profiling data for the Kik-Net sites include only P-wave and S-wave velocities and the composition of soils, we had to approximately estimate another necessary parameters, such as, shear stress in failure, density and damping, and this decreased the accuracy of the obtained results. To evaluate the influence of the profiling parameters on the results of our calculations, two series of calculations were performed for the records at the closest to the epicenter site TTRH02 (epicentral distance 7 km, maximum acceleration 927.2 gal), and the obtained vertical distributions of stresses and strains are compared.

GROUNG RESPONSE OF WEAK AND STRONG MOTIONS IN NEAR DISTANCE

Win-Gee HUANG (Institute of Earth Sciences, Academia Sinica)

 The Taiwan Strong Motion Instrumentation Program (TSMIP), consisting of more than six hundred stations, was widely deployed in Taiwan area by the Central Weather Bureau. One of the particular significant of TSMIP was the amount of high-quality near-source data that it accumulated. The wealth strong motion data recorded at wide range of PGA due to different levels of excitation. Thus offer a good opportunity to study the difference of the amplification effects for a given site in response to different levels of excitation as well as for different geological conditions in near epicenter distance. Regardless the earthquake magnitude, only intensity of ground shaking was considered in this study. We focus on the response spectra calculation and want to realize its behaviors with different surface geology. Also discussed are the results of amplification effects studies for a site in response to weak and strong motions of broad intensity range in near epicenter distance. Our discussion was limited to spectra determined for 5 per cent damping although it could be readily be extended to include other damping values.

EVALUATION OF DYNAMIC GROUND CHARACTERISTICS BASED ON SEISMIC RECORDS, MICROTREMOR AND GEOLOGICAL DATA

Jun TOBITA[1], Nobuo FUKUWA[2], Masaru NAKANO[2] ([1]Department of Architecture, School of Engineering, Nagoya University, [2]Graduate School of Environmental Studies, Nagoya University)

Variation of ground motion characteristics in Nagoya city, Japan, is investigated based on compilation of various soil data, observed seismic ground motions and microtremor data. First, on the basis of microtremor observation at over the 300 sites in Nagoya municipal area, the potential effectiveness of the horizontal to vertical Fourier spectral ratio (H/V) spectrum for the investigation of deep and shallow soil structure is discussed. Several test sites were selected, where various soil tests (boring, PS logging, etc.) were carried out and the borehole strong motion seismometers are installed. At these sites, the H/V spectral characteristics of microtremor and earthquake ground motion were examined, comparing with theoretical characteristics of Rayleigh wave and S wave. It is shown that the peak of the H/V spectrum of microtremor corresponds to layer boundary, of which the impedance ratio (lower layer / upper layer) is large, because the H/V spectrum depends on horizontal - vertical amplitude ratio of the modal shape of Rayleigh wave. The peak period of the H/V spectrum is similar to S wave amplification of surface layers under the condition that the layer boundary has larger impedance ratio over 3. In case of earthquake records, body wave is predominant at mainshock portion soon after the S-wave arrival, and the shape of the H/V spectrum is correspondent to the transfer function by multiple reflection of S wave. Based on the nature of the H/V spectrum mentioned above, the soil structure of Nagoya city area is estimated. For deep soil, predominant period is estimated from a peak in long period range (1 - several seconds) of the H/V spectrum. This period clearly corresponds to the depth of the seismic bedrock with Vs=3km/s. On the other hand, the shape of H/V spectrum is various in the short period range (less than 1 second), showing the variety of shallow soil conditions. Clear peak is observed at the sites where the clear contrast is observed at the engineering-

basis baselayer of Vs=400-500m/s, and the peak period is correspondent to the amplification period of the S wave for the layers above the boundary. It is shown that the existence of the clearly contrasted soil layer is almost detected by the peak period of the H/V spectrum considering the microtremor as a Rayleigh wave. Therefore, the depth of the layers can be estimated from the H/V spectrum by interpolating other exploration information at some sites, for example the deep boring investigation. The nature of the ground in Nagoya city is classified into 6 to 8 areas as Tertiary, diluvium, alluvium, reclaimed land, and so on. Estimated ground vibration characteristics by seismic records and densely measured microtremor records well correspond to these ground conditions.

MULTI-DISCIPLINARY INFORMATION IN THE ASSESSMENT OF EARTHQUAKE HAZARD IN SAPPORO CITY

Tsutomu SASATANI, Kunikazu YOSHIDA (Graduate School of Science, Hokkaido University)

Sapporo City is located on a deep sedimentary basin in the western part of the Ishikari depression, Hokkaido. Mountains exist in the west and southwest part of the city. The population of Sapporo City is about 1.8 million, the biggest city in Hokkaido. In this study, we show multi-disciplinary information in the assessment of earthquake hazard in Sapporo City. Although no disastrous earthquake attacked the city during the last century, we have a lot of evidences of liquefaction induced by the 1834 Ishikari earthquake (M6.5). Recently seismic activity in and around the city has been monitored by several borehole seismometers; detected micro-earthquakes show a linear configuration beneath the boundary between the basin and the mountains. We summarized various data relating to the underground structures. Several PS-logging data show that an S-wave velocity is about 200 m/s at a surface and is 800-1000m/s at a depth of about 500 m. Recently an seismic reflection experiment has been done along Toyohira River near the city center. This experiment delineates shape of the basement-rock layer; the basement becomes shallow toward the mountains. We have also estimated S-wave velocity structures at more than 30 sites by using the microtremor exploration method. The basement-rock has an S-wave velocity of about 3000m/s at a depth of about 3000m. Combining these data, we are now constructing a rough three-dimensional velocity structure beneath the Sapporo basin. We have been carrying out strong motion observations at 30 sites to examine the seismic response of the Sapporo basin. The spatial variation of site amplifications is evaluated as a function of periods based on band-pass filtered records with various pass-bands. At the northern part, long-period seismic waves with a period of about 5 sec are strongly amplified, while at the central part, short-period seismic waves with a period of about 1 sec are strongly amplified. We have also examined the effect of the deep underground structure on seismic motion theoretically. Our goal is to renew the assessment of earthquake hazard in Sapporo City based on multi-disciplinary information mentioned above.

DETERMINISTIC EVALUATION OF REGIONAL SEISMIC HAZARD IN THE IBERIAN PENINSULA

Mariano GARCIA-FERNANDEZ[1], Franco VACCARI[2], Maria-Jose JIMENEZ[1], GiulianoF. PANZA[3] ([1]Institute of Earth Sciences 'Jaume Almera'-CSIC, Barcelona, Spain, [2]Universita di Trieste, Dip. di Scienze della Terra, Trieste, Italy, [3]The Abdus Salam International Centre for Theoretical Physics, Trieste, Italy)

Regional maps of maximum displacement, maximum velocity, and design ground acceleration for the Iberian Peninsula are obtained using a deterministic approach based on the computation of complete P-SV and SH synthetic seismograms. Scenario waveforms are computed in a regular grid covering the region combining input data from a regional seismogenic model, characterized by area sources, a working earthquake catalogue, characteristic fault-plane solutions, and ten average regional crustal models defined after a compilation of available structural studies. Results are compared with previous hazard studies and ground motion observations.

SEISMIC HAZARD ASSESSMENT IN RUSSIA

Valentin I. ULOMOV (Schmidt United Institute of Physics of the Earth, B.Gruzinskaya, 10, 123995 Moscow, Russia)

More than 20% of the area of Russia is occupied by high hazard zones of intensity VIII-IX and IX-X EMS. These include the Russian Far East, the entire southern Siberia and North Caucasus. Some threat is also posed by intensity VI-VII zones in European Russia. The new study of seismogeodynamics and seismic zonation is based on the new methodology, homogeneous data base compiled for North Eurasia and a 3-D lineament-domain-focal (LDF) model of earthquake sources. A set of new General Seismic Zonation (GSZ) probability maps has been made for North Eurasia. The fragment GSZ maps of Russia being accepted as the basis for the national Building Code. The probability of a possible exceedance of seismic intensity within 50 years shapes up as follows: 10 percent (map GSZ-A), 5 percent (GSZ-B), 1 percent (GSZ-C) and 0.5 percent (map GSZ-D). The GSZ-A map was recommended for the construction of residential, public and production buildings; the B and C-maps for the objects that should continue in service even during earthquakes and also for premises housing a large number of people; the GSZ-D map for such high-danger objects as nuclear power stations etc. It is for the first time that seismic zoning involves all of North Eurasia, including the shelves of marginal and inner seas. We have seen that a large part of the Russian territory is subject to stronger seismic hazard than it was believed earlier. In this connection the Government has ratified the Federal Program "Seismic safety of territory of Russia" (2002-2010). Up to this time neither in the former USSR, nor in Russia similar programs did not exist. The purpose of this Program is the maximal increase of seismic safety of the population, reduction of social, economic, ecological risk in seismically dangerous areas of the Russian Federation, decrease of damages from destructive earthquakes by certification, strengthening and reconstruction of existing buildings and constructions, and also preparation of cities and other settlements, transport, power constructions, pipelines for strong earthquakes. A new method is proposed for the monitoring of regional seismogeodynamic processes, and results of studying time variation patterns in the occurrence of earthquakes of various magnitudes. Further research on the ordered patterns in the development of seismic sources in both time and space is required for more reliable localization of potential sources and assessment of seismic hazard. Fixation of the huge file of initial and target data in a digital electronic form within the Geographical Information System is a distinct fundamental achievement of the new technology of seismic zoning as compared with all previous technologies.

A DETERMINISTIC SEISMIC HAZARD MAP OF INDIA AND ADJACENT AREAS

Imtiyaz Ahmed PARVEZ[1], Franco VACCARI[2], Giuliano Francesco PANZA[3] ([1]CSIR Centre for

Mathematical Modelling and Computer Simulation (C-MMACS), NAL Belur Campus, Bangalore-560037, India, [2]Department of Earth Sciences, University of Trieste, Via E. Weiss 4, 34127 Trieste, Italy AND INGV, Instituto Nazionale di Geofisica e Vulcanologia, Naples, Italy, [3]Department of Earth Sciences, University of Trieste, Via E. Weiss 4, 34127 Trieste, Italy AND The Abdus Salam International Centre for Theoretical Physics, SAND group, Trieste, Italy)

A seismic hazard map of the territory of India and adjacent areas has been prepared using a deterministic approach based on the computation of synthetic seismograms complete with all main phases. The input data set consists of structural models, seismogenic zones, focal mechanisms and earthquake catalogues. There are few probabilistic hazard maps available for Indian subcontinent, however, this is the first study aimed to produce a deterministic seismic hazard map for the Indian region using realistic strong ground motion modeling with the knowledge of the physical process of earthquake generation, level of seismicity and wave propagation in anelastic media. The synthetic seismograms at a frequency of 1 Hz have been generated at a regular grid of 0.2×0.2 by the modal summation technique. The seismic hazard, expressed in terms of maximum displacement (DMAX), maximum velocity (VMAX), and design ground acceleration (DGA), has been extracted from the synthetic signals and mapped on a regular grid over the studied territory. The estimated values of the peak ground acceleration are compared with the observed data available for the Himalayan region and found in agreement. Many parts of the Himalayan region have the DGA values exceeding 0.6 g. The epicentral areas of the great Assam earthquakes of 1897 and 1950 in the north-east India represent the maximum hazard with DGA values reaching 1.2-1.3 g. The peak velocity and displacement in the same region is estimated as 120-177 cm/sec and 60-90 cm respectively.

PROBABILISTIC SEISMIC HAZARD ASSESSMENT IN NORTHERN ALGERIA, USING SPATIALLY-SMOOTHED SEISMICITY. PART II: SPECTRAL ACCELERATION AND UNIFORM HAZARD SPECTRA

Mohamed HAMDACHE[1], Jose Antonnio PELAEZ MONTILLA[3], Carlos LOPEZ CASADO[3] ([1]Seismological Survey Department - CRAAG - Algiers - Algeria, [2]High Polytechnic School. University of Jaen. Spain, [3]Theoritical Physics department . University of Granada. Spain)

As a continuation of the first part, seismic hazard in terms of spectral acceleration (SA) for rock soil, has been estimated in the northern Algeria using the spatially-smoothed seismicity methodology. The seismic models, needed in this approach have been obtained by considering all the earthquakes events with magnitude up to Ms 6.5 and greater during the last 300 years. Seismic hazard maps in terms of SA for rock damped at 5%, at the periods of 0.1 , 0.2, 0.3, 0.4, 0.5, 1.0, 1.5 and 2.0 s, with 39.3% and 10% probability of exceedance in 50 years have been obtained. These maps correspond to a return period of 100 and 475 years , respectively. For twelve of the most industrial and populated cities in Algeria, the uniform hazard spectra (UHS) is assessed and examined in details. Using a probabilistic approach, the UHS for rock soil damped at 5% has been derived for the two considered return periods, respectively 100 and 475 years. As a more significant results, observed as well as in the seismic hazard maps than in the UHS results, the expected maximum values of SA are obtained in the region of the Chleff (previously El Asnam), in the central area of the Tell Atlas. Specially, in the vicinity of the Cheliff Quaternary basin, around the location of the most destructive earthquakes of September 9 1954 (Ms 6.8) and of October 10 1980 (Ms 7.3).

NATIONAL SEISMIC HAZARD MAPPING PROJECT OF JAPAN

Hiroyuki FUJIWARA, Shin AOI, Shinichi KAWAI, Toru ISHII, Toshihiko OKUMURA, Yuzuru HAYAKAWA (National Research Institute for Earth Science and Disaster Prevention)

The Great Hanshin-Awaji Earthquake Disaster on January 17, 1995 killed more than 6,400 people. Following on the lessons learned from this disaster, Earthquake Disaster Management Special Act was enacted in July 1995 to promote a comprehensive national policy on earthquake disaster prevention. In accordance with this act, the Headquarters for Earthquake Research Promotion was established. In April 1999, Headquarters for Earthquake Research Promotion fixed ´On Promotion of Earthquake Research - Comprehensive and Fundamental Measures for Promotion of Observation, Measurement and Research on Earthquakes -´. In this article, the Headquarters for Earthquake Research Promotion concluded that preparation of ´Seismic Hazard Map in General View of the Whole Japan´ should be promoted as a major subject of earthquake research. The National Research Institute for Earth Science and Disaster Prevention (NIED) started the special research project ´National Seismic Hazard Mapping Project of Japan´ to support the preparation of seismic hazard maps made by the Headquarters for Earthquake Research Promotion in April 2001. The Seismic Hazard Map in General View of the Whole Japan consists of two kinds of hazard maps. One is a probabilistic seismic hazard map that shows information predicting possibility that a certain area is attacked by a strong ground motion in a certain term by means of probability. The other is a seismic hazard map with specified seismic source fault. This type of hazard map is sometimes called scenario seismic map. As the first step in preparations for producing the seismic hazard maps, which are scheduled to be completed by the end of fiscal year 2004, preliminary versions of probabilistic seismic hazard map for the region centering Yamanashi Prefecture and scenario seismic maps for earthquakes in Itoigawa Shizuoka tectonic line fault zones and Miyagi-ken-oki earthquakes have been prepared. We will present outline of a method to make the national seismic hazard maps and preliminary version of hazard maps.

PROBABILISTIC SEISMIC HAZARD ASSESSMENT FOR LUZON, PHILIPPINES

Jane T. PUNONGBAYAN[1], Louis DORBATH[2], Jean-Philippe AVOUAC[3], Sylvie MARRIN[3] ([1]Philippine Institute of Volcanology and Seismology, C.P. Garcia Avenue, U.P. Diliman, Quezon City, Philippines, [2] Institut de Physique du Globe de Strasbourg, 5 rue RenéDescartes, 67084 Strasbourg, France, [3]Laboratoire de Détection et de Géophysique, CEA, BP 12, Bruyeres-le-Chatel 91680, France)

The philippine archipelago is bounded and transected by active seismogenic zones capable of producing large and destructive earthquakes. The country, one of the most populated in the world with 80 million inhabitants, is submitted to high risks, not only from volcanic activities but also from earthquakes. In this work, we quantify the probabilistic hazards due to earthquakes for its main and largest island, Luzon. The programs used, developed by the Laboratoire de Détection et de Géophysique du Commissariat d´Energie Atomique de France, permit the calculation of probabilistic intensities due to any given earthquake by considering site effects, a given seismicity model and laws enabling the determination return periods of expected intensity for any site or region. The calculations done adopted a model of seismicity based on instrumentally determined earthquake parameters, accounts of historical earthquakes and geomorphological information such as fault length. The process also made use of laws establishing expected intensities for any given distance relative to the

epicenter, which were calibrated using intensity reports and physical parameters of well-documented major earthquakes in the island, as extracted from both instrumental and historical catalogues that span a period of almost 400 years. These laws are also corrected as a function of local geology. Results show that almost the whole of Luzon Island could expect intensity VII in the Modified Mercalli Intensity Scale (MMI) for a 100-year return period. Maximum hazards, for all considered return periods (100, 500, 1000 years), can be found concentrated in eastern Luzon, in the areas of Northern and Southern Sierra Madre ranges (MMI=XIII-X). Fortunately, these regions are not very densely populated. However, this zone of high intensity extends to the Central Valley, which, in contrast, is not only densely populated but is also economically important to the whole country. The hazards in these areas are aggravated by its liquefaction susceptibility. For the extended return period of 1000 years, Metropolitan Manila, an aggregate of twelve (12) cities and five (5) municipalities forming the most important region of the Philippines (politically and economically), becomes highly prone to damaging earthquakes as it can be found in the limits of the highest intensity zones (MMI=VIII-IX). These results should still be considered conservative as not all of the active faults in Luzon and nearby areas were included in the model as information for these faults (precise extension, characteristic earthquake, recurrence period, …) are still at the stage of being established.

EASTERN CANADIAN CRUSTAL DEFORMATION RATES IMPLIED BY CANADA'S FOURTH-GENERATION SEISMIC HAZARD MODEL

Stephane MAZZOTTI, Stephane MAZZOTTI, John ADAMS, Stephen HALCHUK (National Earthquake Hazards Program, Geological Survey of Canada)

The Geological Survey of Canada´s new seismic hazard model for Canada will form the basisfor the seismic design provisions of the 2005 National Building Code of Canada (NBCC). Assuch it represents Canada´s fourth generation of seismic hazard maps (previous ones were in1953, 1970, and 1985). The Cornell-McGuire method is used with two complete earthquakesource models - historical and regional/geological - to represent the uncertainty in where (andwhy) earthquakes will happen in the future. Ground motions for a deterministic Cascadiasubduction earthquake are computed for southwestern Canada, and probabilistic seismic hazardfor the nearly aseismic central part of Canada is assessed based on a global model. A ˝robust˝method is used to combine the probabilistic hazard estimates (at a probability of 2%/50 years or0.000404 p.a.) from the four source models: the mapped value is the largest of the values. The three probabilistic models use a total of 50 source zones, each with an assessmentof the magnitude recurrence statistics and the upper-bound magnitude. The latter were madeconsidering both regional historical activity and the global history of large earthquakes in similartectonic environments. We turn these results into deformation rates with the additionalassumptions: seismogenic crustal thickness 25 km, focal mechanism either thrusting on 45 degreeplanes or strike-slip, and assigned a shortening direction based on crustal stress information,which is predominantly NE-SW over Canada. As expected, the deformation rates from thehistorical model show a similar pattern to the seismicity map, i.e. patches of high deformationthat are unsustainable for geological eons. However, deformation rates from theregional/geological model (with large earthquakes happening in areas of low historical seismicity)seem more sustainable in the long term. These conclusions point out the challenge of bothmeasuring contemporary deformation in and estimating seismic hazard for eastern Canada.

FOURTH-GENERATION SEISMIC HAZARD MAPS FOR THE 2005 NATIONAL BUILDING CODE OF CANADA

John ADAMS, Stephen HALCHUK (National Earthquake Hazards Program, Geological Survey of Canada)

The Geological Survey of Canada´s new seismic hazard model for Canadawill form the basis for the seismic design provisions of the 2005National Building Code of Canada (NBCC). As such it representsCanada´s fourth generation of seismic hazard maps (previous ones werein 1953, 1970, and 1985). The Cornell-McGuire method is used with twocomplete earthquake source models - historical and regional/geological- to represent the uncertainty in where (and why) earthquakes willhappen in the future. Ground motions for a deterministic Cascadiasubduction earthquake are computed for southwestern Canada, andprobabilistic seismic hazard for the nearly aseismic central part ofCanada is assessed based on a global model. A ˝robust˝ method is usedto combine the probabilistic hazard estimates (at a probability of2%/50 years or 0.000404 p.a.) from the four source models: the mappedvalue is the largest of the values. Products will include seismichazard maps, tabulated values, UHS, plots of deaggregated hazard anddocumentation. For the seismic provisions of the 2005 NationalBuilding Code of Canada the median ground motion on firm soil sites forspectral acceleration at periods of 0.2, 0.5, 1.0 and 2.0 second andpeak acceleration will be used. The four spectral parameters will allowthe construction of approximate uniform hazard spectra (UHS) for eachlisted locality, and hence improve earthquake-resistant design.

PROBABILISTIC SEISMIC HAZARD MAPS FOR ALBANIA

Veronika PECI, John ADAMS, Issam AL-KHOUBBI, Stephen HALCHUK (Geological Survey of Canada)

Albania is a country with high seismicity and earthquake risk reduction has been an important, on-going socio-economic concern. We use the experiences and methods for Canadian seismic hazard maps to present (for the first time) probabilistic seismic hazard maps for Albania. We have produced peak ground acceleration values for several cities and communities in Albania, for return periods of 0.0021 and 0.000404 per annum (equivalent to non-exceedances of 10%/50 years and 2%/50 years, respectively) and as well as 5% damped spectral acceleration values for 0.2, 0.5, 1.0 and 2.0 second periods for determining uniform hazard spectra. A revised catalogue of earthquakes of Albania, from historical data up to the year 1995, for events with magnitude Ms >=4.5 and occurring in the region between 39.0N and 43.0N and between 18.5E and 21.5E was used in this study. All magnitudes have been expressed in terms of Ms. Nine seismic source zones are used to define the Albanian Classic model, following the work of Sulstarova and Aliaj. It is intended to work on an improved model. Using the maximum likelihood method of Weichert, we computed the magnitude recurrence parameters and estimated their epistemic uncertainty. Parameters used for the probabilistic seismicity model, which tabulates the seismicity parameters together with maps of the source zones will be given. Both the Boore et al. and Ambraseys relations were applied to Albania for a reference soil condition equivalent to Boore et al.s soil class B . This choice of ground condition near the mid-range between very hard and very soft ground minimizes the uncertainty in the amplification or deamplification factors for the extreme sites. The peak acceleration relation of Theodulidis and Papazachos, developed for shallow crustal Greek earthquakes, was also considered. These maps and associated UHS results are suggested as the basis of the next version of KTP-N.2-89 Regulation in aseismic code in Albania.

STRONG-MOTION MAPS FOR SCENARIO EARTHQUAKES IN KANAZAWA AREA (JAPAN), AROUND MORIMOTO-TOGASHI ACTIVE FAULT

Shin AOI[1], Tatsuo KANNO[1], Nobuyuki MORIKAWA[1], Shigeki SENNA[2], Toshihiko HAYAKAWA[2], Hiroyuki FUJIWARA[1] ([1]National Research Institute for Earth Science and Disaster Prevention, [2]Mitsubishi Space Software Co., Ltd.)

Strong motion map based on the scenario earthquake in Kanazawa area was created. Kanazawa city is a typical middle sized city located in the Hokuriku district and the Morimoto-Togashi active fault, which is about 26km wide, crosses the middle of the city. Probability of the occurrence of an earthquake whose JMA magnitude is more than 7.2 for this fault within 30 years was evaluated as 0-5% by the Subcommittee for the Long-term Evaluation, the Headquarters for Earthquake Research Promotion. This probability is rather high among the 98 main active faults in Japan. Deep structure was estimated mainly based on the gravity anomaly data and geological information. To evaluate the sediment structure of Kanazawa basin, whose maximum is more than 3km, array observation of microtremors was carried out at ten points (Kanno et al., IUGG, 2003). The structure of superficial layers was evaluated mainly by the digital national land information and borehole logging data. By applying ´Recipe´ (Irikura et al., 2002), heterogeneous fault models were constructed which consist of background and one asperity for evaluating ground motion. For periods longer than 1.0 s, responses of wave propagation for 3 dimensional structures were theoretically evaluated using FDM, and the statistical Green´s function method was used for the frequency higher than 1 Hz. The broadband time history was generated by summing them using a matching filer. Spatial distribution of time history, peak accelerations and seismic intensities were evaluated in 60km* 90km region centering on Kanazawa at about every 1 km spacing. Peak accelerations and seismic intensities were evaluated in a larger area with empirical method.

LONG TERM SEISMOLOGICAL HAZARD ASSESSMENT FOR A NUCLEAR WASTE REPOSITORY: DETERMINISTIC AND PROBABILISTIC APPROACH

Guenter LEYDECKER[1], Juergen R. KOPERA[2] ([1]Federal Institute for Geosciences and Natural Resources, Stilleweg 2, 30655 Hannover Germany; guenter.leydecker@bgr.de, [2]BIS-Kopera, Buero fuer IngenieurSeismologie, Seerosenstrasse 10B, 30916 Isernhagen Germany; bis_kopera@hotmail.com)

Existing and planned nuclear waste repositories in Germany are situated in areas of low seismicity. Nevertheless, seismic hazard assessment has to be performed for a very long time period, even though there is a considerable debate whether or not it is possible to quantify the seismic hazard in such an area. A combination of deterministic and probabilistic methods are used to assess the seismic hazard for a site in Northern Germany, fulfilling the standards of the German technical safety code for nuclear power plants. As an example, the site of the former salt mine Morsleben, which now is a nuclear waste repository, is investigated. The deterministic method is based on the assumption that the most strongest earthquakes inside a tectonic region can happen everywhere there, also near the selected site. For the probabilistic method, several models describing the seismicity in an area of 200 km around the site are used to show the influence of the variability in input parameters on the exceeding probability of the site intensity. It is shown that the seismic hazard of a site in an area of low seismicity is mainly caused by the effects of distant but strong source regions, and for very low probabilities by the background seismicity. The probabilistic evaluation has the advantage to quantify the seismic hazard. But deterministic and probabilistic methods together seems a practical tool for mutual control of the results and to overcome the disadvantages of each approach alone. Input data are derived from the German earthquake catalogue with an observation period of about 1200 years. From a comprehensive knowledge about geological development and structural geology, the time history of the surrounding faults are developed. The nearest dominant fault, reaching deep into the crust, was most active in the Upper Cretaceous. Smaller movements occurred 5 Mio. years ago. Only parts of this fault are orientated at a critical angle to the actual stress field which could result in smaller earthquakes only. The combination of both, seismicity and tectonics, provide the basis for a long term prognostic with probabilities of exceedance in the order of 10^{-5} per year. For the investigated site the following parameters are derived: site intensity as a function of exceeding probability; site acceleration; strong motion duration; site dependent response spectra for the surface and the underground inside the mine.

UNCERTAINTIES IN SEISMIC HAZARD ASSESSMENT IN THE MEGACITY OF ALGIERS (ALGERIA) USING DIFFERENT ATTENUATION MODELS

Djillali BENOUAR (Department of Civil Engineering, University of Science and Technology Houari Boumediene (USTHB))

This research presents the evaluation of seismic hazard at the site of Algiers (Capital of Algeria) using four different attenuation models. Seismic hazard analysis was carried out using a simple earthquake occurrence model and the new seismic catalogue compiled recently by Benouar5 for the Maghreb region. The site is defined by longitude 3.00°E and latitude 36.45°N. Because earthquake process around the site is poorly understood, it is assumed that future earthquakes will occur in an area in which they have already occurred in the past. The hazard, expressed in terms of the probability of exceedance of the PGA, is calculated for an economic life of the structure of 10, 50, and 100 years. The absolute acceleration for a given return period is also determined. Due to the shortage of ground motion records, no attenuation law has been derived for Algeria. The main objective of this study is to analyze the influence of the attenuation models on the seismic hazard evaluation, since the results of seismic hazard are sensitive to these models. Thus, a selection of an appropriate attenuation law is very crucial. For this purpose, four attenuation laws which seem to fit the Algerian data were selected from the literature, these are Joyner and Boore1, Ambraseys and Bommer2, Ambraseys3 (controlled depth) and Ambraseys3 (uncontrolled depth). A comparison of the expected seismic hazard allows a first critical estimate showing that seismic hazard is very sensitive to the attenuation models selected and the PGA could be either conservative or not, depending on the attenuation model and the level of acceptable risk. The most recent earthquake disaster that affected the site of Algiers is the El-Asnam earthquake of 10 October 1980 (Ms 7.4) which caused the loss of more than 3000 lives, injuring about 9000 and made homeless at least 400 000; it destroyed more than 60 000 housing units, official buildings and public works of which damage was estimated by official reports at U.S. $ 5 billion (Benouar)5. Algiers has a population of approximately three millions; it represents the most important concentration of investment, government institutions and population in the whole country. The zone under study represents an area of 200 km radius around the site of Algiers. In recent years the disaster risks have increased due to overcrowding, faulty land use planning and construction, inadequate infrastructure and services, and environmental degradation. The topography, the waterfront location and the ancient neighborhoods (Casbah) make it difficult to affect radical solutions to most of its problems.

A STUDY ON PROBABILISTIC SEISMIC HAZARD MAPS IN JAPAN

Toru ISHII[1], Toshihiko OKUMURA[1], Hiroyuki FUJIWARA[1], Yuzuru HAYAKAWA[1], Shinichi KAWAI[1], Shin AOI[1], Yutaka ISHIKAWA[2], Junichi MIYAKOSHI[2], Tomoo SAITO[2], Hideaki SHINOHARA[3] ([1]National Research Institute for Earth Science and Disaster Prevention, [2]Izumi Research Institute, Shimizu Corporation, [3]Oyo Corporation)

A methodology to evaluate spatial strong-motion distributions is studied in order to make probabilistic seismic hazard maps in Japan. A probabilistic seismic hazard map illustrates the relationship between three parameters, which are amplitudes, time period and probabilities, of strong-motions in an area. On this study reflected are the long-term evaluations of active faults and the ones of inter-plate earthquakes along the subduction zones, which have been presented by the Headquarters for Earthquake Research Promotion based on the newest information and data of active faults and historical earthquakes all over Japan. The earthquakes in and around the mapping area are classified into seven different types: 1) the characteristic earthquakes along the major 98 active fault zones in Japan; 2) the earthquakes along the other active faults; 3) the earthquakes in the major 98 active fault zones except the characteristic earthquakes; 4) the characteristic inter-plate earthquakes along the subduction zones; 5) the inter-plate earthquakes along the subduction zones except the characteristic earthquakes; 6) the intra-plate earthquakes along the subduction zones; and 7) the crustal earthquakes whose fault planes could not be identified in advance. With the probabilistic models of earthquake occurrence for these earthquake types, seismic hazard curves are evaluated in terms of peak ground motions and seismic intensities at the points which are arranged regularly all over the mapping area with about 1 km spacing. The attenuation relations with the particular characteristics in and around the mapping area and the surface layer amplification estimated at each evaluation points are used in this study. At several principal points, hazard curves and contribution factors of earthquakes are also presented in order to compare the impact of each earthquake on the strong-motion at each probability level. The developed procedure and techniques are applied to an area including both of Nagano and Yamanashi prefectures located in central Japan, and also applied to Hokkaido and Tohoku districts, a larger area located in northeast Japan.

SS04b/10P/D-024 — Poster — 1400-207

A STUDY ON HAZARD MAPS FOR SCENARIO EARTHQUAKES IN JAPAN

Toru ISHII[1], Hiroyuki FUJIWARA[1], Shin AOI[1], Toshiaki SATO[2], Motofumi WATANABE[2], Toshimi SATOH[3], Shinichi MATSUSHIMA[3], Takashi HAYAKAWA[3], Hideaki SHINOHARA[4], Koji IWAMOTO[4], Kyozo NOZAKI[4] ([1]National Research Institute for Earth Science and Disaster Prevention, [2]Ohsaki Research Institute, Inc., [3]Izumi Research Institute, Shimizu Corporation, [4]Oyo Corporation, [5]Mitsubishi Space Software Co., Ltd.)

