Contents

Key to Abstract Book

1. Symposium and Workshop are listed according to organizing or leading Association, where:

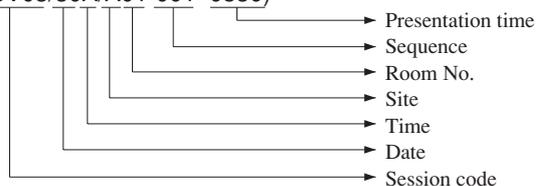
U = UNION
IA = INTER-ASSOCIATION (IAG, IAGA, IAHS, IAMAS, IAPSO, IASPEI and IAVCEI)
G = IAG
A = IAGA
H = IAHS
M = IAMAS
P = IAPSO
S = IASPEI
**V** = IAVCEI

2. Poster Session
Posters are displayed all day at Site D (Sapporo Media Park, SPICA) according to the poster session schedule. All poster sessions are assigned a core time for a morning or afternoon. During this time poster presenters are expected to be present at your poster for at least one hour. Some conveners have given specific times when they would like presenters to be at their posters. For other sessions, presenters can choose the time when they will be present at the poster. There will be a note on the poster where presenters can write when they will be present at their poster.

Key to Index

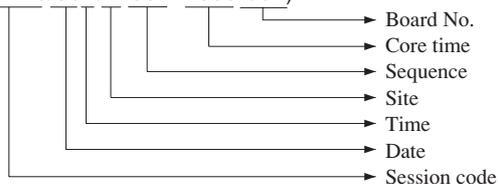
Authors are listed alphabetically, followed by the code of their abstract and indication of date, time and location of presentation, where:

Oral Presentation
SMITH, John Y. (JSV03/30A/A01-001 0830)

→ Presentation time
→ Sequence
→ Room No.
→ Site
→ Time
→ Date
→ Session code


Example: JSV03/30A/A01-001 0830 = JSV03, June 30, presentation in the morning (AM), Site A, Room 1, first paper in that session, Presentation begins at 8:30)

Poster Presentation
SMITH, John Y. (JSA10/30P/D-001 1600-001)

→ Board No.
→ Core time
→ Sequence
→ Site
→ Time
→ Date
→ Session code


Example: JSA10/30P/D-001 1600-001= JSA10, June 30, presentation in the afternoon (PM), Site D, first paper in that session, core time begins at 16:00, Poster Board No.: 001)

MODELING OF THE EARTH'S DYNAMO
Location: Site D, Room 32

UL5/07A/D32-001 0800

MODELING OF THE EARTH'S DYNAMO

Gary A. GLATZMAIER (University of California)

It has been nearly a decade since the first three-dimensional (3D)magnetohydrodynamic computer models produced simulations of convection and magnetic field generation in the Earth´s core. Since then several research groups around the world have developed similar models of the geodynamo. All of these produce dipole-dominated magnetic fields outside the core that resemble the geomagnetic field. The non-dipolar part of these simulated magnetic fields drifts westward, like the Earth´s, and in some models the axial dipole part occasionally and spontaneously reverses. Some models also predicted the eastward super-rotation of the solid inner core that was subsequently inferred from seismic analyses, although early estimates of the amplitude of this rotation rate may have been too large. These highly nonlinear simulations have confirmed the basic concepts of geodynamo theory, i.e., that a magnetic field like the Earth´s can be generated by convection in the Earth´s core. They have also provided much greater insight into the details of how the geodynamo may be operating. However, our understanding of the geodynamo is far from complete. No global geodynamo simulation has yet been able to computationally afford the spatial resolution required to simulate turbulent convection, which surely must exist in the Earth´s low-viscosity fluid outer core. They all employ greatly enhanced ˝eddy˝diffusivities to stabilize the low resolution numerical solutions and crudely account for the transport and mixing by the unresolved(subgrid scale) turbulence. Consequently the simulated convection in current models is very laminar, having only large spatial scales instead of a broad spectrum of turbulence. So, how robust are the results of the current geodynamo models? We will not know until the next generation of geodynamo models are able to run at much higher spatial resolution and much lower viscosity, which will require better numerical methods and computers. In the meantime we can get some insight by testing two-dimensional (2D) magnetoconvection models, which, although lacking the correct geometry, can simulate strong turbulence. Current 2D tests reveal new important sources of vorticity and Alfven waves that are suppressed in current 3D geodynamosimulations. This new vorticity will play an important role in the generation of magnetic field; the high frequency Alfven waves will require more sophisticated numerical methods. Movies of both 3D and 2D simulations are presented that illustrate these issues.

THE EARTH'S CORE: AN APPROACH FROM FIRST PRINCIPLES

G. David PRICE, L. VOCADLO, D. ALFE, M.J. GILLAN (UCL)

The Earth's core is largely composed of iron (Fe). The phase relations and physical properties of both solid and liquid Fe are therefore of great geophysical importance. As a result, the properties of Fe have been extensively studied experimentally over the past fifty years. However, achieving the extreme pressures (~350 GPa) and temperatures (~6000K) found in the core provide a major experimental challenge, and it is not surprising that there are still considerable discrepancies in the results obtained by different experimental techniques. In the past fifteen years quantum mechanical techniques have been applied to predict the properties of Fe. Here we review the progress that has been made in the use of first principle methods in the study of Fe, and focus upon (i) the structure of Fe under core conditions, (ii) the high-P melting behaviour of Fe, (iii) the thermodynamic properties of hexagonal close packed (hcp) Fe, (iv) the rheological and thermodynamic properties of high-P liquid Fe, and (v) the composition and thermal structure of the inner and outer core.

U5/07A/D32-002 0930

CORE-MANTLE BOUNDARY INTERACTIONS

Bruce BUFFETT (Department of Geophysical Sciences, The University of Chicago)

The interface between the core and the mantle defines a dramatic change in physical and chemical properties. The mantle side is composed of a crystalline silicate that slowly creeps under stress, whereas the core side is comprised of a liquid iron alloy with a viscosity comparable to that of water. Convection in each region creates two giant heat engines, which power plate tectonics in the mantle and generate the magnetic field in the core. These two heat engines can interact at the core-mantle boundary in a variety of ways. Current speculations can be divided into mechanical, thermal and chemical interactions. Mechanical interactions permit an exchange of angular momentum between the core and the mantle, which is detectable as a fluctuation in the rotation of the Earth´s surface and may offer clues about the dynamics of the core. Thermal interactions arise mainly from non-uniform heat flow across the core-mantle boundary, profoundly affecting convection in the core and possibly influencing the rate of magnetic reversals. Chemical interactions can result from chemical reactions between the silicate and iron, or may simply reflect the ongoing differentiation of the Earth. An enrichment of Os isotopes in some mantle plumes is often cited as evidence for an exchange of mass between the core and the mantle. Efforts to unraveling the nature and consequences of these interactions are guided by parallel efforts to interpret the structural complexity of the boundary region. Seismic tomography models of the mantle provide evidence of large-scale chemical heterogeneity in the lowermost mantle. More extreme variations in seismic-wave speed have been detected in thin layers at the base of the mantle, called ultra-low-velocity zones (ULVZ). A survey of recent advances in our understanding of structural complexity at the core-mantle boundary is used to motivate discussion of the possible causes and consequences of core-mantle interactions. Suggestions for future work is presented.

U5/07A/D32-003 1030

CORE-MANTLE BOUNDARY STRUCTURES AND PROCESSES

Thorne LAY[1], Edward J. GARNERO[2] ([1]Earth Sciences Department, University of California, Santa Cruz, [2]Department of Geological Sciences, Arizona State University)

The lowermost mantle is now recognized as one of the most heterogeneous regions within the Earth. The presence of a large temperature increase across a thermal boundary layer at the base of the mantle has long been inferred based on estimates of the geotherm. The recent seismological observations of intermittent 10 to 30 percent reductions of shear and compressional velocities near the base of the mantle, often found beneath extensive regions of 2-3 percent low velocities and negative velocity gradients, raise the possibility that partial melting takes place in the lowermost mantle, possibly in an (Mg,Fe)O phase. Observations of shear wave anisotropy in the lowermost mantle are also being mapped out, and the strength of anisotropy tends to correlate with increasing shear velocity anomaly on both regional and global scales. Experimental efforts suggest that it is again the (Mg,Fe)O component of the lower mantle that is the likely cause of these observations, as suitable slip systems develop in that mineral at high pressures that can be reconciled with the predominantly transverse isotropy observed in the boundary layer. The possible presence of partial melting, with resultant viscosity reductions, coupled with the interpretation of dislocation glide mechanisms for producing anisotropy in relatively cool, high velocity areas, provide new perspectives and constraints on boundary layer dynamics at the core-mantle boundary. Continued mapping of lower mantle stratification in the form of P and S wave velocity discontinuities several hundred kilometers above the core-mantle boundary suggests very widespread occurrence of this complexity, which is not uniquely associated with regions of possible mantle downwellings inferred from mantle seismic tomography. Small scale undulations in the reflectors, which appear to involve as much as 100 km of topography over length scales of 250 km laterally appear to preclude explanation of these features as phase changes, and tend to favor interpretations in terms of chemical heterogeneity. Regions with stronger S velocity reductions than P velocity reductions than can be attributed solely to temperature or even partial melting also favor the notion of strong chemical heterongeneity in the core-mantle boundary transition zone. Whether this region serves as a reservoir for volatiles and or slowly recycled slab components continues to be a hot debate.

U5/07A/D32-004 1100

SEISMIC MANTLE STRUCTURE: TRAJECTORY OF MANTLE FLOW

Yoshio FUKAO (Earthquake Research Institute, University of Tokyo (also at IFREE/JAMSTEC))

The three-dimensional structure of the mantle has been revealed by global seismic tomography, and used as a basis for extensive discussion of the mantle flow field. Mantle down flow manifests itself as plate subducton, whereas plate accretion is a shallow process that is different in nature from large-scale mantle upwelling. We review the seismic imaging of plate subduction, and discuss its implications for mantle down flow. The review results can be summarized as follows. 1)Subducted slabs generally extend further than the leading edge of the deep seismic zone. 2)This aseismic portion tends to flatten in the upper and lower mantle transition region, either above, across or below the 660-km discontinuity. 3)There is little indication for direct slab continuation down to the deep lower mantle far beyond the transition region. 4)The subducted slabs imaged in the deep lower mantle are e.g. those of the Farallon and Indian plates, which are separate entities from the presently active surface plates. The slab images summarized above indicate a stagnant nature of mantle down flow in the transition region and its possible role in plate tectonic history, particularly in the global change of plate motions e.g. in the Eocene. Recognizing that the slabs imaged in the transition region post-date the Eocene plate reorganization, slab subduction has a role of mass injection into the mantle transition region, which must induce a counter flow to carry transition region material upward. This counter flow may need to be taken into account in order to understand magmagenic processes in island arcs. We report clear evidence of a hot anomaly (negative P-velocity anomaly with a depression of the 400-km discontinuity) on the oceanic side of the subducted slab that may be associated with this counter flow. We also report evidence of oceanic crust residing near the bottom" of the slab image at depths below the 660-km discontinuity, suggesting a density reversal in the slab between its crustal part and mantle part upon phase transformations at the 660-km discontinuity, and their subsequent overturn within the softened slab body."

U5/07A/D32-005 1130

MANTLE CONVECTION AND GEOCHEMICAL CONSTRAINTS

Yanick RICARD (Laboratoire de Sciences de la Terre, Ecole Normale Superieure de Lyon)

Although more and more robust evidence of whole mantle convection comes from seismic tomography and geoid modelling, the rare gases and other isotopic or trace element signatures of MORB and OIB indicate the presence of various isolated geochemical reservoirs in the mantle. We discuss this discrepancy etween the fluid dynamic views of mantle convection and the chemical observations. It has often been argued that an increase of viscosity with depth could be responsible for some stratification of the mixing properties of the mantle. We test this assumption by means of 2D and 3D models of convection and conclude that a viscosity layering does not induce any vertical stratification of the mixing properties of the mantle (at least for a viscosity increase with depth lower than by a factor ˜200). We discuss the possibility to hide geochemical heterogeneities into the deep mantle in the form of an isolated primitive or enriched reservoir. To be stable and not to be advected by convection, this reservoir has to be dense and with a low thermal expansivity. These two conditions are present in D˝ and seem difficult to hold in the mid lower mantle. We use mineralogical data to constrain the density of the oceanic crust and lithosphere in the lower mantle. We suggest that a significant part of the subducted oceanic crust transformed into dense eclogitic assemblages, partially segregates to form a D˝ layer growing in time. This D˝ layer would trap a significant amount (1/3) of the Earth's radioactive and incompatible elements. A complementary cold and depleted harzbugitic lithosphere remains above. The hotspots would tap in variable proportions material from both the residual deep mantle and D˝. The difference between HIMU and awaiian basalts is attributed to HIMU being mostly from the strongly degassed oceanic crust, though enriched in incompatibles (D˝), while Hawaii is mostly from MORB-source residuals variably degassed and depleted. We will discuss quantitatively the geochemical implications of this models by means of both box-models and fluid dynamic simulations.

THE GRAVITY FIELD OF THE EARTH DETERMINED BY NEW SATELLITE MISSIONS
Location: Site D, Room 32

THE GRAVITY FIELD OF THE EARTH DETERMINED BY NEW SATELLITE MISSIONS

Christoph REIGBER (GeoForschungsZentrum Potsdam, Department 1 Geodesy & Remote Sensing"")

The Earth is a highly dynamic planet, undergoing perpetual change, driven by internal and external forces, and shaped by interactions between its geosphere, hydrosphere, atmosphere and biosphere on diverse spatial and temporal scales. Variations of the land topography, sea level, ice sheets, the water table and changes of the atmosphere can be observed all the times. Phenomena such as core dynamics, mantle convection and plate tectonics characterize changes taking place in the Earth´s interior. All these phenomena are associated with mass movements and lateral density variations , manifested in spatial and temporal variations of the Earth's gravitational field. After remarkable achievements in static gravity field modeling over the last four decades, the new millennium with its just started sequence of dedicated gravity satellite missions shows great promise for order of magnitude improvements of the global mean gravity field modeling and for unravelling the temporal variability of the field. The recently launched German mission CHAMP (2000), the American/German mission GRACE (2002) and the European Space Agency future mission GOCE (2006) provide a progressive increase in gravity field resolution and accuracy. This will allow for the first time- in combination with other geophysical data- comprehensive experiments for imaging and modeling complex Earth structures and processes and to carry out detailed studies of gravitational signals associated with mass exchange between the solid Earth and the hydrological, oceanic and atmospheric components of the Earth system. The striking results obtained from the CHAMP mission data and the very promising initial results from the GRACE twin satellite observations prove that with advanced satellite and sensor technology a permanent high precision monitoring of the global gravity field from space is feasible. Such a permanent monitoring with improved spatial as well as temporal resolution is urgently needed within various fields of environmental and global change monitoring and prognostics. The lecture will highlight the space gravity results obtained so far from the two successfully operating new missions CHAMP and GRACE, will demonstrate on the basis of a few examples the impact gravity modeling improvements can have on our improved understanding of geo-processes and will give an outlook on plans and prospects for further gravity improvements from space.

HIGH-RESOLUTION GRAVITY MAPPING: THE NEXT GENERATION OF SENSORS

Christopher JEKELI (Geodetic Science, Ohio State University)

Gravity sensors have long been used to infer Earth's mass density variations at all spatial scales. Instruments on airborne platforms are now commonly employed for oil exploration and geoid modeling. Satellite systems (GHAMP and GRACE) have recently been launched and new missions are in development (GOCE) to map the gravity field globally up to resolutions better than 100 km. In addition, the precision of these space-borne sensors is sufficient to discern the monthly (and longer-term) temporal variations of the field, thus enabling improved modeling of the time variations in continental hydrology, sea level, polar ice mass, and ocean bottom pressure. Improvements in terrestrial instrumentation, primarily in gravity gradiometry, portend similar capabilities at much finer spatial scales. Regional temporal variations in the continental water storage, and the crust's vertical motion associated with earthquakes, volcanic eruptions, and extractions of water and oil deposits, can all potentially be detected with new gradiometers currently under development. One of the leading technologies is based on the cold-atom interferometer that uses the wave-like properties of laser-cooled atoms to infer their acceleration in a gravitational field. In all cases of sensors deployed on a moving platform, Einstein's Principle of Equivalence (of inertial and gravitational mass) confounds the separation of gravitational quantities from kinematic accelerations (linear and/or angular). This paper gives a statistical analysis of gravitational signals and errors of current and future moving-base sensors and provides an outline of capabilities, limitations, and requirements for applications in geodesy and geophysics.

U6/09A/D32-002   Invited   **0935**

STUDIES OF EARTH'S CORE AND MANTLE USING SATELLITE MAGNETIC FIELD MEASUREMENTS

Catherine G. CONSTABLE (Scripps Institution of Oceanography)

Satellite magnetic field measurements provide a global view of the geomagnetic field. Vector field missions typically consist of a fluxgate magnetometer combined with a star camera to determine attitude of the spacecraft, GPS for positioning, and a scalar magnetometer for calibration of the vector field instrument. From late 1979 the Magsat mission provided vector magnetic field measurements for a period of about six months: prior to that several satellites had carried scalar magnetometers. Following a 20 years hiatus, there are currently several magnetometry satellites are in near-Earth orbit. The measured magnetic field is an admixture of all field sources: external, ionosphere, crust, mantle, and core. It remains a significant challenge to separate the relevant contributions to study aspects of interest here: these are (1) the field generated in Earth´s core and associated secular variations that provide a view of the workings of the geodynamo, and (2) fields induced in Earth´s mantle by external magnetic variations; these are used in studies of electrical conductivity. Crustal magnetization, itself a major topic of geophysical interest, contributes significantly to the measured field, and must be considered in attempts to isolate the fields in both core and mantle. Modeling the core field and its variations relies on identifying quiet measurements that are minimally perturbed by external field variations, and solving Laplace´s equation in a field free region. Under the assumption that Earth´s mantle is source free with zero electrical conductivity, such models are downward continued to the core surface. Additional assumptions are invoked to estimate

the fluid flow at the core surface. New satellite measurements provide an unprecedented view of changes in the core over the past 20 years; further measurements will allow identification of the temporal spectrum of the secular variation. Secular changes are coupled to changes in length of day, and recent modeling of torsional oscillations in the core can provide an explanation for the abrupt changes in the field known as geomagnetic jerks. Mantle induction studies require a comprehensive approach to magnetic field modeling. Unwanted internal field contributions must be removed yielding time series of external variations and their induced counterparts: improved modeling, combined with the increased accuracy in measurements, and longer term magnetic measurements make conductivity studies feasible with modern satellites. The one-dimensional global conductivity response has been estimated under strong assumptions about the structure of the source field. Ongoing improvements to this work will take account of more complicated source-field structure, three-dimensional Earth structure, and spatio-temporal aliasing due to satellite motion. Modeling of three-dimensional near surface conductivity structure, and the use of time-domain rather than frequency-domain techniques to estimate the 3-D Earth response are needed. Progress in this area is likely to be furthered by future magnetometer missions that involve multiple satellite configurations.

U6/09A/D32-003   Invited   **1000**

DENSE GPS ARRAY: NEW VERSATILE SENSOR OF THE EARTH

Kosuke HEKI (Div. Earth Rotation, National Astronomical Observatory)

Dense GPS arrays (average distances of a few tens of kilometers) in regional/local scales would be one of the most versatile tools to sense our planet. Densification of the GPS stations enhances the chance of detecting co- and postseismic crustal deformation from short distances, and provides important information on plate dynamics near boundaries. As for seismology, GPS detected earthquakes too slow to be detected by seismometers, and rapid sampling was found useful to record ground displacements when seismic waves pass by. GPS is also useful to monitor volcanic activities, but recent experiences suggest it necessary to deploy even denser networks temporarily to detect useful signals. Delays of GPS signals in propagating media are rich in information on atmospheric water vapor, which has been found to improve numerical forecast of strong rainfalls. Ionospheric delays are important to study upper atmospheric dynamics, and GPS-derived ionospheric models offer a convenient way to remove ionospheric effects from radio tracking data of spacecraft. By analyzing periodic components in GPS station coordinates, we can study seasonal hydrological cycles in soil, accumulation of snow loads on the surface, etc. in a scale too small to be detected by current accuracy of satellite gravity missions such as GRACE. In this study I review examples of multi-disciplinary applications of the Japanese dense GPS array, GEONET, and addresses its future prospects in various fields such as seismology, volcanology, meteorology, hydrology, tectonics, etc..

U6/09A/D32-004   Invited   **1050**

4-D IMAGING OF THE EARTH'S SUBSURFACE USING INSAR: MOVING BEYOND THE SINGLE INTERFEROGRAM

Howard A. ZEBKER (Department of Geophysics, Stanford University)

Interferometric synthetic aperture radar (InSAR) techniques are perhaps the most exciting advance in geodesy in the past decade. The ability to map surface deformation at fine resolution over wide areas has led to many new insights into geophysical processes. Most studies to date have resulted from analysis of a single radar interferogram, and permit identification of subsurface phenomena such as fault slip, magma chamber inflation, or dynamics of the polar ice sheets. The ready availability of multiple data sets, as afforded by ERS or other spaceborne sensors, coupled with the decrease in computational and data storage costs, now allows analysis of time series data the examination of how deformation patterns change with time. These 4-D images present much more information about how processes at depth evolve and are more predictive about future events, an important capability for observing natural hazards such as earthquakes and volcanic activity. Special filters may be devised to discriminate steadily changing deformation patterns from those that are more episodic in nature. We review here results from several techniques based on temporal analysis of interferograms, including faulting on active volcanoes, pore fluid migration due to changes in seismic stress, hydrologic aquifer analysis, and permanent scatterer analysis of tectonic deformation.

U6/09A/D32-005   Invited   **1115**

REMOTE SENSING OF SOIL MOISTURE AND SOIL WATER STORAGE

James S. FAMIGLIETTI (Department of Earth System Science, University of California, Irvine)

Mass movements in the global water cycle are fundamental Earth system phenomena. In particular, changes in the amount of water stored on land are critical indicators of global change, and have important feedbacks to the climate system. Recent advances in space observations of terrestrial hydrology now make satellite observations of terrestrial water storage variations possible. In particular, microwave radiometers such as AMSR, AMSR-E, TMI and SSM/I can provide information on soil moisture storage in the surface few centimeters of the soil, while GRACE can provide information on variations in total terrestrial water storage variations. The two types of information play complementary roles in understanding the distribution of water on land, both laterally and vertically. This presentation will review the state-of-the-art in water storage monitoring using both microwave and gravity-based sensors. Potential new missions and additional sensors required for comprehensive monitoring of terrestrial water storage will also be discussed, as will novel applications of satellite-based water storage observations in an Earth system context.

U6/09A/D32-006   Invited   **1140**

WIDE-SWATH ALTIMETRIC MEASUREMENT OF OCEAN SURFACE TOPOGRAPHY

Lee-Lueng FU, Ernesto RODRIGUEZ (MS 300-323 Jet Propulsion Laboratory)

This paper describes a new approach to making altimeter measurements from off-nadir radar signal returns and its scientific and operational applications. The approach is based on the technique of radar interferomety and the new instrument is called the Wide-Swath Ocean Altimeter (WSOA). WSOA is designed to be flown with a Jason-1 class conventional dual-frequency altimeter system, including a multi-frequency radiometer for the correction of the effects of water vapor in the troposphere. WSOA will extend the measurement from a line along the nadir to a swath of 200 km centered on the nadir track. The most important application of WSOA is to provide the first synoptic maps of the global oceanic eddy field. The strong currents and water property anomalies (in temperature, salinity, oxygen, etc.) associated with ocean eddies are a major factor affecting the oceanic general circulation and maritime operations such as offshore oil drilling, ship routing, fisheries, marine debris dispersion, etc. WSOA is expected to be an essential part of the future ocean observing

system for addressing these applications. WSOA will also provide measurements that allow the monitoring and study of coastal currents and tides that affect the lives of half of the world´s population.