A methodology to evaluate spatial strong-motion distributions is studied in order to make hazard maps for scenario earthquakes in Japan. A hazard map for scenario earthquake represents a spatial strong-motion distribution in an area that will be caused by a specified future earthquake. On this study reflected are the long-term evaluations of active faults and the ones of inter-plate earthquakes along the subduction zones, which have been presented by the Headquarters for Earthquake Research Promotion based on the newest information and data of active faults and historical earthquakes all over Japan. Heterogeneous fault models of possible earthquakes are established by considering asperities in which slips and stress drops are larger than those in the background area on the fault plane. Three-dimensional propagation characteristics of seismic waves and amplifications in surface layer are estimated based on detailed information and data collected in the mapping area. The strong-motion time histories, peak ground motions and seismic intensities are evaluated by using the theoretical, semi-empirical and empirical methods at all the points which are arranged regularly all over the mapping area with about 1 km spacing. The developed procedure and techniques are applied to the characteristic earthquake along Itoigawa-Shizuoka tectonic line fault zone, one of the largest and the most active major fault zones in Japan. Three different maps for three cases with different asperity distributions and rupture characteristics are produced and compared to each other. The procedure and techniques are also applied to Miyagi-ken-oki earthquake, one of the most active inter-plate large earthquakes along the Pacific coast of northeast Japan. It is confirmed that the results of this study explain very well the recorded time histories at three stations around Sendai during 1978 Miyagi-ken-oki earthquake.

SS04b/10P/D-025 — Poster — 1400-208

INVESTIGATION FOR SEISMIC ZONATION OF ANCHORAGE, ALASKA

Niren N. BISWAS[1], Artak H. MARTIROSYAN[1], Utpal DUTTA[1], Apostolos PAPAGEORGIOU[2] ([1]Geophysical Institute, University of Alaska Fairbanks, [2]Department of Civil Engineering, University of New York, Buffalo)

Anchorage being the largest population center in the State of Alaska, is located in a highly active seismic zone and underlain by a west dipping deep sedimentary basin. Thus, a seismic zonation program for the metropolitan area of Anchorage was implemented in early 1990. In describing the ground motions for local earthquakes, the first order characteristics of the three factors, namely, source, path and site have been determined. In this presentation, however, emphasis has been given to the spatial variations of site class and site response. In order to determine the site class, we used Rayleigh waves in the frequency range of about 1-100 Hz. These were generated by an electromagnetic vibrator at 36 sites in the Anchorage Basin. The phase velocity (c(f)) of the fundamental mode at each site was computed using the phase delay times between two sensors. Next, c(f) data were inverted in terms of shear wave velocity (V_s) structure by stochastic inversion scheme. Of the 36 sites, values of V_s as a function of depth were available at 7 sites from downhole measurements. At these sites, the comparison of the results between surface and downhole measurements showed reasonable agreement. On the basis of NEHRP provision, we obtained the time-averaged Vs structures of the basin for the uppermost 30 m (V_{30}). The results revealed that the Anchorage metropolitan area consists of site class C ($360 < V_{30} \le 760$ m/s) and D ($180 < V_{30} \le 360$ m/s). On the eastern side of the city lies a mountain range (Chugach Mts.) where coverage of the velocity survey was lacking, though rock exposures and a special purpose 9 m drillhole data showed formations of site class B ($760 < V_{30} \le 1500$ m/s). Moreover, from the foothills of Chugach Mts. towards the west side of the city, it is necessary to introduce a transition zone (C/D) between the areas of site class C and D. The V_{30} in C/D ranges from 320 to 410 m/s. Concerning site response (SR), we used data for local earthquakes recorded by a temporary weak motion (WM) and permanent strong motion (SM) networks. We computed SR by spectral ratio (SRM) and generalized inversion (GIM) methods. The results obtained for SR from WM and SM data using SRM and GIM were synthesized. The SR values thus obtained were averaged (logarithmically) for two frequency bands AEa low frequency band (LFB) and a high frequency band (HFB) with center frequencies of 1 and 5 Hz, respectively. In LFB, SR increases from 1.0 along the foothills of Chugach Mts. in the east to about 3.5 in the western side showing the trend of increasing thickness of the sediments in the basin. The area of the highest SR value (>3.0) in LFB in the westcentral part of the city is underlain by the cohesive facies of the Bootlegger Cove Formation, which

suffered extensive liquefaction during the 1964 Prince William Sound earthquake (Mw = 9.2). This trend of SR also has good correlation with that of V_{30} with a correlation coefficient of 0.82; SR values in LFB are close to the NEHRP site coefficients for 1 sec. However, SR values in HLB lack correlation with the spatial distribution of V_{30} and short period NEHRP site coefficients. For SR below 1 Hz, we used microtremor data. The results at center frequency of 0.35 Hz follow closely the trend of that obtained for LFB.

A C LEVEL MICROZONATION MAP OF BUCHAREST, ROMANIA

Carmen Liliana MOLDOVEANU[1], Carmen CIOFLAN[2], Mircea RADULIAN[2], Bogdan APOSTOL[2], Giuliano F. PANZA[3] ([1]Department of Earth Sciences, University of Parma, [2]National Institute for Earth Physics, Bucharest, Romania, [3]Department of Earth Sciences, University of Trieste, Italy, [4]The Abdus Salam International Center for Theoretical Physics, SAND Group, Trieste, Italy)

Bucharest experienced heavy destruction and large number of victims during the extreme 1940 (Mw=7.7) and 1977 (Mw=7.4) Vrancea intermediate-depth earthquakes (located in the 60-200 km depth interval, at the sharp bend of the Southeast Carpathians). The statistics indicate a recurrence interval of 25 years for Mw >6.0 and 50 years for Mw >7.0 in the region. The assessment and mitigation of the earthquake risk are therefore particularly important in the Romanian capital since more than 2 million inhabitants, major investments and vital life systems are concentrated there. The seismic ground motion evaluation implies the analysis of a large database of records provided by dense arrays of seismographs. This allows defining generally valid ground parameters to be used in seismic microzonation estimations. The strong motion registrations in Bucharest area are rather few and available only since 1977. Therefore the ability to compute numerically realistic seismograms represents in our opinion the key element for performing ″present day″ microzonation studies. Using a complex hybrid waveform modeling method that accounts for the source, wave propagation path and local site geology, we investigate which features of the seismic process are predictable in case of Vrancea dominant shocks, and how do they reproduce the strong local effects observed in Bucharest for the 1977 event. Our deterministic results show that the synthetic local hazard distribution supplies a realistic estimation of the seismic input. This method allows the merging of the different specific information collected until now in reasonably well constrained scenarios for a level C realistic microzonation of Bucharest area to be used to mitigate the effects of future strong events originating in Vrancea region.

PROBABILISTIC SEISMIC HZARDS PARAMETERS ESTIMATION IN GUJRAT REGION, INDIA

Jayant Nath TRIPATHI[1], Dileep Kumar TIWARI[2] ([1]Deartment of Earth & Planetary Sciences, University of Allahabad, Allahabad-211002, India; Presently at: Observatori de L'Ebre, c/ Horta Alta, 38; 43520 Roquetes (Tarragona), Spain, [2] Deartment of Earth & Planetary Sciences, University of Allahabad, Allahabad-211002, India)

In the Indian subcontinent Kuchh of Gujarat region is one of the most seismic prone areas. In Kuchh region, the maximum affected areas (by earthquake) fall along the Kutchh Mainland fault (KMF). This fault extends in the direction of east west for about 100 km. Another fault namely South Wegad Fault, also called Adhoi Fault, falls in the line of the KMF and extends for about 50 km. These faults are mainly responsible for the tectonic processes in the past. And a result we had the 7.6 magnitude earthquake on January 26, 2001. Probabilistic assessment of seismic hazard is the initial step for the assessment of realistic pattern of earthquakes in the specified region. The probability of occurrence of great earthquake with magnitude M ≥ 6.0 during a specified interval of time, for this region has been estimated on the basis of four probabilistic models, namely, Weibull Model, Gamma Model, Lognormal Model and Exponential Probability Model. These four models represent the distribution of time interval fairly well. The probability of occurrence of the next large earthquake during a specified interval of time has been calculated for aforesaid each model. The Method of Moment has been applied for computation of the hazard parameters for only three models viz. Weibull, Gamma and Lognormal Model, while the method of maximum likelihood has been used for the computation of hazard parameters for Exponential Probability model. The cumulative and conditional probabilities have been evaluated for each model. According to the present study the probability of occurrence of a great earthquake, having magnitude M ≥ 6.0, reaches 0.9 and above for a time period of 61 to 64 years for each of the models.

RECURRENCE PARAMETERS OF EARTHQUAKES USING METHOD OF MAXIMUM LIKELIHOOD ESTIMATION IN GUJRAT REGION, INDIA

Jayant Nath TRIPATHI[1], Avinash DWIVEDI[2] ([1]Deartment of Earth & Planetary Sciences, University of Allahabad, Allahabad-211002, India; Presently at: Observatori de L'Ebre, c/ Horta Alta, 38; 43520 Roquetes (Tarragona), Spain, [2] Deartment of Earth & Planetary Sciences, University of Allahabad, Allahabad-211002, India)

Kuchh region of Gujrat is one of the most seismic prone regions of India. Recently, it has suffered by a large earthquake of magnitude 7.6 on January 26, 2001. The probability of occurrence of great earthquakes with magnitudes greater than or equal to 6.0 during a specified interval of time has been estimated on the basis of three probabilistic models, namely, Weibull, Gamma and Lognormal for this region. The earthquakes of magnitude ? 6.0 covering 200 years have been used for this analysis. However, method of maximum likelihood estimation (MLE) has been applied for computation of hazard parameter of the earthquakes. The mean interval of occurrence of earthquakes and standard deviation are estimated as 45.4 years and 14.2 years, respectively, for this region. The cumulative and conditional probabilities have been also evaluated, which suggests that the probability of occurrence of a great earthquake in this region of Gujrat reaches 0.8-0.9 for the time period 60-65 years after 2001.

RESEARCH OF GREAT EARTHQUAKE ACTIVITY IN WEST CHINA REGION AND ITS INFLUENCE ON SEISMIC TENDENCY IN NORTH CHINA

Chen YUWEI (4183)

Based on our analysis of the spatial and temporal distributions of great earthquake (Ms ≧ 7.5) in West China since 1900, we further examine the correlated features between great earthquake in West China and strong earthquake (Ms ≧ 6.0) in Great North China Regions. Having made a comparative study between the two seismic activities, we can get the results as follows:Tectonic shows strong control on the earthquake activities. Earthquake activities in each active period caused by great earthquake in West China almost occur consecutively in the same sub-plate, but other tectonic units in surrounding area still keep relatively quite. The earthquake activities show that a block is an active tectonic unit with a series of boundary faults in different directions. A strong earthquake activity with boundary faults will

influence the equilibrium of other boundary faults that lie in the same tectonic unit, which might trigger strong earthquake activities in those boundary faults, suggesting a great earthquake with Ms ≧ 7.5 rifting unceasingly in different boundary faults of the same tectonic unit. This phenomenon is also observed in the paleoearthquake events (Jian wali et al., 2000) and should be paid more attention for strong seismic hazard prediction.Seismic activities have the characteristics of oriented migration. In the first active period, earthquakes occur in the northwest of Xingjiang sub-plate. In the starting phase of second period, the earthquake site migrates to the southwest of Qinghai-Tibet sub-plate and to the south of south-north regions in the late phase. In the third active period, the earthquake site migrates to the northwest of Qinghai-Tibet sub-plate. Earthquakes have no repeatability in spatial distributions. When a series of earthquakes occur, the last earthquake always migrates to the tectonic block and occurs in another relatively placid block. This earthquake might help us locate where the next series of earthquakes will probably occur. Geologists (Ma zongjin et al., 1980) defined the unified activities and oriented migration of great earthquakes in the tectonic units as liner rifted seismic belt or slant cross-rifted tectonic. If seismic activities in West China are consistent with the characteristics of tectonic, we can infer in the future the earthquakes with Ms ≧ 7.5 in the West regions will mainly occur in the near boundary of northwest of Qinghai-Tibet sub-plate and middle zone of south-north belt.

SEISMICITY AROUND CAPITAL ULAANBAATAR, MONGOLIA

Dorjsuren ANKHTSETSEG[1], Tundev DUGARMAA[1], Antoine SCHLUPP[2], Munkhuu ULZIIBAT[1], Chimed ODONBAATAR[1], Chimedtseren BAYARSAIKHAN[1], Adiya MUNKHSAIKHAN[1] ([1]Research Center of Astronomy and Geophysics of Mongolian Academy of Sciences, [2]Departement Analyse, Surveillance, Environnement, BP12, Bruyeres le Chatel, 91680, France)

The main part of Mongolian territory consist to one of the most active seismic intracontinental region of central Asia. In Mongolia, as well as in all high seismic countries of the world, study of seismicity and estimation of probability of future destructive earthquakes are important for economic stability and human protection. Seismological condition of Ulaanbaatar region are directly connected with seismic conditions of the territory of Mongolia. Mongolia characterizes the transition between compressive structures associated with India-Asian collision and extensive structures localized in north of the country as Hovsgol area and Baykal rift. Since 1905, Mongolia suffered four earthquakes with magnitude larger than 8 (Tsetserleg 1905, Bolnai 1905, Fu-Yun 1931 and Gobi-Altai 1957). These events are associated with displacement along the faults up to 12 metres. The cumulative deformation along the Gobi-Altai fault shows that the return period of such great earthquakes on this fault are of the order of 3000 to 5000 years with a strain rate about 1 mm/year. Active faults are numerous and large but the occurrence of these four large earthquakes in less than one century is unusually high. Ulaanbaatar is situated at the east of these main active faults. Therefore, we have to understand better the seismotectonic model of the region by collecting new data about deformation near Ulaanbaatar. At the second half of 1957, a seismological observation begun in Mongolia. At the present, Today, on the Mongolian territory are working 9 analog seismic stations with records on photo paper, and around Ulaanbaatar, Capital of Mongolia, are working 5 high dynamic digital seismic stations, one CTBTO mini-array (10 stations) telemetred in real time to our NDC and one IRIS station For a region about 350 kms radius around Ulaanbaatar city, we present the seismicity with about 10602 events from marcoseismic catalogue (1913 to 1963) and instrumental data (1964-2002). The range of magnitude are from 3 to 7. The detection level of this seismicity is related to the seismic network history. The studied region is divided in several subregion which are characterized by the epicenter´s density, geological structure, active fault and geodynamic model. It shows high activity near the Mogod Earthquake, 5 january 1967, Mw= 7,2 and some dense activity as 180 km south of the capital in Deren region where a recent event was largely felt at Ulaanbaatar. The other seismicity is more widespread. Despite of magnitude are low in that region, they are recognized active faults with no particular seismicity associated where event up to magnitude 7 can occured. This work is associated with paleoseismological survey on particular active faults. From the seismicity map, the region near Ulaanbaatar is seismically active and some earthquakes, which can have destructive effect on the city Ulaanbaatar, can take place.

SS04b/10P/D-031 Poster **1400-214**

STUDY ON POTENTIAL RISK OF LARGE EARTHQUAKE ALONG THE ANNINGHE-ZEMUHE FAULT ZONE, WESTERN SICHUAN, CHINA

Guixi YI[1], Xueze WEN[2], Jun FAN[2], Siwei WANG[2] ([1]Chengdu University of Technology, Chengdu 610059, China; Seismological Bureau of Sichuan Province, Chengdu 610041, China, [2]Seismological Bureau of Sichuan Province, Chengdu 610041, China)

The left-lateral strike-slip Anninghe-Zemuhe fault zone in western Sichuan, China, is a portion of the eastern boundary of the Sichuan-Yunnan fault-block, and one of the main active fault zones with strongly seismic activities. In order to analyze the potential seismic risk, using an earthquake catalogue from Sichuan Regional Network for the past 25 years, we study quantitatively the currently active behaviors of various fault portions according to data of calculated seismicity parameters, re-located focal depths, and geographic and temporal distribution of historical earthquake ruptures. Finally, we identify potential risky fault segments for the coming major earthquakes, estimate average recurrence time and magnitude for the potential earthquakes. Our main work and results are as follows: According to spatial scanning of b-value and calculating of other seismicity parameters, such as *a/b* values, annual-rates of released strain-energy and earthquake number on unit length of fault, the whole fault zone is divided into 5 segments with different behaviors of currently seismic activities. Among the 5, one asperity is identified and mapped from an area with anomalously low b-value located on the segment of the Anninghe fault between Mianning and Lizhou, north of Xichang. Spatially, this asperity coincides with the 1536 earthquake rupture of magnitude 7.5, and has a length of about 62km along the fault. This asperity segment also displays low frequent seismic activity and low level of strain-energy release, but has a relatively high *a/b* value. Seismicity parameters suggest that two segments, the Xichang-Puge segment of the Zemuhe fault and the Shimian-Tuwu segment of the Anninghe fault, are under low and relatively low stress level at present, although they ruptured during the large 1850 and 1480 earthquakes, respectively. Another segment of the Zemuhe fault between Puge and Qiaojia has a middle b-value, displays highly frequent activity of small earthquakes with magnitudes between 2 and 4.9, and shows evidence of creeping. Average recurrence time intervals of characteristic earthquakes have been estimated for the asperity segment of the Anninghe fault from methods of asperity b-value model and geology and basing on the time-predictable recurrence model. Moreover, a possible magnitude range for the coming earthquake on the asperity is also estimated from relationships between magnitude and rupture-length. These calculations suggest that the next large earthquake on the asperity segment of the Anninghe fault would be not far, and have a magnitude of between 7.0 and 7.5. Our investigation suggests that asperities exist on those fault-segments having re-ruptured in the past, but are not always there all the time. Following a large earthquake rupture, activity behaviors of a fault segment could vary with time, meaning that it needs time for the fault plane to couple again and then reform a new asperity.

BACKGROUND AND PRECURSORY SEISMICTIES PRIOR TO THE MS8.1 KUNLUNSHAN EARTHQUAKE, WESTERN CHINA

Xueze WEN[1], Guixi YI[2] ([1]Seismological Bureau of Sichuan Province, Chengdu 610041, China, [2]Chengdu University of Technology, Chengdu 610059, China)

The November 14th, 2001, Kunlunshan earthquake of magnitude (M_s)8.1 has been the greatest earthquake on the Chinese mainland for the last 50 years, which ruptured the Kunlunshan segment of the NWW-trending east Kunlun fault zone. We investigate the background earthquake activities in the region of the fault zone and its surrounding areas in the last over 100 years, and study the precursory seismicities occurred during the last several years and months before the huge earthquake. Our result mainly suggests that 2 large-dimensional rupture gaps without large and strong earthquakes for the recent more than 100 years had formed before the M_s8.1 earthquake along the segments of Kunlunshan and Maqu of the east Kunlun fault zone. Of which, the Kunlunshan rupture-gap and its surroundings had been a quiescence region without earthquakes of magnitudes 5 and larger for at least over 30 years while the mainshock, forming and developing a background seismic gap centered at the Kunlunshan Pass. The M_s8.1 mainshock occurred just in such a Kunlunshan rupture-gap. While, located at about 700 km southeast of the Kunlunshan rupture-gap, the eastern portion of the east Kunlun fault zone, the Maqu rupture-gap was the place where precursory seismicities of smaller earthquakes had arisen before the mainshock, although no any background seismic gap of magnitude 5 and larger earthquakes had formed and developed there. Starting in the July of 1998, the mid-term anomaly of the precursory seismicities at the Maqu rupture-gap lasted totally for about 3.2 years in two sub-stages, and was displayed by seismicity uprising first and then decreasing significantly. The short-term anomaly was characterized by enormously increasing of the frequency of small events there in the about 2.2 months just prior to the mainshock. The revealed feature of the seismicities before the huge Kunlunshan earthquake enlighten us that for those long strike-slip active fault zones on the Chinese mainland, it is possible that mid-long term risky locations for potential large or great earthquake are identified by recognizing abnormal background seismicity patterns that have formed and developed on rupture gaps without recent strong and large earthquakes. Moreover, certain portions of the fault zones, perhaps another rupture gap, would be the important windows from which information of mid to short term precursors would arise before potential large earthquakes occurring.

JOINT SOLUTION OF SEISMICITY PARAMETERS FOR SEISMIC SOURCE ZONES THROUGH SIMULATION

Roger Mw MUSSON (British Geological Survey)

A key issue in seismic hazard modelling is determining seismicity parameters for each source zone in a given model. The three main parameters are the activity rate, the b-value (slope of the Gutenberg-Richter magnitude-frequency curve), and the maximum magnitude. Procedures for estimating these vary from study to study; in recent years the application of maximum likelihood methods, with or without priors, seems to be the most favoured approach. A new approach is presented here, based on Monte Carlo methods, which solves for all three parameters simultaneously. The conceptual basis is as follows: there exists some "true" set of values for a, b and Mmax that governs the long-term occurrence of earthquakes in a zone. Take three values for a, b and Mmax at random and use them to generate a synthetic earthquake catalogue, subject to the same historical constraints as the real catalogue. Is the resulting synthetic catalogue similar to the real one? If so, the a, b and Mmax values are credible. If not, try again. If one repeats the exercise a very large number of times, one easily builds up a weighted distribution of credible values for a, b and Mmax that can be converted directly into a logic tree structure. The method is entirely data-driven, and imposes no preconceived assumptions on the shape of the uncertainty distribution. Also the method tests implicitly whether the Gutenberg-Richter model itself is credible for that data set. If it turns out to be the case that no values for a, b and Mmax can provide a good approximation to the observed data, then a different seismicity model is called for.

CHARACTERIZED SOURCE MODELS FOR SHALLOW INTRASLAB EARTHQUAKES IN JAPAN

Kimiyuki ASANO, Tomotaka IWATA, Kojiro IRIKURA (Disaster Prevention Research Institute, Kyoto University)

Large shallow intraslab earthquakes, occurring within subducting slabs at 30-100km depths, generate earthquake damages by strong ground motions (e.g. the 1993 Kushiro-oki earthquake, the 2001 Geiyo earthquake). Ground motion characteristics of intraslab earthquakes have been pointed out to have some different features compared to those of inland crustal earthquakes or interplate earthquakes by several papers. We have examined seven shallow intraslab earthquakes that recently occurred around Japan (M_{JMA} 5.1-7.0) using strong motion network data. We carried out broadband ground motion simulations based on the empirical Green´s function method (Irikura, 1986) to investigate the source characteristics of shallow intraslab earthquakes. Using the empirical Green´s function method, we can construct the source model to explain observed waveforms in broadband frequency range (Kamae and Irikura, 1998; Miyake et al., 1999). We used the observed waveform of a small event occurring in each source region as the empirical Green´s function so that we could take account of propagation path and site effects implicitly. First, we determined the rupture plane by comparing synthetic waveforms from two possible fault planes assumed by focal mechanisms, because of the lack of sufficient aftershock distribution information for these events. Next, we estimated the size of strong motion generation area (SMGA), rise time, and rupture propagation velocity of the target event by forward modeling. The misfit function is selected as the sum of residuals of displacement waveforms and those of acceleration envelopes for explaining wide frequency band ground motions. For inland crustal earthquakes, the self-similar relation between the asperity area derived from the kinematic waveform inversion and the seismic moment was shown by Somerville et al. (1999). Some studies (Kamae and Irikura, 1998; Miyakoshi et al., 2000; Miyake et al., 2001) demonstrated that the SMGA obtained by the broadband ground motion simulation coincides with the asperity. We compared the SMGA size obtained in our study with the empirical relation for inland crustal earthquakes proposed by Somerville et al. (1999). The size of SMGA obtained for each earthquake is about 14-90% of prediction from that empirical relation. The stress drops on SMGA of shallow intraslab earthquakes are higher than those of inland crustal earthquakes. The ratios between the combined area of SMGA and the value predicted from the empirical relation decrease with focal depth. The stress drops on SMGA of shallow intraslab earthquakes increase with focal depth. We used strong motion data from K-NET, KiK-net, and F-net operated by the National Research Institute for Earth Science and Disaster Prevention (NIED). We also used the hypocentral information provided by the Japan Meteorological Agency (JMA) and the moment tensor solutions by F-net and Harvard University.

IMPLICATIONS OF THE SEPTEMBER 21, 1897 HISTORICAL EARTHQUAKES TO SEISMIC AND TSUNAMI HAZARDS ASSESSMENT IN THE SULU-ZAMBOANGA AREA, SOUTHWESTERN PHILIPPINES

Maria Leonila Pascual BAUTISTA[1], Ishmael Clarino NARAG[2], Bartolome Caparas BAUTISTA[2], Raymundo Santiago PUNONGBAYAN[2] ([1]Department of Science and Technology (DOST) - Philippine Institute of Volcanology and Seismology (PHIVOLCS), [2]Philippine Institute of Volcanology and Seismology (PHIVOLCS))

The review of historical seismicity can help us understand the possible future seismic hazards that could happen in a certain area. More than a hundred years ago on September 21, 1897, two large magnitude earthquakes affected the islands of Sulu, Basilan and Zamboanga peninsula in southwestern Philippines. These two events happened 10 hours apart on the same day at 3:06 AM and 1:12 PM (both local time). Gutenberg and Richter (GR) determined their epicenters at the same point (6.0 N. lat; 122.0 E. long) while Abe determined their magnitudes as Ms 7.4 and Ms 7.5, respectively. The 1:12 PM (Ms 7.5) event also generated the biggest known tsunami in the Philippines. The GR epicentral region is presently characterized by nil seismicity. Meanwhile, the risks in the areas affected by the strong ground shaking and devastated by the tsunami are now slowly increasing. This study aims to review and re-evaluate the epicentral location of the two events based on intensity reports, eyewitnesses' accounts and results of ground shaking and tsunami modeling. Based on the results of the review of recently-discovered archival documents, the areas which experienced the highest intensities and which were also most severely affected by the tsunami are the towns of San Ramon, Ayala, Santa Maria, Zamboanga, Tetuan, Mercedes, Bolong, Magay (all in Zamboanga province), Basilan in the province of Isabela and Jolo (in Sulu province). Meanwhile, the tsunami also affected the coastal towns around the Sulu Sea region including the northern part of Borneo Island of Malaysia. Using intensity data and eyewitness accounts as confirmed through ground shaking and tsunami modeling, the epicentral location of the two earthquakes were determined. With regards to their depths, the earlier 3:06 AM event is thought to have a deep-to-intermediate hypocenter while the 1:12 PM tsunamigenic event is believed to have originated along the shallow portion of the Sulu Trench region based on intensity distribution. The activity of this trench is one of the least understood in the context of the present-day Philippine seismotectonics understanding because of its present low seismicity as compared to other subduction trenches in the Philippines. For the last 106 years, no event of these magnitude sizes had occurred along this trench region. If these events indeed originated from the Sulu Trench, then the results of this study suggests that the trench is still capable of generating M 7s events. The results of this study could be very useful in understanding the seismic hazards in this part of the Philippines.

EARTHQUAKE HISTORY IN OLD MANILA, PHILIPPINES

Maria Leonila Pascual BAUTISTA[1], Bartolome Caparas BAUTISTA[2], Ishmael Clarino NARAG[2], Esmeralda Longino BANGANAN[2], Raymundo Santiago PUNONGBAYAN[2] ([1]Department of Science and Technology (DOST) - Philippine Institute of Volcanology and Seismology (PHIVOLCS), [2]Philippine Institute of Volcanology and Seismology (PHIVOLCS))

Manila, which consist of 14 districts, is the capital city of the Philippines. One of the oldest settlements in the Philippines is an area called Old Manila which includes roughly the districts of Intramuros, Binondo, Tondo, Quiapo, Santa Cruz, Ermita, Pandacan and Santa Ana. Old Manila hosts several centuries-old structures built during the Spanish era and which are also now considered as valuable cultural assets of the country. At the same time, the area is also one of the most densely populated areas in the entire city. In the Philippines, historical records of earthquakes coincide with its written history and this started in the late 15th century. This study is made to identify frequently damaged places in Old Manila and seek possible explanation for it. The results will be useful for land use planning, for risk mitigation as well as for protecting the cultural assets of the country. The frequently damaged areas are also being surveyed using microtremor observations to determine possible effects of site response to earthquake damages. There were 13 historical earthquakes which were strong enough to have caused serious damages to the city. The results of the initial review of historical earthquakes in Manila showed that some places are more frequently damaged than other sites. Almost all of these earthquakes caused damages to the ancient walled city of Intramuros. The second most frequently damaged district is the Binondo area which had been affected eight times by past earthquakes. Following Binondo are the districts of Tondo, Quiapo and Santa Cruz which sustained damages at least four times during the last 400 years. About half a million inhabitants reside in Tondo at present. These frequently damaged places are located in areas underlain by soft soil and are near river channels. Hence, effects of site response is very likely and are being verified using microtremor observations. Numerous points had been surveyed and predominant period are determined. The results are plotted on frequently damaged maps. The results can serve as guide to any future development as well as to any engineering recommendations that must be made for the strengthening of these cultural sites and frequently damaged places.

RESPONSE CHANGES OF SOME WELLS IN THE MAINLAND SUBSURFACE FLUID MONITORING NETWORK OF CHINA, DUE TO THE SEPT 21,1999 MS7.6 CHI-CHI EARTHQUAKE

Fuqiong HUANG[1], Yong CHEN[1], Yi TANG[2], Gui-ming XU[3], Gong-cai CHI[4] ([1]Center for Analysis and Prediction, China Seismological Bureau, [2]Department of Science and Technology Development (Department of International Cooperation), China Seismological Bureau, [3]Seismological Bureau of Jiangsu province, [4]Seismological Bureau of Liaoning Province)

About 60 Hydrologic changes in response to the Chi-Chi earthquake with Ms7.6 on 21st Sept. 1999 occurred in 52 wells, including groundwater level, temperature, discharge rate, well pressure and radon etc. in the subsurface fluid monitoring network. Theses response changes were mainly co-seismic changes, but some pre- and post-earthquake changes occurred mainly within 5 days before and after the Chi-Chi earthquake. The response changes of different wells clustering in different tectonic areas showed different features. These changes are distributed in five areas named as A, B, C, D and E. The response changes in A area with short hypo-central distance (less than 550 Km) were mainly pre-earthquake changes occurring more than 5 days before the event. Those in area B (in Huanan tectonic block) and C (in Huabei tectonic block) were mainly co-seismic changes. The hypo-central distance is about 1,100 to 1,280 Km and 800 to 1,160Km respectively. These changes were high frequency water level oscillations induced by seismic waves and accompanied by prominent and permanent water level jumps and/or drops. There are also some post-seismic changes including discharge rate and water radon concentration and well pressure changes in area C. Those in area D in the Yanshan tectonic block, say, Zhangjiakou-Bohai seismic belt, were mainly co-seismic and post-seismic changes including water level, water temperature, and water radon concentration etc., showing prominent and

permanent water level jumps and drops and increasing of water radon concentrations. The hypo-central distance is about 1,750 to 2,060 Km. Those in Area E, located in Chuan-Dian tectonic block, were mainly co-seismic changes showing prominent and permanent water level jumps. The hypo-central distance is about 1,810 to 2,120 Km. The different features of the response changes might be caused by the changes of local hydrologic conditions (like permeability) induced by seismic waves. On the other hand, these response changes might indicate the near-critical conditions in the area where the response changes clustered. Because three moderate earthquakes occurred in area D and one strong earthquake occurred in area E four months after the Chi-Chi earthquake. Such changes might be understood by the crustal buckling hypothesis. It is thought that the response changes might be a kind of precursor that implies elevated earthquake risk in the region. Key Words: Response changes; the Chi-Chi earthquake; Groundwater.

EVALUATING EARTHQUAKE POTENTIAL DUE TO MAJOR ACTIVE FAULTS FOR THE DENSELY POPULATED KANTO PLAIN, CENTRAL JAPAN: AN EXAMPLE FROM THE SEKIYA FAULT

Yukari MIYASHITA[1], Takahiro YAMAMOTO[2], Yuichi SUGIYAMA[1], Akira SANGAWA[1], Koichi SHIMOKAWA[1] ([1]Active Fault Research Center, Geological Survey of Japan, AIST, [2]Research Center for Deep Geological Environments, Geological Survey of Japan, AIST)

The Kanto Plain, in which the largest population lives in Japan, has been suffered from not only interplate megathrust earthquakes but also shallow intra-plate earthquakes in the past several hundred years. Several known active faults in and around the Kanto Plain are expected to be the sources of such shallow earthquakes in the future. To properly evaluate the earthquake potential by these active faults, we have been performing trench excavation surveys. Here we present an example from one of the precautious faults, the Sekiya fault, located 120 km north of Tokyo. As a result of paleoseismological investigations, we identified three surface-rupturing events and the most recent one is correlated to the historical 1683 M~7 earthquake. This and determined mean recurrence interval of 4000 years implies a low probability that the Sekiya fault will produce a large earthquake in the next 100 years. The Sekiya fault is NS-trending west-dipping reverse fault, which extends 30 km along a range front. We excavated five trenches across the Sekiya fault to reveal it's past earthquake behavior. Trenching survey show evidence for three surface-rupturing events about 8000, 4500 and <1000 years ago. A dozen radiocarbon ages restrict the timing of the most recent surface rupture within the past 600 years. On the other hand, historical documents show that the 1683 Nikko earthquake caused serious damage to the area adjacent to the Sekiya fault. In this area, no other damaging earthquake is known to occur in the past 600 years. These geological and historical data on paleoearthquakes indicate that the most recent surface-rupturing earthquake on the Sekiya fault corresponds to the 1683 Nikko earthquake. This conclusion together with roughly estimated recurrence interval of 3500-4000 years implies a low probability of a large earthquake in the next 100 years. If the recurrence intervals have a lognormal distribution (1 sigma 0.23), the probability is less than 1 percent.

SS04b/10P/D-039   Poster   1400-222

RESTORATION OF BUILDINGS IN ARMENIA

Hrachya Sedrak MURADYAN, Hasmik Hrach NAHAPETYAN (NORTHERN DEPARTMENT of NATIONAL SURVEY FOR SEISMIC PROTECTION OF RA)

Reinforcening and, restoration of buildings which were damaged during the earthquake in Armenia in 1988 have done. The buildings have been reinforcened with different methods. The different methods of reinforcening of the knots have ben used. The cycles of oscillations of the buildings have been measured before and after reinforcening which had been compared with new built buildings and calculating data. On the basis of the studies are given criterions to determine the expediency and the levels of the buildings which have to be reinforcened. The designed solutions are studied and estimated, the albums are created in which the best reinforcening sollutions of the building's elements have been taken into account as the best methodical guide. Generelizing the comparative analysis of done projects we can conclude:1. The reinforcening and restoration of the buildings should be done by individual approach.2. The aim of reinforcening and restoration should be determined by economic calculations.If the difference between new building and the reinforcening exceeds 20% the reinforcening can be considered as an acceptable version.3. The most optimal level of the strength of dwelling house from the view of longevity and value is the level which was before the earthquake,as the reinforcening of the buildings to the calculation seismic strength level is equal to consrtuction of new building and if the level is low the buildings can be ruined. In this case during the second calculation strength earthquake the building will not be ruined but should be demolished and it is not expedient to reinforce or exploit again.

NATURAL FREQUENCY AUTOMATIC VARIATION IN SEISMIC ISOLATION SYSTEM

Federico /BARTOLOZZI (Civil Engineer & Independent Researcher)

This system is not ˝new˝ in the unique meaning of the word, but it could be considered as such,because it originates from the merger of two my original systems, of which it contains the most advantageous relative characteristics. Its operational aspect is as effective as that of the systems from which it originates, but it is considerably better than both of them, due to the reduced planning aspect and the operational simplicity, which, together with the greater economic competitiveness, certainly make it more acceptable. In fact, the replacement of the complicated, electronically started, frequency converters, present in the former reference system, with the naturally started easy device of the second system, is the main change to the former system, which, however, preserves unchanged both the number of bearings and their plane surface of sliding. Having said this, the proposed system is based on the following operations: 1. interruption of the continuity between the building and the foundation-soil complex; 2. laying of four elastic movable bearings with sliding or rolling friction; 3. self-centring of the building after an earthquake.By means of its own elastic deformation, each bearing automatically compensate the rigid deflection variation relative to support due to the horizontal component of the motion. The building remains motionless with respect to the foundation-soil complex, which moves. Due to the sub-undulatory shock, the vertical motion varies the building behaviour only partially. It is subjected to a low vertical translation and to the resonance possibility. In order to prevent the resonance danger, the vertical natural frequency automatic variation of the building takes place because of auxiliary springs, present in each bearing, which increase the action of the main spring during an emergency, characterised by an interval of vertical seismic frequencies, including the resonance one.

A SHORT NOTE ON THE DETERMINATION OF THE CHARACTERISTIC FREQUENCIES OF VIBRATION FOR DIFFERENT BUILDINGS IN CAIRO, EGYPT USING MICROTREMORS

Mohamed Ahmed GAMAL (Geophysics)

Cairo is one of the most areas in the world possess irregularity in building construction work. This random construction work had led to the randomness at building shapes varying between, No. Of floors, building size and weight of buildings at the same location.Based on the previous observation, accurate risk assessment in the area of Cairo is very difficult, since earthquake effects is variable from one building to another depending on differences in their dimensions or characteristic frequencies of vibrations. We tried to show variation of frequencies of resonance for different buildings at Cairo using Spectral amplitude of microtremors base on acceleration recordings, by three-component stations installed at the Building local soil, building base and at different stories.We used three methods:1-Spectral ratios between horizontal and vertical component (H/V) of motion,2-Spectral ratios between two horizontal component of motion one at building floor and the other at building base or soil,And the new technique discussed by us;3-Spectral ratios between building floor spectra and constant spectra.A representative building for Naser City, Giza, Shubra, Ghamra, Airport area, El-Daher, Morad St. and El-Haram, was taken to show the resonant frequency of each. Although the variability of buildings is severs, we tried to choose buildings to represent each area.

BUILDING RESPONSE MEASUREMENT USING AMBIENT VIBRATION TEST IN METROPOLITAN MANILA, PHILIPPINES

Angelito G. LANUZA[1], Ishmael C. NARAG[1], Norio ABEKI[2] ([1]Philippine Institute of Volcanology and Seismology, Department of Science and Technology, Philippines, [2]Department of Architecture, Kanto Gakuin University, Japan)

Lessons learned from past destructive earthquakes show that most of the casualties due to these events were associated with structural failure especially for those structures, which did not conform to sound design and construction principles. During moments of extreme ground shaking, buildings whose natural periods are close to the predominant period of the ground usually experience resonance, which in turn cause severe damage to total collapse. Metropolitan Manila, as a major political and economic center in the Philippines, has undergone rapid structural development for the past two decades and this trend is foreseen to continue for the next decade or so. Owing to its growing population and its proximity to earthquake generators with high potential to generate large-magnitude events, it is important that information on the possible behavior of buildings within the metropolis during a large destructive earthquake should be determined. However, different episodes of changes in the country's structural code and differences in construction practices in the Philippines make it difficult to determine and monitor these parameters from design parameters estimated from structural plans. Towards this end, ambient vibration tests were conducted on medium to high-rise structures in the metropolis in order to determine their natural period and damping which are essential parameters to determine a building behavior during a strong earthquake. A straightforward estimate of a building's fundamental period can be calculated using an empirical formula of the National Structural Code of the Philippines (NSCP). The formula is a function of height of the building and uses various coefficients for different structural systems. Results of the ambient vibration survey on at least 100 buildings in Metro Manila indicate that the natural period of tall buildings (~100 meters high) are nearly equal to NSCP's estimated value specifically those buildings classified as reinforced-concrete. On the other hand, deviations on the measured natural periods on shorter buildings (>50 meters) are found. This can be attributed to the presence of additional engineered structural members such as shear walls and other bracing elements that tend to increase the stiffness of the structure. These buildings are classified as reinforced-concrete with dual structural system which could have been designed assuming conservative design base shear forces due to earthquake and could be less vulnerable to intense ground shaking. Moreover, many of the shorter buildings with simply RC moment-resisting frames may have been designed with less design base shear forces and could be vulnerable to severe ground shaking.

ACCELERATION RESPONSE SPECTRUM OF BUENOS AIRES CITY, ARGENTINE, CAUSED BY DISTANT AND LARGE MAGNITUDE EARTHQUAKES

JUAN S. CARMONA[1], Nora C. SABBIONE[2], Roberto M. PINCIROLI[2], Raquel L. PALAU[1], Luisa B. GARCIA[1] ([1]EARTHQUAKE ENGINEERING RESEARCH INSTITUTE, NATIONAL UNIVERSITY OF SAN JUAN, [2]DEPARTMENT OF SEISMOLOGY, NATIONAL UNIVERSITY OF LA PLATA)

Buenos Aires city, the capital of the Argentine Republic, with a metropolitan population of nearly ten million inhabitants, is sited on the eastern side of an extended plane area formed by deep sedimentary alluvian soil layers corresponding to the Argentinian "pampas". Because the seismic activity around this city is low, the motion due to distant and large magnitude seismic events with epicenters in western Argentina or in Chile, at more than one thousand km of distance, are more frequently perceived on the upper levels of tall buildings in Buenos Aires city, some of them generating strong alarm.From 1996, the three components of the ground motion acceleration of seismic events have been recorded in one broadband seismograph installed in the Seismological Station of the National University of La Plata which is located in La Plata city, at 50km from Buenos Aires and on the same subsoil type consisting of quaternary loess with a thickness of approximately 500 m. Up to date, the two more important motions which have been recorded by this instrument are those corresponding to the Mw = 7.1 Oct 15, 1997 Chilean seismic event and the large earthquake, Mw=8.4, of June 23, 2001 that occurred on the coast of Peru, the former with an epicentral distance of 1300km and the latter with one of 2500km. Their maximum acceleration values have been 0.75 and 0.18gals, respectively, while their strongest interval lasted approximately 100 sec in the former and more than 200sec in the other. In both acceleration records there are outstanding frequencies (period) around 0.35 c/s (T= 2.85sec) and 0.85 c/s (T=1.18sec) whereas in the Peruvian event an additional outstanding frequency of 0.05c/s (T=20sec) has also been detected. The first two frequencies are associated with body and Lg waves, while the last one with surface waves. The 2% damping curves of the acceleration response spectrum of these ground motions recorded in La Plata show important peaks at about the same frequencies (periods) mentioned above. The peak values for the frequencies (periods) 0.35 c/s (T= 2.85sec) and 0.85 c/s (T=1.18sec) depend on the atenuation of Lg waves, while that for the frequency (period) 0.05 c/s (T= 20sec) on the atenuation of the surface waves.Moreover, the measured fundamental period values of the buildings of Buenos Aires city with more than 20 stories are larger than 1 sec and the largest reach 2.7sec., which corresponds to the tallest 160m high Le Parc Tower. In the upper levels of these tall buildings, the absolute acceleration amplitudes of the motion generated by these ground motions reach nearly 30 gals and last more than one minute. This explains why the

S

distant and large magnitude seismic events have been perceived well and also with alarm on the uppermost floors of the tall buildings in Buenos Aires city, although no structural damage has been detected in them.

THE RESEARCH ON EARTHQUAKE LOSS ESTIMATION AND COUNTERMEASURE FOR EARTHQUAKE PREVENTION AND DISASTER REDUCTION IN FUJIAN PROVINCE

Jinhai CHEN (Seismological Bureau of Fujian province, China Seismological Bureau)

The research project on Earthquake Loss Estimation and Countermeasure for Earthquake Prevention and Disaster Reduction in Fujian Province is a multi-layers and multi-size earthquake loss estimation research for meeting the needs of earthquake emergency plan improving earthquake emergency response ability and disaster rescue organizing efficiency it also is great useful in ordinarily management for earthquake prevention and disaster reduction. The main contents of project as following: 1. The research treats a county as an earthquake loss estimation unit. In this type of earthquake loss estimation research we treat the county as research object and build the loss estimation model that takes population and GDP as basic parameters and the historical earthquake disaster site condition and type of building as adjusted parameters. Based on ArcGIS 8.1 we used 1:500000 scale digital map to build database and management information system. 2. The research treats a town (or block) as an earthquake loss estimation unit. In this type of earthquake loss estimation research we build the loss estimation model for rapidly estimating the economic loss casualty and life-line destructive degree under a given earthquake parameter. Based on GIS we used 1:50000 scale digital map to build database and relevant application with spatial analysis and quantitative computing. 3. The research treats an important construction or a community in the city as an earthquake loss estimation unit. In this type of earthquake loss estimation research we select some important cities in Fujian province and carry out loss estimation by analyzing the vulnerability for every important construction and sample of general building. The important construction means schools hospitals important government buildings high buildings and life line engineers. The general building means common civil construction and be analyzed in community unit. In this type of earthquake loss estimation research we use 1:5000 scale digital map to build database and relevant application. 4. Comprehensive research for earthquake prevention and disaster reduction in city swarm. Carrying out research on evaluating for earthquake resistant ability for life line network earthquake disaster relativity and rescue ability by themselves and each other between cities. The GIS-based database is built and decision support system for comprehensive earthquake prevention and disaster reduction is developed.

SCALING LAWS OF EARTHQUAKE LIVE LOSS RATES AND ITS APPLICATION TO LONG_TERM PREDICTION IN CHINA CONTINENT

Fu ZHENGXIANG (Center for Analysis and Prediction, China Seismological Bureau)

China has long-term record of historical earthquakes and its live and economy losses. This paper studied the self-similar power scaling laws of earthquake live loss rates, during a period from 1500 to 2000 for North China, Southwest China and Northwest China respectively. The research shows that the self-similar power scaling laws are as followings: (1) Log(N)=-0.34-0.42LogR, for North China; (2) Log(N)=-0.59-0.49LogR, for Southwest China; (3) Log(N)=-0.25-0.25LogR, for Northwest China. R and N mean the earthquake live loss rate and the cumulative occurrence numbers of the earthquake live loss event respectively. The laws have been used in long-term earthquake live loss prediction. Supposing the process of the events of earthquake live loss follow a Poisson one, the research results show that the occurrence probabilities of earthquake live losses of 1000persons or more in North China and Southwest China, and 100 persons or more in Northwest China would be 0.8 or more before 2020 separately. Because the earthquake live losses might be related mainly to the shock-resistant capacity of houses and buildings people lived in, the shock-resistant capacity of houses and buildings in the future will be better than that during the period of used data in this paper, so that the prediction of the occurrence probability of earthquake live loss could be higher.

EFFECTS OF EARTHQUAKES ON MEGACITIES

Rashmi ARORA (Centre for Disaster Mitigation and Management, 302, Kamadgiri Tower, Kaushambi, Ghazibad-201010, U.P. India)

Natural disasters are a part of the environment in which we live. They do not discriminate between people or countries. And yet, no disaster is entirely natural. Human activity invariably aggravates the risks through insufficient attention to where and how settlements are built, or natural resources are exploited. It is estimated that nearly one million earthquakes occur worldwide each year, and only a few major earthquakes, but when they do, they are among the most destructive natural forces on earth. The shaking of the ground coupled with the liquefaction of some soils wreck havoc on man-made structures. In terms of human and economic losses, seismic shaking is the most significant factor contributes to losses not only directly through vibratory damage to man-made structures but also indirectly through triggering of secondary effects such as landslides or other form of ground failure. When a quake occurs in a populated area, power and gas lines are often ruptured causing numerous fire. In the 1906 San Francisco earthquake, much of the damage was caused by fires which ran unchecked when broken water mains left fire-fighters with only trickle of water. On September 19, 1985, a violent earthquake jolted SW Mexico, devastating sections of Mexico City and killing about 7000 persons. In less than 2 minutes the quake battered downtown Mexico City, causing an estimated 250 buildings to collapse. In 1995 an earthquake in Kobe, Japan caused more than 6000 fatalities and over $US120 billion in economic losses. In Izmit, Turkey, August 1999, an earthquake caused 20,000 fatalities and an estimated $20 billion in economic loss. Those affected most are the poor and the socially disadvantaged in the developing countries as they are the least equipped to cope with the situation. The combination of natural and technological hazards creates an environment in which effects may be multiplied through cascading multi-disasters. For example, an earthquake can lead to a breakdown in the social order and infrastructure, resulting in rioting, the spread of disease through unsafe drinking water, and disruptions to the local economy. Because economic globalization has made the world´s cities increasingly interconnected, events in Manila may affect Madrid, Mexico City and Milwaukee. There are about 450 cities worldwide with a population of more than 1 million. Today´s cities and megacities are unlike any that existed in the past, and thus we cannot expect our experience with historical disasters to guide us in the future. Cities are larger than ever before and growing in size at an unprecedented rate. Furthermore, as cities have grown, they have often expanded onto hazardous lands. About 50 percent of the world´s largest cities are situated along major earthquake belts or tropical cyclone tracks. The concern over the risk to megacities, particularly in the developing world, is their growing vulnerability caused by their hyper-concentrations of population, dependence on complex and aging infrastructure, and unprepared local institutions.

EARTHQUAKE DISASTER ESTIMATION USING GEOGRAPHICAL INFORMATION SYSTEM AND STRONG GROUND MOTION SIMULATION SYSTEM BASED ON MULTI-SCALE ANALYSIS

Tsuyoshi ICHIMURA[1], Muneo HORI[2] ([1]Department of Civil Engineering, Tohoku University, [2]Earthquake Research Institute, University of Tokyo)

Realistic simulation of a possible earthquake disaster is important for making rational countermeasures. The disaster is the accumulation of buildings and structures damages.Thus, a numerical simulation method must compute the strong ground motion with the spatial and temporal resolution high enough to calculate structural responses during the earthquake and to evaluate their damages. In addition, credible earthquake disaster could be estimated by reasonable simulation of buildings and structures, using resulting strong ground motion information. This paper proposes such a simulation method, using strong ground motion simulation system and a simulation model of a whole city from geographical information system (GIS). In order to obtain reliable strong ground motion information, it is necessary to simulate, with 3-D numerical simulation model, the fault mechanism, the wave propagation through the heterogeneous crust and amplification near the surface. There are, however, two major difficulties: (1) the lack of soil-crust structures information; (2) the requirement of huge computation. For resolving these two difficulties, we propose a new analysis method, macro-micro analysis method (MMAM). The MMAM takes advantage of the bounding media theory (BMT) and the singular perturbation expansion (SPE). The BMT can deal with the uncertainty of soil-crust structures information. The SPE can lead the efficient multi-scale analysis, which reduces the computation amount required at one time. Though the SPE can reduce the computation amount, the huge amount of computation remains yet. For more reduction of computation amount, the finite element method with voxel element and the parallelzation computation are applied. In addition, auto-modeling software for soil-crust structures, which contains new estimation tool and database on GIS, is developed for much more efficient modeling. By combination of these components, strong ground motion simulation system is developed. In order to verify the effectiveness of this strong ground motion simulation system, the earthquakes observed in Yokohama City are simulated, and the reproduction of the strong ground motion is attempted. The simulation result is compared with the data observed. It is shown that it succeeded in reproducing the velocity spectrum of each place in frequency domain where the calculation accuracy is guaranteed. In addition, the maximum velocity distribution of each every site is also calculated with the spatial resolution of 1[m] order. These results clearly show the effect of soil-crust structures (material property and topography) on the strong ground motion. And it is confirmed that large-scale numerical simulation is necessary in order to predict the strong motion with high spatial resolution in the sufficient accuracy. For making credible earthquake disaster simulation, much more reasonable simulation model of buildings and structures is needed. Using available GIS information about buildings and structures, virtual city is constructed on computer. The methodology of constructing these models is studied, since available data are usually limited. An example of a city model is constructed and earthquake simulation is made to examine the basic usefulness of this earthquake disaster simulation.

DEVELOPMENT OF AN AUTOMATIC SYSTEM TRANSMITTING-EARTHQUAKE ALARM INFORMATION

Shigeki HORIUCHI, Hiroaki NEGISHI, Kana ABE, Aya KAMIMURA, Yukio FUJINAWA (National Research Institute for Earth Science and Disaster Prevention)

Most earthquake damage occurs after arrival of the S wave, whose amplitude is about five times larger than the P wave. Because the P wave travels faster than the S wave, the interval between their arrival times creates an opportunity to activate an earthquake alarm and take pre-emptive safety measures. We developed an automatic system transmitting earthquake alarm information, which transmit the earthquake shaking data before S wave arrival. Since the alarm system is used to control transportation, industry, business, etc, at a time of a large earthquake occurrence, false alarms cost huge. We solved the technical difficulty of determining earthquake parameters very quickly but without errors by developing a novel method, which use not only P wave arrival times but also time data of P wave not yet arrived. We also developed filters, which can distinguish seismic signal from large amplitude noise generated by many kinds of reasons, to increase the reliability of the system. The system can eliminate extraneous arrival time readings in the hypocenter location by checking automatically measured readings, P wave not yet arrived data, and their station distribution. We use waveform data of Hi-net, which installed about 600 very high quality stations covering whole Japan with space density of 20 to 30 km. All seismometers are installed on wells deeper than 100m. Our system can locate precise hypocenters for 95 % events occurring in and near Japan Islands within a few seconds and transmits earthquake alarm information before most of seismic energy has arrived even to the station closest to the hypocenter. We are planning to broadcast earthquake alarm information for all destructive earthquakes by using the satellite seismic data transmitting system developed by ERI, hoping to promote the development of many kinds of automatic control systems, which stop cars, factories etc to protect people from earthquake damage.

SS04b/10P/D-049   Poster   **1400-232**

SOME EFFECT OF UNCERTAINTY IN SEISMIC SOURCES MODELING ON SEISMIC HAZARD MAPPED PARAMETERS, STUDY CASE

Vladimir Petar MIHAILOV[1], D. DOJCINOVSKI[1], R. VERBERIEN[2], T. CAMELBEECK[2] ([1]Institute of Earthquake Engineering and Engineering Seismology, University, [2]Royal Observatory of Belgium)

Current methods and solutions of seismic hazard analysis take into account the seismological and geological information to arrive at probabilistic forecasting of future earthquakes. However, the lack of knowledge of the cause of earthquake and the short length of seismic history lead to decimal and statistical uncertainty concerning the parameters of seismicity. Statistical uncertainty in definition of some parameters of seismicity, especially type, size and geometrical characteristics of seismic sources, can have a great effect on the calculation of the seismic hazard. The effect is assessed by deriving probability distribution functions of important seismic parameters. Because damaging earthquake occur infrequently to rarely in any region, evaluation of the probability of occurrence and the resulting levels of ground shaking requires the use of various models fit to limited data and extrapolated beyond the range of the data. As a result, significant uncertainty exists in probabilistic estimates of ground-shaking hazard. This uncertainty increases as one moves from hazard assessment in areas of high seismic activity to areas of low seismic activity. In seismically active areas, seismic sources are relatively well defined by recorded earthquakes and geologic data, and there is a large database of recorded strong ground shaking. These data strongly constrain the probabilistic models used to assess the hazard. In areas of low seismic activity, earthquakes sources are poorly understand and ground motion data are limited primarily to records from earthquakes smaller than those of interest in assessing potential damage. Consequently, in these areas there are only weak constrains on the probabilistic models used to asses hazard. Due to the fact that

the seismic model formulation requires availability of seismic source parameters for the purpose of calculating the probabilistic hazard, and because these parameters are subject in practice to considerable variation in the manner of their determination, it is important to judge the sensitivity of the map values to these parameters. The uncertainty in the seismic sources, activity rates and maximal possible magnitude are described using the earthquake data for Belgium and the surrounding area as source data. The influence of these uncertainties on seismic hazard is illustrated where appropriate.

ON THE DEFORMATION CHARACTERISTICS AROUND JIASHI EARTHQUAKES AND AN APPROACH FOR EARTHQUAKE HAZARD ASSESSMENT

Anfu NIU, Jing ZHANG, Xudong YAN (Center for Analysis and Prediction of China Seismological Bureau)

In the early 1997, in Jiashi area of Xinjiang of China, 7 strong earthquakes with magnitude more than Ms6.0 subsequently happened in 3 months. These strong earthquakes occurred in the junction of Tianshan Mountain and Tarim basin. These strong earthquakes were attracted many scholars to investigate the deformation process and its mechanical factors.Before these strong earthquakes there were established 4 GPS basic stations and 4 tilt stations undergoing nearby the epicenters, and an Atushi Ms6.7 earthquake were occurred on 19 Mar of 1996, far from the Jiashi earthquakes around 80km. After the Atushi Ms6.7 earthquake, tilt direction of this block shows a clear turning from SW to NW. The change in tilt direction gives a possible trigger to the Jiashi earthquakes.After Jiashi earthquakes, China Seismological Bureau organized twice GPS campaigns in the area with total number 19 GPS stations in 1998 and 1999,respectively. Based on the GPS observation results, and combined with the continuous tilt observations and seismic activity, we researched the tectonic characteristics of this area by using the dislocation model proposed by Okada (1985,1992). The estimated moment of fault activity is well consistent with the level of seismic activities. So this report also gives an approach for earthquake hazard assessment through monitoring fault movement.Key words: Jiashi earthquake\ GPS \Tilt \ Earthquake Hazard Assessment

THE NEW MANUAL OF SEISMOLOGICAL OBSERVATORY PRACTICE (NMSOP): A CONTRIBUTION TO PROFESSIONAL EDUCATION AND CAPACITY BUILDING

Peter BORMANN (GeoForschungsZentrum Potsdam, Solid Earth Physics and Disaster Research)

The last edition of the Manual of Seismological Observatory Practice dates back to 1979. It covered analog techniques only and is out of print. Since that time, computer and communication technologies as well as the availability of modern broadband sensors have revolutionized seismological observatory practice. Related know-how is chiefly available in industrial countries only. Besides this, classical university curricula do not provide suitable education and training of observatory personnel. Therefore, the IASPEI Commission on Practice (CoP) proposed in 1994 to elaborate a New Manual of Seismological Observatory Practice and established a related international working group. This NMSOP is now available both as a printed version in two volumes, on a CD-ROM and on the Internet via http://www.gfz-potsdam.de/pb2/pb21/index_e.html or http://www.seismo.com. Volume 1 comprises 13 chapters: 1) Aim and Scope of the IASPEI New Manual of Seismological Observatory Practice (NMSOP) 2) Seismic wave propagation and Earth models 3) Seismic sources and source parameters 4) Seismic signals and noise 5) Seismic sensors and their calibration 6) Seismic recording systems 7) Site selection, preparation and installation of stations 8) Seismic networks 9) Seismic arrays 10)Seismic data formats, archival and exchange 11) Data analysis and seismogram interpretation 12)Seismic intensity and intensity scales 13)Volcano seismology These basic Chapters introduce into the topical fundamentals of observatory Practice. They are complemented by an Annex-Volume 2 which comprises datasheets, exercises, information sheets on special topics, program description, a list of acronyms, 34 pages of references, a detailed glossary which explains basic terms in simple language and a very detailed index. A complete copy of the Manual (1252 pages) will be on display and the access to and easy surfing through its website via hyperlinks will be demonstrated. The talk introduces into the basic didactic concept of the NMSOP, demonstrates the easy use of the Manual for the compilation of tailored educational or training models on specific topics, gives an example of animations of seismic ray propagation and seismogram formation which complement the Manual CD-ROM and discusses the further development of the NMSOP into a tool for eLearning.

24 YEARS INTERNATIONAL TRAINING COURSES ON SEISMOLOGY; SEISMIC HAZARD ASSESSMENT AND RISK MITIGATION: CONCEPT, PROGRAM AND IMPACT ASSESSMENT

Peter BORMANN, Jochen ZSCHAU (GeoForschungsZentrum Potsdam, Solid Earth Physics and Disaster Research)

Since 1980 the Potsdam geoscientific research institutes run international training courses on the subjects seismology, earthquake hazard assessment and risk mitigation for the benefit of attendants from earthquake-prone developing countries. These courses are part of the educational program of UNESCO in the fields of geosciences and disaster mitigation and have been a major contribution of Germany to the professional education and capacity building in developing nations during the International Decade for Natural Disaster Reduction (IDNDR) and its follow-up International Strategy for Disaster Reduction. Accordingly, these courses have been regularly supported by UNESCO, the United Nations Office for the Co-ordination of Humanitarian Affairs (OCHA) and IASPEI. By October 2003 about 580 participants from 90 countries will have attended these courses. Since the unification of Germany and the foundation of the GeoForschungsZentrum Potsdam (GFZ) in 1992 these 5-weeks courses are alternately held in Germany as world-wide open courses and every second year as regional courses rotating between Asia, Latin America and Africa. Up to now, regional courses took place in 1993 in India, 1995 in Nicaragua, 1997 in Kenya, 1999 in China and 2001 in Chile. The course 2003 will be held in South Africa. The team of lecturers from the GFZ Potsdam is regularly complemented by international experts from France,

Norway, Slovenia and the USA and in the case of regional courses by lecturers from the hosting and surrounding countries. The courses are strongly application-oriented and consist of about 40% lectures, 40% exercises and 20% field excursions, workshop sessions with presentations by course participants and follow-up discussions. The applications received for these courses every year outnumbers by far the course capacity and amount of available fellowships. This speaks of a continued demand for practice-oriented training in these fields. The extensive lecture and exercise material developed for these courses formed the core part for the elaboration of the New IASPEI Manual of Seismological Observatory Practice. The talk will introduce into the philosophy, educational concept and scientific contents of the courses. To better plan for the future we conducted an impact study aimed at assessing the usefulness of the course program and its didactic concept for developing self-reliant expertise in earthquake research, earthquake and volcano monitoring, hazard assessment and risk mitigation in disaster-prone developing countries. This study was based on the response of about half of all former course participants to a very detailed questionnaire. The results of this analysis will be presented and conclusions be drawn with respect to the continuation of this course and the initiation of new complementary, co-operative German offers for professional education as well as formal and informal education of the public, press and officials in the area of improved disaster management, monitoring, hazard, vulnerability and risk assessment.

SS05/10A/A13-003	0900

TRIAL OF 'REMOTE SCIENCE CLASS' BY USE OF REAL-TIME HDTV VIDEO IMAGE FROM THE SEAFLOOR THROUGH A COMMUNICATION SATELLITE

Takeshi MATSUMOTO[1], Yasuhisa ISHIHARA[2], Tsutomu SHIGETA[3], Tatsuo SUZUKI[3], Masaki MAKIHARA[4], I-Space Education Promotion Taem ([1]Marine Science Department, Nippon Marine Enterprises, Ltd., [2]Japan Marine Science and Technology Center, [3]National Space Development Agency of Japan, [4]National Museum of Emerging Science and Innovation)

Studying natural history by using the real nature is essential for schoolchildren to deepen the understanding. Since they cannot always experience the true nature, it is the key to produce circumstances of "virtual field tour" in the classroom by utilising video image and appropriate materials. In this case, the more precise is the visual image, the stronger is their impression. Therefore, we should invoke IT technology which enables us to make high-speed data transmission and processing. ROV "HyperDolphin" owned by JAMSTEC (Japan Marine Science and Technology Center) is equipped with underwater HDTV-class camera and the video image processing system for scientific use. If the video image is transmitted in real time, both offshore and onshore scientists can share the information. The same system is also effective for education and public outreach by reporting what is going on under the sea in real time. JAMSTEC and NASDA (National Space Development Agency of Japan) are promoting an experiment of telecommunication of HDTV-class high precision video image from a moving research vessel during an expedition to an onland station through a Japanese communication satellite (CS) for marine education and public outreach without downgrading the quality of data and imag. Such high quality image transmitted to the land is a live teaching material to make schoolchildren and non-professionals understand the underwater world and its mystery. In March 2002 we succeeded in a ´remote science class´ by connecting remotely between ROV "HyperDolphin" offshore and National Museum of Emerging Science and Innovation (MeSci) in Tokyo. The clear and high precision HDTV-class video image from the seafloor of 650m water depth on the Izu-Bonin active volcanic arc was transmitted in real time to MeSci through the SNG (Satellite New Gathering) Vehicle on board and the Japanese commercial CS (SuperBird-B2). By following the scenario that had been made in advance, a programme with a presentation at the MeSci auditorium, interactive communication between onshore and offshore by relay, lecture by a marine biologist on board by use of the real-time video image of ROV was planned and carried out without any mechanical error. This was of great help for the people to understand what is going on during the marine observations and to enjoy the deep sea world.NASDA is planning to launch a new high-speed internet communication satellite WINDS (Wideband InterNetworking engineering test and Demonstration Satellite). The current trial is the first step for estimation of the practicability of the remote science class by sharing quite the same information and impression by both offshore and onshore through the communication satellite and suggests the future use of WINDS satellite for marine education and public outreach from offshore.