U6/09A/D32-007 — Invited — 1205

GLOBAL NAVIGATION SATELLITE SOUNDING (GNSS) OF THE ATMOSPHERE AND GNSS ALTIMETRY: PROSPECTS FOR GEOSCIENCES

Thomas P. YUNCK (Jet Propulsion Laboratory)

With the emergence of large-scale geodetic ground networks, both regional and global, and affordable spaceborne GNSS scientific receivers, space geodetic techniques are finding diverse and unexpected new applications in many areas of Earth remote sensing. Basic GNSS navigation receivers are now all but indispensable to low earth orbiting missions of all kinds. Science applications of spaceborne GNSS today include centimeter-level precise orbit determi-nation for gravity mapping, ocean altimetry, geocenter detection, and enhanced global geodesy; high resolu-tion 3D imaging of the global ionosphere; occultation limb sounding to recover precise profiles of atmospheric refractivity, density, pressure, temperature, water vapor, and geopotential heights; and the experimental detection of GNSS ocean reflections for direct ocean altimetry and scatterometry. In the past five years there has been an explosion in the use of both ground and spaceborne geodetic receivers for direct sensing of the atmosphere to provide data for weather prediction and research in global climate change.Atmospheric applications of space geodesy are generating increasing scientific interest. Dense GPS networks in Japan, North America, Scandinavia, Europe, and elsewhere are now routinely providing data for assimilation into daily weather forecasts. A constellation of six orbit-ing occultation receivers, such as the COSMIC mission to be launched in 2005, can measure atmospheric refractivity with a precision equivalent to 0.1 K in temperature within a climate region correspond-ing to 1/30 the earth's surface, with just a few weeks of data. Vertical resolution can reach below a hundred meters. This offers perhaps the most promising approach yet to detecting and discriminating among subtle forced climatic signals, which may amount to only a few tenths of a Kelvin average temperature change per decade. More speculative, but having equally great potential, is the detection of GNSS reflections from the surface, primarily oceans and ice. This bi-static radar technique can be used, for example, to determine sea surface topography, significant wave height, surface winds, and possibly sea surface temperature and salinity, and could become valuable for monitoring the evolution of ice sheets. The technique is already practical from airborne platforms. With the prospect of substantially increased signal strength in the next decade from both GPS and Galileo, it may soon become a reality from space as well. This presentation will survey the techniques and Earth science applications of GNSS atmospheric sounding and bi-static radar, and will describe promising developments for the future.

THE INTERNATIONAL ASSOCIATION OF GEODESY 1862 - 1916: FROM A REGIONAL PROJECT TO AN INTERNATIONAL ORGANIZATION

Wolfgang TORGE (Institut fuer Erdmessung, Universitaet Hannover)

Modern geodesy started in the 18th century with the French arc measurements, which proved the spheroidal shape of the Earth postulated for an equilibrium figure. These large-scale operations naturally required international collaboration, and continued in many parts of the world until the 20th century, mostly within the frame of national geodetic surveys. Around 1850, extended latitude arc measurements existed in western Europe, in Russia, in India and elsewhere. Central Europe, on the other hand, was characterized by a number of astronomical observatories and local triangulations, but due to the political splitting up these surveys were not connected to a large-scale network, and could not be used for the investigation of the Earth's curvature. It was at this point, where the geodesist and retired Prussian General Johann Jacob Baeyer started in 1861, by submitting a memorandum on the establishment of a Central European arc measurement. The aim of this proposal was to connect the astronomical observatories by existing and planned triangulation networks in order to determine the regional and local curvature anomalies produced by the gravity field. The King of Prussia approved this plan, and by the end of 1862 already fifteen European states had affirmed their participation in the ˝Central European Arc Measurement˝. A first General Conference of this organization took place in Berlin in 1864, and fixed both the organisational structure and the research programme, which included the systematic investigation of the deflections of the vertical at all principal triangulation points, the determination of the intensity of gravity and the standardisation of the measurement units. It is notable that this organisation had a governmental character, but was composed by well-known geodesists and astronomers. With Baeyer as its first President, the organisation soon expanded into the ˝European Arc Measurement˝, and the Prussian Geodetic Institute established in 1870 was entrusted with the operation of a Central Bureau. After Baeyer's death, Friedrich Robert Helmert became in 1886 Director of the Geodetic Institute and of the Central Bureau, and with the extension to the ˝Internationale Erdmessung˝ (Association Internationale de Géodèsie), the scientific programme was essentially broadened and extended over the whole Earth. Among the major achievements of this Association are the International Meter Convention and the adoption of the Greenwich Meridian as initial meridian for longitude and time, the establishment of the International Polar Motion Servic and of the Potsdam Gravity System, the determination of gravity values and deflections of the vertical in many regions of the world, investigations on mean sea level, on the geoid and on isostasy, as well as observations of the Earth tides. In 1916, the last intergovernmental agreement for the ˝Internationale Erdmessung˝ lapsed and was not renewed, which ended the first fruitful period of unternational cooperation in geodesy, although several neutral states continued some of the programmes, especially the polar motion observations. When the International Union of Geodesy and Geophysics was established in 1919, geodesy became one of its sections, which started the second period of the International Association of Geodesy.

GRAVITY MEASURING INSTRUMENTS AND GRAVITY REFERENCE SYSTEMS

James E. FALLER (JILA, National Institute of Standards and Technology and University of Colorado)

This paper will describe, in a historical context, gravity measuring instruments and gravity reference systems. The use of pendulum (for relative and absolute measurements), spring-type gravity meters (for measurements on land and at sea) and the development of free fall gravimeters (for absolute measurements) will be discussed. Historic and present-day gravity reference systems, based on measurements made with these various types of instruments, will also be discussed. The development of these instruments and the creation of these reference systems made possible by evolving instrumental and calculating capabilities as well as the active support and encouragement of the IAG.

U7/11A/D32-003 — Invited — 1000

HISTORY AND FUTURE OF THE SERVICES OF THE INTERNATIONAL ASSOCIATION OF GEODESY (IAG)

Gerhard BEUTLER[1], Hermann DREWES[2], Andreas VERDUN[1] (Astronomical Institute, University of Bern[1], Deutsches Geodätisches Forschungsinstitut[2])

Towards the end of the 19th century astrometric observations could be made with an accuracy of a few tenths of an arcsecond. The accuracy stayed roughly on this level, till the space age opened the door for milliarcsecond (mas) astrometry. Astrometric observations allowed it at the end of the 19th century to prove the existence of polar motion. The insight that polar motion is almost unpredictable led to the establishment of the International Latitude Service in 1899. Similar observation techniques allowed it to create geodetic networks of continental size.The ILS is but one example for a service working under the auspices of the International Association of Geodesy (IAG). It was actually succeeded in 1989 by the International Earth RotationService (IERS). The example shows that new technologies (like distance measurements with Lasers, observations of artificial satellites using microwave signals, observation of Quasars withradio-telescopes) have significant impact on the development ofI AG´s service structure.The word ``service´´ implies that products of interest to a broadscientific and other professional communities are generated, documented, and made available. The services of the IAG are basedon the three pillars of modern geodesy, namely geometry, gravity, and Earth rotation. The rapid evolution of measurement techniques (e.g., Laser distance measurements, microwave observations, etc.) led to the creation of new and abolishment of ``old´´ IAG services in the twentieth century. We give an overview of the development of the IAG services in the previous century and conclude with an outlook on the establishment of IGGOS, the Integrated Global Geodetic Observation System, which shall be established as IAG´s key project of the decade. The IGGOS is based on the currently active IAG services. IGGOS intends to make available geometric and gravimetric products on a relative consistency level of one ppb (part per billion). These productsare, among other, the scientific backbone for global change research.

HISTORY OF IASPEI

Eric Robert ENGDAHL (University of Colorado)

When it became evident in the latter part of the 19th century that seismic signals propogate through the Earth over large distances, the need arose for an international organization to coordinate, collect and distribute the data, and promote earthquake research. During two ˝International Conferences on Seismology˝, in 1901 and 1903 in Strasbourg, the establishment of an˝International Association of Seismology˝ (IAS) was proposed. The Association was inaugurated in 1904 and joined by 18 nations. In 1919, the International Union of Geodesy and Geophysics (IUGG) was created with the ˝Seismological Section˝ as one of its founding components. In 1933, the name was changed to ˝International Association of Seismology˝ of the IUGG. In 1951, with the expansion of its scope to include material properties of the Earth´s interior, it was renamed the ˝International Association of Seismology and Physics of the Earth´s Interior˝ (IASPEI), as it is known today. The 1960´sbrought major changes, and much growth, both to seismology and to IASPEI. In this presentation IASPEI´s history and those trends that can be seen,retrospectively, to be important and that have evolved into many of the ongoing activities within IASPEI during the modern era will be reviewed.

U7/11A/D32-005 — Invited — 1130

THE INTERNATIONAL SEISMOLOGICAL ASSOCIATION (ISA) - FORERUNNER OF IASPEI

Johannes SCHWEITZER (NORSAR)

In the 1890s, shortly after the first teleseismic signals could be identified it became evident that for better results in seismology and earthquake research an international and even transcontinental cooperation was needed. In 1895, such global cooperation was proposed by John Milne in England and Ernst von Rebeur-Paschwitz in Germany. After Rebeur-Paschwitz´s death in 1895, Prof. Georg Gerland from Strasbourg in particular promoted the idea of an international organization for earthquake research. He invited all seismologists to the 1st International Seismological Conference in 1901 in Strasbourg. In 1903, a second conference followed and then in 1904, the International Seismological Association (ISA) was founded. Until the beginning of World War I in 1914, 23 states joined the ISA as members. The Central Bureau of the ISA was located in Strasbourg, where Gerland was its director until his retirement in 1910. After World War I, the ISA ceased to be operational, and was officially dissolved in April 1922, and in May 1922 at the First General Assembly of the IUGG in Rome, the new Seismology Section of IUGG was founded, which later became IASPEI.During the few years of ISA´s existence, its staff in Strasbourg mainly worked on earthquake catalogues based on instrumental and macroseismical observations, development and testing of new instruments, installation of seismic stations, research on distinguished earthquakes, and organizing of international meetings.

THE INTRODUCTION AND EVOLUTION OF INSTRUMENTAL SEISMOLOGY IN THE PHILIPPINE ISLANDS (1865 – 1902)

Josep BATLLO (Dept. Matematica Aplicada I, Universitat Politecnica de Catalunya)

Instrumental seismology in the Philippine Islands started at the Manila Observatory after 1865. Its early development shows some characteristic features: It developed faster than in Spain (the dominating power at that time)and it is the unique example of development of the Italian seismological tradition in the Far East. Otherwise, seismological studies on the colonial Philippine Islands were not reduced to the research done at the Manila Observatory. Other interesting developments (mainly related to the seismological engineering) took place at that time. An introductory study,discussion and evaluation of the initial moments of instrumental seismology in Philippines and related seismological research is presented.

SHORT HISTORICAL REVIEW ON COOPERATION IN GEOMAGNETISM

Youry P. SIZOV[1], Thoa Thi Kim NGUEN[2], Hao Quang TRUONG[2], Chau Ha DUYEN[2], Victor N.BOBROV[3], Youry P. TSVETKOV[3], Vladislav N. LUGOVENCO[3] ([1]Geoelectromagnetic Research Institute of RAS, [2]Hanoi Institute of Geophysics, [3]Institute of terrestrial magnetism, ionosphere and radio wave propagation of RAS)

The talk presents the main historical milestones of cooperation in Geomagnetism between academic institutes of Russia, and Vietnam, Mongolia, Cuba, Mozambique, FSU and other countries of the World (Geoelectromagnetic Research Institute of Russian Academy of Sciences (RAS), Institute of terrestrial magnetism, ionosphere and radio wave propagation of RAS and Hanoi Institute of Geophysics of NCNS etc.). To enumeration of milestones it should be included: Installation and adjustment of 3-component Magnetic Variation Stations (MVS) at the geomagnetic Observatories (GMO) of Mongolia,Cuba, Vietnam, and all other above mentioned countries (Ulanbator, Habana, Maputo, Sapa, Dalat, Bac-lieu, Ashgabad, Almaty, Dusheti, Odessa, Lviv, Kiev GMO, etc). Installation and adjustment of the the MVS near Hanoi-city; Construction the new GMO in Dalat city (~200 km to North from Hochiminh city), Installation and adjustment quartz magnetic D, H and Z sensors and registration device with control at GMO mentioned, absolute magnetometers in Dalat GMO; Construction the new GMO near the geomagnetic Equator in Bac-lieu, Installation and adjustment the quartz D, H and Z magnetic sensors and registration device with control in Bac-lieu GMO; Experimental field missions to collect rock samples for paleomagnetic investigations, to carry out absolute magnetic measurements of module and components for the magnetic anomalies investigation. The Main Magnetic Field and Secular variations study; special missions to investigate the Equatorial IonosphericElectroJets by means of the temporal magnetic stations meridian chain (additionally to the Vietnam all GMO net) on the base of MVS and proton magnetometers. This permitted to determine daily and secular movement, dynamics and features of the Equatorial Ionospheric Electrojets and its coupling with high latitude geophysical phenomena etc.

NIKOLAY PUSHKOV, SCIENTIST AND ORGANIZER (1903-1981)

Viktor N. ORAEVSKY, Vadim P. GOLOVKOV (IZMIRAN)

History of a man, who created a powerful infrastructure of Institutes and organized the geomagnetism and aeronomy study in the former USSR, a man who was one of organizers of the International Geophysical Year and joined in this way Soviet Unions scientists to the world scientific community and made the Association of Geomagnetism and Aeronomy to be really the International one.

U7/11P/D32-003 Invited 1505

A BRIEF HISTORY OF IAVCEI

Stephen R. MCNUTT (Geophysical Institute UAF)

IAVCEI, the International Association of Volcanology and Chemistry of the Earth´s Interior, has been in existence for 81 years. The organization is committed to understanding volcanic processes and mitigating their impact on society. IAVCEI was initally formed as the Section de Volcanologie, a section of IUGG at its first General Assembly in Rome, May 1922. The name was changed to Association Internationale de Volcanologie in 1930 in Stockholm, then to its present name in 1971 at the Moscow IUGG General Assembly. IAVCEI is one of the seven associations of IUGG. IAVCEI´s initial main tasks were to 1) inform by telegraph the national committees of the onset of important eruptions, 2) establish a central international volcanological library, and 3) publish a Bulletin Volcanologique and a bibliography of all aspects of volcanoes, from their activity to description of their products. Over the years various communications technologies have changed considerably, however, the basic functions have remained intact. Alfred Lacroix (France) was the first of 15 formally appointed IAVCEI presidents, following A. Ricco (Italy). From 1922 until 1963 the presidents were all from Europe, followed by H. Kuno (Japan) from 1963-1967. There were then 16 years of alternating presidents from the USA and USSR (1967-1983). Since 1983 presidents have been from many different countries, reflecting a global approach to volcanology and studies of the earth´s interior. The current President is Steve Sparks (UK). IAVCEI has had eight Secretaries General, by tradition serving at least two terms. The first six were from Europe (1922-1991), followed by Australia (1991-1999) and the USA (1999-present). The current Secretary General is Steve McNutt (USA). IAVCEI changed its statutes and by-laws to introduce personal memberships in 1995, and the organization now has over 700 members. IAVCEI produces 3 newsletters each year, continues to sponsor the Bulletin of Volcanology, hosts a web site www.iavcei.org, and coordinates the activities of 13 commissions. General Assemblies or workshops are held almost yearly, with an emphasis to assist young scientists and scientists from developing countries. The field of volcanology is so broad that earth scientists from many disciplines must cooperate in studying and understanding volcanoes, and studies of volcanic systems and processes therefore overlap with the fields of interest of many IUGG Associations. This broad interdisciplinary aspect is characteristic of many IAVCEI endeavours and is the primary reason why IAVCEI belongs to IUGG and seeks cross-links with the other six Associations.

U7/11P/D32-004 1535

THE HISTORY OF OCEANOGRAPHY AND IAPSO

Fred E. CAMFIELD (Inter. Assoc. for the Physical Sciences of the Oceans)

The formal study of oceanography owes its origins to scientific voyages in the late 17th and the 18th centuries. While these early voyages made general scientific observations, there was recognition by the late 19th century of a desire for voyages specifically for oceanography. These voyages were carried out by a number of Western European nations. At the same time, formal experimental and theoretical studies were carried out from the 1830´s onward, paricularly on waves and tides, but eventually extending to wind driven currents and to thedeeper ocean. Prince Albert I of Monaco was trained as a naval officer and became interested in oceanography after seeing reports of French voyages. He financed several ships and carried out observations in the Atlantic and theMediterranean in the late 19th and early 20th centuries. He recognized the needfor an international organization and, when IUGG was organized in 1919, he organized the oceanographic section and served as its first president.Most of the early oceanographic work was carried out by Western European nations,and that is recognized by the membership of IAPSO´s early executive committee which was dominated by Western European representative with one from the U.S.A.After 1930, there was strong representation from Denmark, Finland, and Norway, indicative of the oceanographic contributions of those countries, particularly

Norway. While some representatives began to appear from the rest of the world,it was not until after 1957 that IAPSO´s executive committee began to acquire a more global character. Oceanography began to expand after 1946, with an apparentrapid expansion starting in the 1960´s. Many new programs were established. IAPSO´s activities have reflected this expansion of the science. There has also been a recognition since its founding of the need to interact with other sciences,both within and outside IUGG, and discussions of whether IAPSO should reside within an oceanographic union (with biological oceanographers) or a geophysical union (with atmospheric scientists, etc.). There has been a recognition of thefact the oceanography is international, and the science crosses over the boudaries of the oceans into the atmosphere and the solid earth.References:Wooster, W.S., Sciences of the Oceans, Physical and Otherwise, *Oceanography/l,15:1, pages 128-134.Munk, W., The Evolution of Physical Oceanography in the Last Hundred Years,*Oceanography/l, 15:1, pages 135-141.

GEOSCIENCES: THE FUTURE (GTF)
Location: Site A, Room 2

Friday, July 11 AM

This symposium will be a panel discussion among a group of young scientists nominated by the seven Associations. They have been charged with the task of presenting their views on the future of the geosciences in the years to come including issues, challenges, and opportunities. What are the most pressing scientific and societal problems that can be productively addressed by the geoscience community? For example, the past few decades have seen an explosion in quantitative geoscience. Our observational systems now produce data streams at temporal and spatial resolution unprecedented in human history. The computational tools available for interpretation and prediction dwarf the state-of-the-art of merely 10 years ago. Where can we go from here?

SECULAR, TRANSIENT AND PERIODIC CRUSTAL MOVEMENTS AND THEIR GEOPHYSICAL IMPLICATIONS (IAG, IASPEI)
Location: Site A, Room 1

Monday, July 7 AM

THE VERTICAL DISPLACEMENTS OF JAPAN REVEALED BY MULTIPLE GEODETIC TECHNIQUES

Makoto MURAKAMI[1], Tetsuro IMAKIIRE[1], Tadashi SAITO[2], Tsugunori NARITA[2], Seiji OKAMURA[2], Toshio KUNIMI[3], Eiichi HAKOIWA[2], Hiroyuki NAKAGAWA[2], Kazuo KOMAKI[2] ([1]Geography and Geodynamics Research Center, The Geographical Survey Institute, [2]The Geodetic Department, The Geographical Survey Institute, [3]The Tohoku District Office, The Gegraphical Survey Institute)

Japan is situated in one of the most tectonically active region on the earth. Even in the premodern era people noticed vertical deformations associated with destructive earthquakes and volcanic eruptions and documented them. Since the introduction of sophisticated geodetic techniques about 100 years ago the nation has been repeatedly surveyed by precise leveling. Using those data the general trend of the vertical deformation of Japan was illustrated. In addition remarkable deformations associated with seismic and volcanic episodes were detected. A network of tidal gauges was also established and has been in operation for about 100 years, providing precious data to trace the evolution of vertical crustal deformations of Japan. In the last decade, GPS and InSAR are introduced to monitor the deformation of the land. The construction of the nationwide permanent network (GEONET) was initiated in 1994 and the number of sites now counts 1200. Daily positions of all the stations are computed on a daily basis. Although the precision of the vertical component of GPS is less than the horizontal ones, even the crustal deformations as small as a few mm/year become detectable by continuing the measurement for several years waiting the signal sums up. Using the accumulated GPS data since 1994 we computed the secular component of the vertical displacements. They basically agree well with leveling and tidal data but some new findings are obtained. We list them below:1) Subsidence is revealed in the area far apart from the subducting plate boundary and it infers that the plates couples in the deeper portion of the boundary, 2) Subsidence is revealed along Itoizawa-Shizuoka Tectonic Belt where uplift is expected due to collision of two tectonic blocks, 3) Similar subsidence is revealed along a belt running from Niigata to Kobe where uplift is inferred by the dominating horizontal contraction along the belt, 4) Uplift is revealed widely in the north of Usu volcano in Hokkaido before its eruption in March 2000.Those are interesting findings, which may lead us to modifications of existing theories about tectonics of related regions of Japan. In the presentation we will show more the details of vertical displacements revealed by continuous GPS. We also will compare them with other geodetic data from the past and discuss tectonic implications of those new findings.

JSG01/07A/A01-002 0915

ESTIMATE OF COUPLING ALONG THE SUBDUCTING PLATE BOUNDARY AROUND THE JAPANESE ISLANDS BASED ON A NEW INVERSION METHOD

Honglin JIN, Teruyuki KATO, Shin'ichi MIYAZAKI, Muneo HORI (Earthquake Reasearch Institute, University of Tokyo)

The Japanese Islands are located at the boundaries among Eurasia, Pacific, North America and Philippine Sea plates. Collision and subduction of these plates cause overall crustal deformation in the Japanese islands. Recent studies of geodetic inversion of dense GPS array data have shown that the distribution of inter-plate coupling is not homogeneous along the subducting plate boundaries. It is important to elucidate the distribution of coupling rates along the boundaries for understanding subduction process and nature of slow slip episodes as well as for earthquake prediction studies. In the previous inversion scheme, all physical processes involved (surface measurements due to fault dislocation, in this case) are represented by Green's function, and directly computed slip distribution from measurement data using singular value decomposition. This scheme can not determine accurate inverse operator because of the ill-posedness of inverse problem. In order to solve this problem, Hori (2001) introduced a new inverse approach in which inversion operator (Green function as an operator) is determined without considering the method of measurement by introducing the spectral decomposition of Green function. Since inverse operator is obtained through numerical spectral decomposition of Green's function, it clarifies the mathematical reason of the ill-posedness of the inverse problem. Moreover, the new approach can manifest the limit of measurement accuracy, and pick up only measurable modes. Measured data is only used to determine deformation function by least square method, and then the deformation function is used for solving the inverse problem to predict slip function at the plate boundary using inverse operator. We have applied this new inversion method to the Japanese GPS data and estimated the distribution of back-slip (or coupling) on a subducting Philippine Sea plate. Before applying the method, we considered that the vertical component of GPS data is important in estimating distribution of coupling along the plate boundary. For this purpose, first, we reduced the noise in the vertical components of GPS time series by removing correlated scatter among neighboring stations. The calculated slip distribution on the Philippine Sea plate indicates that the slip generally directs to the northwest with the maximum speed of about 8 cm/yr, consistent with motion of Philippine Sea plate. The present is harmonious with the result conventional inversion method (e.g. Yabuki and Mutsu'ura,1992). It is interesting to point out estimated and observed vectors are consistent in Shikoku and Chugoku areas, but are significantly different in Kinki area. This might suggest that surface deformation near Kinki might be affected by other tectonic disturbance.

JSG01/07A/A01-003 0930

SECULAR CRUSTAL DEFORMATION IN CENTRAL HONSHU ARC, JAPAN, DEDUCED FROM WAVELETANALYSIS OF GPS TIME-SERIES DATA, AND ITS SEISMOTECTONIC IMPLICATIONS

Kaoru MIYASHITA[1], Jianxin LI[3], Vijay Kumar KATHAMANA[2], Takahiko SUZUKI[1] ([1]Department of Environmental Sciences, Ibaraki University, [2]School of Marine Science and Technology, Tokai University, [3]GNSS Technologies Inc.)

Secular crustal deformation in the central part of Honshu Arc, Japan was deduced by applying the wavelet decomposition analysis to the GPS time-series data from GSI/GEONET (Geographical Survey Institute/GPS Earth Observation NETwork). The time-series data during the period from April 1996 to March 2002, which have been re-analyzed to be improved (Hatanaka et al., 2001), were considered to be composed of secular (a linear trend), seasonal, discontinuous (co-seismic or artificial jumps), and noisy (white noises) components. The NS (north-south), EW (east-west), and UD (up-down) components of the time-series data were also assumed to be mutually independent. After removing data-jumps in the time-series, we decomposed each of the NS, EW, and UD time-series to the 8th level by using Daubechies wavelets. We could find out a seasonal variation clearly in the detail part of the 8th decomposition component, and could estimate a secular velocity from the approximation part at the same level. We estimated secular velocities at about 450 GPS sites in the study region on the basis of the wavelet decomposition analysis, and then evaluated secular velocities at 7 km x 7 km grid points covering the study region by applying the least-square collocation method. We also estimated distributions of several kinds of secular strain rates, i.e., dilatational, maximum shear, and principal strain rates in the study region. From these distributions of secular strain rates, we could find out several kinds of characteristics concerning the secular crustal deformation in the central part of Honshu Arc. Firstly, we could recognize that (1) the entire region is generally under a compressive regime. Next salient features were as follows: (2) there exist remarkable concentrations of maximum-shear and compressive strains near Tokyo Bay and Boso Peninsula in the Kanto region; (3) there is a dilatational area in and around Mt. Fuji and Mt. Hakone in the Tokai region. We tried to explain the observed characteristics of the secular crustal deformation on the basis of the back-slip model, which has multiple faults along the plate boundaries, i.e., Sagami and Suruga-Nankai Troughs, and Japan Trench. However, there was a need to consider other mechanisms in order to explain the characteristics stated above. It might be a possibility that near Tokyo Bay and Boso Peninsula there locates a relatively weak zone such as a potentially faulting zone. It might be also suggested that near Mt. Fuji and Mt. Hakone there is a compressive source, associated with a volcanic flow.

JSG01/07A/A01-004 0945

ACTIVE FAULT SEGMENTS AND BLOCK MOVEMENT IN NORTH CHINA

Caijun XU[1], Zhicai LI[1], Yanxing LI[2] ([1]School of Geodesy and Geomatics,Wuhan University, [2]First Crustal Deformation Monitoring Center , China Seismological Bureau, Tianjin, 300180, P.R.China)

Research on interseismic fault movements is of considerable importance, not only for academic interest but also for the estimation of hazard zones and earthquake prediction, since any slip deficit at shallow or intermediate depths at a fault could be filled by a future earthquake. North China as a lithospheric dynamics sub-plate is located in the main part of eastern China. It is characterized by more intense neotectonism and seismic activities in comparison with northeast China and south China . North China block could be divided into 5 blocks from geology information and seismic distribution. The Repeated GPS surveys, had been carried out in the region in 1992, 1995, 1996, 1999, 2001 respectively by the First Crustal Deformation Monitoring Center (FCDMC) of the China Seismological Bureau (CSB) , provide a direct measurement of current crustal motions to study the tectonic activity and earthquake hazards in this area. There are more than 70 reoccupied stations after 1995 campaign. At each station, observation was made continuously for at least 72 hours in each campaign. These GPS data were firstly processed together with Global IGS stations using the GAMIT software to get the baseline solutions, then GPS velocity fields in ITRF2000 frame and with respect to Eurasia were obtained based on these baseline solutions and their variance-covariance matrix using the GPS network adjustment software PowerADJ developed by Wuhan University. Methods for the determination of active fault segments and block movements by inversion of GPS velocity and seismic moment tensor are presented. The geophysical implications of the active fault segments and block movements are discussed in this paper.

JSG01/07A/A01-005 1000

JOINT INVERSION OF GPS VELOCITY AND OBSERVED GRAVITY FOR ACTIVE FAULT SEGMENTS IN SICHUAN-YUNNAN RHOMBUS BLOCK

Zhicai LI, Caijun XU (School of Geodesy and Geomatics, Wuhan University)

The rhombus block in Sichuan and Yunnan province, lying northeast margin of the Tibet subplate and adjacent to Southchina subplate and southeast Asia plate, is one of the most active block in China. More than 200 earthquakes (ML>5.0) have occurred in this area since 1970, especially including 14 great earthquakes (ML>7.0). So the block is the key area to do investigations by geophysicists. Since the early 1990s, several regional GPS networks for active tectonic studies were established in continental China (Lai et al, 1992; Abdrakhmatov et al, 1996; Bilham et al., 1997; King et al., 1997; Larson et al., 1999; Li et al., 1995; Shen et al., 2000; Bendick et al., 2000; Wang et al., 2000) We obtain the station velocity in Sichuan–Yunnan block and find that the movement trend of the block is southeast to south. In this paper, We study movement of the Xianshuihe fault in Sichuan province, Honghe fault and Xiaojiang fault in Yunnan province by using GPS and gravity data. we have inverted the fault parameters by using GPS data and gravity data (from 1985 to 1999 in west of Yunnan province) separately and jointly with multi-faults dislocation model. The methodology used here is random cost method, which is one of the Monte Carlo (MA) algorithms. The results from the joint inversion indicate that these faults are presently active. The displacement field and strain-stress field in this block are also discussed in the paper.

JSG01/07A/A01-006 1015

AN IMPROVED APPROACH FOR CALCULATING THE SURFACE STRAIN RATES FROM GEODETIC NETWORKS WITH APPLICATION TO TAIWAN

Ya Ju HSU[1], Mark SIMONS[2], Shui-Beih YU[3] ([1]Institute of Geophysics, National Central University, [2]Seismological Laboratory, Division of Geological and Planetary Sciences, California Institute of Technology, [3]Institute of Earth Sciences, Academia Sinica)

We use the Taiwan GPS velocity field for the time period 1993 to 1999 to estimate spatially varying strain and rotation rates for the entire island. We use a modified version of Ward (1998) for calculating strain rates in spherical geometries. Our particular method considers three different types of weights: observational errors (W_s), distance between the observation and the location of estimation (W_l), and an additional weight to account for variable station density (W_d). Each weight contributes equally to the inversion. The construction of W_s and W_l has been described in Ward (1998). Given the difficulty in interpreting strain rates calculated at using variable length scales at different positions, we choose to make separate strain maps, each with a fixed length scale used in the estimation procedure. This fixed scale approach results in variable numbers of observations used in our strain estimates as a function of space. This variability is reflected in companion error maps. We estimate W_d using the distribution of Voronoi cells associated with the geodetic network. The actual value W_d corresponds to the cell area associated with a given GPS station. We find that our approach provides more stable and interpretable strain estimates than previous studies, especially when stations are irregularly distributed or when we use larger spatial length scale of estimation. In either case, dense pockets of observations would dominate the strain estimates.

JSG01/07A/A01-007   1050

INTERSEISMIC CRUSTAL DEFORMATION IN THE TAIWAN PLATE BOUNDARY ZONE (1993-1999)

Shui-Beih YU, Long-Chen KUO, Ya-Ju HSU, Horng-Yue CHEN (Institute of Earth Sciences, Academia Sinica)

The island of Taiwan is situated in the plate boundary zone between the Eurasian and the Philippine Sea plates. As a consequence of plate interaction, there are highly active seismicity, rapid crustal deformation, and numerous active faults in and around Taiwan. The disastrous Chi-Chi earthquake (Mw 7.6) occurred on 21 September 1999. This event caused very large coseismic movements and significant transient postseismic deformation. Continuous and annually surveyed GPS data collected before the Chi-Chi earthquake from 1993 to 1999 are utilized to study the interseismic deformation in the Taiwan area. The horizontal and vertical velocity fields with respect to the Chinese continental margin are firstly estimated from temporal changes of station coordinates. Then the strain rates are calculated from velocity gradients taking into account the observational errors, distance between the observation and the location of estimation, and variable station density. The convergence across the Taiwan arc-continent collision zone is as high as 80 mm/yr and about 40% of the shortening is accommodated in the Longitudinal Valley area of eastern Taiwan, the suture zone of two plates. The western Taiwan is undergoing compressive tectonic stress with contraction rates of 10-40 mm/yr in the E-W to NWW-SEE directions. The Ilan Plain in northeastern Taiwan shows remarkable NW-SE extension associated with the opening of Okinawa Trough, while the significant NEE-SWW extension in the southern Central Range may be related to crustal exhumation. The lateral extrusion in the Kao-Ping area of southern Taiwan is also prominent. An uplift rate of up to 10 mm/yr is observed in the Central Range and the maximum subsidence of 70 mm/yr due to underground water withdrawal is found in the coastal area of southwestern Taiwan.

JSG01/07A/A01-008   1105

CRUSTAL DEFORMATION IN EASTERN TURKEY CONSTRAINED BY GLOBAL POSITIONING SYSTEM MEASUREMENTS BETWEEN 1992 AND 2002

Mehmet Emin AYHAN[1], Bahadir AKTUG[1], Mustafa OCAK[1], Coskun DEMIR[1], Onur LENK[1], Robert REILINGER[2] ([1]General Command of Mapping, [2]Massachussets Institute of Technology)

To investigate crustal deformation in Eastern Turkey in the east of 35° E, we compute velocity field in a frame fixed to Eurasia from Global Positioning System (GPS) measurements between the years 1992 and 2002. The resulting velocity field reveals the decoupling of Anatolian plate from Eurasia and Arabia along dextral North Anatolian Fault (NAF) and sinistral East Anatolian Fault (EAF). Velocities indicate a westward motion of Anatolia and diffused deformation in Eastern Turkey between the Bitlis suture and the Caucasus. We derive a best fitting Euler vector of Arabia-Anatolia motion $35.18^{o} \pm 0.09^{o}$N, $38.14^{o} \pm 0.11^{o}$E, $1.40^{o} \pm 0.02^{o}$ /Myr. The Euler vector gives about 7 mm/yr for an upper bound on left lateral slip on the EAF. We also compute the strain rate components. Dextral shear strain rates accumulating along the NAF indicate plate boundary deformation zone having a width about 100 km. We obtain dextral shear strain accumulation extending from Karliova triple junction area to the east with a rate of 90 nstrain/yr around Karliova. We compute sinistral shear strain rates along the EAF between Türkoglu and east of Bingöl, reaching maximum of 70 nstrain/yr around Pötürge, within a relatively narrow plate boundary deformation zone. We reckon anticlockwise solid body rotation rates in Anatolia and plate boundary deformation zone along the EAF, and clockwise rotation along the NAF. Rotation rate is about -6° /Myr and 4° /Myr around Karliova and Pötürge respectively. Finally, dilatation rates reveal a general compressional regime in Eastern Turkey although we observe regional extensional areas.

JSG01/07A/A01-009   1120

MEDITERRANEAN SEA LEVEL VARIATIONS, 1985-2002: ALTIMETRY VERSUS TIDE GAUGE DATA

Isabel VIGO[1], David GARCIA[1], Benjamin Fong CHAO[2] ([1]Dpt. Applied Mathematics, University of Alicante, Alicante, Spain, [2]Space Geodesy Branch, NASA Goddard Space Flight Center, Greenbelt, Maryland, 20771, USA.)

We study the sea level variabilities in the Mediterranean Sea, both in space and time, and focus on the complementarity of the two available data sources for sea level: tide gauge data and altimetry data. We will use the sea-surface height (SSH) data from TOPEX/Poseidon (T/P) for the periods 1992-2002 and Geosat data for 1985-1988, and examine selected tide gauge data along the Mediterranean coast and compare them with the closest T/P data point. Also included is a study on Mediterranean-specific oceanic general circulation models that are under development in terms of their applicability. Preliminary results indicates that the SSH rate of change in Mediterranean is about 3 times the global average during the past 10 years. The differences between long-term trends (or linear slopes) of the altimetry data and the tide gauge data are indications of vertical ground motion of the tide gauge location. Apart from possible systematic errors in both data sets (especially in tide gauges depending on the history of data collection) these differences potentially contain information about local deformation and, more importantly, tectonic motions in the region. We will also present a survey of available GPS measurements co-located with tide gauges, but in general the GPS time series are too short to be useful at the present time.

JSG01/07A/A01-010   1135

GUADALUPE ISLAND GPS PRELIMINARY RESULT: IS THE PACIFIC PLATE RIGID?

Jose Javier GONZALEZ-GARCIA[1], Joachim GENRICH[2], Linette PRAWIRODIRDJO[2], Duncan AGNEW[2], Yehuda BOCK[2], Ken HUDNUT[3] ([1]Seismology Dept., Centro de Investigacion Cientifica y de Educacion Superior de Ensenada, Baja California, [2]Scripps Institution of Oceanography, University of California, San Diego, [3]United States Geological Survey, Pasadena, California)

We present results from survey mode GPS data collected in northern Baja California and Guadalupe Island in the Pacific Ocean. This data were combined with data from continuous stations from Southern California Integrated GPS Network (www.scign.org, http://sopac.ucsd.edu); that includes CIC1, SPMX, CORX (Coronados Island) and recently GUAX (Guadalupe Island) in México. Altogether we have 4 sites on Guadalupe Island: GUAD and GAIR (1991-2002), RMGU (1999-2002), and GUAX (2001-2003). Solutions were derived in the International Terrestrial Reference Frame 2000 (ITRF2000) and computed with GAMIT software using global fiducial data from the International GPS Service. Station velocities were computed using a linear regression on the position time series. The motion obtained for sites on Guadalupe Island agree to within 1 mm/yr with a mean of 23.8 ± 1.0 mm/yr for the north component and -44.6 ± 1.1 mm/yr for the east. This result is very close to that of the NNRNuvel 1-A model (23.1, -44.7) and is slightly lower than that predicted by Beavan et al. [2002] (25.2, -48.6), for a Guadalupe Island traveling on a rigid Pacific Plate. We compute a pole of rotation for the Pacific Plate using our results for CHAT, KOKB, KWJI,

MKEA, THTI and Guadalupe Island with the mean result: Lat.= 63.71° S, Long. = 109.25° E and angular velocity = 0.668°/Myr. The χ^2 for fitting a Pacific Plate pole with and without Guadalupe does not differ significantly. If the Guadalupe Island GPS preliminary result obtained here represents its secular motion, the Pacific Plate is rigid ($<$ 3 mm/yr), considering the uncertainties of plate tectonics on a spherical Earth (NNR 1-A) and that of the ITRF realization. This confirms the basic assumption made for Plate Tectonics by Morgan [1968]: ˝If the distances between Guadalupe Island, Wake Island and Tahiti, all within the Pacific block, were measured to the nearest centimeter and then measured again several years later, we suppose these distances would not change˝. Finally, when our ITRF2000 GPS result is rotated into a North America reference frame we obtain a ˝full˝ velocity field of 49.6 ± 1.0 mm/yr between Puerto Peñasco on the northeastern shoreline of the Gulf of California and Guadalupe Island. For the presentation we will include data for the first quarter of 2003.

JSG01/07A/A01-011   1150

VISCOELASTIC DEFORMATIONS DURING A SEISMIC CYCLE AND OVER CYCLES AROUND A SUBDUCTION ZONE - SIMULATION FOR A REALISTIC SNRVEI EARTH

Shuhei OKUBO[1], Jun'ichi OKUNO[1], Yoshiyuki TANAKA[2] ([1]Earthquake Research Institue, University of Tokyo, [2]Geographical Survey Institute, Japan)

Although there are many previous works to estimate crustal deformations around a subduction zone during one or over many repeated seismic cycles, they are not free from unrealistic assumptions to avoid intrinsic numerical difficulties; some ignore the earth´s self-gravitation, some compressibility, and others radial stratification. We develop here a new recipe to compute post-seismic deformation in a realistic, spherically symmetric, non-rotating, visco-elastic, and isotropic (SNRVEI) earth. The calculation is done without the forementioned unrealistic approximations. The essential point of the new algorithm is to perform the Laplace inversion integration without evaluating contribution from the innumerable poles. Using this method, we present a complete set of the Green function, i.e. time variations of displacement, gravity, geoid height on the surface for 4 independent types of point dislocation: strike-slip on a vertical plane, dip-slip on a vertical plane, tensile faulting on a horizontal plane and tensile faulting on a vertical plane. As an earth model, we employ the 1066A together with the standard viscosity profiles. The result shows a diverse spatial pattern due to a viscous structure or a source depth. In particular, ratio of the source depth to the lithosphere thickness governs the evolution of the post-seismic deformation. Of particular interest is that the far-field deformation (epicentral distance $>$ a few hundreds km) clearly reveals transient behavior.This makes a contrast to the near field deformation where coseismic change dominates.It follows that post-seismic gravity change might be detected with satellite missions because the wavelength exceeds 100 km, if a sufficiently large earthquake occurs. If the back-slip hypothesis holds at a subduction zone, integration of the Green functions over a finte fault plane allows us to compute both transient and secular displacement and gravity change. We shall compare the theoretical result with the observed secular uplift and gravity change at the Tokai region where a larege earthquake is anticipated to occur in a near future.

JSG01/07A/A01-012   1205

POSTSEISMIC DEFORMATION MODELING OF THE 1992 LANDERS, CALIFORNIA, EARTHQUAKE

Yuehua ZENG[1], Yongge WAN[2], Zhengkang SHEN[3] ([1]Seismological Lab, UNR and Institute of Earth Sciences, Academia Sinica, [2]College of Hazard Prevention, China Seismological Bureau, [3]Dept of Earth and Space Sciences, UCLA and Institute of Geology, China Seismological Bureau)

We model the postseismic deformation of the June 28, l992 Mw 7.3 Landers earthquake to understand the fault zone rheology and the crust and upper mantle structure. GPS data have been collected periodically from a network of about 2-dozen stations located in the rupture zone and its vicinity since the earthquake. The data were processed to derive the deformation time series at the sites. To model the postseismic deformation we need to account for both secular and the earthquake induced deformation. A regional secular deformation model is developed based on the GPS data collected before the Landers earthquake and EDM data collected in 1970s-1980s. These data are inverted to fit a block-fault model and solve for fault slip rates along block boundaries beneath the locking depth. After removal of the secular effect, the observed deformation shows a ˝butterfly˝ pattern in general, mimicking the coseismic deformation but with much smaller amplitude and with less gradient from the epicenter to far field. The temporal pattern shows a relatively fast acceleration for the first couple of months, and a much longer secular trend afterwards. We model the postseismic deformation as a result of rheological response to the coseismic stress change in a layered crust and upper mantle. The coseismic stress change is produced using the coseismic slip model of the 1992 Landers eartuquake by Wald and Heaton (1994). Our preliminary result suggests that two mechanisms operate simultaneously to produce the observed spatial and temporal patterns of the postseismic deformation: visco-elastic relaxation in the lower crust and rheological afterslip at the downdip of the coseismic rupture zone. We find that a model consisting of a 13-km thick lower crust with a viscosity of 10^{19} pas, an upper mantle with a viscosity of 10^{20} pas, and an afterslip at the downdip of the coseismic rupture equivalent to 5% of the coseismic moment release provides the best fit to the observation.

VARIATION OF STRAIN PROMOTED BY THE SLOW SLIP EVENT IN THE TOKAI REGION REVEALED BY THE CONVERTED STRAIN FROM GPS DATA

Sumio YOSHIKAWA, Takeyasu YAMAMOTO (The Seismology and Volcanology Research Department, Meteorological Research Institute)

The slow slip event (SSE) detected by the GPS network (GEONET) of the Geographical Survey Institute has been growing up steadily in the southern coastal area of the central Japan, that is the Tokai region, since 2001. Appreciable changes corresponding to SSE are not yet observed by the borehole strainmeters of the Japan Meteorological Agency in the area. We evaluated space and time variation of the strain caused by SSE before we can detect it by the strainmeters. Use of strain has merits on evaluation of a localized event. That is, i) strain does not reflect a common displacement observed in a wide area, ii) strain is comparable directly with outputs of borehole strainmeters, and iii) the elastic strain caused by a source diminishes rapidly as compared with displacement, say, in inverse proportion to the cube of distance from it, which means easiness in estimating the source location. We used the GEONET data from 1997 to 2002 for strain analysis. Variation of the horizontal principal strains was calculated from daily changes in lengths and azimuths of three base lines in each triangle elements of GPS network. Spatial distribution of horizontal strain components was calculated from grid-data of displacement vectors transformed from the

original data using the GMT function (e.g. Wessel & Smith, 1998). Annual- and semi-annual variations estimated for the period from 1998 to 1999 were subtracted from the original data, and linear trends for the same period were also subtracted from them when it was necessary. According to the analysis, we could detect strain changes associating with SSE clearly. Expansion appeared in and around Hamanako region of the central part of the Shizuoka prefecture, and at the same time contraction was caused around Omaezaki and Atsumi regions in the east and west of Hamanako region, respectively. The peak of expansion is now moving northeastward and steadily growing up and the contraction is gathering intensity. The maximum principal contraction rates increase three or four times after the commencement of SSE in 2001. The total moment release estimated from the distribution of dilatation in the late 2002 becomes (1.3~1.5) x10**19[Nm] and the moment magnitude becomes around 6.75. High concentration of the Coulomb fracture stress is seen in the eastern Tokai region.

JSG01/07P/A01-002   1415

MIGRATION OF ANOMALOUS CRUSTAL DEFORMATION IN TOKAI AREA, JAPAN

Masaru KAIDZU, Shinzaburo OZAWA (Geography and Crustal Dynamics Research Center, Geographical Survey Institute)

Since early 2001, anomalous crustal deformation is being observed in Tokai area, central Japan. The deformation is supposed to be related to aseismic slow slip on plate interface. The event lasts already more than 2 years. The center of deformation seems to migrate as is the case in normal earthquake, though the deformation in Tokai area is quasi static. Temporal variation of horizontal deformation and upheaval suggests that the center of slip on the plate interface migrated from under Hamamatsu to northeast direction along the western edge of estimated source region of coming Tokai earthquake. The slip started at the northeast slope of ridge like feature of the plate boundary. As the direction of subduction of Philippine sea plate is toward north-north-west in this area, it is likely that the slip started here. After migration of center of slip, GPS station at Hamamatsu started to move in normal direction. Observational study of the process of this slow slip event will provide image of quasi-static analogue of seismic rapture process. Migration of deformation on the surface will be examined using time series of GPS station coordinates.

JSG01/07P/A01-003   1430

POSTSEISMIC DEFORMATION FOLLOWING THE 1997 UMBRIA-MARCHE (ITALY) MODERATE NORMAL FAULTING EARTHQUAKES

Abdelkrim AOUDIA[1], Alessandra BORGHI[2], Riccardo RIVA[3], Riccardo BARZAGHI[2], Boudewijn AMBROSIUS[3], Roberto SABADINI[4], Bert VERMEERSEN[3], Giuliano PANZA[1] ([1]SAND Group, Abdus Salam International Centre for Theoretical Physics & Dept. of Earth Sciences, University of Trieste, Trieste - Italy, [2]DIIAR, Politecnico di Milano, Milan, Italy, [3]DEOS, Faculty of Aerospace Engineering, Delft University of Technology, Delft, Netherlands, [4]Dept. of Earth Sciences, University of Milan, Milan, Italy)

We combine aftershock strain mapping, GPS measurements and leveling profiles with forward modeling of viscoelastic relaxation to study the postseismic deformation of the 1997 Umbria-Marche (Central Apennines) earthquake sequence. We explore the feasibility of GPS monitoring of postseismic transients, for the first time in Italy, generated by shallow and moderate sources. Our data allow us to distinguish a preferred coseismic faulting model as well as insight into the rheology of the Central Apennines Earth´s crust. The faulting model requires a listric geometry with most of the energy released in the lower half part of the elastic crust. The rheological model consists of an elastic thin upper crust, a transition zone of about 10^{18} Pa s underlain by a low-viscosity lower crust, ranging from 10^{17} to 10^{18} Pa s. The postseismic deformation is, both distributed in the transition zone - lower crust and confined to the fault zone.

JSG01/07P/A01-004   1445

THE PRESENT-DAY TRANSIENT AND SECULAR DEFORMATION FIELD OF THE ANDEAN SUBDUCTION ZONE

Juergen KLOTZ[1], Amir ABOLGHASEM[1], Klaus BATAILLE[2], Rodrigo MATURANA[3], Raul PERDOMO[4] ([1]GeoForschungsZentrum Potsdam, [2]Univ. de Concepcion, Chile, [3]IGM Chile, Santiago, Chile, [4]Univ. Nac. La Plata, Argentina)

GPS-observed crustal movements in the Southern and Southern-Central Andes are governed by different phases of the earthquake deformation cycle. Most of the transient deformation can be explained by inter-seismic, co-seismic, and post-seismic phases of interplate thrust earthquakes. The area of the great 1960 Mw 9.5 Chile earthquakes shows a pronounced post-seismic deformation 40 years after the event and a significant change in the displacement field with time. Secular crustal movements are derived by subtracting model velocities from observations. Along the Andes, the most obvious secular deformation signal is visible in the back-arc of the subduction where the Brazilian Shield underthrusts beneath the Subandean zone. Here, GPS observations suggest a slower back-arc convergence than geological rates. The analysis of the residual velocity field and strain rates within the fore-arc of the subduction indicates the presence of trench-perpendicular and trench parallel extension in accordance with geologic findings. Also, part of the transient elastic deformation might be transferred into permanent plastic deformation. Further insight into the plate boundary system comes from 3D FE-Models that we used to explain the present-day deformation.

JSG01/07P/A01-005   1500

THE NATURE OF EPISODIC SLIP ALONG THE NORTHERN CASCADIA MARGIN: REGULAR AND NOT-SO-SILENT

Herb DRAGERT (Geological Survey of Canada)

Data from continuous GPS stations across the northern Cascadia Margin have been re-analyzed and they reveal an intriguing regularity of transient movements on the deeper subduction interface underlying southern Vancouver Is. and the eastern Olympic Mountains. Surface motions at GPS sites in this region are characterized by a pronounced ˝sawtooth˝ displacement pattern reflecting elevated stress increase for a period of about 60 to 70 weeks followed by a two-week period of stress reduction during which motions are reversed. These reversals have been modelled by gradual slips of 2 to 4 cm on the deep subduction interface, downdip from the seismogenic zone. At a given GPS site in the region of detection, the transient surface displacements observed for successive slip events are strikingly similar in amplitude, direction, and duration, indicating a repetitive process within a confined location. The rates of strain accumulation between slip events also appear uniform, again suggesting a recurring process that is spatially confined. To date, this behaviour has not been observed in other subduction zones or even to the north or south of this geographic region. Examination of digital seismic records from the same area has revealed unique, non-earthquake-like, seismic signatures accompanying the slip events. These seismic signals,

similar in nature to those identified in the Nankai subduction zone, appear to have no spatial correlation with earthquake patterns in the region, but the source appears to correlate with the zone of repeating slip. Episodic generation of fluids from pulses of metamorphic dehydration may be responsible for both the slip and the seismic chatter, although details of the process are yet to be understood. The fact that similar slip events have not been observed elsewhere may be due to smaller slip signals combined with a lack of GPS coverage.