SS05/10A/A13-004	0915

THE DPRI-KU SATELLITE OFFICE FOR OUTREACH SUPPORTED BY THE 21ST CENTURY CENTER OF EXCELLENCE PROGRAM

Manabu HASHIMOTO, Haruo HAYASHI, Hironori KAWAKATA, Yoshiaki KAWATA, Kojiro IRIKURA, Shuichi IKEBUCHI (Disaster Prevention Research Institute, Kyoto University)

The Disaster Prevention Research Institute, Kyoto University, was designated to one of the centers of excellence under the MONBUKAGAKUSHO's 21st Century COE program. In order to improve accountability of research works and to enlarge opportunity of education, we opened satellite offices near the Kyoto and Tokyo stations and started a lecture series on almost all disciplines in the field of science and technology related to disaster mitigation. One and half hour-long classes are held in the evening on four days in a week in Kyoto, while once per two weeks in Tokyo. Since DPRI has about 100 faculties, every faculty will have two classes in a year. All the classes are recorded with digital camcorders and audiotape recorders. We plan to edit all the digital records of classes and put them onto our website in the future.Programs and lecturers are announced on our website (http://www.21coe.dpri.kyoto-u.ac.jp). Basically classes on the same discipline are held on the same day of the week: e.g. earthquake prediction and related topics are held on Tuesday. Applicants must apply his/her desired classes on this website. Therefore applicants should be familiar with Internet.By the end of January, 11 classes were held in Kyoto and 10~15 participants attended in average. We had two classes in Tokyo in January. There were more than 60 attendants per one class. Professions of participants are high school teachers, undergraduate and graduate students, journalists, national and local government officials, employees from utility companies etc. Although they depend on the topic of the class, there is a tendency that high school teachers attend earthquake classes and governmental officials and employees from private company are observed in engineering classes. We also periodically report the activity of the satellite office to public and feedback the opinion from the public to our activity.

INTERACTIVE LEARNING IN GEOPHYSICS: IMPLEMENTATION WITHIN THE FRAMEWORK FOR DISTANCE EDUCATION PROGRAM AT THE FEDERAL UNIVERSITY OF FLUMINENSE (UFF)

Luiz V.B. GOMES, Valiya M. HAMZA (IASPEI)

Recent installation of the web-based 'Distance Education Program' at the Federal University of Fluminense (UFF) has opened up an important complementary facility for graduate and undergrtaduate students in the state of Rio de Janeiro (UFF@Distância: www.uff.br/ead).

The software for this platform and related facilities for interactive learning were developed locally. This important technological capability has allowed economy and greater flexibility in implementing a variety of student/professor interactive facilities than is possible under commercially available educational packages. In the first year of operation the system has established itself as a landmark for educational projects and in addition has contributed to development of software for web-based teaching-learning environment in Brazil. The system also allow implementation of interactive educational packages. As a specific example, we discuss the experience gained in implementing Distance Education courses in geophysics, developed at the National Observatory of Brazil. This package provides both passive and interactive learning environments. In the passive environment the course contents are in the form of standard chapter-related HTML modules. However, the student has the option for on-line communication with the professor. The interactive environment consists of modules that interlace object oriented scripts and graphic utilities (used for enhancing capabilities of conventional HTML pages). One of the example sets, currently under development as academic software, have modules for virtual demonstration of borehole temperatures and crustal thermal regimes. The second example set make use of dynamic simulation techniques for illustrating wave propogation in homogeneous media. The third example set makes use of widely available spreadsheet packages for demonstration of numerical methods and illustration of tectonic phenomena such as continental drift. Facility for implementing simulations in response to user inputs is an attractive feature of such modules. These are actually system-independent packages that can be set up without the need to invoke server-based applications. Another major advantage of this approach is that the interactions are processed at the user end, leading thereby to considerable reduction in net traffic. Systematic training of academic staff is a crucial ingredient for the success of web-based educational packages.

GEOPHYSICAL EDUCATION AND INSTRUMENTATION NEEDS IN THE D.R.CONGO

Ndontoni ZANA (Département de Physique, FacultAEdes Sciences, UniversitAEde Kinshasa et Centre de Recherche en Géophysique)

The territory of the D.R. Congo includes several natural fields of geophysical interest that require a strong implication both in education and observational activities by local scientists. The prominent features of this region are: (a) The western branch of the East - African Rift System covers the eastern Congo border over 1200 km. The Virunga volcanic region within this branch is one of the most active in the world. The Nyiragongo lava flow that covered over the Goma city on January 17, 2002 is the severest experience of the local people in recent history. (b) The D.R. Congo area covered by a large cratonic structure is affected by seismic activities: these include intense rifting seismicity and moderate intraplate one with scarce destructive events, e. g.. the 1992 Kabalo earthquake of M 6.7. (c) The crust under the D. R. Congo is important reservoir of mineral resources. In spite of these stimulating features, the field of geophysics has very few trainees in the country. To remedy this lack, a geophysical capacity building program has been set up. This one includes two steps; (1) Education: The Faculty of Science of the Kinshasa University has included some basic lectures of geophysics in its graduate curricula in physics and geology. Due to the dimmed number of professors, the teaching is limited to fundamental topics. The future goal is the establishment of a full department of geophysics. (2) Geophysical observation: As response to the occurrence of the 1992 Kabalo earthquake and to the catastrophic disaster by the 2002 Nyiragongo eruption, a program to construct the National Geophysical Network has been set up and included within the government master plan. This program is operated by the Center for Geophysical Research (C.R.G) a governmental institution within the Ministry of Education and Science. However, the whole program is facing two major difficulties: on the one hand, the Faculty of Science is deserted by students due the lack of attractive jobs on the local marked as well as in the scientific and academic fields. On the other hand, the diet budget allocated to the Ministry of Education does not allow its research institution to build the needed geophysical observatories that could attract young scientists as well as students. This serious lack, if not quickly remedied, is preventing young scientists presently abroad to return to their homeland. It is expected that this project will obtain the due support in order to promote the needed human and instrumentation capacities for geophysical observations over the D.R. Congo territory.

SS05/10A/A13-007   1000
PUBLIC MOVEMENT AGAINST ENCROACHMENT OF LAKE AND ITS CONSERVATION IN BANGLADESH

Mostafa Md. KHALEQUZZAMAN[1], Md. SALEQUZZAMAN[2] ([1]Paediatrics Consultant, Magura General Hospital, Bangladesh, [2]Associate Professor, Environmental Science Discipline, Khulna University, Bangladesh; and Ph.D. Candidate and Researcher, Institute for Sustainability and Technology Policy (ISTP), Murdoch University, Western Australia, Perth, WA 6150, Australia, Tel. +61 8 9360 2898/9284 4222, Fax. +61 8 9360 6421, email: salek@central.murdoch.edu.au / msalequzzaman@hotmail.com)

Bangladesh is a country of water and wetlands, because lots of cress-cross rivers and lakes are passing inside the country. Superficially, this setting of lakes and rivers has a net like panoramic view that makes the country a rich biodiversity. Lots of peoples are depends on it for their livelihood. But this natural settings is now endangered, because of the lakes and other natural water bodies of the whole country including the capital city of Dhaka are regularly being encroached illegally by the corrupted peoples of the country, which upon giving rise to serious environmental and civic concerns. Recently some environmentally friendly peoples and organizations have taken a mass-awareness program in the whole country against the bad effects and threats of this type of encroachment. The programs have finally moved by mass peoples. As a result, the government of Bangladesh finally started to take an action against this encroachment, and some successful outcomes have already achieved. The paper will discuss how the public movement has organized and how much the success has achieved. Finally the paper will recommend the sustainability issues of the public movement against encroachment of lake and its' conservation in Bangladesh.

SS05/10A/A13-008   1015
RIVER RESTORATION THROUGH MASS AWARENESS PROGRAM OF BANGLADESH

Mostafa Md. KHALEQUZZAMAN[1], Md. SALEQUZZAMAN[2] ([1]Paediatrics Consultant, Magura General Hospital, Bangladesh, [2]Associate Professor, Environmental Science Discipline, Khulna University, Bangladesh; and Ph.D. Candidate and Researcher, Institute for Sustainability and Technology Policy (ISTP), Murdoch University, Australia, Tel. +61 8 9360 2898, Fax. +61 8 9360 6421, e-mail: salek@central.murdoch.edu.au / msalequzzaman@hotmail.com)

Bangladesh is a riverine country. As lots of river is passing through Bangladesh; it has a great impact to Bangladesh's economy, environmental and socio-cultural activities. More than 70% of the population directly or indirectly depend on river to their daily livelihood. But during past few decades, most of the rivers have been encroached through illegal structure by the muscle man. Besides, most of the river are seriously polluted from the different river bank industry, sewerage and drainage systems. By these processes, some of the rivers are

totally vanished. However, the encroachment process and pollution has severe impacted to the agricultural, navigational, fishing, recreational and other activities to the neighbouring local communities. As a result, the local communities with the help of environmentalist, journalist, educationist, student, various NGOs, and different other groups have protesting to movement of mass gathering continuously against the river encroachment and pollution activities, and demand for restoration of the river since 1998. For this protest and awareness by the mass population of the society, government of Bangladesh and concerned river management authorities now have started the action against encroachment. The paper will discusses in details the encroachment process and anti-encroachment of restoration of **Buriganga River** of the Capital City, Dhaka as a case study. Finally, the paper will give a policy recommendation on **how the encroachment could removed sustainable way from the all rivers of Bangladesh**.

SS05/10A/A13-009   1045
PUBLIC AWARENESS THROUGH EDUCATION: KEY FOR SEISMIC RISK REDUCTION

Marina TER-ANANYAN[1], Serguei BALASSANIAN[2], Ashot MELIKSETYAN[1] ([1]Armenian Association of Seismology and Physics of the Earth's Interior, [2]Yerevan State University, Department of Geophysics)

It is stated in the paper that for seismic risk reduction in any country the public awareness is crucial. The concept proposed by the authors is based on the following principals: 1) the main mean for awareness increase AEis education and training; 2) all social groups of society should be involved in education; 3) education of various social groups must differ from each other: the volume of the necessary knowledge should increase from elder generation to younger one as well as from ordinary citizens to decision makers; 4) special attention in education have to be paid to youngest generation and decision makers of all levels: community, municipality, local government, federal (state) government; 5) for public awareness increase different approaches have to be used, taking into account level of seismic hazard and risk, social and economic state of the society and country, national traditions, culture and belief, mentality of the nation, state laws. The concept is supposed to develop a system which will: 1) act in the frame of common strategy for seismic risk reduction, developed and implemented by professional state agency; 2) be developed within the State Seismic Risk Reduction Program; 3) be oriented to different ages and social groups with special focus to children; 4) include complete information in wide by understandable form; 5) exclude wrong and non-competent information; 6) support the direct link between professional state agency- mass media-public-decision makers. The Criteria of Concept sufficiency is: 1) awareness of most vulnerable social groups AEold people, children, poor people, invalids, inhabitants of far situated settlement; 2) existence of efficient links between scientists, decision makers and public. The Strategy is permanent information provided for efficient seismic risk reduction by well awarded society. Tactics of public awareness increase includes: 1) information dissemination in form of printed and audio-video materials prepared by professional state agency; 2) training of trainers by state agency for knowledge dissemination at schools, universities, municipalities, governmental and NGOs as well as private institutions; 3) mass media usage; 4) education and training program development for schools and universities; 5) education and training for decision makers; 6) organization of scientific workshops, seminars, conferences in the field of social sciences.

METHOD OF COMPOSING PLANS FOR OPERATIVE AND EFFECTIVE ACTIONS OF MUNICIPAL SERVICES AFTER DESTRUCTIVE EARTHQUAKE

Sergey Norayr NAZARETYAN (Northern department of national survey for seismic protection of RA)

Large areas of a number of Commonwealth of Independent States countries (for example in the Caucasus and in Central Asia) have a high seismic risk degree, which is mainly due to the underestimated seismic hazard of the territory, the poor quality of construction and the lack of preparedness of government, municipal structures and the public to withstand strong earthquakes.Taking into account the hard economic state of these countries, at present the most practical way of reducing the damage from earthquakes is to increase the efficiency of operative actions and the professionalism of municipal services. Besides, a ready compiled plan is necessary to realize effective actions. Unfortunately, the existing p1ans and activities that services have at their disposal have been created for wartime or emergency situations in general. The Spitak earthquake of 1988 revealed the necessity of developing new plans particularly for destructive earthquake conditions. The following principles must be taken into account as a basis for making up such plans:1. The plan must be based on the map of the city´s seismic risk and prediction of destructive earthquake consequences. 2. It is necessary to achieve high efficiency in the plan´s immediate realization after the earthquake, especially during the first 3-5 days, when the probability of rescuing the general population is high enough.3. Actions of all special services must be coordinated with each other in advance; i.e, a complex plan of operative actions must be developed.4. The complex plan must be easy to realize by services and rescue organizations from outside.5. The plan must be worked out for the worst conditions taking into consideration scales of the greatest destruction, the most unfavorable weather conditions, time of day, etc.The plans must have a similar structure, including the following parts:9. the addresses and telephone numbers of services and their objects;10. the main service objects, vulnerability of their buildings and equipment;11. the service's capacity (the staff and equipment);12. communication means;13. autonomous providing of electric power;14. urgent tasks of the service;15. the service action (routes and ways for solution of problems involved);16. action coordination between the services;17. the new place of service location (if necessary);18. necessity for the outside help and the place of its location.

EDUCATION PROGRAM FOR CHILDREN AND YOUTH BY THE SEISMOLOGICAL SOCIETY OF JAPAN

Masato KOYAMA[1], Kazuyuki NAKAGAWA[2], Manabu HASHIMOTO[3], Eiji KUWABARA[4], Masaki TAKAHASHI[5], Kojiro IRIKURA[3], A.D.2002 MEMBERS[6], A.D.1999-2001 MEMBERS[7], Voluntary MEMBERS[8] ([1]Department of Integrated Sciences and Technology, Faculty of Education, Shizuoka University, [2]Jiji Press, [3]Disaster Prevention Research Institute, Kyoto University, [4]Oshima High School, [5]Department of Geosystem Sciences, College of Humanities and Sciences,Nihon University, [6]the Committee for Future Planning of the Seismological Society of Japan, [7]the Committee for School Education of the Seismological Society of Japan, [8]the Seismological Society of Japan and the Volcanological Society of Japan)

The seismological Society of Japan (SSJ) has been conducting programs for education of children and youth since 1999 in cooperation with other associations such as the Volcanological Society of Japan. The first program was held in summer 1999 around the Tanna fault zone in the Izu Peninsula supported by the Kannami town and Shizuoka prefecture. 22 children of 10-18 years in age participated in this program and spent two days. The program consisted of excursion of the Tanna fault and talks on earthquake mechanisms, strong ground motion, and volcanoes, etc. It is emphasized that the program

included a couple of experiments of faulting and liquefaction using materials that we can find at home.In summer 2000, the second summer school was held in Sobetsu and Abuta towns near Usu Volcano, which erupted in spring of the year. The program consists of excursion of Usu Volcano, two experiments (lava-dome making and observation of tephra), and lectures about eruption history and mechanisms.In July 2001, SSJ held the International Children´s Earthquake and Volcano Summit in Izu-Oshima. We invited 166 children aged from 10 to 18, including children from Taiwan and Turkey, and spent three days. All the children formed four groups. A couple of questions on the history of Izu-Oshima Volcano were given in the beginning of the program. During this three-day stay, children must find the answers to the questions learning results of recent researches and performing some experiments including GPS positioning, dyke intrusion, and eruption. They also had excursion to the section of tephra layers since 30ka and eruptive fissures that formed during the 1986 eruption and some lectures on tsunami and earthquakes. They worked very well and left the statements on the basis of three-day experience in an active volcano with scientists. In 2002, we cooperated the Volunteer Coordinator Training Course by the Association of Social Welfare of Ueno City, Mie prefecture. Ueno is the epicentral region of the 1854 Iga-Ueno earthquake. The original course is a one-year program for volunteer coordinators. In average 10-15 children attended. We held a one-day program in fall 2002. In October we performed the similar experiments of faulting and liquefaction. We also made observation of ground vibration using seismographs, recorded the seismic waves generated by participants and measured their velocities. On the second day we had a field trip to the excavation site of the Kizugawa fault and measured its strike using handy GPS receivers.In all programs, we prepare point cards and give them to individual children or group when they raise good questions and answers to staffs. This kind of competition may stimulate children´s interests.

DISCUSSION ON THE DEFINITION OF SEISMIC MOMENT

Zhongliang WU[1], Yun-tai CHEN[2] ([1]College of Earth Science, Graduate School, Academia Sinica (CAS), [2]Institute of Geophysics, China Seismological Bureau)

In recent years, theoretical results imply that a seismic rupture occurred alonga discontinuity interface of two different media can explain many of the earthquake phenomenologies. Observational evidences show that a compliant faultzone within a stiffer medium is a commonly valid model for earthquake faulting.These results lead to a difficulty in the application of the classicaldefinition of seismic moment, because the value of rigidity is not unique at theinterface. Considering this difficulty, one of the extreme ideas is to give upthe concept of seismic moment by going back to potency. But in physics, such adifficulty is not due to the problem of rigidity but due to the application ofthe simplified definition of seismic moment. To discuss this problem one shouldgo back to the general form of representation theorem from which the seismicmoment density tensor is defined as a product of the modulus tensor and the'transformation' strain tensor. Detailed calculation leads to a more generaldefinition of seismic moment which is similar to the classical definition, withthe only change that the rigidity is replaced by the 'effective rigidity', inwhich the 'effective rigidity' is smaller than the average rigidity across theinterface, being determined by both the average and the deviation. Thisdiscussion has important implications for seismological observation practice. For the case that an earthquake rupture occurs along the discontinuity interfacebetween a compliant medium (the fault zone) and a stiffer medium (theenvironmental medium), in the estimation of slip and/or rupture length, usuallythe rigidity of the stiffer medium is used. In this case, the slip and/orrupture length are underestimated significantly.

EARTHQUAKE RESEARCH:STILL A YOUNG SCIENCE WITH STRONG POTENTIALS FOR FURTHER DEVELOPMENT

Yumin LI (Division of Information,Zhejiang Province Seismological Bureau,China)

With disciplinary bias and philosophical bias and with explorations lasted 100 years, the recognition about the earthquakes is just begging by human being. Earthquake events are the phenomenon of nature and the process with planet evolution. 1.The research for Geology science has been experienced more than 200 years from morphology to kinematics then to dynamics with development of the foundational disciplines involving physics, chemistry, mathematics, astronomy, biology and the progress of science and technology. In particular the Theory of Global Plate Structure originated from middle of the 20th century soundly reveals the evolution of the earth followed The International Geophysics Years in 1950s,The Program of Uppermantle in 1960s which leads to the birth of the Theory of Lithosphere Plate Tectonics, The Program of Geodynamics in 1970s and The Research Program of Lithospher in 1980s. It described the basic image of global crust structure. 2.Historical earthquake recorded by people can trace back to 1000 years ago and the original record found in Africa may be existing over 5000 years. 3.The investigation for paleoseismology by United States, Russia and China scientists presents a traces of ancient earthquakes since 20000 years and this at least shows some regularities of seismic activity. In addition, the earthquake traces were found before 5 billion years during Cambrian period and Sinian period. It inspired us that the earthquake is a natural phenomenon of the earth its movement, further more the large event cycling is calculated by thousand-year unit, so time scale for research wasn´t confined to several years. 4.Earthquake prediction is a scientific problem with great difficulty in the field of current natural sciences and many important scientific problems remain to be deeply studied. To reveal the evolution of the earth and other planets from status quo ante to status quo needs earth scientists possess correct research methodology, needs multidisciplinary intersection and cooperation, needs unremitting effort from generation to generation, as ˝We are at the very beginning of time for the human race. It is not unreasonable that we grapple with problems. But there are tens of thousands of years in the future. Our responsibility is to do what we can, learn what we can, improve the solutions, and pass them on.˝ The purpose is to improve the scientific capability for earthquake disaster prevention and reduction.

SS05/10A/A13-014   1200
EARTH SCIENCE EDUCATION AT UNIVERSITIES

Noriko SUGI (Kyoritsu Women's University)

Earth science has a long history. To transmit its brilliant results to the general public is our important role. But recently in Japan, it is remarkable that young people do not feel interested in earth science. This problem serious for the future of earth science originated from the situation where the entrance examinations have not covered earth science at many universities, teachers of earth science in high schools have decreased and consequently students having a chance to learn about the earth are on the decrease. It is our mission to train the next generation for a specialist of earth science and also to educate those who will choose other fields for lifework. We have benefited by natural phenomena on the earth, but on the other hand we have suffered various kinds of natural disasters throughout the world. Especially in Japan located at the converging boundaries of four lithospheric plates, large earthquakes, volcanic eruptions and tsunamis repeatedly damaged people and country. In

order to coexist with the earth it is important that the younger generation will understand and be interested in such an activity of the earth as a whole. This paper describes what I am trying through the lecture of liberal arts to educate students in earth science in our women's university where the majority of students are supposed to marry and have babies during the next decade. Desiring that they are interested in the earth and will initiate the next generation including their children into charms of earth science, I emphasize that earth science is closely connected with lives of themselves and their descendants. How the lecture during one or half a year has influenced the awareness of my students will be reported in this paper.

GEOMAGNETIC BASE FOR AN EPISTEMOLOGY OF THE UNIVERSAL CULTURE

Teodosio Chavez CAMPOS[1], Chavez SUMARRIVA[2] ([1]Post-graduate shool of system, University National of Ingenering, [2]National University of Ingeneering, Lima-PerAEName1-1=Israel)

For an epistemology focus of the universal cultural, it is necessary an naturalchronometer to coordinate and classify the observations, this is a system reference as starting point, and this system becomes determined through the astronomical phenomenon named the precesion of the equinoxes, and it has its confirmation with the stability of the geomagnetic equator, where the inclination (I) of the field is zero degrees, and over to 100 kilometers approximately is located the equatorial electrojet that is more intense in theequinoxes in Southamerica and that at the moment it crosses for the central part of Peru and over the city of Cosco, exactly in this area where it develops the one of the biggest culture of every time, and then it extends to the north of Bolivia and Brazil. With this reference system taking the base of the behavior of the equator geomagnetico, we can focus the study of the epistemology of the Andean cultures of America and the world, that is to say in a process of ahead back comparing periods and subperiods of Eras Preccesional, and to study an archaeological piece, a pyramid, a temple, their monumental constructions, their religious, philosophical, artistic and scientific thoughts, their effects, objectives and reach, their transcendency and evolution. We need to create an epistemology structure in all the fields in that it is possible to apply the thought of the big cultures of America and to compare with them other cultures.

LITHOSPHERIC SHEAR VELOCITY MODELS BENEATH CONTINENTAL MARGINS IN ANTARCTICA INFERRED FROM GENETIC ALGORITHM INVERSION FOR TELESEISMIC RECEIVER FUNCTIONS

Masaki KANAO[1], Takuo SHIBUTANI[2], Atsuki KUBO[3] ([1]Department of Earth Science, National Institute of Polar Resaerch, [2]Disaster Prevention Research Institute, Kyoto University, [3]National Research Institute for Earth Science and Disaster Prevention)

Seismic shear velocity models of the crust and the lithospheric mantle were investigated by teleseismic receiver functions inversion beneath the permanent stations at the continental margins in Antarctica. In order to eliminate the starting model dependency, non-linear Genetic Algorithm (GA) was newly introduced in the time domain inversion of the radial receiver functions at each station. The inversion of the receiver functions to recover crustal and uppermost mantle structure is widely recognized to be sensitive to the starting model if a conventional linearization scheme is employed (Ammon et al., 1990). Such difficulties, however, can be overcome by employing an inversion scheme based on a Genetic Algorithm (GA) (Shibutani et al., 1996). This approach makes use of a cloud or population of models to minimize the dependence on a starting model; a set of biological analogues are used to produce new generations of models from previous generations, with preferential development of models with a good fit between observed and theoretical receiver functions. The approach provides a good sampling of the model space, and enables the estimation of the shear-wave speed distribution in the crust, along with an indication of the ratio between Vp and Vs. Many models with an acceptable fit to data are generated during the inversion, and a stable crustal model is produced by employing a weighted average of the best 1,000 models encountered in the development of the GA. The weighting is based on the inverse of the misfit for each model, so that the best fitting models have the greatest influence.   In this presentation, shear velocity models of the permanent stations at Antarctic margins belonging to the Federation of Digital Seismographic Networks (FDSN), such as of AGSO, GEOSCOPE and IRIS, etc. are presented in relation with geotecnotics and crustal evolution of the each terrain. The shear velocity model around MAW has a sharp Moho at 42 km depth that might have involved re-working of adjacent Archaean craton of the Napier Complex. High velocities in the upper crust around SYO may have a relationship with surface geology of granulite facies metamorphic rocks. Middle grade variations of the crustal velocities for DRV may have been caused by the Middle Proterozoic metamorphism. Broadening low velocity zones recognized at VNDA about 30 km depth, which may be caused by the rift system of Trans Antarctic Mountains. As for the Antarctic Peninsular, Moho was found at 34 km depth from PMSA data. Moreover, shear velocity models by GA inversion for receiver functions were also determined in eastern Australia (R. D. Hilst et al., 1998), then we will make a comparison with those structure as a member of Gondwanaland.

CRUSTAL STRUCTURE BENEATH THE MIZUHO PLATEAU, EAST ANTARCTICA, DEDUCED FROM A REFRACTION AND WIDE-ANGLE REFLECTION EXPLORATION

Hiroki MIYAMACHI[1], Sigeru TODA[2], Takeshi MATSUSHIMA[3], Masamitsu TAKADA[4], Atsushi WATANABE[5], Mikiya YAMASHITA[6], Masaki KANAO[7] ([1]Department of Earth and Environmental Sciences, Faculty of Science, Kagoshima University, [2]Faculty of Education, Aichi Education University, [3]Institute of Seismology and Volcanology, Faculty of Sciences, Kyushu University, [4]Institute of Seismology and Volcanology, Graduate School of Science, Hokkaido University, [5]Department of Earth and Planetary Sciences, Graduate School of Sciences, Kyushu University, [6]Department of Polar Science, The Graduate University for Advanced Studies, [7]National Institute of Polar Resaerch)

The 43rd Japanese Antarctic Research Expedition (JARE-43) carried out the seismic exploration at the Mizuho Plateau, East Antarctica, in the austral summer season of 2001-2002. It is composed of seven large explosions and 161 seismic stations distributed along the 151 km long profile. The first arrival time data are analyzed by a refraction method. It is found that the ice sheet is composed of two layers: the upper layer with a P wave velocity of 2.7 - 2.8 km/s has a thickness of 35 - 45 m, and the lower layer with a P wave velocity of 3.8 km/s continues to the bed rock basement. A lateral velocity variation in the upper-most crust is revealed: P wave velocity for the upper-most crust in the southern and central parts of the profile is 6.1 - 6.2 km/s and that in the northern part is 5.9 km/s. The P wave velocity obtained in the central and southern parts is consistent with that estimated by the JARE-41 seismic exploration on the Mizuho Plateau in 1999-2000 (Tsutsui et al., 2001). The lateral velocity variation also suggests that the rock basement in the southern part is different from that in the northern part. However, the thick ice sheet overspreading the continental crust prevents us from directly observing geological feature of the crust. From a geological investigation of rock exposures distributed sparsely along a coast in Enderby Land in East Antarctica (Hiroi et al., 1991), our seismic profile may be considered to spread in the Paleozoic Lutzow-Holm Complex: the northern part of the profile is located in the amphibolite-granulite facies transition zone and the southern part in the granulite facies zone. Consequently, it can be said that the geological boundary observed in the coast may extend to the inland area. S wave velocity is also obtained to be 3.5 km/s for the whole profile. Two distinct reflection phases lead us a result that a boundary between the upper crust and the middle crust, and the Moho discontinuities are located at 19 and 40 km depth, respectively.

INTEGRATED MULTIDISCIPLINARY SURVEYS BY STRUCTURE AND EVOLUTION OF THE EAST ANTARCTIC LITHOSPHERE TRANSECT: SEAL-2000, -2002

Masaki KANAO[1], Hiroki MIYAMACHI[2], Shigeru TODA[3], Hiroshi MURAKAMI[4], Tomoki TSUTSUI[5], Takeshi MATSUSHIMA[6], Masamitsu TAKADA[7], Atsushi WATANABE[6], Mikiya YAMASHITA[8], Koji YOSHII[9] ([1]Department of Earth Science, National Institute of Polar Resaerch, [2]Faculty of Science, Kagoshima University, Kagoshima, [3]Faculty of Education, Aichi Education University, [4]Earthquake Observation Research Technology Center, [5]Faculty of Engineering and Resource Science, Akita University, [6]Institute of Seismology and Volcanology, Faculty of Sciences, Kyushu University, [7]Institute of Seismology and Volcanology, Graduate School of Science, Hokkaido University, [8]Department of Polar Science, The Graduate University for Advanced Studies, [9]Disaster Prevention Research Institute, Kyoto University)

Lithospheric evolution and deep structure viewed from East Antarctic Shield have significance in relating to the continental growth process in Earth´s evolution. Here, we focus on the lithospheric structure of the early-Paleozoic crust of the Lutzow-Holm Complex (LHC), Enderby Land, East Antarctica. LHC is considered to be one of the collision zones between the East- and the West- Gondwanaland during the formation of a paleo-supercontintnt when the Pan-African orogeny. The ˝Structure and Evolution of the East Antarctic Lithosphere (SEAL)˝ project has been carried out since 1996-1997 austral summer season in the framework of the Japanese Antarctic Research Expedition (JARE). Several geophysical studies and deep seismic refraction / wide-angle reflection surveys have been conducted at LHC. The main target of the SEAL geotransect is to obtain a whole lithospheric section in the different geological terrains from the Archean (Napier Complex) to the early-Paleozoic ages (LHC) between Western Enderby Land and Eastern Queen Maud Land. In the austral summer season in 2000, and 2002, deep seismic probing were conducted on ice sheet in the northern Mizuho Plateau, of LHC by JARE-41, and -43, respectively. In both surveys, more than 170 plant-type 2 Hz geophones were set on the Mizuho plateau 190 km in length. A total of 8,300kg dynamite charge at the fourteen sites on the Plateau gave information concerning the deep structure of a continental margin of the LHC. These investigation revealed that the Moho depth was more than 40 km with the velocity of the surface layer, middle crust, lower crust and mantle, about 6.2, 6.4, 6.7 and 7.9 km/s, respectively. Moreover, the clear reflections from Moho discontinuity have been observed on the record sections; which implies the existence of heterogeneity on the crust-mantle boundary beneath the Paleozoic orogenic zone of LHC. Laminated inner structure around the Moho discontinuity could be also identified by precise spectral anayses for PmP waves.

DEEP CRUSTAL STRUCTURE BENEATH THE MIZUHO PLATEAU, EAST ANTARCTICA FROM SEISMIC EXPLORATION

Mikiya YAMASHITA[1], Hiroki MIYAMACHI[2], Takeshi MATSUSHIMA[3], Shigeru TODA[4], Masamitsu TAKADA[5], Atsushi WATANABE[6], Masaki KANAO[7] ([1]Department of Polar Science, The Graduate University for Advanced Studies, [2]Faculty of Science, Kagoshima University, [3]Institute of Seismology and Volcanology, Faculty of Sciences, Kyushu University, [4]Faculty of Education, Aichi Education University, [5]Institute of Seismology and Volcanology, Graduate School of Science, Hokkaido University, [6]Department of Earth and Planetary Science, Graduate School of Sciences, Kyushu University, [7]National Institute of Polar Research)

The ˝Structure and Evolution of the East Antarctic Lithosphere (SEAL)˝ project has been carried out to focus on the lithospheric structure of the early-Paleozoic crust of the LAEzow-Holm Complex (LHC), Enderby Land, East Antarctica since 1996-1997 austral summer season in the framework of the Japanese Antarctic Research Expedition (JARE). Seismic exploration was conducted on the Mizuho Plateau, East Antarctica, during the 2001-2002 austral summer season by JARE-43. Seismic shot records were obtained with clear arrivals of the later reflected phases by a total amount of 4,900 kg dynamite charges at the seven explosions along the new route is lied at right angles to the Mizuho traverse route of 150 km in length. 162 seismic stations programmed on timer operation were installed. The purpose of this survey is to investigate detailed structure of the crust and Moho discontinuity in view from refraction and reflection by using explosive seismic waves. The obtained seismic records show the clear onsets of the first arrivals in a distance range of less than 100 km from each large shot. In particular, seismic waves traveling through the ice sheet and the dispersed surface waves are distinctly observed. Some later phases are also detected. The structure of the upper crust and overlying ice-sheet are revealed down to 5 km from refraction analysis of the first arrival times. The first layer with a velocity of 3.8 km/s appears

to be ice sheet. The second layer with a velocity of 6.1 km/s of P-wave velocity is the surface layer of the continental crust. We used reflection analysis (band-pass filter, static correction, Normal Move Out, Auto-gain-control) for seven shot records, and obtained single hold section. The reflection profiling shows the several reflections around the Moho discontinuity. We discuss for the structure of upper and lower crust and investigated the velocity structure for the previous results.