JSG01/07P/A01-006   1515

THE SEISMIC SIGNATURE OF TRANSIENT SLIPS ON THE CASCADIA SUBDUCTION ZONE

Garry ROGERS, Herb DRAGERT, Honn KAO, John CASSIDY(Geological Survey of Canada)

Repeated slip events have been detected on the deep interface of the northern Cascadia subduction zone by observing surface deformation on a network of continuous Global Positioning System sites. These slip events, originally characterized through their temporal and spatial surface displacement patterns, have now been found to have unique, non-earthquake, seismic signatures which have been detected by the digital seismic network monitoring the same subduction zone region. The observed tremor-like seismic signatures correlate temporally and spatially with the slip events over the past six years. The sources of these tremors appear to be coincident with, or overlie, the region of the subducting slab interface where transient slip is occurring, migrating with the progression of the slip. During the time-period between slips, this seismic tremor activity is very minor or non-existent. At the time of the slip events, the seismic activity is marked by pulsating bursts of activity lasting from a few minutes to a few hours for the duration of the slip event, usually about 10 to 15 days. The frequency content of the seismic signature, predominantly 1 to 4 Hz, is lower than the frequency content of nearby earthquakes, and most of the energy is in the horizontal components. These seismic signatures have a similar appearance to the deep tremor identified by Obara in the Nankai subduction Zone. However, the frequency of occurrence is different and accompanying slip events have not been identified in Nankai. These slip related seismic signals appear to have no correlation with the deep or shallow earthquake patterns in the Cascadia region. If the one-to-one correlation between transient slip and seismic signatures proves to be robust, then the tremor-like seismic signals can provide real-time indicators of the occurrence of slip. Since slip events on the deep slab interface increment the stress across the seismogenic zone, it is conceivable a slip event would trigger a larger earthquake on the locked subduction thrust. Consequently, the onset of tremor activity could lead to recognized times of higher probability for the occurrence of megathrust earthquakes in the Cascadia subduction zone.

JSG01/07P/A01-007   1530

INTERPLATE COUPLING DERIVED FROM THE GPS TRAVERSE ACROSS THE HINGE-LINE IN KII PENINSULA AND ITS IMPLICATION TO PRESEISMIC CHANGES IN GROUNDWATER LEVEL BEFORE THE 1946 NANKAI EARTHQUAKE

Manabu HASHIMOTO, Yasuhiro UMEDA, Kensuke ONOUE, Fumio OHYA, Yoshinobu HOSO, Kazutoshi SATO (Disaster Prevention Research Institute, Kyoto University)

The hinge-line in the south Kii peninsula, which is the boundary between uplift and subsidence due to the 1946 Nankai earthquake, can be related to the lower margin of the coupling zone. We established 10 GPS observation sites, which fill the gaps in the GEONET operated by GSI, along two lines nearly parallel to the relative motion between the Philippine Sea and Amurian plates. Resultant average spacing is 5~10km. We have repeated the campaign survey of this traverse across the hinge-line in the Kii peninsula using dual-frequency receivers since March 2001. The obtained velocities of observation sites are about 3cm/yr in the middle part of Kii peninsula and 4.5cm/yr at its southern tip, respectively, relative to the Amurian plate. Their directions are WNW. The gradient is almost linear, which suggests that the coupling zone is rather wide.We apply a dislocation model with a uniform slip to this observed velocity field in order to estimate interplate coupling beneath the Kii peninsula. Changing the width of the Ando's(1975) fault model, we compare the fitness of theoretical displacement with the observed one. The calculation indicates that the original Ando's model is too narrow to represent the observed velocities. In order to explain the observed velocities in the middle Kii peninsula, we must double the width of the model fault. This implies the coupling zone between the subducting Philippine Sea and Amurian plates might be extended much deeper than the depth previously suggested from the thermal model and others.Groundwater level drops before the 1946 Nankai earthquake were reported in middle and south Kii peninsula and southern coastal region of Shikoku. We assume this change in Kii peninsula is caused by a preseismic slip on the fault plane or its deep extension, and perform forward calculation of dilatation. The deepest segments of the model faults by Sagiya and Thatcher (1999) produce dilation south of the hinge-line, which does not coincides with the distribution of wells of reported anomalous changes. This result suggests that preseismic slip must occur on the deeper extension beneath the middle Kii peninsula. The coupling zone derived from our GPS observation might be the source region of such preseismic slip.

JSG01/07P/A01-008   1605

TRANSIENT DEFORMATION BEFORE THE 2002 DENALI FAULT EARTHQUAKE, CENTRAL ALASKA

Jeffrey Todd FREYMUELLER, Hilary J. FLETCHER, Sigrún HREINSDÓTTIR, Hisashi SUITO (Geophysical Institute, University of Alaska Fairbanks)

Repeated GPS surveys in central Alaska document two sources of transient deformationpriorto the 2002 Denali Fault earthquake. The first and most obvious is a largetransient interpreted as a creep event on the Pacific-North America plateinterface downdip of the seismogenic zone. This event began in 1998 and lastedfor 2-2.5 years. The creep event produced large displacements at the surface, aslarge as ~10 cm total displacement. Based on dislocation and finite-elementmodels, we interpret the source of the event to be accelerated creep on a patchof the plate interface roughly 100x150 km in size, with 15-20 cm of creep abovethe normal rate of plate motion (5.5 cm/yr). The large displacements caused bythis event were centered well to the south of the Denali fault, but it causedmeasureable extensional strain normal to the Denali fault, which would havethe effect of unclamping the fault and bringing it closer to failure.A second, more subtle transient event appears to have occurred near theepicentral region of the 2002 Denali fault earthquake between mid-2000 andmid-2002. Summer 2002 GPS surveys of sites near the Denali fault aresystematically offset from the trend of the previous surveys, which weredone from 1997-2000. West of the 2002 epicenter, the anomalous motion appearsas an eastward displacement of 1-2 cm for sites south of and very close tothe Denali fault. Out of all sites in central Alaska that were surveyed in2002, only sites very close to the Denali fault deviate from their priortrends. If these displacements result from precursory slip, they do notappear to result from slip on the Denali fault, but might be related toslip on thrust faults such as the fault that initiated the Denali earthquakerupture.

POSTSEISMIC DEFORMATION FOLLOWING THE 2002 DENALI FAULT EARTHQUAKE

Jeffrey Todd FREYMUELLER[1], Roland BURGMANN[2], Eric CALAIS[3], Andy FREED[3], Evelyn PRICE[1], Hilary J. FLETCHER[1], Sigrún HREINSDÓTTIR[1], Christopher F. LARSEN[1] ([1]Geophysical Institute, University of Alaska Fairbanks, [2]Department of Earth and Planetary Science, University of California, Berkeley, [3]Department of Earth and Atmospheric Sciences, Purdue University)

The November 3, 2002, Mw=7.9, Denali fault earthquake was the largest on-landstrike-slip rupture in the US since 1857. Geodetic measurements of thepostseismic response triggered by this event are providing significant insightinto postseismic deformation processes and lithospheric rheology. Data fromcampaign GPS sites showpostseismic displacements up to 60 mm of horizontal motion over the first 11days after the earthquake at near-field sites. These rates of motion are ~200times the interseismic rates. Significant vertical displacements are alsoobserved, and most sites everywhere within 50-75 km show significant postseismicmotion within the first few weeks. Within two weeks after the earthquake, we installed 10 continuous GPS sites inthe region of the rupture. Displacements of these sites over the next sixweeks are as large as ~45 mm. The data show evidence for a veryrapid pulse of deformation within the first few days to two weeks, followedby a slower rate, although this slower rate is still ~50 times the interseismicrate. We will report on the latest results and models to explain the rapidpostseismic deformation we have observed.

JSG01/07P/A01-010   1635

POST-EARTHQUAKE DEFORMATION FROM INSAR AND STRAINMETERS CORRELATED TO PORE-PRESSURE TRANSIENTS

Paul SEGALL[1], Sigurjón JÓNSSON[2], Rikke PEDERSEN[3], Kristjan AGUSTSSON[4], Grimur BJORNSSON[5] ([1]Geophysics Stanford University, [2]Earth and Planetary Sci, Harvard University, [3]Nordic Volcanological Institute, Reykjavik, Iceland, [4]Iceland Meteorological Office, Reykjavik, Iceland, [5]National Energy Authority, Reykjavik, Iceland)

Despite considerable effort, it has proven difficult to distinguish between competing models of postseismic deformation based on direct field observations. Here we present unique measurements consisting of satellite radar interferograms, borehole strainmeters, and water level changes in geothermal wells following two magnitude 6.4 earthquakes in the South Iceland Seismic Zone. The deformation recorded in the interferograms cannot be explained by either afterslip or visco-elastic relaxation but are consistent with poro-elastic rebound in the first one to two months following the earthquakes. This interpretation is confirmed by direct measurements which show rapid (1-2 month) recovery of the earthquake induced water level changes. In contrast, the duration of the aftershock sequence is projected to be ~3.5 years, suggesting that pore-fluid flow does not control aftershock duration. However, because the surface strains are dominated by pore-pressure changes in the shallow crust, we cannot rule out a longer pore-pressure transient at the depth of the aftershocks. The aftershock duration is consistent with models of seismicity rate variations based on rate and state dependent friction.A borehole dilatometer located ~3 km from the June 17, 2000 rupture recorded a large (~10 microstrain) compression followed by a roughly one month strain relaxation (dilation). For an instantaneously introduced fault in a poroelastic medium the postseismic volume strain is predicted to increase as the induced pore pressure gradients relax, that is the strain increases with the same sign as the instantaneous coseismic response. However, because there is no fluid exchange with the dilatometer, the strain measured by the strainmeter is not in general the same as the strain in the surrounding rock. More generally, the instrumental strain is related to the strain within the rock far from the borehole and the change in fluid pressure. If the rock strain is held constant, the dilatometer response relaxes from the undrained to the fully drained states. Two dimensional poroelastic solutions demonstrate that the observed strainmeter response is qualitatively consistent with theory.

JSG01/07P/A01-011   1650

STRESS-INDUCED MIGRATION OF SEISMIC SCATTERERS ASSOCIATED WITH THE 1993PARKFIELD ASEISMIC TRANSIENT

Fenglin NIU[1], Paul G. SILVER[2], Robert M. NADEAU[3] ([1]Department of Earth Science, Rice University, [2]Department of Terrestrial Magnetism, Carnegie Institution of Washington, [3]Berkeley Seismological Lab., Univ. of California, Berkeley)

A major goal of seismologists is to identify temporal variations in the seismic structure ofthe crust in response to stress changes near a fault zone. One of the approaches to thisproblem is to compare waveforms generated by repeat earthquakes, which have nearly thesame location and mechanism and produce nearly identical seismograms when recorded atthe same station. We have chosen to measure the difference in waveforms of several tightclusters of repeat events that occurred on the Parkfield segment of the San Andreas Faultand recorded by a network of borehole seismometers in the same area (HRSN). An exceptionally well-documented aseismic transient took place on this segment around the beginning of 1993, and we wanted to determine whether it produced observable structural changes in the medium as well. We used two parameters: the lag time, $\tau(t)$, anddecorrelation index, $D(t)$, to characterize the difference between two seismograms atelapsed time, t. The lag time $\tau(t)$ is evaluated at the maximum of the cross correlation,C_{m0}, and the decorrelation index $D(t)$ is defined as $1-C_{m0}$. We have found a significant change in a particular section of the S-wave coda between two sets of events (1988-1992 and 1993-1997), which appears as a spike in both $\tau(t)$ and $D(t)$. We have run a series of tests which strongly suggests that the observed changes in waveforms are not due to variations in earthquake location (verified by relocating the events from the observed S-P times at different stations) nor due to a uniform change of the background medium. Instead, the likeliest explanation is that there has been a change in the location of distinct scatterer(s) by a few meters. We utilize a simple procedure for locating spatially those scatterers whose properties havechanged in time. For each station, we first construct a differential seismogram $\delta s(t)$by taking the difference of the average of the pre- and post-1993 seismograms. For noise-free seismograms, $\delta s(t)$ will consist only of energy from any scatterers whosepropagation characteristics (travel time or amplitude) have changed, while an unchangedscatterer will be removed by this procedure. We then performed an nth-root (n=1) stack ofthe amplitude, $A(x)$, of $\delta s(t)$ from each station, stacking on the predicted arrival time of a candidate scatterer originating from location x. This function reaches a maximum about 2 kilometers to the southeast of the cluster and atabout 3 km depth. The migration of the scatterer(s) occurred at seismogenic depth and therefore is less likelydue to the environmental effects. As the difference is almost absent in the P-wave coda, weinfer that the scatterer(s) is probably related to the redistribution of fluid-filled fractureswhich are more efficient in scattering S-wave energy compared to P. The location and timing of this change in the medium strongly suggests that it is a manifestation of the 1993 Parkfield aseismic transient. As such, it likely represents the stress-induced redistribution offluids in the crust at seismogenic depths.

JSG01/07P/A01-012   1705

INSAR-BASED SEISMISITY STUDY OF SOUTH-WESTERN AUSTRALIA EARTHQUAKE PRONE ZONE

Diana POLONSKA[1], Clive COLLINS[2], Phil CUMMINS[2], Craig J.H. SMITH[2], Linlin GE[1], Chris RIZOS[1] ([1]Satellite Navigation & Positioning Group, School of Surveying and Spatial Information Systems, The University of New South Wales, Sydney NSW 2052 Australia, [2]Geoscience Australia GPO Box 378 Canberra ACT 2601 Australia)

An analysis of intraplate seismicity within a seismically active area of Western Australia using spaceborne Synthetic Aperture Radar Interferometry (InSAR) was made. Despite the limitations imposed by availability and timing of satellite passes, ground relief and instabilities influencing the radar signal, the demonstrated resolution and accuracy of InSAR make this technique feasible as a tool for exploring regional tectonics. The manifestations of regional tectonics in earthquake prone areas are highly site-dependent so SAR images at fine spatial and temporal scales and information on low intensity earthquake events were incorporated within the analyses. High precision georeferencing of the input layers was assisted by GIS technology. Preliminary findings of this study suggest that there is correlation between crustal deformations and local patterns of geological origin. In particular, the concentration of hypocentres of the earthquakes along the direction of interferometric fringes, corresponding to the chosen time interval, can clearly be identified. This indicates that clustering in time and space of shallow seismic events can be traced using InSAR-based analysis, and that the method can be used to improve our understanding of intraplate earthquakes. Combined with the precise positioning of ground reference points using GPS for InSAR data processing, new insights into transient crustal deformations studies can be expected. Using this approach, the determination of the magnitude of strain rates and orientation of crustal stress associated with earthquake generation is possible.

SEASONAL VARIATION OF SCALE OF GEONET NETWORK AND ZTD BIASES

Yuki HATANAKA (Geographical Survey Institute, Japan)

The seasonal signals in the time series of the site coordinates were evaluated based on the new solutions of GPS Earth Observation Network (GEONET) of GSI, Japan, which were obtained by the reanalysis with an improved and uniform analysis strategy by Hatanaka et al. (2003). There are spatially systematic features in the seasonal motion of the solutions. A dominant part of them is the seasonal change of the network scale of 6.4 ppb, which accounts about 70 % of the whole power of the seasonal signals for the horizontal components. The comparison of the tropospheric zenith total delays (ZTD) estimated in the GEONET analysis with those derived from radiosonde data of Japan Meteorological Agency also shows the seasonal variation of the bias in the ZTD estimates. The sense and magnitude of the scale variation roughly agree with those expected from the variation of ZTD bias. The residuals of the seasonal signals, after removing the systematic components, do not show correlations with the direction of plate motions around Japan, although they still show spatially coherent signals, parts of which are explained by the snow loading effect proposed by Heki (2001) and by the neglect of tropospheric gradient (Hatanaka, 2003, presented in this assembly).

SEASONAL CRUSTAL DEFORMATION IN JAPAN: FINAL SYNTHESIS

Kosuke HEKI (Div. Earth Rotation, National Astronomical Observatory)

Strong annual signatures found in the Japanese dense GPS array were partly caused by seasonal scale changes of possibly non-crustal origin, but significant part is caused by real seasonal crustal deformation caused by change of various surface loads. Recently, Heki (2001) studied the northeastern Honshu area and found snow load the most important source to drive seasonal crustal deformation there. In the present study, I extend the investigation to the whole country and evaluate every potential contributor including snow, atmospheric pressure, soil moisture, water storage in dams, and non-tidal ocean loads. Most of these effects can be calculated a-priori using various meteorological and geophysical data and models, although their reliabilities vary among items. I compare synthesized annual GPS site displacement curves with the observed ones and discuss their differences, to be attributed to factors yet to be modeled, such as dependence of snow depth on ground elevations (meteorological sensors do notnecessarily represent the whole country), water storage changes related to agricultural activities, etc..

THE KINEMATICS OF ANATOLIA: SPECTRAL ANALYSIS OF CONTINUOUS GPS DATA

Ali TURKEZER, Onur LENK, Ali Ihsan KURT, Semih ERGINTAV (Geodesy Department, General Command of Mapping)

Three-dimensional geodetic networks supported by continuous GPS data are capable of yielding valuable tools in order to account for regional realization of International Terrestrial Reference Frame (ITRF) and monitoring deformationsof the solid earth in the area of interest. Turkish Permanent GPS Network (TPGN)stations consisting of 16 stations, played an utmost role in the analyses and the surveying stage of Turkish National Fundamental GPS Network (TNFGN), which was completed in 2000, by providing 24-hour continuous data in connection with International GPS Service (IGS) global stations. Being in Alpine-Himalayan collision zone, Turkey and its surrounding have very active tectonic nature characterized by the collision of African, Arabian and Eurasian tectonic plates.Such a phenomena made use of TPGN data with a great extent in the evaluation of both secular variations of the positions of the stations and the abrupt changesof the positions associated with the earthquakes. At the preliminary stage of TURPEGN analyses, the horizontal velocity values have been obtained in ITRF96 and they have been used in order to constrain the inter-seismic velocity field of the area. Also, the acute displacements during 17 August 1999 İzmit(Mw=7.5),earthquake yielded the information for co-seismic velocity field as well as post-seismic process utilizing the data from more dense stations. The analysis of five stations operating before the earthquake showed the actual co-seismic displacements with a magnitude of 53 cm and –33 cm in east and north componentsrespectively near the epicenter of the earthquake and the post-seismic behaviorof the region which has an exponential function delay time of about 70 days and 50 days in East and North components respectively. The analysis includes 900 days beginning from 1999 day 185 till the end of year 2001. Also, the periodical components of the time series have been investigated using power spectrums. Finding the index coefficient of about 1 revealed that there is significant periodicity on the obtained series. The periodicity analysis of time series

indicates the meaningful annual periodicity in height components and about 300 days in north and east components. It is anticipated that time series evolution and the signal analyses of TPGN stations in the long-term period excluding abrupt events will help to monitor the kinematics of the region as well as the stability of the stations.

JSG01/08A/A01-002   0915

DEFORMATION IN YELLOWSTONE'S UPPER GEYSER BASIN: ARE DEEP PRESSURE FLUCTUATIONS DRIVING FLUID FLOW AT OLD FAITHFUL GEYSER?

Anahita A. TIKKU[1], David C. MCADOO[2], Mark S. SCHENEWERK[3], Ralph C. TAYLOR[4] ([1]Lamont-Doherty Earth Observatory of Columbia University, [2]NOAA Laboratory for Satellite Altimetry, [3]Give 'em an Inch Inc., [4]National Park Service volunteer)

We present the first absolute gravity and global positioning system (GPS) time-series analysis from a geyser basin. Observations were made in 2000, 2001, and 2002 over periods of 2 to 10 days within 200-800 meters from the Old Faithful geyser in the Upper Geyser Basin of Yellowstone caldera located in Wyoming, USA. Over the course of three campaigns we observed consistent large vertical motions of up to 10 cm over a large areal extent (up to 600 m) and corroborative gravity anomalies of up to 15 microGals occurring on the timescale of hours to days. Deformation on this timescale has been previously undetected in active magmatic or hydrothermal systems. We postulate that the vertical motions are due to fluctuations in pressure at depth in the hydrothermal-magmatic system. We also find that the gradient of the large vertical motions are correlated with deviations in the time between eruptions at Old Faithful geyser and postulate that this is caused by lateral fluid flow into and out of the geyser conduit. The correlation is significant because Old Faithful's eruptions are periodic and predictable. Changes in the verticalload will either eject or inject water into the geyser conduit if the conduit is treated as a permeable zone of intensely fractured rock with high compressibility surrounded by a less permeable rock matrix with a lower compressibility. Changing the volume of water in the geyser conduit changes the interval between eruptions assuming this time is controlled by the volume of water available for an eruption. Our new work is important as it reveals the processes of fluid movement both in the larger scale geyser basin hydrothermal-magmatic system and at the scale of individual geysers.

SIGNAL OF ATMOSPHERIC PRESSURE LOADING IN LASER RANGING DATA

Toshimichi OTSUBO, Toshihiro KUBO-OKA, Tadahiro GOTOH, Ryuichi ICHIKAWA (Communications Research Laboratory)

Ranging precision of satellite laser ranging technology has improved to 5-7 mm in a single shot basis and 1 mm or even better in a normal point (compressed data) basis. Compared to other microwave-based geodetic techniques, laser observation has an advantage in accurate model of propagation delay, which must result in accurate determination of a vertical component of station coordinates. Variation of a vertical component due to atmospheric loading effect has been researched throughout the last decades, and is typically 1 cm peak-to-peak or less. The effect was already seen in GPS and VLBI data, and we found it also possible to detect the vertical variation as a function of atmospheric pressure from recent LAGEOS laser ranging data. In our orbit analysis software "concerto", a new adjusting parameter, height per pressure, was implemented. The parameter was estimated simultaneously with other parameters such as orbits and station coordinates, and we obtained -0.1 to -0.5 mm/hPa for major 12 laser ranging stations in the world.

JSG01/08A/A01-004   0945

RESPONSE OF WELL WATER LEVEL TO HEIGHT CHANGE IN HAMAOKA, SHIZUOKA PREFECTURE, JAPAN

Norio MATSUMOTO, Makoto TAKAHASHI, Ryu OHTANI, Naoji KOIZUMI (Geological Survey of Japan, AIST)

Height change of BM 2595 in Hamaoka town, Shizuoka prefecture, Japan as referenced to BM 140-1 in Kakegawa city has been observed to detect an uplift prior to the anticipated Tokai earthquake since 1962 by the Geographical Survey Institute. The height of BM 2595 has subsided persistently about 5 mm/year accompanied with about 1 cm of seasonal fluctuation. Our three observation wells and subsidence meter are located around BM 2595. In order to evaluate response of well water level to the height of BM 2595 quantitatively, we compare well water levels and subsidence meter data with the height data. Depths of the observation wells are 55 m, 210 m and 270 m, respectively. The subsidence meter was installed the 210 m well. This instrument can measure the vertical length between the bottom of the 210 well and the ground surface. During the period from 1985 to 2002, well water level in the 55 m well decreased 3.5 m accompanied with 1.2 m of seasonal change, and well water level in the 270 m well changed one third of that in the 55 m well. On the other hand, 4 mm subsidence together with 0.5 mm of seasonal change was observed by the subsidence meter in the same period. The subsidence observed by the subsidence meter is obviously caused by the decrease in well water level at the 55 m well, because the data of subsidence meter changes several days after the changes in the well water level. A seasonal adjustment analysis is applied to the observed height and corrected height eliminating the subsidence change, respectively. Persistent subsidence rate and amplitude of seasonal change in the corrected height are reduced by 10% and 5% in the observed height, respectively.

JSG01/08A/A01-005   1000

A STUDY ON SEASONAL VARIATION OF LEVELNG DATA IN OMAEZAKI REGION

Tetsuro IMAKIIRE[1], Minoru TAJIMA[2] ([1]Geography and Crustal Dynamics Research Center, Geographical Survey Institute(GSI), [2]Chuo College of Technology)

Geographical Survey Institute(GSI) has been carrying out leveling survey in Omaezaki region, four times per year, since 1981. This leveling survey revealed that Hamaoka(BM2595) is subsiding about 5mm/yr referred to Kakegawa(BM140-1). Though the rate of subsidence is steady for long term, it is pointed out that seasonal variation is laying over the trend. The amplitude of seasonal variation is as mach as 1cm(peak to peak). Various hypothesis has been proposed for the origin of this variation. As GPS data does not show such significant seasonal variation, it is suspected that the origin of this variation would be a factor which is uniquely related to leveling observation. One of such doubtful sources is atmospheric refraction. This study deals the statistic parameters of this seasonal variation for 13 unit sections, which is the leveling route from one bench mark to another neighboring bench mark. If the atmospheric refraction is the cause of seasonal variation, two characteristics would be expected. 1)The amplitude of variation is proportional to the height difference of two bench marks. 2)The phase of variation is reverse between ascending sections and descending sections. We examine 13 sections of the leveling route from Kakegawa to Sagara(SF1354) to estimate the long term trend and seasonal variation using least square method. We compared AIC(Akaike Information Criterion) values

calculated from two different types of the models to examine which model is preferable. One is a linear model, which means the subsidence rate is constant and seasonal variation is random. Another model is linear function plus sine function with one year cycle, which means seasonal variation can be modelized by sine curve. We found the latter model is better than linear model in nine of the thirteen sections. However we also found linear model is preferable for other four sections. The phase of variation in the most sections agree with each other. The residual from linear trend is positive in summer and negative in winter. This means the phase does not relate whether the section is ascending or descending. The amplitude of seasonal variation seems to have no relation between the height difference in each section. Therefor the current result is negative for concluding that seasonal variation is related to atmospheric refraction.

ENVIRONMENTAL EFFECTS AND OCEAN TIDAL LOADING IN TILT DATA OF NOKOGIRIYAMA OBSERVATORY

Steffen GRAUPNER[1], Hiroshi ISHII[2], Gerhard JENTZSCH[1], Shigeru NAKAO[3], Adelheid WEISE[1] ([1]Institute for Geosciences, University of Jena, Germany, [2]Tono Research Institute for Earthquake Science, Japan, [3]Earthquake Research Institute, University of Tokyo, Japan)

Nokogiriyama Observatory of Tokyo University, Earthquake Research Institute (ERI), established in summer 1993, is situated on Boso peninsula at the eastern side of the entrance to Tokyo Bay, located at the foot of a hill at about 600 m distance east from the coastline. It comprises underground galleries and a building for data acquisition. In connection with several neighbouring observatories the purpose is the monitoring of seismicity and crustal deformation in the earthquake area around Tokyo, as well as the testing of new sensors. We compare the results of the ERI water tube tiltmeters and the borehole tiltmeter No. 106 of the Askania type, in April 1997 installed in a 10 m deep borehole inside the gallery close to the ERI tiltmeters. It operated with only a small drift until June 1999. The analyses show a good correspondence between the signals of the two instruments, not only regarding the tides but also concerning meteorological effects like air pressure changes and precipitation, predominant in E-W direction. Due to the short distance to the sea we observe strong ocean loading signals disturbing the body tide parameters. Amplitude factors are amplified up to values of 10 and phases are shifted between 150° and 360° (N-S) and 40° and 120° (E-W), respectively. Loading computations were carried out using the ocean tidal model of the National Astronomical Observatory NAO99b and NAOJb (global and for the Japanese area, resp.), and the software GOTIC2 based on GOTIC. The loading signals in E-W are bigger than in N-S by a factor of about 2 to 3. In N-S the observed loading is explained by the models by about 60% to 90%, whereas in E-W the fit is between 40% and 50%. We do not assume that the existing discrepancy between computed and observed loading tides are due to a misfit of the models; we rather suggest another explanation: The short distance to the sea is a great drawback, esp. for tilt, because the modling of such small scale loading is not possible. Further, we must take into account strain-tilt coupling due to the strong ocean loading and the rough topography, which may be the cause for the slight differences in the tidal parameters.

JSG01/08A/A01-007   1050

ON THE SEASONAL VARIATIONS OBSERVED IN THE GSI SOUTH PACIFIC GPS NETWORK SOLUTIONS

Hiroshi MUNEKANE, Shigeru MATSUZAKA (Space Geodesy Research Division, Geographiscal Survey Institute, Japan)

A significant seasonal variability was found in the coordinate solutions from the Geographical Survey Institute (GSI) South Pacific GPS Network, which covers a wide range of the Pacific Ocean. The ocean mass loading is a very plausible cause for this variability since the ocean surrounds every site. In this presentation, the characteristics of the variations are shown, and the effect of the ocean mass loading is evaluated. The seasonal variability is seen in almost all sites. It is found that dominant frequencies are annual and semi-annual from the spectrum analysis, though the amplitudes vary from year to year. The amplitudes are strongest in the vertical components, and annual amplitudes reach 1cm at the maximum. The annual amplitudes and phases are changing systematically from site to site, though there is no clear latitude dependence. As for the IGS stations, Dong et al. (2001) already presented the amplitudes and phases of the annual variations. Those are consistent with our results. As a preliminary estimate for the effect of the ocean mass loading on the coordinate variability, the admittance between amplitudes of annual signals in coordinates and tide-gauge data nearby is estimated. First, the amplitudes of annual signals in the nearest tide-gauges are estimated. The tide-gauge data archived by Univ. Hawaii Sea Level Center are used for this purpose. After correction for atmospheric loading effect using IB model, steric-height correction is done assuming the linearity between SST and steric height. Then linearity between annual amplitudes of tide level change and annual variability of the vertical coordinates is examined. It is found that there exists a linearity between them, and the admittance factor is estimated to be 0.1mm(annual vertical displacement)/1mm(annual sea level change). However, to evaluate the ocean mass effect more quantitatively, it is necessary to employ the green-function method with altimetry data. In the presentation, the synthetic variability calculated with the green function method will be presented, and its ability to explain the spatio-temporal variations observed in the coordinates is discussed.

JSG01/08A/A01-008   1105

STABILITY OF GEODETIC REFERENCE POINTS IN PERMAFROST REGION - A CASE STUDY

Hans-J. KUEMPEL[1], Marcus FABIAN[2] ([1]Leibniz Institute for Applied Geosciences (GGA), [2]Section of Geophysics, Geological Institute, University of Bonn)

Comparison of station velocities of VLBI and GPS reference points at the Ny-Ålesund Space Geodetic Observatory, Spitsbergen has questioned the stability of the basements of the antennas over time spans of several years. Due to its high latitude of almost 79° N, the site is of crucial importance for the world geodetic reference frame. The two antennas which became operational some ten years ago are roughly 100 m apart from each other. They have been fixed to concrete basements, erected in the permafrost ground, at 40 m above sea level. At the test site, the subsoil is melting down to 3 or 4 meters during the arctic summer. The basement of the VLBI antenna which has a diameter of 20 m is more massive than that of the GPS antenna. Both the basements are in contact with the bedrock, consisting of a folded sedimentary hard rock at several meters depth. In near distance from the basements, the terrain falls steeply to the Kongsfjord. From August 2001 up to October 2002 we have operated three continuously recording tiltmeters of resolution 0.1 microrad on the tops of the basements. The purpose of this campaign was to monitor micro-movements over a period where relevant changes in ground frost conditions take place which might affect the stability of the antenna basements. By using tiltmeters we are unable to see any translational movements e.g., in vertical direction; rather we can infer from the presence of significant tilt movements that the stability of the basement is reduced. Several tests with various configurations of instrumental set-ups were conducted in the initial phase of the

IA

campaign. Analysis of these tests has revealed that the magnitude of tilt induced through repositioning of the VLBI antenna is of order 10 microrad. The dominant part of this tilting appears to be internal deformation (bending) of the concrete basement. Inspection of the 13 months long recordings suggests stable conditions for the basement of the GPS antenna at Ny-Ålesund, on the 50 microrad level. For the basement of the VLBI antenna, the situation is less clear. There is evidence for permafrost-driven instability in May - July 2002 at this place, however, with some doubts remaining due to partial malfunctioning of the single tiltmeter that was operated here. The instrument was exposed to large temperature variations and presents questionable temperature sensitivity in one of its components. Still, adopting conservative estimates, the total observed tilt signal reflects rotational movements of the entire basement, which do not exceed 1 millimetre (per length of the basement).

ON THE VERTICAL CRUSTAL MOTION AND GRAVITY AT METSÄHOVI, FINLAND

Heikki J. VIRTANEN, Joel J. AHOLA (Finnish Geodetic Institute)

Metsähovi is a geodetic laboratory with a large number of observations program: permanent GPS, satellite laser ranging, DORIS beacon, absolute gravity and superconducting gravimeter. We present results on vertical crustal motion as seen in the gravity data of the superconducting gravimeter GWR T020 at Metsähovi station for years 1994 - 2002. The refined tide free gravity have corrected by known seasonal hydrological effect, such as groundwater level changes. We have associated temporal height variations with the loading effects of the atmosphere and of the nearby Baltic Sea at the distance of 15 km. Theoretical loading calculations using Green´s functions formalism are performed for both vertical motion and gravity and the modelled gravity is compared with a large amount of observational data. For Baltic Sea loading effects we have used data of the nearest tide gauge in Helsinki at the distance of 30 km as well as data of several tide gauges around the Baltic. The loading by atmosphere has been computed using a detailed surface pressure field from HIRLAM (High Resolution Limited Area Model) for North Europe. The gravity data are congruent with loading calculations. The loading effect of the Baltic Sea can exceed 10 mm and the deformation by atmosphere 25 mm. However, the effects partly oppose each other. Though the sensitivity of superconducting gravimeter is far of other co-located instruments, the loading effects of air pressure and Baltic Sea level can be large enough affect the observations with other techniques. We show comparisons between variation in GPS height and in gravity observations for some shorter periods. We discuss the results of the loading calculations and achieved improvements in gravity residuals.

JSG01/08A/A01-010   1135
THE SOLID EARTH RESPONSE ON CHANGING ICE LOADS IN WEST GREENLANDINFERRED FROM REPEATED GPS OBSERVATIONS

Reinhard DIETRICH, Axel RUELKE, Mirko SCHEINERT (TU Dresden, Germany)

Bedrock areas in the marginal regions of ice sheets are especially suited to study vertical crustal deformations caused by the viscoelastic response of the Earth on changing ice loads. Our research concentrates on the ice-free part of West Greenland. In this region, a GPS network consisting of 14 stations was established and observed in 1995. A complete reobservation was carried out in 2002. We will describe the design of the network as well as the observation strategy, which aims especially at a control of systematic effects andat a high accuracy of the height determination. The data analysis has been carried out using the Bernese Software v4.2.Since we were looking for height changes the analysis was concentrated onsingle baselines. The achieved accuracies will be discussed. Finally, the obtained results will be compared with the present knowledgeand model predictions of recent crustal uplift rates in West Greenland.

JSG01/08A/A01-011   1150
DERIVING NEW CONSTRAINTS ON GLACIAL LOAD HISTORY BY GEODETICOBSERVATIONS IN DRONNING MAUD LAND, ANTARCTICA

Mirko SCHEINERT[1], Erik IVINS[2], Reinhard DIETRICH[1], Axel RUELKE[1] ([1]TU Dresden, Germany, [2]Jet Propulsion Laboratory, USA)

A variety of geodetic and glaciological observations in central Dronning Maud Land (DML), East Antarctica provide information that may constrain both the recent isostatic crustal uplift pattern and the recent and past ice sheet configuration and flow character. Using GPS observation campaigns in 1996 and 2001, it is possible to bound regional postglacial uplift rates. These geodetic data, when coupled with additional constraints on recent and past ice mass changes, allow a self-consistent glacial load history to be investigated. We examine a spectrum of viable load histories and compute the associated isostatic deformation signatures. Our limited goal is to reconcile the modelled signals and the observations and to define what further observational strategies might be undertaken to simultaneously constrain combinations of DML load history and the deep solid earth rheological response.

JSG01/08A/A01-012   1205
VERTICAL MOTION AND GLACIAL ISOSTATIC ADJUSTMENT IN THE GREAT LAKES REGION

Alexander BRAUN[1], C.K. SHUM[2], Laramie V. POTTS[2], Chung-Yen KUO[2], Andrew TRUPIN[3] ([1]Byrd Polar Research Center, The Ohio State University, [2]Department of Civil and Environmental Engineering and Geodetic Sciences, [3]Oregon Institute of Technology)

The deglaciation cycles of the Laurentide ice sheets havedominated the Glacial Isostatic Adjustment (GIA) in theGreat Lakes region in the Northern United States/Canada.However, beside the GIA induceddeformation, it has been shown that tectonicprocesses and mantle flow have a significantcontribution on the deformation of the lithosphere. A separation of thesetwo signals is necessary before assimilating deformation datato constrain Earth parameters, like the viscosity, or the ice loading history. The Great Lakes region is covered by a suite of differentgeodetic sensors allowing to quantify the vertical motion atparticular sites. A combination of GPS, absolute gravity,satellite altimetry and water-level gauges provide independent meansto measure present-day crustal motion. Absolute gravity measurements have beencarried out for almost a decade at some sites west of the Great Lakes.The technique to use satellite altimeter dataand water-level gauges to measure vertical motion has been validatedby comparison with vertical motions from the BIFROST project inFennoscandia. The derived results are highly accurate and can also be obtainedin regions, where permanent GPS is not available.In general, the vertical motion in the Great Lakes region shows uplift in the Northern part, whilethe Southern part, namely Lake Erie and Lake Michigan, is subsiding. Since the maximum Southern extend of the Laurentide ice sheet was locatedin that particular area, analyzing the present-day deformation can deliver valuable constraintson Earth parameters. The visco-elastic response at the former ice margindue to deglaciation shows a significantly different sensitivity toviscosity comparedto the former center of the ice sheet or the far field.Here, the visco-elastic response is

especially sensitive to the uppermost mantle viscosity.The Great Lakes area is therefore an excellent opportunity to studythese specific parameters, which are difficult to constrain in the centraluplift regions, where the signal is largest, but spatially uniform. Verticalmotions in the Great Lakes region from multiple observations (GPS, GIA models,altimetry-water level gauges) are presented together withresults of the separation of the tectonic and GIA induced signals. Amulti-resolution analysis of gravity data using wavelets has been employed tofind spatial and spectral characteristics. These characteristics help toidentify regions, where tectonic or GIA influence dominates the verticalmotion signal.GIA modeling with assimilation of vertical motion observations has been carried outin order to get improved constraints ofGIA parameters. The model results obtained so far are presented togeher withresults of geodetic observations to estimate spatial distribution of verticalmotion in the Great Lakes region.

STRAIN DISTRIBUTION AROUND THE HANAORI FAULT IN KINKI DISTRICT OF JAPAN BY DENSE GPS NETWORK

Fumio OHYA, Kunihiro SHIGETOMI, Yoshinobu HOSO, Kajuro NAKAMURA (Disaster Prevention Research Institute, Kyoto University)

We have constructed a dense GPS network around the southwest half of the Hanaori fault in Kinki district, Southwest Japan since 1997. This fault is one of the major active faults in Japan. The surface trace of the fault is about 45km long and the slip direction is right lateral inferred from some geological evidences, but ongoing creep on the fault surface is not recognized on the outcrop. On geological point of view, central Kinki area forms a triangular shape named as ˝Kinki Triangle˝ by Huzita(1962). The Hanaori fault is a part of northwest border of the Triangle. On seismological point of view, the northwest side of this fault is Tamba highlands, where the seismic activity has increased after the Hyogo-ken Nanbu Earthquake(Jan.17,1995, M7.2). And the result of the triangulation surveys over a century revealed the strain contrast around the fault. Surveys in our dense GPS network were started motivated by two interesting points, one is the cause of the contrast in various data, such as geological, seismological and geodetic. The second point is earthquake prediction on this fault. The analysis of the coordinates of the permanent stations in GEONET, which is national GPS array in Japan operated by GSI, proved high strain rate zone from Awaji Island, located at southwest of Kobe, to Niigata at the Japan Sea coast. The northwest border of ˝Kinki Triangle˝ is located in this zone and also the Hanaori fault is. The mechanism causing this zone is not obvious and the information on strain distribution in this zone is necessary to reveal the mechanism. Our network consists of 17 newly constructed observation points and the data are analyzed including those at neighboring GEONET stations and some existing stations of Kyoto University. We operate continuously single or dual frequency receiver at four stations of new stations and have made epoch observations twice a year in the other stations. A GEONET station whose seasonal variation in their coordinates is smallest in the surrounding area is decided as a reference point in the analysis. The displacement field referred to the reference point reveals the clockwise rotation. We will finally present the strain distribution in this network. The strain distribution in space is mainly contractive and the dominant direction of the strain is NW-SW direction. But obvious discontinuity in strain cannot be found.

JSG01/08P/D-002   Poster   1400-002
INTER-PLATE COUPLING BENEATH THE NE JAPAN ARC INFERRED FROM 3 DIMENSIONAL CRUSTAL DEFORMATION

Yoko SUWA, Satoshi MIURA, Akira HASEGAWA, Toshiya SATO, Kenji TACHIBANA (Tohoku University)

NE Japan is located at a typical subduction zone, and is a seismically very active region where large interplate earthquakes have occurred repeatedly. The nation-wide network of GPS observation (GEONET) recently constructed enables us to investigate the crustal deformation in detail. Based on data obtained by this network, interplate coupling has been studied by inverse methods (e.g. Nishimura et al., 2000). Because of relatively poor accuracy in the vertical component of displacements, however, they estimated model parameters by weighting the horizontal components largely, and sometimes encountered the inconsistency between calculated vertical displacements and observed ones. In this study, we devise a new model for interplate coupling by means of 3D displacement field to explain not only horizontal components but vertical ones. We used data of continuous GPS stations operated by GSI and Tohoku University from 1997 to 2001, and the data was analyzed using the Precise Point Positioning (PPP) technique of GIPSY/OASIS-II in order to derive vertical displacements more reliably. We assumed each displacement component as a linear function of time to estimate the velocity. Obtained result shows that vertical displacements near the Japan Sea coast show uplift, while those near the Pacific Ocean coast show subsidence. This characteristic pattern of vertical deformation is in good agreement with the result of leveling survey operated by GSI, which indicates that vertical components of the velocity derived by GPS are reliable and can be used as the data of the inverse method. In this study, we used a geodetic inversion method, GDBYS, developed by Yabuki and Mtsu'ura(1992). Obtained result shows that strong coupling is estimated in two areas, off Tokachi and off Miyagi, which correspond to the northern asperity of the 1968 M7.9 Tokachi-Oki earthquake, and to the asperity of the 1978 M7.4 Miyagi-Ken-Oki earthquake, respectively. The depth of the aseismic front is seismologically estimated to be 50-60km, and the region shallower than this depth is regarded as the coupled zone of the plate boundary (e.g. Igarashi et al., 2001). The back-slip distribution derived from 3D displacement field in this study, however, extends down to about 100-120km depth. One possible cause for this may be the existence of a transition zone, where the coupling rate decreases from about one at about 60 km depth to zero at around 100km depth, due to the subduction of old and cold oceanic slab.

JSG01/08P/D-003   Poster   1400-003

TECTONICS IN THE KINKI DISTRICT, JAPAN

Kunio FUJIMORI (Graduate School of Science, Kyoto University)

A GPS array with about 1,000 stations (GEONET) is operating in Japan. The GPS data obviously show secular crustal deformation in the Japan island. When homogeneous strain was removed from observed strain field, spatial distribution of local crustal deformations can be found. Based on daily coordinate data of the GPS stations in the center part of the Kinki district, the E-W and N-S components of GPS horizontal displacements were reduced by 0.04 mm/km/year and 0.02, respectively. As a result, a fine boundary appeared in displacement vector distribution. On the northwest side of the boundary the vectors are small, and on the southeast side the vectors to the west are large. The vectors show a right lateral movement of about 3 mm/year on the boundary. A vertical movement of about 3 mm/year is seen too. Therefore, it is thought that the boundary is a creep fault with a share zone of about 20km in width. The fault will extend from the Akashi strait to the north part of the Chubu district through the north Biwa lake. In addition, it is recognized that historical large earthquakes (M≧7) occurred in the fault neighborhood and that the fault crosses a lot of active faults. The existence of this creep fault will mean that a giant shear fracture is progressing slowly in the center part of the Japan island, the Kinki and Chubu districts, under the E-W compression. It is said also that the large earthquakes in Western Japan were generated before and after the great earthquakes on the Nankai trough. When the great earthquake are compared with the historical large earthquake along the creep fault at occurrence time, it seems that the cycles of the large earthquake occurrences along the creep fault were reset by every other great earthquake on the Nankai trough. It is thought that earthquakes of M7 class can be predicted if continuous observation stations for crustal deformation are arranged along the creep fault because strain changes before earthquakes were observed at the stations which were located on this creep fault.

SPATIO-TEMPORAL DISTRIBUTION OF INTERPLATE COUPLING IN SOUTHWEST JAPAN DEDUCED FROM INVERSION ANALYSIS

Takeo ITO, Manabu HASHIMOTO (RCEP, DPRI, Kyoto University)

From the viewpoint of long-term forecasts of great earthquakes, it is important to clarify the accumulation process. In order to clarify the accumulation process of tectonic stress, one strategy is to perform an inversion analysis using the available crustal deformation data. The crustal deformation data contain useful information about the spatio-temporal distribution of slip on the plate interface. We try to obtain the spatio-temporal distribution of the strength of interplate coupling from geodetic data such as leveling, triangulation and trilateration, and GPS surveys during recent 100 years in SW Japan. To evaluate this spatio-temporal distribution on the plate interface, we develop a new inversion method. This inversion method can treat the long-term crustal deformation data, the earthquake cycle and the stress relaxation of the viscoelastic asthenosphere. In our inversion method, the spatio-temporal slip rate distribution is expressed by the superposition of basis functions (B-spline functions of one degree in time domain and bi-cubic B-spline functions in space). Therefore, we can deduce the amount and direction of slip rate, and their temporal change by determining the coefficients of each basis function. We used the dislocation theory in viscoelastic body to calculate displacement rates at each observation points from slip rates on the plate interface. We also apply prior information about the smoothness of spatio-temporal distribution of slip rates. We construct a highly flexible model in which relative importance between observed and prior data is controlled by hyperparameters. To determine the most optimal hyperparameters, we used ABIC. Therefore, we can uniquely determine the spatio-temporal distribution of slip rates. From this analysis, we obtain afterslips in the deeper part of the plate interface following the 1946 Nankaido earthquake at postseismic stage. The maximum afterslip is found beneath central Shikoku, and the total afterslip is about 1.0m. The slip deficit rate at interseismic stage is 5-6 cm/year in the N45W-N70W direction, which is almost consistent with the relative plate motion between the Philippine Sea and the Amurian plates. A strongly coupled region is found in the shallower portion than 30 km, and the slip deficit rate takes its maximum at the depth of about 20 km. The interplate coupling is very weak on the plate interface deeper than 30 km. If we assume recurrence time of interplate earthquakes to 92 years, the predicted amount of coseismic slip may reach about 6m off Shikoku and about 3m off Kii peninsula.

A MODEL WITH RIGID ROTATIONS AND SLIP DEFICITS FOR THE GPS DERIVED VELOCITY FIELD IN SOUTHWEST JAPAN

Sou NISHIMURA, Manabu HASHIMOTO (Research Center for Earthquake Prediction, Disaster Prevention Research Institute, Kyoto University)

In order to know kinematic tectonics of southwest Japan, GPS derived velocity field is analyzed. It consists of two factors; the one is the elastic deformation caused by slip deficits on the locked portion along the block boundary, and the other is rigid motion of regional tectonic blocks (or plates).   Therefore rigid motions cause significant errors to the estimation for slip deficits. For example, the velocity field in southwest Japan cannot be fully explained only by a model with slip deficits. Residuals in such model imply the influence of E-W collision between southwest Japan and northeast Japan and the backarc spreading along the northern extension of the Okinawa trough.   We interpret the velocity field in southwest Japan by a superposition of the elastic deformation caused by slip deficits and rigid motions. Based on strain rate field and crustal seismicity, we apply a model with 3 blocks (Inner Arc, Outer Arc, and the northern Ryukyu) and slip deficits along the block boundaries.   Some interesting features of southwest Japan are revealed: (1) westward motion of the outer arc relative to the Amurian plate and the inner arc, (2) southward motion of the northern Ryukyu block relative to the Amurian plate, (3) small right lateral slip deficits along the boundary at the latitude 32°N in southern Kyushu, (4) small left lateral slip deficits along the Median Tectonic Line and the Beppu-Shimabara Graben, (5) slip deficit rates on the plate interface smaller than in the case that rigid rotations are not considered, (6) clockwise deflection of the direction of slip deficits from that estimated in the case that rigid rotations are not considered.