HIGH P-T MEASUREMENTS OF P-WAVE AND S-WAVE VELOCITIES OF GRANULITES FROM ENDERBY LAND, EAST ANTARCTICA

Masahiro ISHIKAWA, Eisuke SHINGAI, Makoto ARIMA (Graduate School of Environment and Information Sciences, Yokohama National University)

Determination of the ultrasonic velocities and Poisson´ ratio in natural granulites at lower crustal conditions of pressure and temperature are necessary to interpret the seismic profiles in terms of chemical composition and petrology. The results of high P-T velocity of natural rocks provide direct measurements of the effect of pressure and temperature on P-wave and S-wave velocities of natural rocks, which is of critical importance in evaluating crustal models at different geotherms. In order to understand crustal structure of Pan-African orogenic belt in East Antarctica, P-wave velocity (Vp) and S-wave velocity (Vs) in granulites were determined up to 1.0 GPa from 25°C to 400°C using a piston-cylinder-type high-pressure apparatus. The rock samples are cores of pyroxenite (SiO_2 44 wt. %), mafic granulites (52wt%, 49wt %) and felsic gneiss (SiO_2 65wt %) with dimensions of 14mm in diameter and ca. 12mm in length. LiNbO3 were coupled on both ends of core sample in talc pressure medium. The temperatures were determined by the Pt-Rh13 thermocouple, which is placed upon the top-end of the core sample. Measurements of travel time were carried out using the pulse transmission technique. Errors of the velocity measurements are estimated to be less than 0.1 km/s. All rocks show a rapid increase of velocity at low pressure up to 0.4 GPa and nearly constant at higher pressures. The Vp and Vs at 1.0 GPa and 400°C are 7.17 km/s and 4.24km/s for pyroxenite, 6.93 km/s and 3.81km/s for mafic granulite (49wt%), 6.88 km/s and 3.72km/s for mafic granulite (49wt%), and 6.17 km/s and 3.59km/s for felsic gneiss. The experimentally determined rock velocities are compared with seismic data of Mizuho Plateau. For the range of expected continental geotherms, our data show that Vp for pyroxene granulites (low-pressure type of mafic granulite) are consistent with the lower crustal seismic velocity (6.95 km/s) at 33 to 40 km depths. Our data require a mafic component (20 vol %) to fit middle crustal seismic velocity (6.6km/s). The present results suggest that the lower crust is composed of lower-pressure type mafic granulites (garnet-free pyroxene granulite) rather than higher-pressure type granulite (garnet granulite). These evidences demonstrate that the lower and middle crust of the Pan-African orogenic belt is composed of lower-pressure type granulite-facies rocks which are main lithologies of Archean craton (Napier Complex).

RAYLEIGH-WAVE GROUP VELOCITY DISTRIBUTION IN THE ANTARCTIC REGION

Reiji KOBAYASHI[1], Deo D. SINGH[2], Dapeng ZHAO[1] ([1]Geodynamics Research Center, Ehime University, [2]National Geophysical Research Institute)

Analysing surface waves is a very suitable way to estimate structure beneath the whole Antarctic plate. In this study, the 1-D S-wave velocity structures beneath five regions of Antarctica and the group velocity distribution beneath whole Antarctica are estimated. The data include not only ones of permanent networks but also ones of temporary arraies. The Antarctic region is divided into five regions according to tectonic features, and the 1-D S-wave velocity structures beneath these regions are estimated from the group velocity dispersion curves. In the lower crust and upper mantle beneath East Antarctica, the S-wave velocities are slightly higher than the previous models. The group velocity distribution beneath whole Antarctica are estimated by means of a tomographic technique. In East Antarctica, the velocities are high at periods of 90-150s, and suggest that the root of East Antarctica is very deep. On the other hand, the velocities in West Antarctica are low at all periods. Low velocity zones appear around the Southeastern Indian Ridge and Pacific Antarctic Ridge, but the velocities are not so low around the Southwestern Indian Ridge, where the spreading rates are small. The spreading rates could affect the seismic velocities, and vice versa. Around two adjacent hotspots, the Mount Erebus and Balleny Islands, there is a peak of low velocity at periods of 50-150 s. This low velocity area suggest that and the origins of these hotspots are plumes.

CRUSTAL DENSITY STRUCTURE OF THE MIZUHO PLATEAU, EAST ANTARCTICA FROM GRAVITY SURVEY

Shigeru TODA[1], Hiroki MIYAMACHI[2], Tomoki TSUTSUI[3], Takeshi MATSUSHIMA[4], Hiroshi MURAKAMI[5], Masamitsu TAKADA[6], Atsushi WATANABE[7], Mikiya YAMASHITA[8], Masaki KANAO[9], Yoichi FUKUDA[10] ([1]Faculty of Education, Aichi University of Education, Kariya 448-8542 Japan, [2]Faculty of Science, Kagoshima University, Kagoshima 890-0065 Japan, [3]Faculty of Engineering and Resource Science, Akita University, Akita 010-8502 Japan, [4]Institute of Seismology and Volcanology, Faculty of Sciences, Kyushu University, Shimabara 855-0843 Japan, [5]Technical Center for Seismological Observations, Amakubo, Tsukuba 305-0005 Japan, [6]Institute of Seismology and Volcanology, Graduate School of Science, Hokkaido University, Sapporo 060-0810 Japan, [7]Department of Earth and Planetary Sciences, Graduate School of Sciences, Kyushu University, Fukuoka 812-8581 Japan, [8]Department of Polar Science, The Graduate University for Advanced Studies, Itabashi, Tokyo 173-8515 Japa, [9]National Institute of Polar Research, Itabashi, Tokyo 173-8515 Japan, [10]Graduate School of Sciences, Kyoto University, Kyoto 606-8502 Japan)

Structure and Evolution of the East Antarctic Lithosphere (SEAL) project have been caring out in a framework of the Japanese Antarctic Research Expedition in recent few years. The gravity survey was installed in the 41st and 43rd Japanese Antarctica Research Expedition (JARE 41st, 2000 and JARE 43rd, 2002) to study crustal density structure of the Mizuho Plateau, along the traverse route from Syowa Station to Mizuho Station and across this traverse route. The main purpose of the survey was to obtain the detailed gravity anomalies. The gravity measurements were conducted by a SCINTREX (CG-3M) gravity meter at about 1 km-interval along the survey lines. The number of the stations was 312 and the total number of the measurements was 414. Free-air and simple Bouguer gravity anomalies based on gravity disturbance along the survey lines were obtained by use of both data of surface elevation from GPS positioning and of the bedrock elevation from radio-echo sounding. The simple Bouguer gravity anomaly was calculated by assuming the layered structure to fit the observed Bouguer anomaly. These results were correlated to the results of the JARE 21st 33rd and 38th.

MAGMATIC AND METAMORPHIC EVIDENCE FOR PALEO-THETHYS SUTURE IN THE NORTHWEST OF IRAN

Mohsen MOAYYED (Dept of geology, University of tabriz, Tabriz, Iran)

Remnants of ancient ocean floor forming rocks, which are emplaced due to northward movement of the Gondwana plate, are found in the Misho Mountain in NW of Iran. The Misho Mountain situated between Marand and Uromia lake depressions. Magmatic and metamorphic evidence indicates tracing of suture zone between Eurasia plate and Gondwana plate in this area. Ultramafic and mafic metamorphosed rocks appear melanges and show tectonic contacts with other units. These rocks consist of spilitised basalts, metamorphosed gabbro, spinel-norite, spinel-orthopyroxenite, dunite and diabasic dikes. These sequences intruded by S and A type granites. S-type granites have sharp contact with Precambrian rocks (Kahar formation) and are produced contact metamorphism accompanied with retrograde metamorphism and deformation in ultramafic and mafic rocks. Emplacement of these granites can be attributed to continent-continent collision and are characterised as allochtonus granites.Overlay sediments of Permian ultramafic-mafic sequence and therefore suggest that closure of oceanic basin has occurred during Hercynian orogeny. The Misho Mountain is bounded by Tabriz fault in the north part and Southern Misho fault in the south. The Southern Misho fault is charcterised with north dip-slip and can be interpret as suture line of Paleo-Thethyan in northwest of Iran. Dip-strike of the fault is corresponds with subduction trend and Beniof zone slope. Sediments of passive continental margin of Gondwana plate are exposed in the south of mentioned suture zone while at the north of Tabriz fault such sediments are not recognised. The discrepancy in sediment types also can be documented for the suture zone of Paleo-Thethys in the northwest of Iran.

ANOMALOUS CRUSTAL ROOT BENEATH SAURASHTRA PENINSULA, INDIA-INFERENCE FROM ISOSTASY

Bijendra SINGH, S.K. PRAJAPATI, D.C. MISHRA (National Geophysical Research Institute)

Bouguer anomaly map of Saurashtra plateau depicts (i) large number of circular gravity high associated with known volcanic plugs of Deccan magmatism and (ii) a large wavelength circular gravity low centred over the peninsula suggesting deeper causative. Since, this low bears an inverse relation with the regional topography it may result from mass deficiency resulting from thickening of crust caused by isostatic compensation. Deep seismic sounding (DSS) result along Navibander-Amreli profile over the southern part of the peninsula indicates variation in crustal thickness from 35 Km towards the coast to 42 Km beneath the high lands. Presence of zero free air anomalies in the region of high topography may suggest that the net buoyancy of the thickened crust (crustal root) is close to zero. An unbiased estimate of isostatic regional anomalies is obtained using zero free air anomalies. Assuming that the compensation is at Moho level, modeling of isostatic regional anomalies in terms of Moho variation along DSS profile has yielded a density contrast of - 0.15 g/cm3, which is much less than the expected density contrast of - 0.40 g/cm3 across the Moho in normal region. This discrepancy can be explained due to two factors (i) either the crustal root is anomalously dense (ii) or the upper mantle is anomalously light. However, DSS result has not indicated any anomalous velocity structure across the Moho interface hence the issue could not be resolved. In the absence of any conclusive evidence, it is suggested that the region, which has experienced extensive volcanism, lower crust must have been modified due to accretion of mafic igneous layer at the base of the crust and the metamorphism in the crustal root might have increased the root density. Hence it may be argued that, decrease in crustal root buoyancy due to increase in root density may be more plausible explanation for the existence of large crustal root beneath the Saurashtra peninsula.

PROTEROZOIC PRISM ARRESTS SUSPECT TERRANES: INSIGHTS INTO THE ANCIENT CORDILLERAN MARGIN OF CANADA FROM SEISMIC REFLECTION PROFILING

Ron M. CLOWES[1], David B. SNYDER[2], Fred A. COOK[3], Philippe ERDMER[4], Carol A. EVENCHICK[5], Arie J. VAN DER VELDEN[3], Kevin W. HALL[3] ([1]LITHOPROBE and Dept. of Earth and Ocean Sciences, University of British Columbia, [2]Geological Survey of Canada, 615 Booth Street, Ottawa, ON K1A 0E9, Canada, [3]Department of Geology & Geophysics, University of Calgary, Calgary, AB T2N 1N4, Canada, [4]Department of Earth & Atmospheric Sciences, University of Alberta, Edmonton, Alberta T6G 2E3, Canada, [5]Geological Survey of Canada, 101-605 Robson Street, Vancouver, BC V6B 5J3, Canada)

The Canadian Cordillera is one of the principal regions from which the hypothesis of exotic, accreted or suspect terranes was developed a few decades ago. However, seismic reflection profiling and field mapping in northwestern Canada reveal a vast volume of Proterozoic strata of largely North American affinity along the margin, leaving little room for the suspect terranes. The Proterozoic strata were deposited in at least three distinct periods between 1840 Ma and 540 Ma, during which compressive deformational events of unknown origin also occurred. The strata form a reflective tectono-depositional prism or wedge that extends as much as 500 km across strike and 1000 km along strike, has a volume greater than a million cubic kilometers, and makes up most of the crust of the northern Canadian Cordillera. The suspect terranes apparently grounded upon and were arrested by this metamorphosed sedimentary prism during a complex interplay of thrusting and strike-slip displacements between 190 and 170 Ma. Thus, the Cordilleran accreted terranes, with the exception of one major terrane, have shallow roots only a few kilometers deep, with no deep crust or mantle attached. The Proterozoic prism was discovered on two new deep seismic reflection profiles in the Yukon (Line 3, ~ 650 km) and northern British Columbia (Line 2, ~ 1245 km in two segments) that were acquired as part of the LITHOPROBE Slave - Northern Cordillera Lithospheric Evolution (SNORCLE) transect. Along Line 3, the layering is visible between 5.0 and 12.0 s (~15 to 36 km depth). It is followed southwestward for nearly 650 km (~ 500 km across strike) and thins to less than 1.0 s (~ 3.0-3.5 km thickness) near the Moho at the

Yukon-Alaska international boundary. Along Line 2, the upper part of the layering correlates with outcrops of Proterozoic (1840 -1000 Ma) strata on the east. Near the outcrop, the layering is >15 km thick. It projects westward into the middle and lower crust for ~ 700 km (~ 350 km across strike) where it disappears as a thin taper at the base of the crust. The layering is disrupted at the Tintina fault zone, a late to post-orogenic strike-slip fault with up to 800 km of displacement, which appears as a vertical zone of little reflectivity on both profiles (~ 300 km apart). Correlation of reflectivity between the profiles and the fault displacement indicate that the metasedimentary layers extend for at least 1000 km along strike. We thus associate this major part of the Cordilleran crust with the Precambrian passive margin following Paleoproterozoic rifting. As shown by structural features in the seismic images, the Precambrian margin experienced tectonic deformation during its long history. The base of the layered reflection zone coincides with the Moho, which exhibits variable reflective characteristics and undulates in a series of broad (~150 km) arches.

VARIATIONS IN CRUSTAL THICKNESS AND MANTLE STRUCTURE ACROSS THE KAAPVAAL CRATON FROM PN AND SN ARRIVALS AND RECEIVER FUNCTIONS

Cedric WRIGHT[1], M. Tarzan O. KWADIBA[2], Eldridge M. KGASWANE[3], Teresia K. NGUURI[4] ([1]Bernard Price Institute of Geophysical Research, School of Earth Sciences, University of the Witwatersrand, Johannesburg, Private Bag 3, Wits 2050, South Africa., [2]Also: Geophysics Division, Department of Geological Survey, Private Bag 3, Lobatse, Botswana., [3]Present address: Council for Geoscience, Private Bag X112, Pretoria 0001, South Africa., [4]PREPCOM CTBTO, Vienna International Centre, P.O. Box 1250, A-1400, Vienna, Austria.)

Pn and *Sn* wavespeeds in the uppermost mantle of the Kaapvaal craton arehigh and uniform, indicating the presence of highly depleted, magnesium-richperidotite. Pervasive P wave azimuthal anisotropy with maximum wavespeedsof about 8.40 km/s at azimuths of about 15° and 35° in the northern andsouthern regions of the craton, respectively, agrees well with the fastdirections for a thicker region of the upper mantle inferred from shear wavesplitting. The presence of such small wavespeed variations in the uppermost mantleallows the use of a simple method of estimating crustal thicknesses below thestations of the Kaapvaal broad-band network using *Pn* times, providing resultsthat have been compared with thicknesses calculated from receiver functions. Theaverage crustal thicknesses for 19 centrally-located stations on each of the northernand southern regions of the craton that yielded well-constrained thicknesseswere 50.52 +/- 0.88 km and 38.07 +/-0.85 km respectively. In contrast, thecorresponding average thicknesses determined from receiver functions were43.58 +/- 0.57 km and 37.58 +/- 0.70 km respectively. The systematicallylower values for receiver functions in the northern part of the Kaapvaalcraton that was affected by the Bushveld magmatism at 2.05 Ga, suggest thatthe receiver functions do not enable the petrological crust-mantle boundaryto be reliably resolved due to variations in composition and metamorphicgrade in a mafic lower crust.

SW03/10P/A04-003   1430

SEISMICITY OF UGANDA DURING THE PAST DECADE

Fred Alex TUGUME (Geological Survey and Mines Department)

Earthquake occurrence in Uganda is mostly related to the East African Rift System. The country's western border lies within the western branch of this System while the eastern branch is only 200Km from the eastern border in Kenya. The two tectonic features contribute to Seismicity in Uganda. The other tectonic features are the Aswa shear zone running from Nimule at the border of Uganda and Sudan, to Mount Elgon on the eastern border and Katonga fault break which stretches from the foot hills of mount Rwenzori to the western side of Lake Victoria This unique tectonic setting makes Uganda one of the most seismically active countries on the African continent as exemplified by some destructive earthquakes that have hit the country. The negative consequences of earthquakes greatly affect adversely the Gross Domestic Product (GDP) of the country. Realizing the significance of this, the Government of Uganda, in the effort of planning for sustainable socio-economic progress has set up a Network of earthquake-recording stations. The Network has been in place for the last decade. Several earthquakes have been recorded and located by the Network. This paper compares the Seismicity of Uganda during the past decade to other previous decades

SW03/10P/A04-004   1445

DEEP STRUCTURE AND COLLISION TECTONICS OF PAN-AFRICAN OROGENIC BELT: LUTZOW-HOLM COMPLEX, ENDERBY LAND, EAST ANTARCTICA

Masaki KANAO[1], Masahiro ISHIKAWA[2] ([1]Department of Earth Science, National Institute of Polar Resaerch, [2](2) Graduate School of Environment and Information Sciences, Yokohama National University)

Combination of rock velocities with seismic structures has been presented clues to understand structure and evolution of continental lithosphere. Most fruitful works have been addressed for northern hemisphere such as North America and Europe, however, only a few studies have focused on the continental segments in the southern hemisphere that once were the fragments of Gondwanaland. Here we present a tectonic model of the Pan-African orogeny by comparing geophysical data such as by deep seismic probing with laboratory velocities of granulite/gneiss of the Lutzow-Holm Complex (LHC), East Antarctica. The ″Structure and Evolution of the East Antarctic Lithosphere (SEAL)″ project have been carried out under the framework of the Japanese Antarctic Research Expedition in recent years. Several geophysical studies including deep seismic refraction / wide-angle-reflection surveys have been conducted on continental ice sheet at the LHC. Velocity models and reflection images within the lithosphere had been presented by both active and passive seismic-sources analyses by teleseismic receiver fucntions. From laboratory measurements, metamorphic rock velocities could reveal that the lower crust (6.9 km/s from refraction) consists of pyroxene granulite. Moreover, middle crustal velocities are equivalent to velocities of mixture of pyroxene granulite (20%) and felsic gneiss (80%). The ratio of pyroxene granulite is similar to that geologically observed as meta-mafic sills which were probably related with mafic magma underplating at Archean. The idea is also supported by model calculation about acoustic impedance that shows middle and lower crustal laminations. These evidences demonstrate that a part of the East Gondwanaland (i.e., Napier Complex) lied under the Pan-African orogenic belt (LHC) and subducted westward. Because it is pointed out that West Gondwanaland descended eastward under the Pan-African belt, the coalescence of both Gondwanalands, i.e. formation process of Gondwana supercontinent is regarded as collision tectonics along with symmetrical subductions where late Proterozoic island arcs and ophiolites were put between East and West Gondwanaland. Lithospheric structure of the Pan-African belt will be clarified by making deep seismic surveys and the other related geophysical approach to cross over the continental segments in the southern hemisphere that once were the fragments of a Gondwanaland. Deep seismic profiling by LEGENDS (Lithospheric Evolution of Gondwana East iNterdisciplinary Deep Surveys) project would be expected to reveal the architecture and lithosperic evolution of these regions. SEAL transect has also been carrying out as a chief contribution for

S

LEGENDS, to delineate a crustal section in different geological terrains from Western Enderby Land to Eastern Queen Maud Land, Antarctica.

SW03/10P/A04-005   1500

WET LITHOSPHERE OF PAN-AFRICAN OROGENIC BELT

Masahiro ISHIKAWA (Graduate School of Environment and Information Sciences, Yokohama National University)

Plate tectonics is the dominant process on Earth´s lithosphere. In restrict meaning, earth´s shell is composed of not only rigid plates but also fragile plates, and tectonics of earth´s surface is regarded as a mixture of rigid-plate tectonics and fragile-plate tectonics. For example, the Asian continent of Eurasian plate never behaves as rigid plate that was destructed and deformed intensely and extensively when the Indian continent collided with it. The similar extensive intraplate deformation (up to 2,500 km wide) together with strike-slip shearing are found in the late Proterozoic Pan-African orogenic belt along East Africa, Arabia, Madagascar, Sri Lanka and East Antarctica (East African orogen) that is a suture zone between East Gondwanaland and West Gondwanaland during the assembly of Gondwana supercontinent. Practically the Pan-African orogenic belt are older than 550 million years, and the area has been extensively remobilized until 550 million years ago (almost Proterozoic/Phanerozoic boundary) in the last stage of amalgamation between East Gondwanaland and West Gondwanaland. In contrast, Archean-Proterozoic continental collisions did not give rise to extensive intraplate deformation. In my opinion, fragile continental lithospheres have been established during late Proterozoic to Phanerozoic assembly of continents, and the fragile-plate tectonics started to operate on earth at Proterozoic/Phanerozoic boundary. Why are the central Gondwanaland and Asia continent so fragile? The common feature is that each continent was a relatively young continent that was established during the coalescence of a number of small geologic bodies such as island arc and microcontinent. For example, the Arabian-Nubian Shield is composed of island arcs and ophiolites that are distributed throughout the area of about 1500 km wide, suggesting that numerous island arcs were amalgamated and probably a large amount of slabs descended beneath the region along the numerous arc-trench systems. Today slab dehydration is the dominant process at subduction zone to add water into Earth´s mantle. In particular, the amount of water is expected to be remarkably large during coalescence of island arcs and microcontinents because it involves subduction of oceanic lithosphere along numerous trenches. As mentioned above, a number of subduction zones were apparently working during assembly of Gondwana supercontinent, Pangea supercontinent and Asian continent. Therefore contamination of water into lithosphere must have occurred. As a result of wetting of lithosphere, rheological strength of these continental lithospheres should have been reduced dramatically. I expect that deep seismic profiling across Gondwanaland detects some evidences for water in the uppermost mantle of Pan-African orogenic belt.

SW03/10P/A04-006   1515

UNUSUAL LITHOSPHERIC STRUCTURE AND EVOLUTIONARY PATTERN OF THE CRATONIC SEGMENTS OF THE SOUTH INDIAN SHIED

Pramod Kumar AGRAWAL (National Geophysical Research Institute)

South Indian shield, characterised by several prominent geological and geophysical features, forms one of the most interesting segments among cratonic areas of the earth. It is made up of three distinct tectonic regions: Western Dharwar craton (WDC), Eastern Dharwar craton (EDC), and Southern Granulate terrain (SGT). Except WDC, the entire crust beneath EDC and SGT has been remobilized several times since their formation during Mid to Late Archeans. In order to understand its evolutionary history, a multiparametric geological and geophysical study has been made which indicates that the south Indian shield, characterized by a reduced heat flow of 23-38 mW/m² has a much thinner (88-163 km) lithosphere compared to about 200-450 km found in other global shields. Significantly, in the EDC-SGT terrain, high velocity upper crust is underlain by considerably low lithospheric mantle velocity with a thick high conductive/low velocity zone sandwiched at mid crustal level. Our study reveals that the entire EDC region is underlain by granulite facies rocks with a density of about 2.85 to 3.16 g/cm³ at a shallow depth of about 8 km in the southern part and at even shallower depth of about 1 to 2 km in the northern part below the Archean granites of the Hyderabad region. Cratonic mantle lithosphere beneath EDC may contain a highly conductive and hydrous metasomatic zone between the depth of 90 and 110 km where estimated temperatures could be in the range of 900-1000°C. It is likely that before the early Proterozoic, the entire south Indian shield may have been a coherent crustal block which subsequently got segmented due to persistent episodic thermal reactivations during the last 2.6 Ga. These reactivations may have led to self destruction of cratonic roots giving rise to negative buoyancy at deeper levels which may have caused crustal remobilisations, regional uplifting and erosion of once substantially thick greenstone belts. It is thus surmised that the crustal column beneath the EDC may be highly evolved corresponding closely to granulite facies rocks at depth.

SW03/10P/A04-007   1530

CHIPPING OF CRATONS AND BREAKUP ALONG MOBILE BELTS OF A SUPER CONTINENTAL ASSEMBLY

Veeraswamy KOPPIREDDI, Upendra RAVAL (National Geophysical Research Institute (NGRI))

Probably the most important heterogeneity of a continental lithosphere is the significant difference in the thickness and properties of its cratonic and mobile parts. It is seen that the trans-continental mobile belts (Paleo-orogens/paleo-sutures) represent a thinner lithosphere possessing relatively warm, wet and weak nature. This makes it quite vulnerable to episodic thermomechanical interactions due to asthenospheric (mantle plume) upwelling as well as compression. This study presents evidences from the Indian continental lithosphere to show that these properties of mobile belt facilitate channeling of thermomagmatic flux in both lateral as well as vertical directions and can account for the concentration (or focusing) of geophysical anomalies, tectonomagmatic features and strain along these mobile belts. From the example of three continental breakups of India since the Cretaceous it is seen that a combination of sufficiently weakened mobile belt and mantle plume could become fatal for the super continental stability. On the other hand thick or deep-rooted (>200 km) continental lithosphere beneath cratons are characterized by relatively dry, cold and rigid lithospheric column, which resists the penetration of asthenospheric mantle upwelling. From this the long term stability of the cratons also follows since the deepseated thermomagmatic disturbances are channeled mostly along and through the mobile belts. This difference in cratonic and mobile belt regimes is exhibited in form of strongly heterogeneous thermal blanketing. However, in certain situations the edge of a cratonic region may get chipped-off as exemplified by the Antongil and Masora blocks (now lying on the Madagascar) from the Western Dharwar craton during India-Madagascar separation. On the basis of worldwide case histories it seems that the process of breakup along pre-existing mobile belts and chipping of cratons is globally applicable.

SW03/10P/A04-008   1600

HOW GEOPHYSICAL SIGNATURES STRENGTHEN THE GEOLOGICAL MODELS OF SUPER CONTINENTS-INDIAN EXAMPLES

Reddy Ramachandra P. (CSS Division, National Geophysical Research Institute)

Models on Gondwana assembly breakup and reassembly are based on wealth of geological, geochemical, geochronological and geophysical data. Those who are actively involved in building up evolutionary models of super continents should visualize the assembly, disruption and reassembly of super continental configuration through an understanding of the continental dynamics. For this it is essential to synthesize both geological and geophysical results. In support of the necessity to synthesize various data sets especially usage of deep geophysical surveys data some salient features associated with the south Indian shield are listed below.Geophysical studies on deep continental crust assume great significance in terms of continental lithospheric dynamics (a vital component in the assembly, break up and reassembly of super continents) primarily because much of the upper crust has developed in processes that involve the deep crust. The architecture of the cratons, especially their relationship with mobile belts and the intersecting sheare zones (eg. Palghat-Cauvery, Moyar-Bhawani and Achankovil vis-AEvis Ranatsor in Madagascar) that may mark collisional sutures, are primary targets for deep geophysical studies as they provide greater insight into the configuration and depth extension of the mega and macro lineaments and their control over the present day tectonic configuration of the area and adjoining segments of the East Gondwana super continent. This has been amply proved by the studies in India.The significant oppositely angled crescent shaped Cuddapah basin and trends of Chitradurgh-Shimoga schict belt and Clospet granite indicate presence of collision tectonics. Results from seismic tomography, deep seismic refraction and seismic receiver function studies have clearly shown that the middle part (known as Eastern Dharwar Craton, EDC) is underlain by thin crust compared to the adjacent Western Dharwar Craton, (WDC) and Eastern Ghat Mobile Belt (EGMB). The distribution of proterozoic diamondiferous Kimberlite province of India along a NE-SW trending linear belt falls within the EDC suggesting the dual impact caused by super plume activity and collisional tectonics. This resulted in updoming of crustal (which subsequently got eroded leaving a thinner crust) with presence of deep seated vents.When we look at the structural and evolutionary signatures associated with different granulite-facies terrains, (even though of different geologic periods) especially the two western segments of Gondwana east super continent viz southern Granulite terrain of India, the Mozambic belt and Madagascar we notice that as in the case of east-central, north east- Tanzania and south east Kenya the northern segment of southern granulite terrain of India has granulite-facies metamorphism resulting from crustal thickening. Seismic reflection/refraction experiments have helped in bringing out crustal structure of the region, stressing the need for an integrated data analysis and initiation of LEGENDS programme.

SW03/10P/A04-009   1615

A PLATE TECTONIC MODEL FOR EVOLUTION OF SCHIST BELTS AND GRANITE PLUTONS OF DHARWAR CRATON, INDIA AND MADAGASCAR DURING 3.0-2.5 GA: INSIGHT FROM GRAVITY MODELING CONSTRAINED IN PART FROM SEISMIC STUDIES

Dinesh Chandra MISHRA, S.K. PRAJAPATI (National Geophysical Research Institute)

Gravity modeling of an E-W profile across Dharwar Craton, India and Madagascar,integrated with the results of Deep Seismic Sounding (DSS) across the Dharwar Craton suggest a thick crust of 40-42 km under the Eastern Dharwar Craton (EDC), the Western Dharwar Craton (WDC) and the central part of the Madagascar. Towards east of these blocks, the crustal thickness is reduced to 36-38 km along the Eastern Ghat Fold Belt (EGFB), Shear Zone between the EDC and the WDC and the east coast of Madagascar, respectively. These zones of thin crust are also characterized by high density lower crustal rocks associated with thrusts. The seismic section across Dharwar Craton shows domal shaped reflectors in the lower crust and upper mantle under the WDC which may be related to asthenopheric upwelling during an extension phase. The occurrences of large schist belts with volcano sedimentary sequences of marine origin of late Archean period (3.0-2.7 Ga) as rift basins in the WDC and Madagascar also suggest an extensional phase in this region during that period. It is followed by a convergence between the WDC and the EDC giving rise to collision related shear and thrust zones between the WDC and the EDC associated with high density lower crustal rocks. The seismic section shows upwarped reflectors in the upper crust which may be related to this convergence. Eastward dipping reflectors under WDC and EDC and west verging thrusts suggest convergence from the west to the east which resulted in easterly subduction giving rise to subduction related K-granite plutons of the EDC of 2.6-2.5 Ga. In this regard, the Clospet granite in the EDC which extends almost parallel to the shear zone between the WDC and EDC and shows an I-type calk-alkaline composition may represent relict of an island arc and the linear schist belts with bimodal volcanics of the EDC east of it might have developed as back arc rift basins. Subsequent collision between India and Antarctica along the EGFB during middle Proterozoic, indicated by eastward dipping reflectors in the crust and the upper mantle and west verging thrust gave rise to contemporary high grade rocks of the EGFB (1.6-1.0 Ga) and associated mafic and felsic intrusives of this belt. The part of adjoining Cuddapah basin contemporary to the EGFB towards the west consisting of marine shelf type of sediments which are highly disturbed and thickest at its contact with the EGFB may represent a peripheral foreland basin.