CRUSTAL DEFORMATION OF THE NE JAPAN ARC AS DERIVED BY CONTINUOUS GPS OBSERVATIONS

Toshiya SATO, Satoshi MIURA, Yoko SUWA, Akira HASEGAWA, Kenji TACHIBANA (Research Center for Prediction of Earthquakes and Volcanic Eruptions, Graduate School of Science, Tohoku University)

A dense GPS network was established in 1997 around Ou Backbone Range (OBR), northeastern Japan, by deploying 9 new continuous GPS stations so as to complement sparse portions of GPS Earth Observation Network (GEONET) operated by Geographical Survey Institute of Japan (GSI). This observation network is aimed to investigate the present surface deformation and to understand the relationship between the occurrence of intraplate earthquakes and the deformation process of the island-arc crust. Our GPS data are analyzed using a precise point positioning technique of GIPSY/OASIS-II. Coordinates of the GEONET stations have been supplied in daily SINEX files by GSI. Obtained results of vertical displacements show slight upheaval near the Japan Sea coast, while subsidence near the Pacific Ocean coast. This overall pattern is in good agreement with the result obtained from the leveling surveys operated by GSI. In addition, the subsiding rates in the region between 39.0N and 39.6N are slightly larger than the surrounding regions. This may be related to the strain accumulation in OBR.Producing grid data of horizontal displacement velocities and taking spatial derivatives, we can draw a map of strain velocity distribution. The result shows that a region between 38.8N and 39.8N in OBR demonstrates notable concentration of EW contraction. The region coincides with the area of active seismicity and includes the focal areas of 1896 (M7.2), 1962 (M6.5), and 1970 (M6.2) events. Observed strain is too large to explain by a total moment release of earthquakes that occurred in the same period as the GPS observations. There must be some possible sources of the strain concentration: viscoelastic deformation due to the large earthquakes, or aseismic slip along the deeper extension of active faults.

TECTONIC CREEP OF THE ATOTSUGAWA FAULT SYSTEM, INFERRED FROM GPS OBSERVATION

Yuki MATSUURA, Akira TAKEUCHI (Department of Earth Sciences, Toyama University)

The Atotsugawa fault system (AFS) consisting of a series of NE or ENE striking right-lateral strike-slip faults, such as the Atotsugawa fault, Ushikubi fault, and Mozumi-Sukenobe fault, is the most active structure in the northern Hida region of central Japan. Previous studies had been conducted on the fault system, and revealed high seismicity of micro earthquakes along the fault trace, for example. Recent geodetic studies have suggested the creep movement of Atotsugawa fault, the main fault of the AFS, probably. But, so far, laser ranging across the fault only shows the creep movement near surface on the central portion of the Atotsugawa fault. It is not clear whether creep movement on the other fault of AFS is possible, and depth of creeping. In this study, in order to reveal nature of creep movement of area inserted into the fault system, we analyzed the GPS data around the AFS, from both Geographical Survey Institute of Japan, and the Atotsugawa GPS array observation points of Nagoya University. In a data of period from April 24 1997 to August 31 2002, the solution results in creep movement of the AFS: (1) the results show right-lateral creep movements occurring on both the Atotsugawa fault and the Ushikubi fault. (2) All observation points in central and eastern areas between the Atotsugawa and Ushikubi faults show clockwise rotation, suggesting one rigid block of between the two faults. (3) Furthermore, for a rate ingredient of the perpendicular displacement to the fault trace of the AFS, it shows that the Atotsugawa fault is possessed of bigger distortion than the Ushikubi fault. Lastly, (4) it is possible that Atotsugawa fault system might extend northeastwards, based on the displacement of eastern end region of the AFS. This study shows an interesting result of rotational displacement of area between the Atotsugawa fault and Ushikubi fault. But to reveal the detailed feature of this area, we will install additional observation points.

CURRENT DEFORMATION AT THE ITOIGAWA-SHIZUOKA TECTONIC LINE IN CENTRAL JAPAN DETECTED BY GPS

S. Jason ZHAO, Y. KANEDA (Japan Marine Science & Technology Center)

The Itoigawa-Shizuoka Tectonic Line (ISTL) represents the boundary between the Amurian and North American plates in central Japan. Geological investigation reveals that it is a left-lateral strike-slip fault with a motion rate of 3~10 mm/yr. Results from Paleo-seismological study show that at least three events occurred in 224-186 A.D., 150-334 A.D., and 839-189 B.C., respectively, and the left-lateral coseismic slip during the last earthquake is about 6~9 m (Okumura and Imura, EOS, 76, No. 46, F363, 1995). Although there are more than 40 permanent GPS stations near or around ISTL, there is no direct assessment available for the current motion of ISTL. Crustal deformation in the region is dominated by subducting Pacific (43~50 mm/yr) and Philippine Sea plates (73~79 mm/yr), so that the deformation of small magnitude (<10 mm/yr) associated with active faults has been masked. In this study, using GPS observations and geometry of subducted slabs as constraints, we first construct a three-dimensional kinematic model to simulate the subduction of the Philippine Sea plate at the Suruga and Sagami troughs and the Pacific plate at the Japan trench. Then, we determine local deformation by removing the regional deformation associated with plate subduction from the GPS observations. As a result, relative motion between two flanks of ISTL is clearly exposed. In northern Kanto, the west-southwestward motion of GPS stations indicates the motion of the North American plate relative to the Amurian plate. The distinct boundary between two different types of motion trend revealed by GPS clearly demonstrates the current motion of ISTL. An inversion analysis of observed surface deformation for active segments on the ISTL indicates that the motion of ISTL in the north has been mostly accommodated by its NE branch with a right-lateral strike-slip, which could be connected to the Nagano fault system. The upper part (depth < 15 km) of the central segment of ISTL is locked, whereas slip at the lower part of the crust accommodates the relative motion between the Amurian and North American plates in the region. Deformation in the south is compounded with interplate deformation and displays a complex pattern. Since the horizontal width of locked middle segment of ISTL is large (~100 km), its capability of generating large earthquakes is relatively low comparing with a narrow locked fault zone. However, inland earthquakes could occur in the surrounding area of the ISTL due to stress localization at the margin of locked zone. http://www.geocities.com/subduction99/index.html

CURRENT PLATE KINEMATICS IN NORTHEASTERN ASIA BY GPS DATA: INTERACTION OF AMURIAN OKHOTSK, EURASIA AND NORTH AMERICAN PLATES

Hiroaki TAKAHASHI[1], Evgenii I. GORDEEV[2], Vilory F. BAKHTIAROV[2], Vasily E. LEVIN[2], Nikolay F. VASILENKO[3], Alexei IVASHCHENKO[3], Mikhail D. GERASIMENKO[4], Nikolay SHESTAKOV[1], Vladimir A. BORMOTOV[5], Minoru KASAHARA[1] ([1]Institute of Seismology and Volcanology, Hokkaido University, [2]Kamchatka Experimental and Methodical Seismological Departhment, Russan Academy of Sciences, [3]Institute of Marine Geology and Geophysics, Russian Academy of Sciences, [4]Institute of Applied Mathmatics, Russian Academy of Sciences, [5]Institute of Tectonics and Geophysics, Russian Academy of Sciences)

A continuous GPS network has been established in far eastern Russia with more than 15 new stations to investigate the current plate kinematics in northeastern Asia. We succeeded to install new sites in Kamchatka, Komandorski Island, Sakhalin, Khabarovsk and Primorskiy regions. These data have helped to illustrate the crustal deformation associated with the plate interactions in this region. We recognized the independent eastward motion of the Amurian plate relative to the Eurasian plate, which generates the plate convergence along

the eastern margin of Sea of Japan with 2-3cm/yr and gives new framework of plate kinematics around Japan. The station at Komandorskiy island clearly indicates full coupling of the transform boundary between the North Amerincan and Pacific plates. Stations at Kamchatka have been secularly affected by the subducting Pacific plate and both coseismic and post-seismic rebound have been recorded. Our data so far does not yet indicate whether the Okhotsk plate exists or not because the Kamchatka region is very complex and the data observation period has been too short to separate the effects of the plate subduction along the Kamchatka trench. Combined with the IGS network, our GPS data will give geodetic constrains needed to establish plate kinematics in northeastern Asia, Bering and Alaska regions.

ON THE CRUSTAL DEFORMATION STUDY FROM PERMANENT GPS STATIONS IN KOREA

Hong-Sic YUN, Jae-Myoung CHO (Department of Civil & Environmental Engineering, Sungkyunkwan University)

The Korean peninsula is 200~300km wide and 1000 km long from north to the south, protruding from the eastern part of the Eurasian continent. The Korean peninsula extends southward from northeast Asia and has a close affinity with the Asian continent, especially with the Northeast China paraplatform, in geological and tectonic setting. In historical documents many destructive earthquakes were recorded, especially in 6th~7th, 13th and 16th~18th centuries. They remarked that steady accumulation of crustal strain and its sudden release by earthquakes occurred repeatedly in the Korean peninsula during those times. In Korea, National Geography Institute (NGI) has established fourteen permanent GPS sites in a continuously operating reference station network since 1995 for the purpose of cadastral surveying, geodynamic application and atmospheric research. The purpose of this study the characteristics of strain pattern by using permanent GPS stations in Korea in terms of seismic activity and tectonics. In this study the GPS network is composed of fourteen permanent GPS stations. Each of the analyzed fourteen stations has at least 3 years of continuous data during 1999 and 2002. The data were analyzed using the GIPSY-OASIS II. For the solution of baseline vectors we designed the triangulation network which consist of fourteen stations. One baseline was allocated to each ten day and ten daily solutions were computed for each baseline. Allocation of one baseline per ten days ensured that separate baseline solutions were independent. We could calculate horizontal strains from the difference of the mean baseline vectors of ten daily solutions between the time span of three years, if they had enough accuracy for the present strain calculation. The main characteristics of the strain change during the three years in Korea obtained from the present study are revealed that the mean rate of the maximum shear strain change is 0.122μ/yr and the direction of the principal axis is about 85°. The mean rate of dilatation is also -0.004μ/yr. The GPS network composed of fourteen stations in Korea shows localized deformation with maximum shear oriented NNE-SSW and compression deformation from negative dilatation. This mean rate of maximum shear strain is nearly one third of the mean rate of Japan deduced from the data of the revision survey of the first order triangulation net. Considering the relationship with the results of present research, there is a clear difference in the direction of the axis between the Korean peninsula and the East sea side of Chugoku district of Japan, notwithstanding the similarity in the seismicity and the strain rate in the both areas. This gives a strong likelihood of the existence of a certain tectonic line between the southern part of the Korean peninsula and the Chugoku district, Japan.

CRUSTAL DEFORMATION ALONG PLATE BOUNDARY OF TAIWAN

Chi-Ching LIU (Institute of Earth Sciences, Academia Sinica)

Geodetic monitring, including precise leveling, trilateration, tidal guage station, and GPS, have been conducted for two decades along the eastern coast of Taiwan. These geodetic networks covers several significant tectonic regimes such as the Ryukyu trench-arc system, the Okinawa Trough north of the arc, and the collsion boundary between the Phillipine Sea Plate and the Eurasian plate. The Ilan Plain which located at the southwest continuation of the Okinawa Trough, show that the whole basin tilted to the east at a rate of 0.44 μradian/yr. The subsiding rate is faster at the center axes of the trough with rate of 20 mm/yr. At south bound of the basin, the subsidence was episodic, and was controlled by the local seismicities. Both precise leveling and GPS results show that he southern edge of the plain has been opening clockwise with rate of about 1 μradian/yr, and the process is still going on. The Hualien area right above the subduction zone experienced several episodic uplift during the period of study. Uplifts of several decimeters were observed as cosiesmic or postseismic events. Evidences from both sea level obervation and precise leveling also indicated fast uplifting of 20cm during the six month period between two major earthquakes in this area. For the hundred km long coast along the collsion boundary show a consistent overall northward tilting rate of about 0.2 μrad/yr. There are several events occurred during the last two decades which caused some signicant elevation changes in the local area, but the overall tilting rate is still kept constant. Uplift rate derived from the morphology of the marine terraces and their dates also shows similar tilt pattern with rate of about 0.1 μrad/yr. However the rates derived from the marine terraces, which indicate the average uplift rate for the past thousands of years, are only about half of the rated derived from precise leveling in the past two decades. Borehole strainmeters and densed continuous GPS network are deployed in this area, and an integrated geodetic network will cover this plate boundary as part of the Plate Boundary Observatory of Taiwan in the next few years.

NICOYA, COSTA RICA, TRANS-PENINSULA GPS EXPERIMENT AND INTER-PLATE COUPLING

Takeshi IINUMA[1], Marino PROTTI[2], Koichiro OBANA[3], Shin'ichi MIYAZAKI[1], Victor GONZALEZ[2], Rodolfo VAN DER LAAT[2], Teruyuki KATO[1], Yoshiyuki KANEDA[3], Enrique HERNANDEZ[2] ([1]Earthquake Research Institute, University of Tokyo, [2]Observatorio Vulcanologico y Sismologico de Costa Rica, Universidad Nacional, [3]Institute for Frontier Research on Earth Evolution, Japan Marine Science and Technology Center)

We have been carrying out a GPS (Global Positioning System) observation project in Nicoya peninsula, Costa Rica, since 2001. Costa Rica is located in the western margin of the Caribbean plate, and the Cocos plate is subducting beneath the Caribbean plate from the Middle American Trench. The convergent rate between these two plates is about 90mm/yr in this area. Because of this rapid convergence, large earthquakes often occur at the western coast of Costa Rica. The Nicoya subduction segment in northwestern Costa Rica has ruptured with large earthquakes in 1853, 1900 and 1950. Recently, two large earthquakes occurred around this peninsula (Mw 7.0 in 1990 to the southeast and the 1992 Mw 7.6 off Nicaragua to the northwest). There is a clear seismic gap, the ″Nicoya seismic gap″ between the rupture areas of these two earthquakes. In the Nicoya seismic gap, a strong coupling of the two plates is manifested by low background seismicity, the sharp edge of aftershock zone of the 1990 and 1992 earthquakes (Protti *et al.*, 1995), and the northeastward

movement of the Nicoya peninsula recorded with GPS observations (Lundgren *et al.*, 1999). Protti *et al.* (2001) estimates that a Mw=7.5 earthquake is likely to occur in the Nicoya seismic gap. Since Nicoya peninsula lies above this gap, GPS observations in this peninsula provide invaluable data for various studies about the seismic coupling, the updip and downdip extends of the seismogenic zone and the potential earthquake. Thus we started a new GPS survey program in Nicoya peninsula in 2001 by Observatorio Vulcanológico y Sismológico de Costa Rica, Universidad Nacional (OVSICORI-UNA) and Japan Marine Science and Technology Center (JAMSTEC) with support of the Japan International Cooperation Agency (JICA). Seven new benchmarks for GPS campaign observations were installed completing a 10 sites transect across Nicoya peninsula (Obana *et al.*, 2002). In 2002, the project was progressed by OVSICORI-UNA, JAMSTEC and Earthquake Research Institute, University of Tokyo (ERI) as a cooperative operation of JICA. The second campaign observation was held during the period from September 23, to October 12, 2002, and we obtained displacement vectors from the data. We will be presenting the results of GPS campaign observations and results from one-dimensional inversion analysis about inter-plate coupling using obtained displacement data.

DETECTION OF RECENT TECTONIC MOVEMENTS AT THE WESTERN PART OF NORTH ANATOLIAN FAULT ZONE (NAFZ) BY GEODETIC TECHNIQUES

Haluk OZENER, Asli Garagon DOGRU, Onur YILMAZ, Bulent TURGUT, Onur GURKAN (Department of Geodesy, KOERI, Bogazici University)

Turkey, having a long history of destructive earthquakes, is located in the Alpine-Himalayan seismic belt. In the past years, many researchers have focused on the activity in the North Anatolian Fault Zone (NAFZ) which is one of the most active fault zones in the world. Since 1972 geodetic studies have been concentrated at the Western Part of NAFZ. The region that has a high risk of earthquakes is about 150 km east of Istanbul with a high density of population and industrial infrastructure. The aim of these geodetic studies is to detect crustal deformations in this area. Three microgeodetic networks that are at Iznik with 10 points, Sapanca with 7 points, and Akyazi with 10 points on NAFZ have been established in order to monitor crustal displacements by Geodesy Department of Kandilli Observatory and Earthquake Research Institute (KOERI) of Bogazici University. These microgeodetic networks were constructed to control the Iznik-Mekece fault zone, the Izmit-Sapanca fault zone and their intersection area, the Mudurnu fault zone. The first period observations were performed by using terrestrial methods in 1990 and these observations were repeated annually until 1993 by using total-station and electromagnetic distance-meter instruments. Since 1994 GPS measurements have been carried out at the temporary and permanent points in the area and the crustal movements are being monitored. Horizontal deformations which have not been detected by terrestrial methods were determined from the results of GPS measurements. During the recent 3 years after the August 17, 1999, M=7.4, Izmit Earthquake that caused extreme damage in the region, many investigations have been pursued. One of them is an international project performed with the collaboration of MIT, Turkish General Command of Mapping, Istanbul Technical University, TUBITAK Marmara Research Center and Geodesy Department of KOERI. In this project, GPS campaigns have been performed at least twice a year at distributed 49 points that spread over Marmara region. During these surveys, another network with 6 points has been formed by using 2 points from each 3 microgeodetic networks on NAFZ with appropriate coverage and geometry. These points have been connected by GPS observations to monitor the deformations. This expanded microgeodetic network has been occupied with Istanbul-Kandilli continuous GPS point (KANT). This study reports the evaluation of data from expanded microgeodetic network observations.

3-D VISCOELASTIC FEM MODELING OF POSTSEISMIC DEFORMATION CAUSED BY THE 1964 ALASKA EARTHQUAKE, SOUTHERN ALASKA

Hisashi SUITO[1], Jeffrey T. FREYMUELLER[1], Steven C. COHEN[2] ([1]Geophysical Institute, University of Alaska, Fairbanks, [2]Geodynamics Branch, NASA's Goddard Space Flight Center)

To complement previous modeling efforts to understand the postseismic deformation following the 1964 Alaska earthquake, we are implementing a three-dimensional viscoelastic model using the Finite Element Method. Rapid postseismic uplift reached as large as 125 cm, was observed on the central part of the Kenai Peninsula over the 35 years following the earthquake. Recent precise GPS observations show heterogeneous plate coupling, and a vigorous ongoing postseismic response to the 1964 earthquake. Past models of the postseismic deformation have focused on afterslip models because earlier viscoelastic-only models did a poor job at predicting the cumulative uplift observations, but this might be due to unrealistic assumptions for the model geometry. We are working toward a realistic 3D viscoelastic model that, in concert with afterslip models, can be used to understand how much each component contributes to the total postseismic deformation. We must develop a model with a realistic three-dimensional structure, viscoelastic response, and coseismic slip distribution. The rupture distribution was highly non-uniform, with most of the moment being released by two separate asperities. The largest moment release occurred offshore and beneath the Prince William Sound and the eastern Kenai Peninsula. The other moment release occurred beneath Kodiak Island, and much less slip occurred in the area between these two asperities. We will report the results of two-dimensional models with layered structure, with a dipping subducting slab and very low dip fault. We will generalize these models to three dimensions, and evaluate which aspects of the model are most important for predictions of total uplift and present deformation rates. We compare these simpler models with the results of realistic three-dimensional model.

SECULAR AND TRANSIENT CRUSTAL MOVEMENTS IN THE 1964 ALASKA EARTHQUAKE SUBDUCTION ZONE

Steven Charles COHEN[1], Jeffrey FREYMUELLER[2], Chris LARSEN[2], Hisashi SUITO[2], Chris ZWECK[3] ([1]Geodynamics Branch, Goddard Space Flight Center, [2]Geophysical Laboratory, University of Alaska Fairbanks, [3]Alfred-Wegner-Institut)

Precision leveling surveys, tide gauge measurements, and GPS observationsconducted over the four decades since the 1964 Great Alaska earthquakehave revealed a temporally and spatially complex pattern of crustal deformation.In the years immediately following the earthquake, rapid uplift occurred in theregion that subsided coseismically. Initially the uplift rate exceeded150 mm/yr, in some locals, but the rate of uplift decreased rapidlyafter a few years. The mechanism most likely to have been responsible for the uplift is aseismic slip occurring down-dip of the earthquake rupture. The cumulative postseismic uplift since the earthquake is 1 m or more where thepostseismic uplift was most rapid. In other locales, postseismic uplift ratehave changed with time, but the initial rates were smaller and the transientrelaxation times are longer than those just mentioned. At yet other locales,there has been no apparent change in the rate of uplift since the earthquake,but a variety of arguments suggest that the uplift rates will not be sustainedover the entire recurrence time

until the next major event. It is likely thatsome of the longer lived transient deformations are associated with viscoelasticrebound. There are other forms of transient deformations that have beenobserved including deep aseismic creep events on the plate interface (silentearthquakes), whose signal at the surface is a reversal in the direction ofhorizontal crustal movement from that seen when strain is accumulating. Takenas a whole the observations suggest that there are temporal and spatialvariations in the coupling at the plate interface. Some of the spatialvariations appear to correlate with the complex asperity rupture pattern ofthe earthquake.

POSTSEISMIC DEFORMATION FOLLOWING THE 2000 WESTERN TOTTORI EARTHQUAKE, SOUTHWEST JAPAN, USING GEONET AND URGENT CAMPAIGN GPS DATA

Manabu HASHIMOTO[1], Takeo ITO[1], Takao TABEI[2], Takeshi SAGIYA[3] ([1]Disaster Prevention Research Institute, Kyoto University, [2]Kochi University, [3]Geographical Survey Institute)

The 2000 Western Tottori earthquake of Oct. 6, 2000 is a typical inland earthquake in Japan with left-lateral strike-slip faulting on a NNW-SSE trending vertical fault plane. The Geographical Survey Institute have been operating continuous GPS observation network (GEONET). Since the average spacing of observation sites are too sparse to observe postseismic deformation, GSI and The Japanese University Consortium for GPS Research (JUNCO) deployed temporal observation sites. JUNCO deployed a dense GPS network with 16 dual frequency receivers surrounding the source region immediately after the main shock. Most observations were carried out continuously until the end of October 2000, and some sites equipped with dual frequency receivers were reoccupied in March 2001. GSI established two temporal sites with dual frequency receivers in October 2000 and continued the observation till the end of 2001. We observed a slowly decaying movement at every site. The spatial pattern shows left lateral motion across the source fault, similar to the coseismic displacements. We derived the amount of afterslip on a shallow part of the source fault from this spatial pattern. We also estimate the distribution of afterslip using a multi-segment fault model and obtain the largest slip of about 4cm near the epicenter of the mainshock, while the northernmost segment appears to have the smallest slip of about 2cm.If we fit exponentially decaying functions to the data from the JUNCO sites occupied in March 2001, we obtain time constants of 20 to 40 days. However, this may be inconsistent with the idea of afterslip on the source fault or its extension, since an exponential decay function is closely related to the relaxation of stress in a viscoelasitc layer.Here we fit the temporal variation of coordinates of JUNCO sites with the following logarithmic decay function proposed by Marone et al. (1991). In this nonlinear fitting, we assume a non-negative constraint on the parameter related to coseismic velocity. We obtained positive coefficient of friction at 6 of 12 sites. They give a value of (a-b) consistent with laboratory data for a velocity-strengthening layer at a shallow depth. Mainly because of the lack of data between October 2000 and March 2001, appropriate values could not be obtained at other sites. We will present results of the analysis using both GSI and JUNCO's data.

SYSTEMATIC DETECTION OF TRANSIENT AND PERMANENT CRUSTAL DEFORMATION USING HIGH-DENSITY GPS NETWORK DATA

Yuzo TOYA, Minoru KASAHARA (Institute of Seismology and Volcanology, Hokkaido University, Japan)

A scheme is being developed for systematic detection of transient and permanent crustal deformations using large-scale GPS network data. Network operated by the Geographical Survey Institute of Japan covers the Japanese Islands with approx. a thousand observation stations, 25 km apart. Their recordings of station position changes that we used here have accumulated length of about 5-6 years. To systematically measure transient and permanent deformations, we started by evaluating the validity of our linear approximation to each time-series dataset. For example, how ´transient´ an event is depends on the reference-duration of observation, or sampling time-interval. First, we (1) removed most obvious high-frequency noise, with five-point median filtering, and (2) removed additive seasonal variations (annual and semi-annual components) from observation time-series, hypothetically to isolate geodynamic signals besides other noises. Before subtracting the seasonal components, the drift (approximated by 2nd-order polynomial) and a major step were temporarily eliminated from each time-series. (3) Datasets containing significant irregularities in their time-series were isolated and later classified according to source types of those transient events or noises. Mean absolute error [MAE] was used to measure the deviation of observation data from our linear approximations. At the onset of a transient event, say a step of given positive height and slope, absolute (apparent) velocity would become much higher than the background rate for a duration [Tp] that of a fixed sampling time-interval plus the transient event length. Maximum absolute velocity and its corresponding MAE are, in general, positively correlated with step height and slope, while the parameters also depend on the duration of observation. The longer the observation period is, the less significant a transient event appears. (4) Datasets that have good fits to linear approximations (the goodness of fit with 95% conf.) were then applied to map horizontal distribution of strain rates. Before calculating strain rates, velocity vectors were interpolated and filtered with a median averaging window (e.g., R=50km; grid spacing=0.15deg). This technique helps reduce noises and outliers; besides it upholds robust trends in data. Spatial resolution in the original high-density station arrangement was well- maintained in result. Resultant maps effectively highlighted many known tectonic features. Bands of high maximum shear-strain and shortening rates characterize active transient and/or permanent geodynamic processes. Recently discovered distribution of low-frequency tremors along Sanbagawa Metamorphic Belt, western Japan, matches well with one of the bands of high strain rates. Furthermore, a sequence of strain-rate maps markedly suggests intermediate-term transitions in the regional stressing environment. It is partly supported by the observable shifts in orderly strain-rate distribution patterns from one period to another. Moreover, strain rates in southern Kanto and along Itoigawa-Shizuoka Tectonic Line to Suruga-Bay are noticeably increasing.

PRECISE MEASUREMENT OF SOUND VELOCITY AND ATTENUATION IN SITU FOR AN ESTIMATION OF SMALL STRESS CHANGE

Osam SANO[1], Keiko YAMAMURA[2], Yasuko TAKEI[1], Shigeru NAKAO[1], Hisashi UTADA[1], Yoshio FUKAO[1] ([1]Earthquake Research Institute, University of Tokyo, [2]Osaka University)

It is often difficult to get high reliability in the observation of small change for long period, e.g., 0.01 micro-strain even for a month, by using extensometers, tilt meters and borehole strain meters, although it is easy to get high resolution for short period. Environmental disturbances and possible time-dependent deformation within the stress concentrated region could be responsible for such a low reliability. Drifts in the DC-offset and gain of the amplification are also responsible. A measurement of the sound velocity is one of the candidates to overcome such a problem, because the reliability of the temporal change in the sound velocity is fundamentally determined by the base clock of the system and the

clock is one of the most stable transducers. Timing error in the triggering the waveform recorder can easily be reduced by an averaging method. A phase drift can also be reduced by employing an amplification system with sufficiently wide frequency range. Precise and continuous measurements of in situ sound velocity and attenuation have been carried out for the past 8 years, 4 years and 2 years in the vaults at Kamaishi (Iwate, northeastern Japan), Aburatsubo (Kanagawa, central Japan) and Mizunami (Gifu, central Japan), respectively. The overburden depth at Kamaishi was 450 m, and those of Aburatsubo and Mizunami were 10 m and 50 m, respectively. In order to get high stability and resolution, piezoelectric transducers were used as ultrasonic wave sources. The resolution of the temporal change in the sound velocity was about 1 ppm at Kamaishi, 10 ppm at Mizunami and 100 ppm at Aburatsubo. At Kamaishi test site, a clear dependence of the sound velocity on the barometric pressure was found. The stress sensitivity of the sound velocity at Kamaishi was estimated as 1.4 ppm/hPa, based on the effect of barometric pressure. At Kamaishi, an increasing trend of the sound velocity has been observed for the past 8 years. The estimated increasing rate of the compressive stress was about 600 hPa/yr, corresponding to the strain rate of 0.7 micro-strain/yr. This rate is several times higher than the strain rate of the northeastern Japan estimated by GPS measurement. At Aburatsbo, near the coast of Miura bay, replatively large periodic variations in both velocity and attenuation, corresponding to the diurnal and semi-diurnal lunar and solar tides, were found. These variations correlate well with the in situ areal strain change due to tidal ocean loading. The highest peak of the velocity and the lowest peak of the attenuation occurred at every time of the minimum peak in the areal strain. The opening/closure of pores or cracks due to stress change was responsible for these periodic variations. The velocity variation showed a remarkable 14-day-periodicity corresponding to the spring and neap tides. This periodicity in the sound velocity was explained in terms of a nonlinear response of the velocity change, brought from the strain rate dependence of the closure process of the cracks and pores.

CRUSTAL DEFORMATION IN THE KANTO-CHUBU DISTRICT AT AND AFTER THE 2000 SEISMO-VOLCANIC EVENT IN THE NORTHERN IZU ISLANDS

Akio KOBAYASHI[1], Hiromi TAKAYAMA[1], Takeyasu YAMAMOTO[1], Akio YOSHIDA[2] ([1]Seismology and Volcanology Research Department, Meteorological Research Institute, Japan Meteorological Agency, [2]Kakioka Magnetic Observatory, Japan Meteorological Agency)

The GPS observation network of the Geographical Survey Institute has revealed that the 2000 seismo-volcanic event in the northern Izu islands produced a remarkable crustal deformation in the Kanto-Chubu region, central part of Honshu Island, Japan (Nishimura et al., 2001). By subtracting average movements during the period from May 1997 through May 2000 as well as seasonal variations, we investigated detailed time evolution of the crustal deformation since the outbreak of the 2000 seismo-volcanic event. We found that three kinds of crustal deformation of different spatial pattern occurred successively in the Kanto-Chubu region. The first and most prominent one was the deformation produced by the activity in the sea region between Miyake and Kozu islands, where a large earthquake swarm occurred. The source can be modeled as a combination of a dike intrusion, fault motion of major earthquakes and a creeping slip. A creeping source is needed to explain eastward movements. The second kind of deformation appeared after the peak of the first one, and is characterized by a southward displacement of the crustal block in the Chubu district. A notable feature of the deformation is that it showed a diffusive pattern. The third kind of deformation is the ongoing southeastward displacements in the Tokai region that became noticeable in early 2001. Ozawa et al. (2002) explained the displacements by an occurrence of an aseismic slip on the plate boundary in the western Tokai region centered on Lake Hamana, adjacent to the anticipated Tokai earthquake source area. We think it is very probable that physical and/or mechanical condition on the boundaries between the Philippine Sea plate, Izu microplate and Eurasian plate was affected by the unusually large 2000 seismo-volcanic event in the northern Izu islands, and that change in the coupling condition between the plates has produced three kinds of the crustal deformations in the Kanto-Chubu district successively. We are grateful to the Geographical Survey Institute for providing the GPS data.

HORIZONTAL STRAIN CHANGES IN SOUTHWEST JAPAN USING PARTITIONING MODEL AND GPS DATA (1997-2000)

Sayyed Keivan HOSSEINI[1], Takeshi MATSUSHIMA[2], Sadaomi SUZUKI[1] ([1]Department of Earth and Planetary Sciences,University of Kyushu, [2]Institute of Seismology and Volcanology, University of Kyushu)

Southwest Japan is located at the east-central margin of the Eurasian plate, and is underthrusted beneath the Nankai Trough by the Philippine Sea plate, converging with the margin suborthogonally along a general northwesterly trend. In order to estimate the horizontal strain of southwest Japan for the period of Nov.1997 to Nov.2000, using GPS data of Geographical Survey Institute of Japan, after making an unbiased data, we derived two empirical covariance functions by applying least-square prediction method. During a repeated calculation, we compared the effect of correlation distances with the measurement vectors of different points and partitioned whole Japan in to two main regions, where the correlation distances for two E-W and N-S components could be equal. The partitioning boundary has a good coincidence with the Fossa Magna where assume to be a plate boundary between Okhotsk and Eurasian plates. We estimated the correlation distance of southwest Japan as 270 km and derived two new covariance functions to compute the horizontal strain of this region. During Nov.1997-Nov.1998, from central Kyushu toward east, there is a widespread shear anomaly, ~0.24×10⁻⁶/yr, that could refer to the Hyuganada earthquake (Mw 6.7) effect. Also this anomaly is extended into Shikoku Island and could be related to some slow slip displacements because of lacking any large events. Most of the Shikoku Island is under shear strain that extended to the south part of the Kinki area too. The strain state in Southwest Japan is NW-SE contractional in most of place that may be attributed to the convergence of Eurasian, Philippine Sea and pacific plates. In central Kyushu Island, N-S extension could be due to the mantel pluming under western off the Kyushu. Also the NW-SE and E-W extension in southwest of Kyushu and west off Yakushima Islands could be consider for the expansion of Okinawa trough.

CHARACTERISTIC SILENT EARTHUAKES IN THE EASTERN PART OF THE BOSO PENINSULA, CENTRAL JAPAN

Shinzaburo OZAWA[1], Shin'ichi MIYAZAKI[2], Yuki HATANAKA[1], Tetsuo IMAKIIRE[1], Masaru KAIDZU[1], Makoto MURAKAMI[1] ([1]Geographical Survey Institue of Jpana, [2]Earthquake Research Institute, University of Tokyo)

The Philippine Sea plate is subducting beneath the Boso peninsula, central Japan, with the Pacific plate underlying the Philippine Sea plate. Because of this complicated tectonic setting, seismic events are numerous off the coast of the Boso peninsula. Permanent GPS observation sites set up by the Geographical Survey Institute of Japan (GSI) detected

southeastward ground motion deviating from the steady northwestward deformation in 1996. From the detected abnormal crustal deformation, an aseismic slip was estimated off the east coast of the Boso peninsula with its rupture propagating to the south with time duration of about 7 days [Sagiya, 2003]. Six years after the 1996 event, quite similar abnormal crust movements started from around October 4 2002 for about fifty days, indicating occurrence of another interplate aseismic slip in this region. By employing a Kalman filter, we estimated the time evolution of the 2002 Boso aseismic slip and compared the 2002 event with the 1996 silent earthquake to investigate the nature of silent earthquakes. Our result shows an area of aseismic slip with moment magnitude (Mw) 6.6 centered off the Boso peninsula, adjacent to associated seismic activity. Slip evolution of the 2002 aeismic slip migrated from north to south with temporary subsidence and restart of slipping in a southerner area. Southward aseismic slip migration which occurred both in 1996 and 2002 events suggests a tendency of aseismic slip nucleation in a weakly coupled northern area and propagation to a more tightly coupled southern area. Similarities in focal area and slip process between the 1996 event and the 2002 aseismic slip suggest the Boso aseismic slips share characteristic features as is observed for characteristic radiative earthquakes. In addition to similarities between the past two Boso events, repetitive swarm seismicity of six to seven years interval supports the hypothesis that Boso silent earthquakes are characteristic silent earthquakes with recurrence interval of about six years. A more tightly coupled southern area that did not release enough energy in the 1996 event may have caused differences in magnitude and central slip area between the 1996 and the 2002 events despite having similar duration for strain accumulation, if characteristic earthquake hypothesis holds.

APPLICATION OF KALMAN FILTERING TECHNIQUES TO POST-SEISMIC SLIP PREDICTION OF THE 1999 TAIWAN CHI-CHI EARTHQUAKE

Din-Yao JENG, Wei-Cheng HUANG (.Department of Earth Science,National Cheng Kung University)

From the 1999 Chi-Chi earthquake (Mw = 7.6 ; 1999/9/20 , 17:47:15.9 GMT ; at 23.853N , 120.816E , depth of 7.5km) , The Ministry of Interior , ROC , started the work of verification and survey of first-order GPS control point and re-announced related resulting data to meet the requirment of re-construction work . This study focus on the point if there still exist apparent affect of GPS network displacement , especially the Post-seismic Slip of the Chi-Chi EQ , for the verification work has been done over three years.The Kalman Filtering Techniques can be applied to problems that can be described or approximated by linear time-varying equations, with non-stationary system and measurement input noise statistics . And, the Kalman Filter formulation can then be readily designed for estimation, smoothing, and prediction of the physical parameter of interest . An advantage of a Kalman Filter is that it allows one to use ˝state noise˝ to compensate for errors in the mathematical model. This study use the received data of GPS from 1999 to 2002, and combined the received data from the GPS tracking stations set by The Ministry of The Interior to acquire the coordinates of each GPS control point. Then, we use kalman filtering techniques to predict the Post-seismic Slip of the Chi-Chi EQ . We propose a high resolution prediction results . We also compare the results with re-announced coordinates . There is 5~30cm displacement of points around the earthquake stripe of the central part of Taiwan, 5~10cm of displacement for the points at the northern part of Hsin-Chu which are not verified and surveyed, 10~20cm displacement for the points at the southern part of Chai-Yi which are not verified and surveyed from the result of analysis.

THE SILENT EARTHQUAKE OF 2002 (MW=7.3) IN THE GUERRERO SEISMIC GAP, MEXICO: MAPPING OF SLIP ON THE PLATE INTERFACE AND THE ASSOCIATED STRESS CHANGE

Shri Krishna SINGH[1], Vladimir KOSTOGLODOV[1], Kristine M. LARSON[2], Anthony R. LOWRY[3], Roger BILHAM[4], Takeshi MIKUMO[1], Miguel SANTOYO[1], Arturo IGLESIAS[1] ([1]Instituto de Geofisica, UNAM, Mexico, [2]Department of Aerospace Engineering Science, University of Colorado, Boulder, CO, USA, [3]Department of Physics, University of Colorado, Boulder, CO, USA, [4]Department of Geological Sciences, University of Colorado, Boulder, CO, USA)

Guerrero seismic gap is a 200 km-long segment along the Mexican subduction zonethat may rupture in an earthquake of Mw 8.4. An aseismic, slow slip event beganin the gap in January 2002 and lasted for 4 months. The slow slip was detected by 7 continuous GPS receivers located over an area of ~550x250 km². We inverted the GPS displacement data for slip on the plate interface. The result shows that during the steady-state phase, the plate interface, lying ~50 to 170 km from the trench, was almost completely locked. The slow slip, however, occurred mostly down dip from the seismogenic, locked plate interface, presumably on the transition zone, in the depth range of ~35 to 40 km and the distance range of 100 to 170 km from the trench. The average slip was about 16 cm. The event released a seismic moment of ~1.2 x10²⁷ dyne-cm (equivalent Mw=7.3). The strain release due to slow slip over the plate interface in the distance range of ~100 to 170 km from the trench essentially cancelled the strain accumulated during the previous 3 years of steady-state loading. The slow-slip phase resulted in an increase of ~0.1 bar of Coulomb failure stress, favoring reverse faulting on the shallow part of the completely locked interface, thus enhancing the probability of rupture of the Guerrero seismic gap in the near future. Some features of two important earthquakes, which occurred in the region before and during the slow-slip phase, may also be explained by the change in the Coulomb failure stress.

PRINCIPAL COMPONENT ANALYSIS FOR THE DISPLACEMENTS OF GPS STATIONS IN THE KANTO AND TOKAI DISTRICTS IN JAPAN

Masashi KAWAMURA[1], Koshun YAMAOKA[2] ([1]Division of Earth and Environmental Sciences, Graduate School of Environmental Studies, Nagoya University, [2]Research Center for Seismology and Volcanology, Graduate School of Environmental Studies, Nagoya University)

Principal component analysis (PCA) is applied to the displacements recorded bymore than 100 GPS stations in the Kanto and Tokai Districts in Japan for theperiod including the following three major events. (1) The Miyake-Kozu event in2000, which includes large-scale dyke intrusion between Miyake and Kozu volcanoto the south of Japanese main island. This event was accompanied by fivephreatic eruptions in Miyake Volcano, and intensive earthquake swarm near Kozuvolcano. (2) The Tokai slow slip event, which started and is still continuingat a plate boundary between the Eurasian plate and the Philippine Sea plate inthe Tokai District in 2000. (3) The Boso slow slip event, which lasted for lessthan a month in October 2002 at a plate boundary between the North Americanplate and the Pacific plate near the Boso Peninsula. Such events have beendetected as displacements of GPS stations around their sources. Using PCA, weattempt to decompose the data into representative spatial modes and theirtemporal modes. We apply PCA to the following four data sets to check thereliability of the analysis; (A) Horizontal and vertical components from January2000 to December 2002 (2) Horizontal and vertical components from January 2001to December 2002 (3) Only horizontal components from January 2000 to December2002 (4) Only

---

horizontal components from January 2001 to December 2002. Wesuccessfully decomposed the data into the modes corresponding to the Miyake-Kozuevent, the Tokai slow slip event and the Boso slow slip event, as a majorcontribution to the total displacement field. Some prominent characteristics areas follows. In the temporal mode corresponding to the Miyake-Kozu event, theramp-like step is followed by a prolonged tail which asymptotically approaches aconstant level up to now. The development of the Tokai slow slip event isrevealed to be initiated soon after the Miyake-Kozu event from its temporalmode. Eastward motion in the Kanto District also synchronizes with the Tokaislow slip event. The Boso slow slip event is more clearly observed in the datasets for only horizontal components than that for both horizontal and verticalcomponents. This may be due to larger variance and smaller amplitude of thesignal on the vertical components than on the horizontal ones. The totalcontribution of the above three modes to the data is more than 70 percent.

POSTSEISMIC CHANGES OBSERVED IN JAPAN NATIONWIDE TILTMETER ARRAY

Hitoshi HIROSE, Fumio YAMAMIZU, Kazushige OBARA (National Research Institute for Earth Science and Disaster Prevention)

National Research Institute for Earth Science and Disaster Prevention(NIED) has installed over 500 tiltmeter stations that cover most partsof Japan. The tiltmeter can detect smaller crustal deformations thanthose which can be done by GPS, so that this is expected to be apowerful tool for exploring the crustal deformations due to faultmotions during earthquakes. We report the postseismic deformationsdetected by this tiltmeter array during its observation period. Oneexample is the records following the October 6, 2000 West Tottoriearthquake (Mw 6.7). It is shown that the GPS sites near the source areadetect the postseismic surface displacements following the earthquake(Hashimoto et al., 2001). On the other hand, the tiltmeters which arelocated at least 60 km away from the epicenter detect tilt changes whichobey logarithmic decay. Second example is the March 24, 2001 Geiyoearthquake (Mw 6.8, 47 km in depth). The tiltmeter at KURH station,which is located about 20 km from the epicenter, clearly detects thepostseismic decay, whereas there is no report for postseismicdeformation which observed by GPS due to this earthquake. Postseismictilt changes following the smaller earthquakes are also detected. OnJanuary 4, 2001, a moderate earthquake (Mw 5.3) occurred at CentralNiigata. At the YZWH station, 15 km away from the hypocenter,logarithmic decay with time constant of about 1 hour is recordedfollowing the large step caused by the main shock. We attempt toexplain these postseismic deformations by afterslips on the sourcefaults. Some studies point out that the time constant of the postseismicdeformation correlates with the magnitude of the main shock (Yamauchi,1975; Takai et al., 2000). This correlation possibly shows an aspect ofthe physical process of the earthquake source.We show the tiltmeters can detect smaller postseismic crustaldeformation than GPS. This demonstrates that the tiltmeters have apotential to constrain the earthquake source process by constructing astatistical property of the afterslips.

SPATIAL AND TEMPORAL DISTRIBUTION OF AFTERSLIP FOR THE 1995 HYOGO-KEN NANBU EARTHQUKAE INFERRED FROM SURFACE DISPLACEMENT DATA OBTAINED WITH GPS OBSERVATIONS

Takehide NAKANO, Kazuro HIRAHARA (Graduate School of Environmental Studies, Nagoya University)

Global Positioning System (GPS) observations indicate that significant postseismic deformation occurred following the January 17 1995 Hyogo-ken Nanbu earthquake (M=7.2). The postseismic deformations reached 2.0 cm at some stations. In order to estimate the spatial and temporal distribution of the afterslip on the fault and on its possible extension, we use an inversion method. We seek the best explained slip distribution that minimizes the discrepancy between the observed displacements by GPS and the predicted ones in a least squares sense with some smoothness constraints of slip distribution, starting from the search for the fault size and the location. It is concluded that the afterslip of about 40cm occurred in the deeper portion under the fault at 15 to 25 km from the middle of the north segment. Though the GPS stations are distributed mainly along the fault strike but not in the fault normal direction, which makes it rather difficult to obtain good spatial resolution of estimated afterslip distribution, some resolution tests require the existence of the obtained afterslip including that at depths, The time dependent analysis indicates that afterslip started at different time at a few points on the fault surface and continued for different durations.

IS THE MOTION OF THE SOUTH HEMISPHERE SLOWING DOWN?

Shuanggen JIN, Wenyao ZHU (Shanghai Observatory, Chinese Academy of Sciences)

The earth is a rotating planet in the universe, but the variation of rotating attitudes with time will cause the change of the inertial force, which leads to it's interior motion, especially the relative glide or extrusion along the rotation axis of the Earth. In addition, the variations of the inertial and eccentrical force of the Earth, and the interactions of the atmosphere, Ocean and other celestial bodies perhaps bring on changes of the Earth motion state. Now the higher-accuracy space techniques, such as VLBI, SLR and GPS, with a longer observation time span, a much wider and more average distributions of observation sites, can detect the current slight variation of the Earth hemisphere state. In this note, we measure the contemporary relative motion rates of adjacent plates in the South hemisphere using space geodetic data in recent 20 years. Comparing them with results from the NUVEL1A model in three millions years and geological data in 25 millions years displays that the motion of the South hemisphere is slowing down. In order to know about the stability and continuity of the South hemisphere motion, we calculate divergent and convergent rates of adjacent plates in the South hemisphere at year25, 35, 45, 55, and 70 million using hotspot data and geomagnetic data. Comparing the results in 80 millions years shows the South hemisphere is stable in 80 millions years. Accordingly the motion of the South hemisphere is slowing down in 25 millions years and yet is quite stable in whole 80 millions years.

THE STRAIN FIELD AROUND THE NORTHERN PART OF THE NASSER LAKE, EGYPT, DERIVED FROM GPS MEASUREMENTS AND ITS TECTONIC IMPLICATIONS

Gamal EL-FIKY[1], Divakar REDDY[2], Ali TEALEB[1] ([1]National Research Institute of Astronomy and Geophysics, Helwan, Cairo, Egypt, [2]Indian Institute of Geomagnetism, Mumbai 400005, India)

GPS measurements collected in campaign mode during 1997 - 2002 have been analyzed to derive velocity vectors around northern part of the Nasser Lake, Egypt. Estimatedhorizontal velocity vectors in ITRF2000 are found to be in the range of 28.8 - 32.2 mm/yrwith an average of 30.4 ± 2.1 mm/yr in N31 ± 3W. The horizontal velocity field further usedfor quantitative estimation of crustal deformation parameters. The Least-Squares

prediction(LSP) technique was employed to segregate the signal and noise from the velocity vectors.Estimated signals (displacement vectors) were used to reconstruct the strains; dilatations,maximum shear strains, and principal axes of strains. The distribution of the dilatationalstrains indicates that the region around the northern part of Nasser Lake is mainlydivided into two areas: the northern part with predominant compressive strainand the southern part exhibiting extensive strain of about 0.6 ppm/yr. In addition to this,there are some of the areas with low compressional and extensional strains in themedial of the studied region. Maximum shear strains show some patches of high valuesof strains over northern, northwestern, and southwestern parts of the studied region.The paper also presents the relationship among the crustal strains, the hydrologicalsituation in the lake, and the seismic activity in the area.

RELATIVE DISPLACEMENT ACROSS THE FRACTURE ZONE

Keisuke TANIGUCHI[1], Kazou OIKE[2] ([1]Department of Education, Kyoto University of Education, [2]Faculty of science, Kyoto University)

Geodetic survey and continuous observation of crustal deformation across faults or fracture zones have led to many evidences that crust was consisted of loosely coupled blocks mostly bounded by faults or fracture zones. In order to study the relative movement of two crustal blocks bounded by the fracture zone in the tunnel of Hokuriku observatory of Kyoto University in Japan, three-dimensional relative displacement meters were designed and have been set up across that fracture zone since 1986. They have measured tidal and seismic relative displacements between two fixed points in three orthogonal directions. Results are 1) Tidal strain across the fracture zone was about four times as large as the theoretical, whereas that near the fracture zone was only half of the theoretical. Strain seismograms across the fracture zone are from 5 to 15 times as large as at the neighborhood and larger than the calculated strain seismograms with seismographs set up in the same tunnel. 2) Deformation by earth-tide and seismic waves mainly take place at fracture zone. 3) Amplification factor of earthquakes is related to propagation azimuth of them. This result indicates that the amplification of seismic waves is caused by the change of the width of fracture zone, in other words, compress-extension motion at the fracture zone. 4) The vector of each tidal and seismic relative displacement across the fracture zone is almost fixed. This may be caused by the existence of plane-like fracture zone. 5) It was confirmed that block bounded by that fracture zone spreads in vertical. The calculation with FEM suggests that fracture zone extends to several km in dip direction.

QUANTITATIVE EVALUATION OF LOADING EFFECTS ON SEASONAL VARIATION IN GEONET GPS DATA

Hiroshi TAKIGUCHI, Yoichi FUKUDA (Graduate School of Science, Kyoto University)

Murakami and Miyazaki [1999] reported that seasonal variation could be seen in the daily solutions of GEONET (the GPS Earth Observation NETwork) GPS site coordinates. Since then, several scientists tried to interpret the seasonal variation (e.g. Hayashi et al. [2000], Heki [2001, 2002] and Hatanaka [2001, 2002]). We also investigated seasonal variation in the baseline length changes and reported most of the baselines expand in summer and contract in winter (Takiguchi and Fukuda [2000, 2001]). From these studies, we could summarize that the seasonal variation does not depend on the strength of plate coupling nor analysis software/strategy, and it is manly caused by the systematic scale changes suggested by Hatanaka [2001] and the loading effects due to local or broad mass changes, i.e., snowfall, ocean tide, non-tidal ocean load and atmospheric pressure. Using the globally network data, D. Dong [2002] showed that 40% of the observed annual vertical variations can be explained by the joint contribution of pole tide, ocean tide, atmospheric pressure, non-tidal ocean, and groundwater loading. Other contributions were some modeling errors (wet troposphere effect and orbit etc) and bedrock thermal expansion. In this study, we investigate the seasonal variation in GEONET GPS sites to confirm whether the above estimations are valid for the GEONET data. For this purpose, we employed surface vertical variation and area strain which calculated from annual baseline changes of three baselines shaping a triangle. And then we compared the vertical variation and area strain with seasonal variation of snowfall load calculated from 1997 to 1999 AMeDAS data sets and atmospheric load calculated from atmospheric pressure data at the Japan Local Metrological Observatory. We found that the seasonal variation of GPS data could not be explained by snowfall load nor atmospheric load. We will search for other load sources and discuss the joint contribution of them.