SW03/10P/A04-010   1630

HEAT FLOW IN THE INDIAN SHIELD: INTERPRETATION FOR CRUSTAL THERMAL STRUCTURE

Roy SUKANTA, Labani RAY, Senthil Kumar P., Koti Reddy G., Srinivasan RAMASWAMIAH (National Geophysical Research Institute)

Data on geothermal gradients representative of regional crustal conditions have been acquired through temperature measurements in 183 boreholes and 2 deep mines. Combining with thermal conductivity data on rocks over relevant depth sections, heat flow could be evaluated at many localities in India covering Precambrian provinces, Gondwana basins, and the Tertiary Cambay basin. The following general characteristics emerge from the data set. (i) The Archaean Dharwar greenstone-granite-gneiss province (DP) and the adjoining Southern Granulite Province (SGP) have heat flow ranging from 25 to 50 mW m⁻². This low heat flow level is found to hold over the Deccan Volcanic Province in the region south of the Son-Narmada-Tapti lineament zone in central India, and also in the western fringes of the Proterozoic Cuddapah basin, both of which have the DP basement. The Proterozoic segments covered so far have revealed heat flow higher than 50 mW m⁻²; 59 to 63 in the Singbhum Thrust Zone, 51 to 62 in the Bastar craton, and 56 to 96 in the Aravalli province. The Gondwana basins have a generally high but variable heat flow, 46 to 107 mW m⁻². The Tertiary Cambay basin has high heat flow of 75 to 96 mW m⁻² in the northern part, and a lower heat flow, 55 to 67 mW m⁻² in the southern part. With data on radiogenic heat production of major crustal litho-units, and structural constraints from other geological and geophysical data, 1-D models of crustal heat production have been envisaged for the DP, and in the case of the SGP, for the block to the north of the Palghat-Cauvery lineament (NB).

Based on these models and heat flow data, crustal contribution to heat flow has been estimated and the mantle heat flow has been deduced. Estimates of crustal temperatures have been made using generalized functions for depth dependence of thermal conductivity in the crust. Mantle heat flow is 11 to 19 mW m^{-2} in the DP, similar to other Precambrian provinces of the world studied so far. However, it is significantly higher, 25 to 30 mW m^{-2}, in the NB of the SGP. This result is in conformity with the crustal and sub-crustal velocity structure emerging from tomographic studies, and with geochemical and isotopic data that point to LILE-enriched mantle. Temperature at the Moho is estimated to be in the range 285 to 410 °C in the DP and 580 to 660 °C in the NB of the SGP. Crustal thermal structure(s) for other parts of the Indian shield can be established with confidence only when additional heat flow coverage and information about the structure and composition of the Indian lithosphere are obtained from on-going as well as planned geophysical studies.

DEEP ELECTRICAL STRUCTURE ALONG KOLATTUR - PALANI PROFILE IN SOUTHERN GRANULITE TERRAIN, INDIA

Harinarayana T. TIRUMALACHETTY, Naganjaneyulu K. (Magnetotellurics, National Geophysical Research Institute)

Broad band magnetotelluric (MT) investigations were carried out along a profile from Kolattur in the north to Palani towards the south in southern granulite terrain (SGT). This 160 km long profile was covered with 18 stations at an interval of 8- 12 km and traversing across the Palghat-Cauvery shear zone (PCSZ). The MT data is subjected to robust processing, Groom-Bailey decomposition and static shift correction before deriving a 2-D model. The 2-D model showed anomalous electrical conductivity at mid-lower crustal depths bounded by shear zones. The salient features of the model are: the upper crust is high resistive (10 000 – 40 000 ohm-m) and the mid-lower crust is less resistive ($<$ 3000 ohm-m) between the Chennimalai Shear zone (CSZ) and PCSZ. These results have shown good correlation with results from other geophysical studies like deep seismic soundings (DSS), gravity and magnetics. The conductive layer at mid-lower crustal depth correlates with low velocity layer and anomalous gravity high observed in the region. The relation between the geophysical signatures and the tectonics of the region is discussed.

SW03/10P/A04-012   1700

THE CAUVERY SHEAR ZONE, SOUTHERN GRANULITE TERRAIN, SOUTHERN INDIA: PALAEO- AND NEOPROTEROZOIC TECTONICS

Talari Ramakrishnaiah CHETTY, Rao Jyothi Bhaskar YERRAGUNTLA (Geological Studies Division)

Structure and tectonics of the southern Granulite Terrain (SGT), southern India is highly relevant to the models of Gondwana supercontinent reconstruction. The east-west trending Cauvery Shear Zone (CSZ) is the most prominent crustal-scale (~ 350x70km) tectonic feature in the SGT straddling the boundary between the Archean Dharwar Craton and the Proterozoic granulite terrains. Amphibolite and granulite-facies rocks retrogressed variably are exposed all along this deep crustal ductile shear zone. A synoptic structural interpretation of Landsat TM data was followed by extensive geological mapping and structural analysis along a 100 km - wide north-south corridor orthogonal to the shear zones. The study reveals several prominent east-west trending shear zones, many of which are delineated for the first time. Some of the shear zones separate distinct geological domains in terms of lithology, structural style, and their crust formation and metamorphism of the basement gneisses (Model Nd ages, Rb/Sr mica and Sm/Nd garnet ages). The shear zones include: the Moyar-Bhavani (MBSZ), the Chennimalai-Noyil (CNSZ), the Dharapuram (DSZ), the Devattur-Kallimandayam (DKSZ), and the Kodaikanal-Oddanchatram (KOSZ). From the foliation geometries, it is observed that the MBSZ at the northern limit of the CSZ dips steeply to south while others dip moderately to north. Kinematic observations such as deflection of foliations, fish-tail structures and S-C fabrics indicate dextral movements. Our studies indicate that the regional deformation can be rationalised in terms of two major episodes: the Palaeoproterozoic and the Neoproterozoic. The former resulted in large-scale north verging thrusts accompanied by north-south shortening while the latter (750-500 Ma) is manifest in extensive shearing, granite emplacement and migmatisation. The MBSZ acts as a major zone of kinematic partitioning and represents a southerly dipping Palaeoproterozoic frontal thrust. The disposition, regional geometry, kinematic patterns, and the contemporanity of mylonitic fabrics based on Rb-Sr mica ages suggest that the shear zone network could form a crustal scale flower structure during the Neoproterozoic, which is structurally akin to many collisional orogens elsewhere. This Neoproterozoic deformation was progressively more transpressive with high-angle convergence and flattening strains consistent with the collisional regimes. A critical reappraisal of contemporaneous structures in other juxtaposed continental blocks of the East Gondwana would be rewarding.

SW03/10P/A04-013   1715

ACID MAGMATISM IN SOUTH INDIAN GRANULITE TERRAIN AND ITS IMPLICATIONS IN RECONSTRUCTION OF EASTERN GONDWANALAND

Rao Mallikharjuna JUPUDI, Rao Rama P. (Geological Studies Division)

India, which is a part of Eastern Gondwanaland together with Madagascar, Sri Lanka, Antarctica and part of Australia till their break-up and moved apart during Mesozoic time, is important in understanding the tectonothermal and metamorphic events recorded in Precambrian times. The south Indian craton has well preserved tectonic features, acid and basic magmatic activity of different ages, and different grades of metamorphic terranes subjected to multi-deformational events during the past. Two distinct age groups of granitic activity noticed, one in the northern part of Dharwar craton which is partly of Archaean age and the other in the southern Proterozoic mobile belt of Pan- African time (800- 500 Ma).In an attempt to study acid magmatism and crustal structure in south India, multidisciplinary studies were taken-up along the N-S trending Kuppam- Palani geotransect. The area has been divided into three blocks based on the structure, lithology, tectonic features and metamorphic assemblages namely, the northern block from Kuppam to north of Moyar-Bhavani shear zone, the central block encompassing the area between the Moyar- Bhavani shear zone and Palghat- Cauvery shear zone and southern block from south of Palghat-Cauvery shear zone up to Palani. Thermobarometric studies on the granulites from the three blocks have shown that the northern and southern blocks depict similar P-T conditions (600-700oC and 6-7 kb) while the central block between Moyar- Bhavani and Palghat- Cauvery shear zone depicts a higher P-T regime (740- 950oC and 8.2- 10 kb).The Proterozoic granitoids mostly show tonalitic character and similarity to the granite- gneisses of the low-grade terrain and are restricted to the north of Palghat- Cauvery lineament. The younger granitoids are leucocratic and are mostly white and medium to coarse grained while the pink phases of coarse grained to pegmatoidal types also occur at places. Geochemical characters of these granites indicate their anorogenic nature. The granites from the northern block are tonalitic and metaluminous in character while these from central and southern blocks are granodioritic to granitic and are peraluminous. Rare earth element fractionation trends vary considerably within the granite plutons and exhibit both positive and negative Eu

anomalies.Geochrnological data on these granites indicate that the entire south Indian craton had witnessed a major extensional tectonic regime during the Pan-African times leading to large scale crustal anatexis resulting in the emplacement of several granites of Neoproterozoic age. Such wide- spread granitic activity has also been documented in Madagascar, Sri Lanka and Antarctica thereby providing similarities in   the crustal fragments of East Gondwanaland.

SW03/10P/A04-014   1730

SHEAR WAVE STRUCTURE OF THE DHARWAR CRATON (INDIA) FROM RECEIVER FUNCTIONS

Sarkar DIPANKAR[1], Ravi Kumar MANGALAMPALLY[1], Joachim SAUL[2] ([1]National Geophysical Research Institute, [2]GeoForschnugs Zentrum)

Modelling of receiver functions using teleseismic data from six broadbandstations on the Archaean Dharwar craton indicates that the shear structureof the entire crust is largely simple. The crust is devoid of major intra-crustal discontinuities, and shows a low Poisson´s ratio. However,the results of earlier wide-angle experiments indicated presence of a mid-crustal boundary in the compressional velocity models. It is possiblethat the Dharwar crust is divided into a more felsic upper crust with a Poisson´s ratio lower than 0.25 and a mafic lower crust with a correspondinglyhigher Poisson´s ratio. Such a partitioning need not necessarily require astrong mid-crustal S velocity contrast and may manifest as a contrast in P velocities only. The Western Dharwar Craton (WDC) is distinctly thickerthan its eastern counterpart (EDC). Formation of the Cuddapah basin did notsignificantly alter the crustal configuration, as testified by thin and simplecrust. It appears that WDC does not extend much to the north underneath theTrap cover, as the crust below the Deccan Volcanic Province is more akin toEDC crust in terms of thickness.

SW03/10P/A04-015   1745

LITHOSPHERIC STRUCTURE OF EAST GONDWANALAND: REVIEW AND PREVIEW

Larry Douglas BROWN (Institue for the Study of the Continents, Cornell University)

Deep seismic reflection profiling over the past two decades has revealed critical aspects of lithospheric structure beneath many of the continents. However, such surveys are notably lacking for most of the continental fragments that once constituted the supercontinent of Gondwanaland. In fact, seismic data in general on deep structure in these regions are quite sparse. Previous work in East Gondwanaland has been limited to only two large scale field initiatives (e.g. the KRISP refraction studies of the East African Rift (EAR) zone; the Kaapval passive seismic study of lithospheric structure beneath the Archean of southern Africa), a few smaller scale studies (e.g. heat flow and passive seismic studies of the Tanzania craton and adjacent EAR) and some attempts to image mantle structure using global/regional techniques (e.g. surface wave tomography of upper and lower mantle beneath Africa). More extensive are the oil industry surveys of the passive margins of East Africa/Madagascar and potential field coverage. However, most such studies have focused on recent tectonics (the East Africa Rift system or suspected mantle plumes), Archean craton evolution (e.g. Kaapval Project) or continental breakup (oil exploration on margins). Geophysical constraints on lithospheric structure associated with the late Proterozoic amalgamation of Gondwanaland are particularly wanting, even within India where an ambitious program of deep geophysics has probed a number of continental structures over the past several decades. The main exceptions to this generalization are the deep seismic surveys in Australia and a few deep surveys in Antarctica. Here I will review the existing deep geophysics for East Gondwanaland as a preview of proposed future deep seismic profiling (LEGEND) in the circum-Indian Ocean region and the major geotectonic issues that can be addressed.

SEISMIC VULNERABILITY OF INDIA'S URBAN AREAS

Sitharama Murty KOTTAPALLI (Coordinator of Geoarchives, International Commission on the History of Geological Sciences (INHIGEO))

India has been long know for its villages and agricultural economy. But its demographic trends reveal that at the beginning of the 20th century its urban population was less than 11 % (25.8 million) and it rose to 17.29 % in 1951 after Indipendence (62.4 million). The 1991 census indicated that 217.2 million live in urban areas, constituting 26 % of the total population. By 1995, it increased to 281.2 million, 30 % of the population. The urban population may have risen to 335 million (33.5 %) at the beginning of the 21st century. In terms of growth of urban centers, between 1901 and 1991 the number was 1811 with number of cities (100,000 and above) being 24. these figures correspondingly rose to 2795 and 76 in 1951. the 1991 census figures are 3609 urban centers and 300 cities. The extra - peninsular region of India has been know to the one of high sesmic activity, with al least 30 major earthquakes measuring above 5.5 on Richter scale striking it between 1720 A.D. and 1988. the main urban centers of India are located in this region that extends from Jammu and Kashmir to North - east along the Himalayan belt, apart from the western India that includes Rajasthan and Gujarat. The Peninsular part was for long believed to be free from seismic activity though there were some significant quakes in that part also. The 1967 Koyna earthquake proved this belief wrong and it compelled revision of the seismic zoning of India quite radically. The 1969 Bhadrachalam quake, 1993 Latur quake and 1997 Jabalpur quake confirmed the seismic nature of the peninsular region. The recurrence of this activity in Maharashtra, Andhra Pradesh and Central India in the last five years leaves very little part of India that is free from seismic vulnerability, e.g. Kerala, Orissa, Rajasthan and West Bengal being the exception. Mumbai, Delhi, and Hyderabad are vulnerable, while Chennai and Calcutta may not be. The seismic zonation points out that majority of the urban areas and cities have the seismic risk.

SW04/09P/A13-002   1415

MODELLING OF SEISMIC GROUND MOTION AND ITS AMPLIFICATION ALONG SOME 2-D PROFILES IN THE CITY OF DAMASCUS, SYRIA

Randa MOHAMAD[1], Peter SUHADOLC[2], Franco VACCARI[3], Wathek RASOUL-AGHA[4] ([1])

General Establishment for Geology and Mineral Resources, Damascus, Syria, ²2) Department of Earth Sciences, University of Trieste, Trieste, Italy, ³3) The Abdus Salam International Center for Theoretical Physics, Trieste, Italy, ⁴4) Department of Geology, Damascus University, Damascus, Syria)

Damascus is the capital and the largest city of Syria, with a population of about 7 million people. It is located at the southern part of the country not far from the Lebanese border and the Dead sea fault system, in particular from one of its branches the Sergayah fault. The latter in particular is a quite active fault system and the main seismic source for both destructive historical events felt and instrumental seismicity recorded in Damascus. To model seismic ground motion in Damascus basin and to estimate its amplifications we use a 2-D hybrid method coupling modal summation with finite differences. This technique allows us to compute ground motion in laterally heterogeneous anelastic media. Synthetic seismograms with a cutoff frequency of 5 Hz are created along four 2-D profiles passing through the city of Damascus for four possible seismic sources with assumed magnitudes around 6.5 located on the Dead sea fault system and on the Sergayah fault. The average regional structural model and the laterally heterogeneous parts of the profiles have been derived from detailed geological and geotechnical data available for the investigated area. From the computations we can infer that the maximumground motion amplification values in Damascus basin are generally found at frequencies around 2 Hz and 4 Hz.

RUPTURE PROCESS OF THE KUNLUN MOUNTAIN PASS EARTHQUAKE OF NOVEMBER 14, 2001 FROM LONG PERIOD WAVEFORM DATA

Yuntai CHEN, Lisheng XU (Institute of Geophysics, CSB)

We have inverted long period P-waveform data recorded by the Global Digital Seismmogragh Network (GDSN) to obtain the temporal and spatial rupture process of the Kunlun Mountain Pass earthquake of November 14, 2001. The inverted final slip-distribution indicates that while the length of the rupture area with slip amplitude greater than 0.5m was about 600km, 250km in the west and 350km in the east to the epicenter (35.97˚N,90.59˚E), which was greater than the length of the observed surface rupture (about 440km), the length of the rupture area with slip amplitude greater than 1.0m is about 420km, 120km in the west and 300km in the east to the epicenter, which was nearly agreed with the length of the observed surface rupture. Two high slip areas, i.e., the area with slip amplitude greater than 1.5m, were recognized. One is between the positions of 30km east to the epicenter and 80km west to the epicenter, with the length being about 110km, and the other is between the positions of 150km and 280km east to the epicenter, with the length being about 130km. The later high slip area just corresponds to the Kusai Lake segment of the observed surface rupture and its eastern extension where most heavily broken ground surface was observed. The inversion results indicate that the slip distribution on the fault plane was heterogeneous, with the maximum slip amplitude being 2.2m and the average one being about 1.2m. The maximum stress drop was estimated to be 7.9MPa, and the average one was about 4.0MPa. Three distinct subevents could be recognized in the inverted temporal and spatial rupture process. The first subevent was temporally from the beginning to the 60th second, and spatially between the positions of 30km east and 150km west to the epicenter, which was overall a unilateral rupture from east to west, with an average rupture propagation velocity of 3.8km/s. The second subevent was temporally from the 52th second to the 92th second, and spatially between the positions of 100km and 200km west to the epicenter, which was overall a unilateral rupture from west to east, with an average rupture propagation velocity of 3.1km/s. The third subevent was temporally from the 56th second to the 140th second, and spatially between the positions of 30km and 330km east to the epicenter, with an average rupture propagation velocity of 2.7km/s. These three subevents had different sizes, respective overall rupture directions and variable rupture velocities, whereas as a whole the rupture of the Kunlun Mountain Pass earthquake was unilateral from west to east.

SW04/09P/A13-004   **1445**

EARTHQUAKE FATALITY SYNDROME

Vasile I. MARZA (Seismological Observatory, Institute of Geosciences, University of Brasilia, CP 04598, Campus Universitario, Brasilia, DF, CEP 70910-900, Brazil, email: ＜marza@unb.br＞, On leave from Seismological Laboratory, NI(RD)EP, Bucharest, Romania)

There is fairly convincing anecdotal evidence that, in many instances of fatal earthquakes, the formal death toll counts are biased. Indeed, a closer look at the earthquake fatality estimates shows that many of them are underestimated, a condition referred to as ˝earthquake fatality syndrome˝, i.e., a rather large inconsistency between the official assessment and the informal appraisal(s). This discrepancy may be quantified by a ˝fatality syndrome factor˝, defined as the ratio between informal to formal estimates, having as a rule a value 2 to 3 (at least). The thesis is exemplified through several typical and well-substantiated case events like: the Tangshan, China, 1976 infamous earthquake (approx. 750,000 informal human cost **vs.** 242,000 official life loss), the Izmit, Turkey, 1999 calamitous shock (around 45,000 **vs.** 18,000), the Gujarat, India, 2001 hard-hitting earthquake (in between 30,000 to 50,000 **vs.** 20,000), the Michoacán, Mexico, 1985 horrendous event (about 20,000 **vs.** 9,500), the Vrancea, Romania, 1977 freak earthquake (close to 5,000 **vs.** 1,700), or the San Francisco, California, 1906 refashioned earthquake [roughly 3,000 (modern estimate) **vs.** possibly 700 (contemporary estimate)] etc. The above figures are documented, their confidence is assessed and some simple statistics is worked out in order to provide a foundation and certain insights towards the existence of an earthquake fatality syndrome. Among the possible causes/explanations for this elusive but rather systematic bias in earthquake fatality assessment we advance: the lack of transparency and slowness in communicating the earthquake effects, the emotive/idiosyncratic and pressing working environment in the aftermath of the killer earthquakes, the incompetence to manage disaster crises, the inadequate information systems available at the best of times or simply trivial mistakes. Often the totalitarian penchant for secrecy and as well as the closed character of some authorities undoubtedly contribute to the above causes. A by-product of this note is the revising/producing of ˝the top ten˝-like lists of the deadliest ever earthquakes and of the 20th century worst earthquakes. Finally, the author aware that the idea set out here is likely to be distasteful or even heretical for someone from the conventional wisdom or officialdom, he hopes that the discussion will trigger a paradigm shift in death toll count methodology for a decent, more reliable and realistic earthquake (or other disasters) fatality/casualty estimates.

EVALUATION OF THE CITY'S ABILITY FOR SEISMIC DISASTER PREVENTION

Li-Li XIE¹, Feng-Hua ZHANG³ (¹Institute of Engineering Mechanics China Seismological Bureau, ²Harbin Institute of Technology, ³Department of Bridge Engineering, Tongji University)

In 1994 the Chinese Government made an important decision that through the ten year's consensus effort by each level of government and whole society, all the large and middle-sized cities in China, with the location along the coast, or with dense population, or with well

---

developing of economy should be enhanced their abilities for mitigating earthquake disaster with the goal to resist earthquake of Magnitude of six. This paper presents the definition of a city's ability for earthquake disaster mitigation, the components, which affect significantly the city's ability, the criteria, by which, the city's ability for mitigating seismic disaster can be evaluated, and a framework that can quantitatively evaluate the city's ability for seismic disaster prevention. As a result, a simple index is used to describe the comprehensive city's ability for earthquake disaster mitigation. For evaluation of the city's ability for seismic disaster mitigation, the designed framework includes the six major factors: they are the ability of earthquake monitoring and prediction, the ability of seismic hazard assessment, the ability of civil engineering for earthquake resistance, the ability of non-structural elements for earthquake resistance, the ability of communities for earthquake disaster prevention and the ability of seismic emergence responding and recovering after the earthquake. And for each major factor, it also includes several levels sub-components. For example, the ability of civil engineering covers the abilities of buildings, lifelines, infrastructures and so on. Finally as examples, ten cities over the world have been evaluated for their abilities in seismic disaster mitigation. Some important and interesting issues are concluded.

SW04/09P/A13-006   **1515**

DAMAGE AT AHMEDABAD CITY DUE TO INTRAPLATE MW 7.7 BHUJ, INDIA EARTHQUAKE OF 26 JANUARY 2001

Bal Krishna RASTOGI, Prantik MANDAL (Seismology Group, National Geophysical Research Institute, Hyderabad, India)

The Intraplate Mw 7.7 Bhuj, Western India earthquake of 2001 caused destruction/damage of reinforced concrete buildings, collapse of some weak single or double storey houses, damage to several archeological monuments and cracks in almost all the buildings in Ahmedabad city situated at 250 km distance from the epicenter. For the first time in India multistorey buildings have been ruined due to any earthquake. The maximum intensity was X+ in the epicentral zone and VII in Ahmedabad. The acceleration estimated at the epicenter is 1g and at Ahmedabad the recorded acceleration is 0.11g. Ahmedabad city falls in Seismic Zone III of the seismic zoning map of India where MMI intensity of VII is expected. Alluvium thickness of about 300 meters partially influenced the damage pattern as Ahmedabad city is located along Sabarmati River in the Cambay Rift Basin. Out of about a thousand high rises (G+10) and 12000 odd low-rise (G+4) buildings, 69 collapsed resulting into 746 casualties. About 2350 such buildings suffered structural damage. The buildings that conformed to the codes survived. Faulty designs (structural engineers were hardly consulted and others were generally unaware of earthquake codes), as mentioned below, are the main causes of destruction of multistorey buildings:• ˝Soft first storey˝ for parking space without adequate column strength resulted in collapse or tilting of whole structure. Shear failure at the gap between top of ground floor columns and the beams above to accommodate beam reinforcements. Concrete quality in columns was poor. Columns were often of small 1/2 brick width for embedding in masonry partition walls and beams of shallow depths often equal to slab width to save on height. • Deficiency in structural formwork (shuttering) as reinforcement cage is not properly tied and spacers are avoided.• Shallow (only 75) footings for columns below the basement floor level without tie beams even in soft soil for even 11storey buildings. Pile foundations are not used. • To meet the "floor space index" and for providing more floor space from 1st floor onwards, large portions of buildings are constructed on floating columns and with balconies on cantilevers giving flower-shaped plans. • Out of phase vibrations of two or more blocks in different directions joined together through a common staircase or elevator.• The reinforced concrete elevator shaft and plain masonry staircase was not tied adequately to the reinforced concrete floors.• Huge concrete water tanks (swimming pool in one case) at the top where seismic forces are amplified, due to their eccentricity, resulted in overturning effects on the buildings. • Total absence of detailing provisions to accommodate lateral shearing.

CATALOGUE BY LOSSES FORMATION FACTORS INFLUENCE VULNERABILITY OF BUILDING AND CONSTRACTIONS IN SEISMOACTIVE TERRITORIES OF UZBEKISTAN

Ikramov TIMUR (Post Graduate Student of the Institute of Seismology of Academy Sciences of Uzbekistan)

Objective: Implementation of GIS-based earthquake loss estimation methodology for use in Uzbekistan. **Scope:** Deterministic earthquake hazard analysis (scenario earthquake) for Tashkent Metropolitan Area utilizing data from the RADIUS project. **Features:** 1. Application of GIS software. 2. Developing of digital maps for structure inventory (cadastre) and soil conditions. 3. Computation of ground motion intensity through empirical relationship attenuation of the seismic waves. Thus, the first for the Uzbekistan have composed (first variant) of Catalogue all loss of factors that consist of the next parameters: seismically, seismotectonically, engineering-geologically, technogenic and geophysically (Ibragimov R.N., Khuday-bergenov A.M., Nurmatov U.A. and others, in published, 2002). With aim of define more precisely of estimation seismic hazard, that Catalogue is compare with vulnerability curves of civil construction, those today are exploitation. Catalogue and out work methodology of 'Estimation Economic Consequences of Large Earthquake˝ for example on the Tashkent metropolitan area that will be very usefully for estimation seismic hazard of the capital of Uzbekistan the Tashkent city. To serve above mentonied purposes it is advisable to take advantage of risk based approaches to the problem of urban planning and disaster preparedness in Tashkent metropolitan area located in high seismic areas, to use state of the art techniques, including GIS-technologies, for development of seismic risk management plans. On this basis it would be possible to indicate reasonable criteria for decision makers to be used when selecting priorities and immediate directions for disaster mitigation measures for this urban areas. Another important subject is seismic risk assessment for individual private construction sites, buildings with the purpose of optimum antiseismic design. It is a matter of great significance to introduce the concept of seismic risk into practice of seismic design and construction in Uzbekistan and other countries of Central Asia.

SEISMIC RISK IN THE NEW CITIES OF THE UNITED ARAB EMIRATES, AN APPROXIMATE ESTIMATE

Max WYSS¹, Azm AL HOMOUD² (¹WAPMERR, ²American University, Sharjah, United Arab Emirates)

We estimate the losses due to 10 scenario earthquakes in 150 settlements of the United Arab Emirates (UAE). For southern Iran, we use four source zones and the maximum magnitudes in them as determined by GSHAP (7.2<=M<=8.1). For six local scenario earthquakes, we use the range 5.5 <=M<=6.5, place the sources mainly on mapped faults and vary the distance to major cities from 10 to 60 km. In the test case of the Masafi earthquake (M5, 11 March 2002), the method and data bank we use yield the correct results, suggesting that our approach to the problem is valid for the UAE. The sources in Iran are expected to cause only minor damage, except for an M8.1 earthquake in the Makran region.

For such an event we expect some deaths, several hundred injured and a loss of 3-6% of the value to the building stock in the northeastern UAE, including Oman. The losses for local scenarios with epicenters in the unpopulated areas of the UAE and for scenarios with M< 5.8 are estimated to be minor. Because the two major mapped faults run through several of the large cities, scenarios with short epicentral distances from cities have to be considered. Scenarios with M6 near cities lead to estimates of about 1000 ± 500 deaths, and several thousand injured. Most buildings are expected to be damaged to a moderate degree and the loss to buildings is estimated around 1/4 of their value. If the magnitude should reach 6.5, the losses to humans and to building value could be staggering. These estimates are approximate because: (1) there exists no local seismograph network that could map active faults by locating microseismicity; (2) there exist no historically old buildings that could serve as tests for effects due to strong ground motion in the past; (3) there exist no microzonation of the subsurface properties in this region of unconsolidated building ground; (4) there exist no detailed inventory of building fragility. Nevertheless, our conclusion that there exists a substantial seismic risk in the UAE is reliable, because our method yields accurate results in the cases of earthquakes with known losses during the last several decades in the Middle East.

SW04/09P/A13-009   1615
ISTANBUL EARTHQUAKE RAPID RESPONSE AND EARLY WARNING SYSTEM

Mustafa Ozder ERDIK, Oguz Asim OZEL, Yasin FAHJAN, Hakan ALCIK, Aydin MERT, Muzaffer GUL (Bogazici University, Kandilli Observatory&Earthquake Research Institute, Earthquake Engineering Department, 81220, Cengelkoy, Istanbul, Turkey)

As part of the preparations for the future earthquake in Istanbul Kandilli Observatory and Earthquake Research Institute of Bogazici University (KOERI-BU) in cooperation with other agencies have installed a Rapid Response and Early Warning system in the metropolitan area. For the rapid response system one hundred (100) 18-bit resolution 'dial-up' strong-motion accelerometers were placed in quasi-free field locations (basement of small buildings) in the populated areas of the city, within an area of approximately 50x30 km, to constitute a network that will enable early damage assessment and rapid response information after a damaging earthquake. Early response information will be achieved through very fast acquisition, analysis and elaboration of data obtained from the network. In normal times these stations will be interrogated on a regular basis by the main-data center located at the KOERI-BU. However, after triggered by an earthquake, each station will process the streaming strong-motion data to yield the spectral accelerations at specific periods, 12 Hz filtered PGA and PGV and will send these parameters in the form of SMS (Short Message Service) messages at every 20 s directly to the main-data center through available GSM (Global System for Mobile Communication) network services. A shake map and damage distribution map (using aggregate building inventories and fragility curves) will be automatically generated using the algorithm developed for this purpose. Loss assessment studies are complemented by a large citywide digital database on the topography, geology, soil conditions, building, infrastructure and lifeline inventory. The shake and damage maps will be available on the Internet and will also be conveyed using spread spectrum radio-modem communication to several user nodes, including the governor's and mayor's offices, fire, police and army headquarters within 3 minutes. Full-recorded waveforms will later be retrieved. For the Early Warning system ten 24-bit resolution strong-motion stations were installed on the shoreline as close as possible to the fault area in 'on-line'. The continuous on-line data from these stations will be used to provide near-real time warning for emerging potentially disastrous earthquakes using several alarm levels on the basis of the algorithm developed. The spread spectrum (2.4 GHz) system is the communication system between these stations and the main data center with appropriate repeater stations selected in the region. The initial users of the early warning signal will be nuclear research facilities and critical petro-chemical factories within the region, subway system and several high-rise building. The central data acquisition and processing center houses the dedicated GSM and radio modems and three access servers to provide interface to an Ethernet LAN.

STRESS-MONITORING SITES FOR MITIGATING EARTHQUAKE HAZARD

Stuart CRAMPIN[1], Yuan GAO[2], Sebastien CHASTIN[1], Theodora VOLTI[3] ([1]School of GeoSciences, University of Edinburgh, Scotland UK, [2]Centre for Analysis and Prediction, China Seismological Bureau, Beijing 100036, China, [3]Institute for Frontier Research in Earth Evolution, JAMSTEC, Yokohama, Japan)

A new understanding of the way fluid-saturated microcracked rocks deform suggests that networks of stress-monitoring sites could lead to earthquake forecasting analogous to the way networks of meteorological stations allow weather forecasting. In principle, the build up of stress before large earthquakes threatening large cities can be recognised and mitigated by hydraulic fracture operations. Both observations and theory for the evolution of fluid-saturated microcracked rock under stress (anisotropic poro-elasticity or APE) demonstrate that in situ rock is weak to shear stress. Consequently, the accumulation of stress before the largest earthquakes necessarily takes place over 10s to 100s of M km3. The principal effect is that varying pore-pressures modify crack aspect-ratios in systematic ways that can be monitored by analysing shear-wave splitting. Seen with hindsight before about ten earthquakes world wide, this phenomena allows the time and magnitude of impending earthquakes to be stress-forecast. On one occasion we successfully stress-forecast the time and magnitude of a M AE5 earthquake in SW Iceland. Suitable seismic swarms for shear-wave signals are very uncommon. Routine stress-forecasting requires controlled-source Stress-Monitoring Sites (SMSs) in crosshole seismics between 1km-to-2km-deep boreholes to monitor shear-wave splitting along appropriate ray path directions. The first (preliminary) SMS was developed (the EC-funded SMSITES Project) near the onshore continuation of the Húsavú^-Flatey (Transform) Fault at Húsavú^ in northern Iceland. Although the borehole geometry is not optimal, we were fortunate to record multi-variable sensitivity to small scale seismicity at 70km distance, confirming both the science and technology of SMSs for stress-forecasting earthquakes. Single SMSs can stress-forecast the times and magnitudes of impending large earthquakes several hundred kilometres from eventual epicentres. This is analogous to a single barometric weather station, where a rapid drop of air pressure indicates the likelihood of nearby storms. Networks of weather stations, allow systematic patterns and variations of weather to be recognised so that weather can be forecast (with all the inherent uncertainties of critical systems). Similarly, networks of SMSs, with a grid size of 200km-to-300km, say, should enable earthquakes M = 5 to be stress-forecast. Since the accumulation of stress is pervasive, if a SMS network indicated that accumulating stress was threatening a vulnerable city, in principle, the overall increase in stress could be reduced by the release of accumulated stress almost anywhere within the larger stressed volume. This could be by a program of hydraulic fracturing in a non vulnerable region, perhaps offshore. Programs for stress mitigation would be extremely expensive, but would be a small premium to pay for mitigating earthquake hazards for a major city. The Kobe earthquake cost $147B. The overall cost to Tokyo, Beijing, or Los Angeles, could be very much greater. A reasonable premium of 0.5% on $147B is $735M ($735,000,000 US) which would finance a large number of hydraulic fracturing operations.

SW04/09P/A13-011   1645
REALISTIC MODELING OF SEISMIC INPUT FOR MEGACITIES AND LARGE URBAN AREAS: THE UNESCO/IUGS/IGCP PROJECT 414

Giuliano Francesco PANZA[1], Fabio ROMANELLI[2], THE UNESCO/IGCP/IGCP 414 PROJECT TEAM ([1]Department of Earth Sciences, University of Trieste and The Abdus Salam International Centre for Theoretical Physics, SAND Group, [2]Department of Earth Sciences, University of Trieste)

The project addressed the problem of pre-disaster orientation: hazard prediction, risk assessment, and hazard mapping, in connection with seismic activity and man-induced vibrations. The definition of realistic seismic input has been obtained from the computation of a wide set of time histories and spectral information, corresponding to possible seismotectonic scenarios for different source and structural models. The innovative modeling technique, that constitutes the common tool to the entire project, takes into account source, propagation and local site effects. This is done using first principles of physics about wave generation and propagation in complex media, and does not require to resort to convolutive approaches, that have been proven to be quite unreliable, mainly when dealing with complex geological structures, the most interesting from the practical point of view. In fact, several techniques that have been proposed to empirically estimate the site effects using observations convolved with theoretically computed signals corresponding to simplified models, supply reliable information about the site response to non-interfering seismic phases. They are not adequate in most of the real cases, when the seismic sequel is formed by several interfering waves. The availability of realistic numerical simulations enables us to reliably estimate the amplification effects even in complex geological structures, exploiting the available geotechnical, lithological, geophysical parameters, topography of the medium, tectonic, historical, palaeoseismological data, and seismotectonic models. The realistic modeling of the ground motion is a very important base of knowledge for the preparation of groundshaking scenarios that represent a valid and economic tool for the seismic microzonation. This knowledge can be very fruitfully used by civil engineers in the design of new seismo-resistant constructions and in the reinforcement of the existing built environment, and, therefore, supply a particularly powerful tool for the prevention aspects of Civil Defense. We present a selection of the main results obtained for the cities of Algiers, Beijing, Bucharest, Cairo, Debrecen, Delhi, Naples, Rome, Russe, Santiago de Cuba, Sofia, Thessaloniki and Zagreb.

COSEISMIC GROWTH AND SEISMIC HAZARDS OF BLIND THRUST FAULTS IN THE OSAKA BASIN, JAPAN - THE UEMACHI FAULT SYSTEM

Eric Christopher CANNON[1], Karl J. MUELLER[1], Yuichi SUGIYAMA[2], Naoko KITADA[3], Sean SUNDERMANN[4] ([1]Geological Sciences, Colorado, [2]Active Fault Research Center, Geological Survey of Japan, [3]Geo-Research Institute, [4]William Lettis and Associates)

We investigate segmentation, long-term slip rates, coseismic folding mechanisms, and deterministic earthquake scenarios for the Uemachi fault system in the Osaka Basin, Japan using shallow continuously cored borings and seismic reflection profiles. We seek to understand coseismic growth of fault-propagation folds above blind thrust faults. The segmented 45-km-long Uemachi fault system dips east beneath the Osaka Plain and is overlain by shallow subsurface flexures. We analyze gridded surfaces of marine clay layers Ma13 (9 ka) and Ma12 (127 ka) from cores to determine fault segmentation, vertical displacement, and earthquake events recorded in fold limbs. The Suminoe and Shiomibashi flexures, along with the central Uemachi flexure are clearly defined by vertically displaced marine clay layers. We interpret a S-wave seismic profile tied to core where the Yodogawa River crosses the Uemachi flexure. An early Holocene angular unconformity is folded and deformed by layer-parallel faults emerging from strata previously folded in the forelimb of the flexure. A west-dipping, layer-parallel fault appears to have propagated from the upper Tenma Formation into the lower Namba Formation at depths of around 40 m below sea level. A horizon dated at approximately 9.5 ka in the lower Namba Formation is folded upward approximately 3 m westward across the flexure. An 18-m-thick package of growth strata located above the 9.5 ka horizon maintains relatively constant thickness across the fold. These strata are overlain by 2.5-2.9 ka strata that thicken approximately 3 m across the fold, consistent with vertical offset in the 9.5 ka horizon. Assuming a 33° fault dip from Trishear modeling, our preliminary conclusion is that 5.2 m of slip may have resulted from a faulting event 2.5-2.9 ka. We estimate M_w = 7.4 for this event, based on a rectangular fault plane 45 km long and 21 km wide in the downdip direction, 5.2 m of average displacement, and a shear modulus of 3*10[11] dyne*cm[2].

SW04/09P/A13-013   1715
DATA BANK OF THE SEISMIC SOIL RESPONSES FOR SOME DENSELY POPULATED AREAS IN ROMANIA

Stefan Florin BALAN, Carmen Ortansa CIOFLAN, Gheorghe MARMUREANU, BogdanFelix APOSTOL (National Institute of R-D for Earth Physics)

For building safe in Romania, a medium seismicity country, one of the main elements needed to be very well known are the seismic soil responses of the future building sites. In this paper will be analyzed some sites from the cities of Bucharest (capital of Romania), Ploiesti, Iasi and Bacau (important industrial and cultural towns). On these sites were carried out boreholes and geophysical tests to have the geotechnical and geological profiles.As input data for computing the seismic soil response have been chosen the synthetic input of the following Vrancea earthquakes: 30 August 1986 (7.2 MW), 30 May 1990 (6.9 MW) and 31 May 1990 (6.4 MW). Vrancea region is the most active seismic zone of Romania, past earthquakes were of magnitude 7 – 7.5 on the Richter Scale with a lot of life loss and property. All cities mentioned above are on the direction N – E, S – W, main directivity of Vrancea earthquakes.For Ploiesti site were used several variants of fault plane solutions in order to investigate the sensitivity of the method to variations of the seismic source parameters.At present exist many methods of evaluation of the seismic response at the surface of the earth, the majority based on the modeling of the soil deposit like a pack of homogenous and horizontal layers relying on a harder rock, also homogenous but theoretically with infinite thickness, named base rock. Most of these methods are based on the hypothesis that the principal responses of the soil deposit are due to the vertical propagation of shear waves from the base rock. The analytical procedures based on these models/hypothesizes which take into account the non-linear behavior of the soil have given results in accordance with the real behavior of the soil observed "in situ". The authors used a modified Shake91-based program for computing the seismic soil response of our sites of interest in urban areas.In our methodology we determine the variation of G (shear modulus) and D (damping) with the strain in every layer. Soil samples are tested in our Drnevich resonant column and triaxial. As input data, for layers, we use the data got from the geotechnical and geological profiles. For these sites we have computed: stresses and strains for some strata of interest, maximum accelerations at the surface of the soil, amplification spectrum of the soil deposit, response spectrum with different dampings of: 5%, 10% and 20%, acceleration on the base rock - input in deterministic analysis. The data bank consists of 126 graphs. Taking into account the fact that the strong motion records for urban areas

S

are rather scarce, this data bank will be very useful in assessment of seismic hazard and seismic site effects for microzonation purposes.

ASSESMENT OF SEISMIC POTENTIAL BENEATH SAPPORO-CITY AND ON-GOING ACTION PLAN FOR REDUCTION OF SEISMIC DISASTER

minoru KASAHARA[1], Kunikazu YOSHIDA[2], Tsutomu SASATANI[2], Masayoshi ICHIYANAGI[1], Yoshihisa SUZUKI[3], Kazuyoshi MISONOU[3] ([1]Institute of Seismology and Volcanology, Hokkaido University, N10 W8, Kita-ku, Sapporo, 060-0810, JAPAN, [2]Department of Geophysics, Hokkaido University, N10 W8, Kita-ku, Sapporo, 060-0810, JAPAN, [3]Sapporo Fire Bureau, Sapporo-city Government, S4 W10, Chuo-ku, Sappopro, 064-0804, JAPAN)

Sapporo-city was newly established in 1868 and has rapidly developed as one of mega-city of Japan with 1.9 million populations. Therefore there is no historic record of earthquake damage. However many paleoliquifactions are found in urban area of Sapporo-city. At least three times paleoliquifaction have been identified in campus of Hokkaido University during recent 2000 years. The last one might be caused by the 1834 event with magnitude grater than 6.5 which is only one oldest event recorded on documents and might occurred just beneath Sapporo urban area. 36 Felt earthquakes with magnitude greater than 3 originated just beneath Sapporo city have been recorded from 1900 to 2000. The maximum events with magnitude 5 occurred at November 29, 1927 and July 18, 1951. We assessed that Sapporo area may have higher seismic potential than the former assessment. Since 1996 Sapporo-city Government and Hokkaido University have started a project for making new program of seismic disaster reduction. The first step is to establish the basic data acquisition system. A part of the system is to monitor micro-seismicity in and around Sapporo area by employing 3 borehole-type seismic stations with 500m deep. In 2001 one more borehole station with 750 m deep was established in the campus of Hokkaido University. In addition a network of strong motion seismometer consisted of 20 stations are operating since 2000. For 2001-2003, prospecting of seismic basement structure beneath Sapporo-city is now going on. In this prospecting microseism-array measurements at 30 points with maximum 2km diameter, seismic reflection experiment in 17 km long, and seismic refraction experiment of 30 kmlong have been carried out to reveal fine seismic velocity structure to the depth of 4km. By using these results we will make very precise provisional seismic intensity map of Sapporo. Most of these projects are sponsored by National Foundation of The Headquarters for Earthquake Research Promotion.

SW04/09P/A13-015   **1745**

STRONG GROUND MOTIONS IN OSAKA METROPOLITAN AREA FROM THE NEXT NANKAI-TROUGH EARTHQUAKES

Kojiro IRIKURA[1], Hiroe MIYAKE[1], Tomotaka IWATA[1], Katsuhiro KAMAE[2], Hidenori KAWABE[2] ([1]Disas. Prev. Res. Inst., Kyoto University, [2]Res. Reac. Inst., Kyoto University)

The Osaka metropolitan area in Japan has repeatedly suffered from heavy damage caused by subduction zone earthquakes with magnitude 8 or more than 8 occurring along the Nankai-trough. The last ones occurred in 1946 called the Showa-Nankai earthquake as the source area off the Kii-peninsula to the Shikoku-island westward and in 1944 called the Showa-Tonankai earthquake as the source area off the Kii-peninsula to the Enshu eastward. Further going back to the past, the 1854 Ansei-Nankai earthquake occurred in almost the same source area as the 1946 Showa-Nankai earthquake and 32 hours before that the 1854 Ansei-Tokai earthquake occurred with a source area than easterly wider than the 1944 Tonankai earthquake. Moreover, the 1707 Hoei earthquake occurred as the source area including the 1854 Nankai and Tokai earthquakes. Very high probability is estimated for generation of the next Nankai-trough earthquakes. It is an emergent subject to establish a reasonable methodology for predicting strong ground motions from the next Nankai-trough earthquake. Accumulated data of strong ground motions near large earthquakes have been providing us very important knowledge about rupture processes of earthquakes. In particular, the waveform inversion of rupture process using strong motion data showed fault motions consist of some asperities with large slip and background region with less slip. Such slip heterogeneity on the fault plane plays an important role on strong ground motions causing to earthquake damage of structures. Based on the source inversion results for inland earthquakes we found slip heterogeneity inside the fault plane as well as entire rupture area follow the self-similar scaling laws with respect to total seismic moment (Somerville et al., 1999). It means that such inner fault parameters are predictable if the total seismic moment or the source area for a future earthquake is given. For subduction-zone earthquakes, accurate source inversion results have not been obtained enough to make scaling relations of slip heterogeneities. Some inversion results using near-field displacements with low-amplification seismographs and teleseismic data from the 1944 Tonankai and 1946 Nankai earthquakes as well as those using the strong motion records from the 1994 Sanriku-Haruka-Oki earthquake and the 1985 Michoacan earthquake have showed slip-heterogeneity similar to the inland earthquakes. So, we apply the procedure similar to the inland earthquakes to estimating strong ground motions from the future Nankai earthquakes. The applicability of the methodology has been examined comparing the simulated ground motion maps with damage distributions for historical earthquakes.

DEVELOPING A COMMUNITY BASED VELOCITY CRUSTAL MODEL FOR EUROPEAN BORDER REGIONS

Rita DI GIOVAMBATTISTA[1], Remy BOSSU[2], EPSI TEAM[2] ([1]Istituto Nazionale di Geofisica e Vulcanologia (INGV), [2] European Mediterranean Seismological Centre (EMSC))

We present a new community-based, velocity crustal model for European border regions obtained in the frame of the EU funded project "European Parameters forStandardized Information (EPSI)". The 3 main objectives of the EPSI projectwere the following: produce and make available an homogeneous seismological catalogue for M >3 in the Euro.-Med. Region; improve location accuracy in borderregions and create a large Euro.-Med. Database of arrival times. The latter could be used for specific studies(http://www.emsc-csem.org/Html/EPSI_home.html).Although the station coverage in Europe is quite dense,

---

location accuracy remains an issue when events are located outside regional networks. The accuracy of the hypocenter locations is influenced by many factors such asnetwork geometry and knowledge of the velocity models. This become a problemwhen related to seismic risk assessment in near real-time for civil security purposes, knowing that the most seismically active parts of Europe are naturalborders between many countries. To improve the knowledge of propagation models,when available, we used events accurately located by local networks operating for short time periods or artificial events whose exact locations are well known. For every border a dataset of events accurately located by permanent and temporary networks has been realized thanks to the cooperation among the partners. These hypocenter determinations have been used to constrain the propagation models on a regional scale. As a result of the simultaneous inversion of a large number of events, including shots and quarry blasts, specific 1D regional models have been calculated for many borders. The models estimated have been used to locate the events recorded only by the permanent networks to assess the real accuracy of the hypocenter determinations released by the European Mediterranean Center (EMSC).Results are available in the following WEB page:http://www.ingv.it/~roma/reti/epsi/index.htm

AN ENGINEERING APPLICATION OF SURFACE WAVES ON OVERBURDEN SURVEY- A MODEL STUDY

Chao-Hui HSIEH[1], Yue-Hong KUO[2] ([1]General Education Center, Kao-Yuan Institute of Technology, [2]Institute of Geophysics, National Central University)

In this study we used a 2-D wedge plate and a gradually diminishing step model to simulate superficial dip layer to analyze dispersion curves of the surface waves for estimating the thickness of dipping layer. The material plexiglas was used for simulating near surface overburden and then aluminum layer for underlying half-space hard rock. The velocity contrast between these materials is sharp and its ratio is almost 1 to 2.38. To analyze the dispersion curve of surface waves, the peak-trough method in time series was used for velocity determination based on abundant seismograms along a long profile in dense spacing. We found that the surface wave velocity is proportionally related to the ratio λ/d of wavelength (λ) to overburden thickness (d). Due to resolution and wavelet spreading in time domain, it resulted in an ambiguity and uncertainty in velocity analysis. Additionally, the technique of optimum bandwidth filter (OBF) in frequency for group velocity analysis was used to improve the velocity scatting and Wiener de-convolution filtering was applied for phase velocity to eliminate the source problem. In comparing to both dispersion curves, the dispersion of group velocity of Rayleigh waves against the ratio of λ/d was sharply clustered and focused whereas the phase velocity shown more scattering. An empirical formula for group velocity dispersion was derived and was applied for thickness estimation. Based on the results of the model study and field survey, it shows that the energy of surface waves decays linearly in distance and the dispersion curve of group velocity in respect to the ratio of wavelength to overburden depth can be regressively fitted by the empirical formula $V=a(\lambda/d)-1+b$, where a, b are fitting constants, while the velocity changing drastically with λ/d in the range of 3 to 6. Furthermore, a field survey with a multi-channel recording seismograph for the laterite with a thickness 3 -5 m has been carried out and is also shown that an estimating fluctuation ±15% at the depth exploring in comparison with the drilling data was made. Apparently, dispersion curve analysis in small scale for overburden distribution study is available and feasible and it might be, due to low cost and efficient, as a new tool for reconnaissance in engineering application in the near future.

SW05/10A/D-003   Poster   **0900-246**

ON THE DEVELOPMENT OF A SIMPLE HAZARD AND RISK SIMULATION TOOL FOR THE USE OF CIVIL DEFENSE OFFICIALS, DISASTER MANAGERS, DECISION MAKERS AND CITY PLANNERS

Bautista Caparas BAUTISTA[1], Maria Leonila Pascual BAUTISTA[2], Ishmael Clarino NARAG[1], Arturo S. DAAG[1], Ma. Lynn Paladio MELOSANTOS[1], Angelito Galvez LANUZA[1], Raymundo Santiago PUNONGBAYAN[1] ([1]Philippine Institute of Volcanology and Seismology, [2]Department of Science and Technology - Philippine Institute of Volcanology and Seismology (DOST-PHIVOLCS))

The idea of developing a simple hazard and risk simulation tool stemmed from two objectives that we want to achieve at PHIVOLCS. The first of these objectives is to address one of the lessons that we learned from the magnitude 7.8 earthquake which severely affected the central and northern areas of Luzon Island in 1990. Several hours after the occurrence of this earthquake, information about the possible effects or extent of the damage the earthquake had caused could not be obtained because most of the telecommunication systems were either severely damaged or were clogged by heavy communication traffic from people inquiring about the safety of their relatives. For example the City of Baguio, one of the heaviest hit cities was completely isolated from the rest of Luzon due to extensive landslides which blockaded roads and access routes to and from the city. A system that can give a rapid estimate of the possible seismic hazards and the severity of the impacts to population, buildings, lifelines, road networks and other elements at risks is highly needed to generate necessary information for guiding civil defense officials and disaster managers in making quick, timely and reliable decisions for deploying rescue and relief operations. The second objective is the minimization of seismic risk by convincing land use planners, policy makers and city planners to consider earthquake hazards in their planning and development efforts. The provision of this simple and easy-to-use simulation tool will give them a deeper understanding and appreciation of the earthquake hazards and risks and will thus motivate them to do more serious planning and intensive formulation of effective disaster prevention policies such as serious land use regulation, strict enforcement of the building code and retrofitting of critical structures. To realize the above objectives, the simulation tool should be developed in such a way that it will be low cost, widely distributable and easy-to-use. It should not be GIS-based because GIS has a steep learning curve and disaster managers and town/city administrators do not have time to study complicated software. Another reason is that we want to minimize the cost so that it can be widely distributed to as many users as possible. To complete the system within the allotted project schedule of two years, we designed the resolution to be regional to semi-regional in scope and to shorten our programming time, we adopted other existing freely distributable software and algorithms. The hazards that are being modeled in the simulation tool are ground motion, landslide, liquefaction and tsunami hazards. The risk database includes population, road and communication networks, lifelines, high rise buildings, hospitals, schools, fire stations, town, government administration buildings, dams, power plants, fuel depot and other critical facilities.

ROLE OF GERORADAR IN PAVING ROADS

Yehia E. ABDELHADY, Essam A. MORSY, Sherif M. HANAFY, Eid R. ABOEZZ (Department of Geophysics, Cairo University)

Enlarging the road connecting Cairo city and Mokattam Plateau is planned and studied due to the narrowness of this road. The road is planed to be enlarged by 4 m from one side and 3

m from the other side. The subsurface geological section in this area is characterized by Eocene limestone, which is highly fractured and cavernous. Ground Penetrating Radar is a very efficient tool for mapping shallow targets for applications such as those in geological engineering and environmental managements, so GPR technique is selected to resolve this problem due to its ability through or into solid earth instead of physically probing into it with boring, particularly where a closely spaced series of boreholes might threaten the integrity of the soil structure. A 100-MHz antenna GPR survey was performed along the road under study. A total of 6 GPR profiles were conducted with a total length of 1580 m. Two major subsurface anomalies and some other buried utilities are detected at both sides of the road, these anomalous objects are studied in details to evaluate their sources. The reasons of most of the small objects are small buried electric cables or water pipes, while the two major subsurface anomalies are due to two big buried waste pipes. The area is highly fractured but with no evidence of any large cavities.

A STRATEGY OF EARTHQUAKE PREDICTION IN THE BAIKAL RIFT ZONE

Victor S. SELEZNEV[1], Sergey V. GOLDIN[2], Anatoliy S. ALEKSEEV[3], Petr G. DJAD`KOV[2], Vladimir Yu.TIMOFEEV[2], Victor M. SOLOVIEV[4], Alexander F. EMANOV[4], Genadiy I. TAT`KOV[5] ([1]Geophysical survey of Siberian Branch of Russian Academy of Science, [2]InstituteInstitute of Geophysics, Novosibirsk, Siberian Branch of RAS, [3]Institute of numerical analysis and mathematical geophysics of Siberian Branch of Russian Academy of Science, [4]Altay-Sayan Experimental and Methodical Expedition of Siberian Branch of Russian Academy of Science, [5]Geological Institute, Ulan-Ude, Siberian Branch of RAS)

A new strategy of geophysical monitoring in the Baikal rift zone directed toward middle-term earthquake prediction is advanced. To the end of the last century a new level of understanding many aspects of the earthquake physics was achieved. It was understood that each earthquake has its own scenario (and it explains why precursors often are contradictory), that the zone of preparation is much larger than the size of the future foci, that the earthquake is not a result of temporal accumulation of stresses, but result of complicated interaction of different blocks of the Earth Crust, that the earthquake preparation is not only mechanical process but interaction of many processes of different physical nature, that active zones can rather fast change their stress conditions, that seismic activity can be considered as ˝critical-state˝ process only in the context of the whole zone activity. We understand that a good middle-term forecasting must be based only on massive data of different geophysical, hydrogeological, geodetic, etc. observations, that has to be obtained in a rather dense network in the regime of monitoring. And, finally, we must understand the nature of temporal variations of different geophysical characteristics in a framework of a reasonable physical conception. Probably the kinetic theory of fracture is capable to give only schematic explanation of the stages of brittle fracture, as for very important stages of plastic deformation we have to attract a recently developed physical mesomechanics. Authors of the paper concentrate their efforts in developing of following directions: 1) developing of a new model of the surface dilatancy zone, which generates many strongly variable interrelated anomalies in geophysical fields; 2) solution of inverse problem for determination of coordinates of initial stress concentration in a block media with no rigid contacts, based on observations of surface deformations, tectonic-magnetic fields, earthquake mechanisms; 3) development of methods for solving multidisciplinary inverse problems of geophysics directed to construction of integral earthquake precursor; 4) understanding that the process of weak events strongly reflects different stages of the earthquake preparation stipulates for search of Ginsburg-Landau type equation, which could give adequate description of the process and new possibilities for prediction of time of the main event; 5) development of methods of vibroseismic monitoring , methods of high-resolution tomography of focal zones, and methods of seismic and geodetic study of active fault zones. Today there is concentrated a complex of geophysical observations at the South Baikal predicted ground for carrying out of geodynamic and seismic processes control. It includes both seismological observations and more then 15 methods of geophysical monitoring. As a result of long-term analysis of connection of seismic activations and changes in geophysical fields there were revealed some criteria of middle-term prediction at the south of Baikal Lake.

WLH 1.0 - WAVELAB AT HOME - A NEW TOOL FOR SEISMIC WAVES ANALYSIS ON PERSONAL COMPUTERS

Andrea BONO, Lucio BADIALI (Istituto Nazionale di Geofisica e Vulcanologia, Rome, Italy)

A new system for acquiring and processing digital signals has been developed in the last few years at the Istituto Nazionale di Geofisica e Vulcanologia (INGV). The Italian National Seismic Network at present gathers into the computer data centre in Rome the seismic signals from its own sensors and from other regional and local collaborative networks. The result is a virtual network larger than the original one. Communications are partly through wired analog and digital ones, and partly through satellite digital ones.The WLH (WaveLab at Home) system has been developed to show the waveforms recorded by the brand new automatic system, to make manipulations such as filtering and baseline corrections, to pick seismic phases and quickly manage their weight. It can also import and export phases in Hypoinverse 2000 standard and so launch standard localisation routines. Waveforms come from the reliable triggering system and from the continuos file buffer recording, and are normalised according an internal format, but SAC (Seismic Analysis Code) format is also available. More file formats as a user´s choice can be added if needed by the scientific community.So WLH is a very fast and user friendly system that allows the user to study seismic events on every windows personal computer with 700KBytes of free disk space. It can be used at home, on a workstation or on a notebook and it's completely free.

RESEARCH ON ESTABLISHING ECOLOGICAL INFORMATION SYSTEM OF WETLANDS WITH GIS

Min HAN[1], Xue TIAN[1], Hua MENG[1], Jixin YANG[2] ([1]School of Electronics and Information Engineering, Dalian University of Technology, [2]Songliao Water Resources Commission)

Wetlands are a very important kind of multi-functional resource. In the last few decades this rare resource attracts many people's attention. At present, it becomes to be a trend to apply some new methods and information technology to study interdisciplinary scientific problems. Wetland is an intercross research field. On the aspect of utilizing Geographic Information System in wetland research, there are already some positive results. For example, the researchers in Alabama Agriculture and Mechanical University have applied GIS and Remote Sensing technique to manage natural reserves in kakum national park, Ghana, and Natl biological organization of U.S.A applies GIS to the ecosystem management of wetlands. In China the study of GIS started in the early 1980's But until now there is no much work to apply GIS into wetlands management. Zhalong wetland, one of important National Natural Reserves and Ramsar sites, is located in northeast of China. The total area of the wetland is 2100 km2 and the water surface is about 800 km2. it is the natural habitats of numerous

animals and plants, especially some higher grades national protection rare birds. For instance, there are only 2000 Red Crown Cranes in the world, while Zhalong Wetland has 346 in the same time (data 1996). As a whole, the ecological resource of Zhalong Wetland includes 277 species of insects, 46 species of fish, 266 species of birds and 21 species of beasts. There are also 468 species of plants and a lot of microorganisms. Combining with the geographical, geological and hydrological information, Geographic Information System (GIS) should be an efficient tool to manage and analyze all of these kinds of spatial data. So that setting up a perfect ecological information system is indispensable for wetland protection and management. This paper, aiming at establishing an ecological information system of Zhalong Wetland based on GIS, presents a procedure to sort ecological resources of wetlands and establish a wetland GIS. The Zhalong Wetland GIS is established by use of ARC/INFO8.2 software. By designing suitable formats of maps, photographs, video records, figures and tables, the information can be easily understood. The designed links make the data visit conveniently and friendly. Some simple data analysis functions are also considered. In order to build a general system, the combination of GIS and GPS has been tested. The system can show the current situation and historical background of the wetland comprehensively. The result proves that GIS is an effective tool to set up an Ecological Information Systems of Wetlands.

GTOOL: I/O LIBRARY AND ANALYSIS TOOL FOR GRIDDED DATA

Eizi TOYODA[1], Shin-Ichi TAKEHIRO[2], Masaki ISHIWATARI[3], Yoshi-Yuki HAYASHI[4] ([1]Numerical Prediction Division, Japan Meteorological Agency, [2]Faculty of Sciences, Kyushu University, [3]Graduate School of Environmental Earth Science, Hokkaido University, [4]Graduate School of Science, Hokkaido University)

As the capacity of computer and network grows, scientists face to needof more efficient handling of vast and multi-source data. Making commondata format and sharing software will reduce efforts of such kind. Theauthors will report on ˝gtool˝, a software infrastructure for atmosphericsimulation models of GFD-Dennou Club. GFD-Dennou Club has distributed freely AGCM5 (Atmospheric GeneralCirculation Model), shallow water model, and barotropic model on itswebsite (http://www.gfd-dennou.org).AGCM5 was developed by A. Numaguti and colleagues at theUniversity of Tokyo in the early 1990s, through reorganizing GSM (GlobalSpectral Model) of Japan Meteorological Agency. Input and output data ofthese models are unified to the GTOOL3 format which is accessed throughsubroutines in GTOOL3 library. Data analysis tools distributed with thelibrary provide simple data analysis like sub-array extraction,averaging over axis, or visualization. Software is mostly written inFortran. GTOOL3 file format is a unformatted sequential file of Fortran. It is alist of record pairs called header and data; the header containsmetadata of main data. Header is designed so as to be dependent to domainknowledge as little as possible. For example, it describes coordinatesystem of data without depending meaning like latitude or longitude;averaging tool works for data notonly in spherical grids on earth, but also in any curvilinear orthogonalgrids. The header record also includes fields to control graphic appearance of data.Therefore, users can exchange figures by sending only data files, and thefiles can be used for furthur analysis. However, the GTOOL3 environment have following limitations. Firstly, thefile format, originally derived from magnetic tape of mainframecomputers, has portability problem like byte ordering.Secondly, the file format has little extensibility;it has no room to handle additional attributes orarray with four or more dimensions. At last, the interface of the library is hard to memorize, due tolimitations of FORTRAN 77. Therefore the authors started a project ˝gtool4˝ to rewrite theinfrastracture from scratch. The file format is based on NetCDF, that providesdata portability and extensibility. The software is written in Fortran90 to have simplier interface and clearer layer structure. Though the gtool4library and tools are still in experimental state, the authors areworking to improve it and link it to future AGCM.

NONSTATIONARY TIME SERIES MODELING FOR SIGNAL EXTRACTION PROBLEMS IN SEISMOLOGY

Genshiro KITAGAWA[1], Tetsuo TAKANAMI[2], Norio MATSUMOTO[3] ([1]The Institute of Statistical Mathematics, Minami-azabu 4-6-7, Minato-ku, Tokyo 106-8569 JAPAN, [2]Institute of Seismology and Volcanology, The Graduate School of Science, Hokkaido University, Kita 10 Nishi 8, Kita-ku, Sapporo 060-0810 JAPAN, [3]Geological Survey of Japan, National Institute of Advanced Industrial Science and Technology, 1-1-3 Higashi, Tsukuba Ibaraki 305-8567 JAPAN)

Due to recent progress of measurement and telemetry devices, it becomes possible to access to huge amount of observations obtained at many locations automatically. However, in the analysis of micro-earthquakes data, we face two difficulties. Firstly, the seismic signals observed by seismometers are contaminated by various kinds of natural forces, such as micro-tremors, microseisms, wave, wind, tide, air pressure, precipitation and a variety of human induced sources. Since the noise level is almost a constant independent on the signal, the effect of the background noise becomes more severe for earthquakes with smaller magnitudes. Therefore, to analyze seismic signals with smaller magnitudes, we need to develop a sophisticated procedure that can handle very noisy data. Secondly, the number of earthquakes increases exponentially as the magnitude decreases. Seismograms have been conventionally handled by empirical methods based on the human expertise to separate real seismic signal from various noises. However, for the processing of huge amount of micro-earthquakes, it becomes necessary to develop a computationally efficient statistical method that can automatically detect seismic signal from noisy data. In this paper, we use various non-stationary structural time series models for the extraction of seismic signal from noisy data. We describe five specific examples of time series modeling for signal extraction problems related to seismology. Namely, we consider 1) the estimation of the arrival time of seismic signal, 2) the extraction of small seismic signal from noisy data, 3) the detection of the co-seismic effecting groundwater level data contaminated by various effects from air pressure etc., 4) analysis of OBS (Ocean Bottom Seismograph) data and 5) the estimation of changing spectrum of seismic record. In most cases, the models can be expressed in state space model form, that enable us to apply a computationally efficient Kalman filter or an extension of it. Throughout the paper, we use the Akaike Information Criterion (AIC) for the evaluation of the goodness of the model that plays crucial role in establishing automatic signal extraction procedures.

DATA BASES AND SYSTEM OF THE SATELLITE ALTIMETRY AND GEOPHYSICAL DATA PROCESSING FOR APPLICATION TO SOLVING GEOPHYSICAL, GEODETIC AND OCEANOGRAPHIC PROBLEMS WITH REMOTE ACCESS

Petr P. MEDVEDEV[1], V. NEPOKLONOV[2], D. MEDVEDEV[3] ([1]Geophysical Center of Russian Academy of Science, [2]Research Institute of the Defence Ministry RF, Moscow, Russia, [3]Bauman Moscow State Technical University, Moscow, Russia)

The system creating for the solving problems of geophysics, oceanography, geodesy, and environment monitoring. Presented general structure of the system, the structure and configuration of its main technical, informational and software means. The processing

S

methods and forms of representation of the processing results of the satellite altimetry and geophysical information were developed and discussed. For development of the system and remote access technology used local area system server (with WEB-server Apache and MySQL database server).The activities of the geophysical database creation were started. The software modules for some separate analysis stages and processing of the satellite altimetryand geophysical data were developed and discussed. The modules include programs for processing of the geophysical fields digital models and solution of the separate problems of preprocessing and graphical visualization data. The programsfor the modelling of the gravity potential and the satellite altimetry data processing was development also. They include defining the instant and average level of sea surface, detailed characteristics of the gravity field, display of tides and other geophysical parameters in the ocean in the form of digital models and images. The problems of optimizing satellite altimetry database and the system of measurements processing are discussed. The structure of a databaseand processing programs providing a sufficiently fast access to data and processing procedures that were developed in the Geophysical Center RAS is presented. The problems of the application of the distributed data archives and of the parallel processing data are discussed. The technology of the remote access to a system was tested on the example of some fragments of the geophysical database. The samples of the satellite altimetry data application to the studies of the instant and mean level variations of the Sea of Okhotsk, Baikal Lake and of the geodynamics of the Western Pacific seismic volcanic belt are presented. The research was supported by RFBR (project 01-07-90106).

PROTOTYPE OF THE LOGICAL BASIS FOR GEOLOGICAL DATA REPRESENTATION IN INTERNET

Pavel Yu. PLETCHOV[1], Sergey V. TROUSOV[1], Dmitry A. VARLAMOV[2], Kirill A. BYCHKOV[1] ([1]Moscow State University, Geological department, Moscow, Russia, [2]Institute of Experimental Mineralogy, Chernogolovka, Russia)

In recent years goes the active search for the united basis, on which the classification of information can be built, its search and representation in Internet.Very frequently, GIS or other cartographic systems are proposed for geological data.However, there is an enormous quantity of geological information, which cannot be directly attached to the cartographic basis or this tying is deprived of large sense.To this information can be related practically all information flows in the geosciences, represented in Internet: descriptive (articles, books, lectures)event-related (monitoring, news, conferences)debatable (considerations, questions/answers)reference (databases, catalogs, library)interactive resources (simulations, the specialized calculations, demonstration programs)Descriptive, event-related or debatable information flows are served well in standard content control scheme (Content Management System).Such systems successfully work on all large dynamic WWW-servers, including the scientific content (for example, Russian-language system in the geosciences is supported in http://geo.web.ru). These types of information flows can be easily represented in the ˝pseudo-static˝ form and integrated in Internet by different level search engines (internal navigators, local search, global search engines).On the other hand, presentation in Internet of different databases and data collections, actual catalogs and interactive resources causes both technical and conceptual difficulties.The main problems include the different (often incomparable) structure of data, the absence of the standards scheme of the specialized information, the ˝variety˝ of database interfaces and difference in the tasks of the information compilers. The development of the additional semantic links between the information objects of different directivity is a promising trend in development of common information space in the opinion of the authors.The first realization of system with the additional dynamic links between the information objects is represented in the Russian Virtual Geoscience Network (http://geo.web.ru).The basis of the construction of dynamic links composes the common space of search algorithms of different purpose, which consider coordinate and contextual information, type of information, subject directivity and other factors. Articles, lectures, term definitions, answers to questions, conference proceedings, databases, programs, internet-resources etc. can be included by a similar system.This work was supported by Russian Foundation for Basic Reasearch.

THE IRIS DATA MANAGEMENT CENTER: ENABLING DATA ACCESS THROUGH NEW TECHNOLOGIES

Rick B. BENSON, Tim K. AHERN (IRIS Data Management Center)

The IRIS Data Management Center is an example of a highly automated, activedata center dedicated to managing various geophysical timeseriesdata, specializing in access to seismic data. The DMC has adopted robust technologies that allow for the continuous acquisition of realtimedata, an automated, tape-based mass storage approach to management of thesedata, and electronic distribution of a large percentage of its´ holdings onan annual basis to a globally distributed community. The IRIS DMC manages approximately 30 terabytes of waveform data, seperatelymanaged metadata, and ingests approximately 8 terabytes of data annually. Withthe addition of data from USArray portion of Earthscope, this rate of ingestion should double in the next few years. Inaddition, requests are serviced in a near real time mode for a large percentageof customized requests, and completes approximately 50,000 individual requestseach year. This discussion will focus on the newest technologies that have been introducedwithin the last couple of years that illustrate how research has been supportedby the IRIS DMC. In particular, we will illustrate how software hasbeen adopted that support the idea of ˝information-to-application˝ mechanisms,utilizing web services, which keep researchers connected to the most up-to-date information stored inmanaged databases, and accessed directly by client-side applications. This will reduce the need for extensive middleware that powered the 1990´s ˝request-and-deliver˝ mechanisms. In addition, we will illustrate a networked data center concept, called NetDC, whichallows data retrieval across distributed archives with no need to know where the dataexist. In conclusion, we will discuss the newest adoption of technology, the CORBA-basedFISSURES project, and illustrate how information can be passed between networkeddata centers and into client side applications. By defining classes to seimological˝objects˝, clients have been written that access distributed databases and importresults into applications. We will show examples of this Data Handling Interface

(DHI),a service designed to directly connect information at the IRIS DMC with applications running on the client side.

SW05/10P/A13-003 **1435**

AN INTERNET-BASED COMPREHENSIVE EARTHQUAKE DATABASE AND USER SERVICE SYSTEM

Zhonghe ZHAO[1], Chao ZHOU[2], Zhe ZHANG[2], Xinheng LUO[2] ([1]WDC for Seismology (Beijing), National Center for Seismic Information, CSB, 56 Sanlihe Road, Beijing 100045, China, [2]TAIDE Enterprise Co., Ltd., Chengxin Building, 284 Meihuadonglu, Xiangzhou, Zhuhai 519000, China)

We have developed an Internet-based comprehensive earthquake database and user service system. The main purpose of our work is to find a proper way to provide scientists with different kinds of earthquake-related data, so that users can browse and download required data easily and effectively via Internet. On the other hand, with this system, the service provider can maintain the system easily and effectively, including user's authorization management and database updating. The prototype system is built on a Linux platform and uses a relational database management software (Oracle). The system is a type of Browser-Server-Database system, users can get into it with their own Web browsers. With an earthquake catalogue search as the basic search, the user will obtain a list of earthquakes within given ranges of date, space and magnitude. Then the user can select one event (instead of this search, one can directly point to an important event in a short list at the first page), so as to get all or selected kinds of data related to this event , for instance, the basic parameters of the event (origin time, latitude, longitude, focal depth and magnitude), list of seismic stations which recorded the event, waveform data, phase data, Centroid Moment Tensor and/or focal mechanism, isoseismic map, related field pictures etc., as long as they exist in the database (For small events, there may be not so many kinds of data.). Also, for this group of events, the system can show the epicenter distribution map, focal mechanism distribution map and so on. Another aspect for this data service system is the routine maintenance of it. In addition to the continuous operation of the system hardware and software, user's authorization management and data updating are two of important issues. It is desirable to establish a flexible user authorization scheme so that the system manager can give different authorization (read only specific kind(s) of data, modify or update specific kind(s) of data, etc.) to different users. As to the updating of data, we have established some mechanism to receive data in the form of e-mail messages and automati- cally decode and put them into the database. Besides, with this prototype system as an example, discussion will be given to the general solutions for helping users to get data they need more effectively via Internet and helping data service providers to maintain the system and update the data more easily.

SW05/10P/A13-004 **1450**

CHALLENGES IN MANAGING AND DISSEMINATING DATA IN THE CANADIAN NATIONAL DATA CENTRE

Jim LYONS, Nina MARKOVA, Xiuying JIN, Luc SAUMURE, Philip SHOTT, Jim BLINKHORN, Chris MAJEWSKI, Tim COTE, Khalil HAYEK (Geological Survey of Canada)

The Canadian National Data Centre (CNDC) in Ottawa receives real-time datafeeds from over 100 stations of the Canadian National Seismograph Network(CNSN). In addition, since January 1, 2002, real-time data streams from POLARIS(a Canadian geophysical research consortium focused on the estimation ofearthquake ground motion and Earth structure) has been acquired and processedalongside the CNSN data. A combined total of ~2 Gigabyte/day (andgrowing) of continuous, compressed real-time data must be acquired,quality-controlled, processed, and archived. Since archiving of continuous waveformdata began in 1989, ~3 Terabytes have accumulated. In addition, over 39 GB ofsegmented data have been acquired from the former digital regional telemeterednetworks and numerous special data sets comprising field studies, aftershocksurveys, etc. Efforts continue to focus on two main areas: To capture and manage allCanadian seismological data in a consistent fashion suitable for loading into anational database, and to make as much data as possible freely available to theglobal research community over the Internet. Problems and challengesencountered have included: (1) With the lengthening history of analog anddigital stations, extending the traditional notions of station and networknaming to handle cases where stations may change location, changenetwork/deployment affiliation, or even change name over time; (2) Developingsoftware to reformat digital waveform data to a standard internal format, andfrom internal to various commonly-used external formats; (3) Gathering andcharacterizing the time history of associated station information such as timecorrection and station response, and tying the time-appropriate information towaveforms when distributing data; and (4) Developing usable tools to satisfyrequests for diverse data sets in as automated a fashion as possible. Since May 1994 the CNDC AutoDRM program has been extremely successful indistributing waveform data. Recently, even the need to learn the AutoDRMcommand set has been relieved via installation of a clickable web-based request form. Tohandle event-related (time-segmented) files, a new web-based facility has beendeveloped that generates graphical images and triggers format conversionon-the-fly. This eliminates the need to store event data in more than oneformat. In its role as Canada´s CTBT National Data Centre, the CNDC provides continuous real-time data from three primary stations and time segments on request from six auxiliary stations to the CTBT InternationalMonitoring System (IMS). Meeting stringent IMS requirements for overallavailability and timeliness of contributed data has led to the development of anumber of specialized tools for quality control.

SW05/10P/A13-005 **1505**

MULTIPLE APPLICATIONS OF REAL-TIME SEISMIC INFORMATION

Yukio FUJINAWA, Shigeki HORIUCHI, Hiroaki NEGISHI, Yoshinari HAYASHI, Aya KAMIMURA, Takaki IWATA, Kana ABE, Shouhei MIURA, Takumi MATSUMOTO, Hiroyuki FUJIWARA, Takashi KUNUGI (National Research Institute for Earth Science and Disaster Prevention(NIED))

Extensive seismic networks have been constructed nationwide composed of high sensitivity seismographic network (Hi-net), broadband seismographic network (F-net) and strong motion seismographic network (K-NET). All these data from NIED and those from JMA and universities have been collected and distributed through NIED to scientists and engineers through the Internet under the coordination of the National Seismic Research Committee of MEXT. As a practical application of those data we are now developing a real-time seismic information system (REIS) for the purpose of providing estimated seismic parameters to prescribed users concerned with seismic risk reduction. Contents of information to be issued from NIED include seismic focal parameters (several seconds after detections of seismic signal at the nearest site), seismic fault plane solutions (some 10-20 seconds), after-shock activities (several minutes ~ a few days). Once earthquakes occur those parameters are to be calculated as soon as enough data are collected, and revised successively as seismic signals are received at a larger number of sites in time with the result that more accurate and more sophisticated earthquake information is transmitted to any of the prescribed users. The transmitted parameters are used by application systems at sites to build specific

information for particular users in order for triggering various disaster mitigation countermeasures including automated and/or half-automated responses. The focal parameters are used for short-term warning of imminent strong grounds motions from major earthquakes. Another important application is an immediate estimate of expected shaking distribution and damages in a district using synthetic database and site effects for local governments to take initial proper measures of hazard mitigation. Many of applications are to be developed under the coordination of consortium of concerned organizations and private companies (real time earthquake information consortium: REIC). Tasks of REIC include standardization of data format of real time seismic information in order of easy handling of data by various kinds of users concerned. The system has been tested from early June in 2002 for evaluation of the whole system. In the initial stage of development we are using high sensitivity data including Hi-Net, Kanto-Tokai belonging to NIED to estimate focal parameters. The REIS has been evaluated using true data, and now we are able to estimate the focal parameters of targeted earthquakes in sufficient speed and accuracy. The remaining errors or mistakes have been tried to reduce with the result of progressive increase of performance. The first test user is Fujisawa City in the Kanagawa prefecture of population of 380,000. The REIS of the first phase can estimate strength and arrival time of selected earthquakes. The system for the second phase will be able to estimate disaster from seismic wave and tsunami for any number of particular sites. Those data are to be used for the development of particular safeguard equipment and personal actions in the early stage and for the practical use afterward.

SW05/10P/A13-006   1520

THE INFORMATION SYSTEM OF SATELLITE GEODESY DATA IN GEODYNAMICS AND SEISMOLOGY

Yuri S. TYUPKIN[1], Peter P. MEDVEDEV[1], Mikhail N. ZHIZHIN[2], Andrei N. POLYAKOV[2] ([1]Geophysical Center, RAS, [2]Institute of the Physics of the Earth, RAS)

The information about deformations of the Earth´s crust and velocities of the present Earth´s crust motions are of great significance for a wide range of geodynamics and seismology problems. Modern observation systems are based on the techniques of satellite geodesy, which allow us to determine the deformations of the Earth´s crust and velocities of its motion with a high degree of accuracy. The information system ˝Satellite Geodesy Data Interpretation in Geodynamics and Seismology˝ is reported. The information system includes: - Database of the present Earth´s crust motion data. - Database management system based on a GIS approach. - Problem oriented software. The database contains the results of international networks of GPS, VLBI, SLR and DORIS observations, data of regional and local GPS networks: CORS, REGAL, RGP, SCAR, SIRGAS, and data of temporal observation campaigns in Western Alps (GPS ALPES group), in South and South-East Asia (project GEODYSSEA), in China (CMMN and CMONC stations) and in Central Asia (project IVTAN). All data are obtained from public Internet sources and from publications. The software provides a user with the following functions: - To display the spatial distribution of velocities of the present Earth´s crust motion obtained by different networks in ITRF 2000 frame; - To recalculate this distribution in the frame linked with the individual tectonic plate; - To calculate the velocities of motion of tectonic plates on the basis of NNR-NUVEL-1A model and Actual Kinematics Model; - To calculate statistical parameters of Earth´s crust motion velocities for a selected area; - To compare the distributions of Earth´s crust motion velocities of different areas; - To calculate the gravity anomalies for selected area. A local version of the system is presented. The network version of the system is under the construction. The research is supported by the Russian Basic Research Foundation (Projects 02-07-90087, 02-07-06006 mas, and 01-07-90101).

SW05/10P/A13-007   1530

APPLICATION OF STRESS INVERSION METHOD TO GPS ARRAY DATA OF JAPANESE ISLANDS

Muneo HORI, Takeshi IINUMA, Teruyuki KATO, Kenji OGUNI (Earthquake Research Institute, University of Tokyo)

The stress inversion method is aimed at identifying stress distribution for a body whose stress-strain relation is partially known. While the method is applicable to a body in plane stress or strain state, the validity of the method is rigorously proved. The method finds equilibrating stress for a given strain distribution, by solving a well-posed boundary value problem; the problem is derived from the two equations of equilibrium and one known stress-strain relation for the three stress components. The usefulness has been examined in experiments of various materials. This paper reports the applicability of the stress inversion method of identifying stress distribution to the Japanese Inlands by using displacement increment data which are measured by the nationwide GPS array of the Japanese Islands. The method is applied to several data sets. The boundary value problem of the stress inversion method is numerically solved when the GPS data are used as input. The accuracy and the stability of the numerical calculation are verified. When the GPS data which are not spatially filtered are used, the stress inversion method finds non-uniform distribution of regional stress. This is because the displacement increment accompanies regionally varying strain increment and stress increment spatially varies to satisfy the equilibrium. The results of the stress inversion method are discussed. The limitation of the method in applying the GPS data is discussed as well. References M. Hori, T. Kameda and T. Kato: Application of stress inversion method to predict stress distribution in Japanese Islands, *International Journal of Geophysics,* 144, pp. 597-608, 2001. M. Hori and T. SW05/10P/A13-008   1545

ANALYTICAL WEB GIS FOR DECISION SUPPORT IN SEISMOLOGICAL PROBLEM DOMAIN

Valeri G. GITIS[1], Gennady L. ANDRIENKO[2], Natalia V. ANDRIENKO[2] ([1]Institute for Information Transmission Problems, Russian Academy of Sciences, B.Karetnyi Lane, 19, 127994 Moscow, GSP-4, RUSSIA, http://www.iitp.ru/projects/geo/, e-mail: gitis@iitp.ru, [2]Fraunhofer Autonomous Intelligent Systems Institute, Schloss Birlinghoven, Sankt-Augustin, D-53754 Germany, http://www.ais.fhg.de/and/, e-mail: gennady.andrienko@ais.fhg.de)

Geoinformation approach to seismological modeling deals with (A) a continuity variation of geological environment and man made infrastructure as well as with (B) geographical objects such as earthquake epicenters, geological faults, seismic source areas and infrastructure elements. Both grid-based and vector data types are necessary to present this models in GIS. Key problems of GIS application to seismology are (i) forecasting social and economy loses, (ii) spatial forecasting of seismic hazard, and (iii) earthquake prediction. The goal of analytical Web-GIS oriented to the seismological problem domain is to provide online access to seismological data analysis for everyone, from everywhere, and at any time. It appears that web-GIS tools must be powerful enough to support decisions in (i), (ii), (iii) problems and must be easily controlled and understood for persons who are not experts in GIS. Often analytical web-GIS or its part are realized in Java applet architecture and enter into the web-page. After web connection such web-GIS is automatically loading and stating on client computer. Java applets can work on any platform where standard Internet browser has been installed. Modern analytical web-GISs support the following facilities for seismological spatial and spatio-temporal data mining: (A) Visualization: interactive dynamical visual data exploration, (B) Analytical transformations: calculating a wide class of functionals, which include transformations from grid(s) to grid-based data, from grid and vector to vector attribute data, from vector to grid based data, and from vector to vector based data, and (C) Plausible inference: discovery of multidimensional relationships to forecast the goal properties and to detect the goal objects. Analytical tools realized in CommonGIS (http://www.ais.fhg.de/and/), GeoProcessor and COMPASS (http://www.iitp.ru/projects/geo/) as well as applications of sophisticated dynamical visualization to earthquake prediction research, analytical transformations to seismic loses assessment and plausible inference to delineation of potential seismic zones by geological and geophysical features are considered. The work was partly supported in 2000 AE2002 by projects 'Spatial Mining for Data of Public InterestAE(IST Program, IST-1999-10536 SPIN!) and ˝Web GIS for presentation and analysis of spatio-temporal information referring to Earth Sciences and human dimension (Russian Basic Research Foundation, 00-07-90100).

INTERACTIVE INVERSE MODELLING FOR NON-LINEAR EARTH PROCESSES

Chris WIJNS[1], Fabio BOSCHETTI[2], Hideyuki TAKAGI[3], Louis MORESI[4] ([1]School of Earth and Geographical Sciences, University of Western Australia, Crawley, WA 6009, Australia, [2]CSIRO Exploration and Mining, PO Box 1130, Bentley, WA 6102, Australia, [3]Kyushu Institute of Design, Shiobaru, Minami-ku, Fukuoka 815-8540, Japan, [4]School of Mathematical Sciences, Monash University, VIC 3800, Australia)

Inverse modelling of earth processes, in the absence of established numerical criteria to act as targets, requires an approach which incorporates human interaction in directing the inversion. For example, geologists often draw tectonic models to illustrate some concepts of crustal evolution. Often, such conceptual models cannot be translated into numerical target data; first, because the model is only approximate and features are representatively, not exactly, located; and second, due to the experience-based, empirical nature of geology, because the evaluation criteria reside inside the mind of the geologist, and do not constitute hard data. However, the merit of such a conceptual model will still follow from its physical plausibility, *e.g.* from the ability of a numerical model to reproduce the concepts and answer related questions. Recently, research in artificial intelligence has resulted in systems to support human interaction in optimisation problems. The technique of interactive evolutionary computation (IEC) provides for the inclusion of qualitative expertise within a rigorous mathematical inversion scheme, by simply asking an expert user to evaluate a sequence of forward models. The traditional numerical misfit is replaced by a human appraisal of misfit. Successive rankings of model outputs are linked to an evolutionary computation algorithm, in our case a genetic algorithm, which provides optimal convergence into the target parameter space. The method is particularly geared towards cases of highly non-linear interactions between model parameters, where resultant behaviour is difficult to predict. We use this interactive technique to successfully invert a tectonic model for a conceptual pattern of fault spacing during crustal extension. By letting a number of rheological parameters vary, we quickly find a few combinations which produce forward models satisfying our visual target. Our IEC system, linked to different forward modelling codes, has become a standard tool for modelling at CSIRO in Perth, Australia. Where previous trial-and-error approaches have taken weeks to produce target results, using IEC, we have found solutions within days for thermal profiles during mantle convection, tectonic deformation patterns, and mineral assemblages in geochemical systems. Since the genetic algorithm optimises an ensemble of solutions, the non-uniqueness of the problem may be explored to some extent. We choose a visualisation technique known as self-organised mapping to represent the parameter space covered by the model outputs. This is one type of mathematical projection which produces a simple view of an otherwise complicated multi-dimensional problem. For our example of crustal extension, we use a few graphical displays of the data to characterise the influence of the different rheological parameters on the resulting pattern of faulting in the model.

NEW ENGINEERING-GEOPHYSICAL TECHNIQUES FOR GEOPHYSICAL AND GEODYNAMIC MONITORING OF SIBERIA TERRITORY

Victor S. SELEZNEV, Victor M. SOLOVIEV, Alexander F. EMANOV (Geophysical survey of Siberian Branch of Russian Academy of Science)

The outcomes of modern geophysical researches of the Geophysical Survey SB RAS, directed on study of geodynamic situation in large industrial and civil centers on the territory of Siberia with the purpose of an evaluation of seismic risk of territories and prediction of origin of extreme situations of natural and man-caused character, are presented in the paper. First of all it concerns woks with use of high-output digital equipment for study of seismic regime of territories with the purpose of evaluation of influence of weak but long seismic actions for various constructions and people. Lately, along with passive seismic monitoring, there are developing in GS SB RAS works on active vibroseismic monitoring with use of powerful 40-60-tons vibrators in territories of large oil-and-gas fields with high man-caused seismicity and at control of particularly dangerous structures. There are also given the outcomes of researches with use of new engineering-seismological method on evaluation of physical state of industrial and civil objects (buildings and structures, hydroelectric power stations, bridges, dams and so on). This technique allows to carry out observations of wave field in investigated objects (as a source it could be used both artificial ones and seismic noise) with use of multiplex equipment by detailed system of observation. Orientation was made on standing waves appearing in buildings and structures, which carry information about structural peculiarities of the investigated objects. Along with engineering-seismic techniques at solving of geological, engineering-geological, ecological and other important economical and scientific problems, tomographic technique of electromagnetic scanning was widely adopted in the regions of Siberia. This technique was developed in Siberian Branch of RAS. There are given the examples of efficient use of this technique in solving of some important problems, such as: localization of zones of invasion, determination of subterranean and man-caused waters level, rock failure and landslide prediction, monitoring of communications and underground reservoirs.

SOFTWARE TOOLS FOR ANALYSIS OF SEISMICITY VARIATIONS AND ITS APPLICATION FOR THE PREDICTION OF THE LARGE KAMCHATKAN EARTHQUAKES

Vladimir V. IVANOV, Nadejda M. KRAVCHENKO (Kamchatkan Experimental and Methodical Seismological department, Geophysical Service, RAS (KEMSD GS RAS))

There are several methods of intermediate-term earthquake prediction based on the investigation of weak seismicity variations. It is supposed that a seismic quiescence followed

by foreshock activation can be found before earthquake in its epicentral area. Therefore for the earthquake prediction it is important to clearly recognize an areas with anomalies of seismic quiescence and foreshock activation. The technique proposed by Sobolev and Tyupkin (1996) is used to discern areas of seismic quiescence. It is based on calculation of a predictive parameter, RTL. RTL parameter is the composition of three functions: epicentral R, time-dependent T, and L corresponding for the size of the earthquake source. Seismic quiescence can be characterized by negative values of the RTL parameter in comparison to its perennial background. Analysis of density of seismogenic faults can be used to recognize areas of the foreshock activation. We present the application software specially designed for study of weak seismicity variations using RTL prognostic parameter and density of seismogenic faults. Anomalies in low magnitude seismicity can be discerned more clearly and precisely using this software. It has interactive visual workspace and easy to use interface. This software has a lot of special features for seismic quiescence area localization and detailed study of the seismic process. This software is used at Kamchatkan Experimental and Methodical Seismological Department, Geophysical Service, Russian Academy of Sciences (KEMSD GS RAS) since 1999. A retrospective analysis of the regional earthquake catalog of Kamchatka has been performed for events with magnitude M greater or equal to 6.0 since 1985 till the present time. Aftershocks have been preliminarily eliminated from earthquake catalog before applying the RTL algorithm. It was found that in 8 cases of 14 anomaly of the RTL prognostic parameter can be recognized within 2 years before earthquake in its epicenter surroundings. Generally the main shock occurred at the edge of the anomalous area.

DETECTION OF IMPACT CRATERS BY PROCESSING OF THE DEM DATA

Andrei G. MARCHUK[1], Konstantin V. SIMONOV[2], Sergei A. PERETOKIN[2], Anton L. SCHEMEL[2] ([1]Institute of Computational Mathematics and Mathematical Geophysics, [2]Institute of Computational Modeling Siberian Division RAS)

A new attempt for the detection of the impact craters and the other morphologicstructures on the Earth's surface was made using the modern computational technologies. For detection and allocation of such structures, a complex application of the fast two-dimensional wavelet transformation and the fast nonlinear multiparameter regression analysis for the digital elevation (DEM) data subsets and 3D shaded images, which are drawn using these data. The organization of computing process for the solution of the indicated problem takes the form of a computational experiment and includes, in particular, the procedure of training on the known reliable impact structures, the procedure of testing of the constructed regression model and detection and identification of the required shapes on the Earth's surface with their subsequent contrast improvement. This technology was used for the detection of the big circle structures on the territory of North America and Central Siberia. In this case the GTOPO 30 data were used. The obtained results seem to be promising. The known circle structures are effectively detected and clearly distinguished on the surface area under study. The quantitative information is represented in the convenient form for the subsequent processing and analysis.

SW05/10P/A13-013 — 1715

A DETECTION OF THE LATENT SPATIAL AND TEMPORAL PERIODISITIES OF NATURAL HAZARDS IN THE PACIFIC REGION

Elena V. SASSOROVA, Boris W. LEVIN (Shirshov Institute of Oceanology Russian Academy of Science)

The material of the lithosphere is periodically subjected to forces caused by such astronomical effects as the tidal perturbation, precession, and Chandler pole motion. The stress tensor in the Earth 's crust was reconstructed and the total free-energy balance was estimated on the theoretic level (Levin, Pavlov 2001). It was shown that the variations of the lithosphere energy in the 100km layer due to astronomical effects are comparable with the energy released annually in the seismic process. Thus the Earth's seismicity and probability of the earthquake occurrence depends on the astronomical reasons: the geographical latitude of the event, the relative attitude of the Earth and the Moon, position of the Earth on ecliptic and the Chandler pole motion. The main goal of our study is the searching of the latent regularities for the Pacific event occurrence, the picking up of special periods which are typical for the temporal and spatial distribution, and the assessment of possibility for advance in the understanding of seismicity generation process in this region. For that we use integration of multi-disciplinary information: electronic worldwide seismic catalogs (NEIC, ISC), local seismic catalogs, Historical Tsunami Data Base, several electronic tables (Chandler pole motion, Moon and Sun tides and others). The special software based on the pattern recognition and fuzzy set methods and used the asynchronous slip-multi windows system for detection of the latent spatial and temporal periodisities was developed. The study of the latitude distribution of the earthquake number and its energy showed that the region seismic activity depends on the geographic latitude of the observed area and varies with time. The time-dependent variations of seismicity demonstrate existence of the 6-year-period of activity increasing. The analysis of the Pacific tsunami distribution showed that temporal regularity in the tsunami occurrence series is occurred in turn for Northern Hemisphere and then for Southern one and vice versa. The typical periods of the changeover from one to another hemisphere were 6 and 18 years approximately. It was revealed periodicities of the natural hazards in the course of year.

SW05/10P/A13-014 — 1730

RESCUE OF PAPER RECORDS: IMAGERY DATABASE OF SEISMOGRAM AND MAGNETOGRAM SCANS WITH AUTOMATED DIGITIZER

Mikhail Nikolaevich ZHIZHIN[1], Alexei Alexandrovich BURTSEV[1], Eugeny Petrovich KHARIN[2] ([1]Department of geoinformatics, Institute of Physics of the Earth, Russian Acad. Sci., [2]World Data Center on Solar-Terrestrial Physics, Moscow)

We present an effort of the World Data Centers for Space Physics and Solid Earth to digitize the analog records by scanner and digital camera and to create a database of scan images with metadata and automated digitizer accessible from the web. Time series records from the most of the geophysical observatories in Russia are still preserved in WDCs on paper and microfilms. Collection of historical seismograms and strong motion records begins from 1912 Golitsin records. Geomagnetic variations were recorded by tenths of stations for 50 years. We have developed algorithms and software to automatically digitize the scanned seismic and geomagnetic records using mathematical morphology and dynamic programming. Users can download from the database high-resolution images and digitizing program to convert the analog records into digital waveforms.

SW05/10P/A13-015 — 1745

APPLICATION OF NON-DESRUCTIVE GEOPHYSICAL TECHNIQUES FOR RISK EVALUATION (SANNOUR PROTECTED AREA, BENI SUEF, EGYPT)

Yehia E. ABDELHADY, Sherif M. HANAFY, Essam A. MORSY (Department of Geophysics, Cairo University)

A great Cave was discovered in the Wadi Sannour area, which is located on the Eastern bank of the Nile, facing Beni-Suef, upper Egypt. The site of Cave was quarried about 200 years ago for extraction of Marble. The cave has a crescent cross section with a span of up to 300m, 10 to 30m width, and height of 15m, the opening is about 39.5 m below ground surface. The forming of the Cave is due to running and subsurface water actions, which slowly moved along fracturesand bedding planes and dissolved the carbonates rock in the area. To evaluate of the risk, vulnerability and damage assessment at the Reserve site of Wadi Sannour Cave, to be more secure for the visitors (as a Tourist Site) and also to protect cave features against irreversible damage. Geophysical, geological, and engineering studies were made in the area using nondestructive techniques in and around the cave. The Ground Penetrating Radar (GPR) technique was used to evaluate the area inside the cave as well as the area around it. 20 GPR reflection lines were acquired in a rectangular flat area (35 x 11 m) in front of the entrance of the great cave in a uniform mesh grid. A new subsurface cavity is discovered in this area. The depth and dimension of this newly discovered subsurface cavity is determined from the acquired GPR data.

The IUGG2003 Office has made every effort to list family names and given names in the correct order in this index. We apologize for errors and suggest that if in doubt, you check both names as entries in the index. Thank you