THE SEA LEVEL VARIATION IN THE RANGE OF PERIODS FROM 1 HOUR TO 2 DAYS IS THE NEW SOURCE OF INFORMATION ABOUT TO UNDERWATER EARTHQUAKE

Vladimir V. IVANOV (Institute of Marine Geology & Geophysics Eastern Branch of Russian Academy of Science)

1.The sea level variations, which were recorded by tidal stations, which were smoothed by time interval 2 hours, are the new source of information about development of the earthquake process with characteristic time several hours. The amplitude of variations –1 – 5 cm, the duration of variations 10 – 30 hours for the great earthquakes in Pacific ocean. 2. The signal of the low frequency variations of sea level is the recording of changing of the Earth's volume if the eartquake occurs in closed basin. 3. The basin is the closed basin if the duration of the wave propagation is less than the time of the level conservation. 4. For Japan sea the time of wave propagation is 2 hours, time of sea level conservation is 30 hours. The Japan Sea is the closed basin if duration of variations is less than 1 day. 5. The regarded signal for earthquake July 12,1993 at Japan Sea did not depend from point of observation inside the Japan Sea, had the amplitude 3-4 cm, frontal time 4 hours, duration 20 hours 6. The physical parameters of the full pirocess of the earthquake July 12, 1993 are the next: volume variations - 10 16 cm3 , energy- 6 10 24 erg,ZZ component of seismic moment 2 10 28 dn cm.

GEODETIC INFRASTRUCTURE IN INDIA, WHAT IS WRONG AND WHAT NEEDS TO BE DONE

Nand Kishore AGRAWAL (Director,Retd., Survey of India, National Correspondent,IAG,MD, Geodesy and GPS Services)

Geodetic Infrastructure in India is inadequate. It needs a fresh look and complete revision. Indian Geodetic Datum, Reference Surface, Horizontal Control, Vertical Datum, Height Control, Indian Geoid and Mean Sea Level, Gravity datum, Projection System for Maps, and Indian Grid, are all inadequate or inappropriate. Indian Geodetic Datum is based on Everest Spheroid as Reference Surface. Center of this reference surface is estimated to be about 1 km away from the center of gravity of the Earth. The datum is a local datum and in error. Scientific and Defense studies of vital cannot be based on such a system. It is necessary that the datum should be redefined at the earliest. Horizontal Control resulted from The Great Trigonometrical Survey. Different triangulation series are inconsistent between each other and not adjusted properly. Stations are burdened with varying degrees of error. It is necessary that fresh observations be carried out to get a set of vectors by GPS and least square adjustment is done for the whole country at one go to get control points. Vertical Datum for Heights was chosen as Mean Sea Level at a group of nine tidal observatories at Indian ports. Level network in India is of moderate to high precision at different places. No gravity observations were carried out. Network has not been properly adjusted. It is required that a fresh datum for heights based on MSL at one tidal observatory is adopted. High Precision Leveling should be carried out afresh to get a network along with gravity observations and adjusted. It is necessary to have a Gravity Datum. Presently there is no absolute gravity station in India. Gravity values in India are based on relative observations based on gravity datum in another country. It is necessary to establish some absolute gravity stations, adopt a gravity datum and carry out relative observations to get a 1st order gravity network. No satisfactory Indian Geoid is available. To get heights above MSL by GPS observations we need a geoid that can give geoidal undulation of accuracy of 25 cm or better. A project should be taken up to obtain such geoid. Projection for topographical maps in India is Polyconic. Each individual sheet is projected assuming no distortion along parallels and neglecting distortion along meridians. Meridians and parallels are assumed as straight lines. We can say that The Earth/Ellipsoid has been assumed to be flat for individual sheets. This creates problems in digitization, integration and compilation of maps. It is necessary to abandon polyconic projection and adopt either Lambert Conformal Conic or Transverse Mercator Projection. Indian Grid on Lambert Conformal Conic Projection for superimposition on topographical maps has 9 zones with scale factors at central parallel as 649/650 and 823/824. The design is unsatisfactory as scale error at central parallel should be 1 in 2000 or better. It is necessary to design grids on Transverse Mercator or LCC similar to SPCS in USA.

STRAINMETER UNITS IN A TERRESTRIAL REFERENCE FRAME SERVING

Ludmila A. LATYNINA[1], Mstislav N. DUBROV[2] ([1]Institute of Physics of the Earth, RAS, [2]Institute of Radio-engineering and Electronics of RAS, Fryazino, Russia)

Recent developments of the Global Positioning System (GPS) and its wide spreading to the Earth´s crustal motion measurements have advanced the problem of a terrestrial reference significantly. Nevertheless the concept of modern reference frame service still needs the close networks of high accuracy geodetic and geophysical instrumentation. Whenever geophysical aspects of global change are concerned the quality assessment of the network data has to be carried out. Actually, after the past decade of geodynamical phenomena monitoring by such global networks as Very Long Baseline radio Interferometry (VLBI), GPS, etc. the necessity of anchoring them to the limited number of the fundamental stations has been evidently shown. This circumstance can be explained by two main reasons. (1) When the local crust motions are taken into account the accuracies of such global systems as VLBI or GPS lose 1-2 orders in comparison with the precision of such modern geophysical instruments as gravimeters, tiltmeters and strainmeters. (2) The temporal resolution of the global systems is restricted by the principals of measurements and rates of data processing, while the modern wide-band geophysical instruments allow the continuous real time observations to be made. In comparison with gravimeters and tiltmeters the Earth´s strain measuring instruments allow to detect simultaneously the number of spatial component of the geological medium deformations. High sensitivity of strainmetrs is ensured by their constructions and technology of fabrication. The top instrument resolutions of the rod strainmeters dL/L = 10(-10) and the laser strainmeters dL/L = 10(-12) have been proved on the great variety of geophysical experiments. We present our experience in the achievements of these parameters and their verification. The results of observations of the aseismic fault movement and the earth surface strains due to meteorological and hydrological effects at the observatories Protvino and Fryazino will be discussed. The information on local tectonic strains and plate motions would be very important for every GPS or VLBI user to reduce undesirable antennas or receivers mechanical displacements. One should be able to eliminate another anthropogenic or atmospheric effects. We guess the terrestrial reference based on the space radio nets is to be added by the multi-component deformation measuring systems. The gathering of the local, regional, and global measuring tools should give both more accurate positioning frame and more intelligent geodynamic data source.

AN INVERSION METHOD OF CRUSTAL DEFORMATION ON THE BASIS OF DISCONTINUOUS DEFORMATION ANALYSIS (DDA) AND BOUNDARY ELEMENT METHOD (BEM)

Yun WU, Chong-yang SHEN, Shao-qun JING, Hui WANG (Department of Geodecy and Crustal Deformation, Institue of seismology, CSB, P. R. China)

In this paper, an inversion method on the basis of Discontinuous Deformation Analysis (DDA) and Boundary Element Method (BEM), is presented for determining boundary relative movements, displacements and stresses of blocks in a multi-block system, in which the kinematic constraints required for reasonable movement between blocks in the system is discussed, and the judgment for contact between blocks, that indicates where a kinematic constraint is necessary, is also investigated in detail. This method, simply called as «DDA and BEM » has characteristics of linearity, uniqueness and stability of the solution, that is, the linearization foundation is the dispersion of integral equations. This is reasonable logically in the mathematics, the uniqueness condition that the simultaneous equations for each block is dependent on the number of the points measured in any block, which must be greater than the number of the boundary elements, and not collinear, and for the unstable called as "ill conditionÅe the Damping Least Square Method can be used to obtain damping solution. So that, it seems theoretically that the method of ˝An Inversion Method of Crustal Deformation on the Basis of Discontinuous Deformation Analysis and Boundary Element Method˝ would be more suitable for the problems in which the relative movements on the block boundaries and the deformation inside the blocks need investigating and analyzing.

MODERNIZATION OF THE NATIONAL GEODETIC NETWORK

Maturana Alejandro MATURANA (Geodetic Department , Military Geographic Institute)

Rodrigo Maturana, Hector ParraMilitary Geographic Institute (IGM), Nueva Santa Isabel 1640, Santiago, Chile In Chile, owing to its special geographic location and resulting from its long and very extensive territory, has had to adopt several geodesic reference systems. These, as a whole, make up the National Geodesic Network (RGN) upon which the cartographic structure of the country can be based.Current requirements for precision in horizontal measurements, which are growing ever greater, and the need for homogeneity in

this data among related sectors of territory, have made it necessary to modernize the current framework for geodesic measurements and checks. The efficient incorporation of satellite systems (GPS) into the implementation of extensive networks for horizontal control and the adoption in the South American region of the "Geocentric Reference System for the Americas" (SIRGAS), has established a basis for structuring a modern Geodesic Network for Chile, a single and homogenous network for the whole country and the rest of the continent.This text has as its objective the presentation of the structure, the measurement campaigns and the final results of the processing and adjustments for the new National Geodesic Network, which will be the new official reference framework for all cadastral, cartographic and geodesic activities to be carried out in Chilean territory. Also , the transformation parameter between local and new datum will be presented.

SEISMIC GROUND MOTION OBSERVED BY THE TAIWAN CONTINUEOUS GPS ARRAY - IN THE CASE OF 31 MARCH 2002 HUALIEN EARTHQUAKE

Horng-Yue CHEN[1], Long-Chen KUO[1], Wang-Shung CHUNG[1], Shui-Bei YU[2] ([1]Research Assistant, [2]Research Fellow)

A ML=6.8 earthquake occurred on 31 March 2002 off northeastern Hualien. The instantaneous relative displacements have been tracked by newly established continuous GPS stations, which are part of the TCGN. There are seven stations of the TGCN with 1 Hz data sample rate, which recorded the instantaneous ground motion of the 331 earthquake.Applying the post-processing QIF algorithm to study the 331 earthquake, the displacements with respect to station TSHO are computed. Based on the relative positioning, the displacement of the computing station with respect to the fixed station can be obtained at the arrival time, and the displacement of the fixed station can be acquired at the time of the second maximum ground motion. Hence the first arrival times are different at each of subplots and the time of the second maximum ground motion is at the same location. It is obvious that the seismic ground motion can be observed by 1 Hz sampling rate continuous GPS stations.

DISTORTIONS IN DENSITY DUE TO INACCURATE AVERAGE DEPTH OF A LAYER IN THE LOWER HALF-SPACE

Ateya Ismail LUKANDU, Shuzo TAKEMOTO (Department of Geophysics, Kyoto University)

The position of an intermediate horizontal layer in the lower half-space can be given inaccurately without any change in the thickness of the effective layer either by a slight layer shift upwards or downwards. Even though the layer shifts might be minimal, it could significantly alter the density variations of the disturbing masses in the effective layer. Here we investigate and demonstrate the effect of the variations in the position of the horizontal layer to the determined density variations. Subsequently due to the direct relationship between disturbing masses and the positions of the contact surfaces in an intermediate horizontal layer, the later are also determined. We finally demonstrate the efficacy by applying to actual geophysical data i.e. gravity data, for a micro-gravimetry site and/or localized structures in the Central Ranges of the Chubu District in Japan.

EFFECTS OF A HORIZONTAL SURFACE LAYER ON STATIC AND DYNAMIC DISPLACEMENTS

Ryou HONDA[1], Kiyoshi YOMOGIDA[2] ([1]Institute of Seismology and Volocanology, Hokkaido University, [2]Graduate school of science, Hokkaido University)

Recent development of geophysical observation instruments such as GPS have allowed us to obtain precise broad band data in wide dynamic and wide frequency range, including static displacements in a large area. While detailed crustal structure around a damaged area is surveyed for source parameters obtained by seismic waveform inversions, the effects of a layered medium are often not considered in practical analyses of geodetic data. In this study, we calculate static as well as dynamic displacements with the discrete wavenumber method and compare them with analytical as well as numerical solutions for a half-space. The existence of a soft surface layer is found to affect both amplitude and spatial distribution of static displacement near a fault, which is not in a similar manner to those of dynamic displacement. In a horizontal surface layer case, the largest effect of a surface layer is shown in the case of a vertical strike-slip fault. While dynamic motions are amplified monotonically with the thickness of the surface layer, the amplification of static displacement is limited if the surface layer reaches the top of the fault because the moment release there is then reduced. Errors in the estimation of the fault depthand the amount of slip reaches as large as 30 % of the true values in the worst case. If we introduce a non horizontal layer (e.g., a basin), the spatial distributions of static displacement should be affected strongly. The effects are important not only for inland earthquakes but also inter-plate earthquakes which causing a large tsunami. Our results strongly suggest that strong bias may be introduced to the conventional estimation of fault parameters, assuming a medium to be a half space, from static displacement or geodetic data by the existence of a low-velocity or low-rigidity surface layer.

A DIGITAL METHOD FOR AUTOMATIC 3-D GRAVITY INVERSION OF DENSITY INTERFACES USING VARIABLE DENSITY

Chakravarthi VISHNUBHOTLA, Harinarayana TIRUMALACHETTY (National Geophysical Research Institute, Uppal Road, Hyderabad, India.)

A new 3-D inversion technique to interpret the gravity anomalies of density interfaces above which the density contrast shows a systematic variation with space coordinates is presented. The technique involves both a robust methodology and the associated software to achieve the task. Initial depth estimates of a density interface below the said grid nodes of a

rectangular/ square mesh are computed automatically from the measured gravity anomalies and are improved iteratively until the theoretical gravity anomalies fit the observed ones. The quantum of misfit function is allowed to vary in the downhill direction in the parameter space, thus paving a way for obtaining more accurate results. An automated computer program AUTOGR3DIN is developed based on the suggested algorithm. Two gravity anomaly maps are interpreted and the results are compared with borehole information.

OVERVIEW OF THE GRAVITY FIELD OF ANTARCTICA

Muriel LLUBES, Nicolas FLORSCH, Benoit LEGRESY, Jean-Michel LEMOINE, Frederique REMY (LEGOS-OMP)

CHAMP, flying at an altitude of about 400 km, is the first of a new generation of satellites dedicated to Earth gravity field observation. The high quality data hasgenerated new gravity field models: EIGEN-1S in 2001, and EIGEN-2S more recently.The gravitational potential is decomposed into spherical harmonic coefficients and weuse, in this study, the free-air gravity anomalies reconstituted up to degree 60, ata zero altitude. The anomalies for the Antarctic continent range from -57 to 65 mGal.We have modeled the gravity effect from the ice, the ocean and the bedrock, using a666 km cut-off filter to simulate the resolution obtained by CHAMP. Computing thedifferences between this terrain effect and CHAMP map provides a map of the Bougueranomalies. Because of the dominant influence of the crust, we first used a crustalthickness model from seismology. This gives a map of the mantle Bouguer anomalies, therange of which is still large (between -255 and 216 mGal) indicating imperfections inthe crust model. By appealing to isostasy we then imposed the condition that thismantle Bouguer anomaly should vanish and therefore solve for a new resulting crustalthickness. This gravity-based crust model gives thicknesess from 8.5 to 42.6 km in thezone of interest. There is a good general agreement with seismological models, but ourmodels shows more detail, particularly in the western part of the continent. Thesedetails are in agreement with geological studies.

GEOID AND OCEAN CIRCULATION IN THE NORTH ATLANTIC (GOCINA)

Per KNUDSEN[1], Rene FORSBERG[2], Ole B. ANDERSEN[1], Dag SOLHEIM[3], Roger HIPKIN[4], Keith HAINES[5], Johnny JOHANNESSEN[6], Fabrice HERNANDEZ[7] ([1]National Survey and Cadastre - Denmark, Geodesy, [2]National Survey and Cadastre - Denmark, Geodynamics, [3]Statens Kartverk, Norway, [4]University of Edinburgh, UK, [5]University of Reading, UK, [6]Nansen Environmental and Remote Sensing Center, Norway, [7]Collecte Localisation Satellites, France)

The investment in Earth observing satellites has been significant. It is therefore of great importance that the value and utilization of space borne data can be properly demonstrated in the context of ocean monitoring. The aim of the EU supported project GOCINA is to enhance European capacity in Earth observation technologies by promoting and developing methods for the joint exploitation of the approved European Space Agency ENVISAT (Radar Altimeter) and GOCE missions for ocean circulation studies and associated climate modelling and operational data assimilation. The central quantity bridging the geoid and the ocean circulation is the mean dynamic topography, which is the difference between the mean sea surface and the geoid. The initial studies will focus on the assessment of the initially available models of the geoid, the mean sea surface and the mean dynamic topography to obtain the current state of these geoid models and to identify areas of problems from their discrepancies. In some areas the residual will be small enough to be within the error bounds of the other fields. In other regions the residuals are larger than expected on the basis of the individual calculations. This mismatch will indicate areas where one or more of the error analyses are inaccurate.

GRAVITY MODEL DEVELOPMENT FOR ICESAT PRECISION ORBIT DETERMINATION

Hyung-Jin RIM, John C. RIES, Sungpil YOON, Charles E. WEBB, Srinivas BETTADPUR, Bob E. SCHUTZ (Center for Space Research, University of Texas at Austin)

The main scientific objective of the EOS ICESat mission is to measure long-term changes in the volumes (and mass) of the Greenland and Antarctic ice sheets with sufficient accuracy to assess their impact on global sea level, and to measure seasonal and interannual variability of the surface elevation. To monitor the ice sheet topography, ICESat features the Geoscience Laser Altimeter System (GLAS) to determine the height of the GLAS instrument above the ice sheet by measuring a laser pulse round-trip time of flight, emitted by the GLAS and reflected by the ice sheet. This laser altimeter measurement combined with the satellite height information from the Precision Orbit Determination (POD) will result in the geocentric height of the ice surface. To achieve the main scientific objective, the position of the GLAS instrument should be known with an accuracy of 5 cm and 20 cm in radial and horizontal components, respectively. This knowledge will be acquired from data collected by the on-board GPS receiver and ground GPS receivers. Following the successful launch of ICESat on Jan. 13, 2003, 00:45 UTC, the GPS receiver was turned on successfully on Jan. 17, 2003, tracking up to 9 GPS satellites. It has been shown from pre-launch POD studies that the gravity model error is the dominant source of ICESat orbit errors. Pre-launch gravity models, such as TEG-4 and EGM-96, predict about 7 cm and 15 cm radial orbit errors for ICESat, respectively. To meet the 5 cm radial orbit determination requirement using these models, it is necessary to either 1) estimate many empirical parameters to reduce the effect of the gravity model errors, or 2) tune the gravity model with ICESat tracking data. Recent gravity models from the GRACE mission also show promising results on ICESat POD. This paper summarizes the gravity model development efforts for ICESat POD.

ON THE COMBINATION OF ALTIMETRY AND SATELLITE DERIVED GRAVITY FIELD MODELS

Wolfgang BOSCH (Deutsches Geodätisches Forschungsinstitut (DGFI))

The gravity missions CHAMP, GRACE and GOCE willconsiderably improve the spatial and temporal resolution of the Earth gravity field. Nevertheless, satellite altimetry willbe further needed to derive very small-scale features of the gravity field:The potential of altimetry is indicated by the 2´x2´-resolution ofmost recent mean sea surface models (a 5´x5´ grid corresponds to aharmonic series above degree and order 2000). Up to now, altimetric derived gravity anomalies were used for the combination with satellite derived gravity field solutions.The anomalies are either derived by solving the inverse Stokes equation orby a ˝synthetic geoid˝, obtained by reducing the mean sea surface by anindependent (e.g. oceanographic) model of the sea surface topography.The first approach is rather indirect and numerically instable. In the latter case errors of the sea surface topography are directly projected into the high resolution gravity field model. Here, a more direct approach is considered to combine altimetry and satellite derived gravity field solutions. The large-scale

structure is assumed to be sufficiently accurate determined by the satellite based gravity solution. Slope and even more the curvature of the mean sea surface are little ornot at all affected by the (unknown) dynamic topography. Therefore,slope and curvature are used to set up observation equations that areaccumulated to the normal equation system of a satellite derived gravity field solution. It is then investigated how much the combined solution becomes more stable and to what extent the resolution of the gravity fieldcan be improved by adding satellite altimeter data.

3D ASPHERICAL EARTH'S MODEL AND 3D ATMOSPHERIC LOADING FOR THE NEW GRAVITY MISSIONS

Pascal GEGOUT, Hilaire LEGROS, Jacques HINDERER (IPGS UMR 7516)

High precision modelling of temporal variation of the gravity field generated by atmosphericmasses redistributions and Earth's masses redistributions are nowadays neededto separate accurately atmospheric contributions from oceanic and hydrologic contributions.We therefore developed a deformation model of an aspherical Earth withlateral heterogeneities. The corresponding pressure, tidal and loading Love numberscharacterizes these deformations. Boundary conditions on this Earth's model imposed by the atmosphere are revisited:we distinguish surface stress induced by the pressure and winds/currents at the solidEarth's topography from the gravitational force generated by the three dimensionalstructure of the atmosphere. Taking into account the 3D structure of the atmosphere tocalculate direct gravitational attraction on low orbiting artificial satellites is required.A static response of the ocean to solid earth deformations and barometric forcing isincluded. A model of a non-global ocean overlying an elastic deformable earth andforced by ECMWF atmospheric pressure surface fields is used to predict and interpretthese global masses redistributions. These processes lead to a wide range of gravity variations, from global to local spatialscales, and from diurnal to interannual variations. From these model results we identifythe significant processes and their corresponding signatures in geodetic observations(Earth's surface deformation, global gravity changes and surface gravity measurements).We focus on high frequency gravity perturbations, which may be aliasedduring the recovery of the global gravity field from the new generation of gravity satellites.Possible comparisons between spatial and ground gravimetric measurements arealso investigated.

TEMPORAL GRAVITY FIELD RECOVERY FROM CHAMP AND GRACE

Shin-Chan HAN, C.K. SHUM, C. JEKELI (Department of Civil and Environmental Engineering and Geodetic Science, The Ohio State University)

The CHAllenging Minisatellite Payload (CHAMP) and Gravity Recovery and Climate Experiment (GRACE) satellite missions are mapping Earth mean and temporal gravity fields with unprecedented accuracy and resolution. Measurements from these gravity mapping satellite missions have demonstrated and are expected to provide significant improvement in our knowledge of the Earth´s gravity field whose temporal components are climate-sensitive signals. CHAMP and GRACE are expected to monitor these signals for a time period of 5 years or longer. New models and observations of Earth´s mean and time-variable gravity fields will be available with a temporal resolution of one month (primarily by GRACE). For the successful recovery of time-variable gravity fields, geophysical effects such as ocean tides, atmospheric mass redistribution, and high-frequency barotropic ocean signals should be removed from the GRACE measurements to observe climate-sensitive signals such as hydrology, ice sheet mass balance, and oceanic mass redistribution. Imperfect modeling of these corrections, resonant orbit errors, and effect of temporal aliasing will contaminate GRACE monthly solutions. In this study, we quantify the effects due to the inherent modeling error and temporal aliasing caused by ocean tides, atmosphere, and ground surface water mass on monthly mean GRACE gravity estimates. By simulating GRACE range-rate perturbations due to modeling error along the orbit, we analyze their effects on the estimated gravitational coefficients, as well as the temporal aliasing, by fully inverting monthly GRACE data. Finally, we discuss the feasibility of the CHAMP mission to recover the long wavelength temporal gravity fields by analyzing one year of CHAMP data.

REPEATED HIGH-PRECISION GRAVITY AND GPS MEASUREMENT TECHNIQUES

Paul GETTINGS[1], Robert N. HARRIS[1], Rick ALLIS[2], David S. CHAPMAN[1] ([1]Department of Geology & Geophysics, University of Utah, [2]Utah Geological Survey)

Repeated high-precision gravity and GPS measurements are becoming acommon tool for tracking changes in subsurface reservoirs. Despite this,there is little literature which discusses measurement techniques andthe expected errors. Our research has focused on improving measurementtechniques to be applied to ground water and geothermal steam reservoirs,including quantifying the minimum error levels with modern equipment.We applied these methods in two studies: ground water monitoring ofthe southern Salt Lake valley, Utah, USA, and steam monitoring of theGeysers geothermal field, California, USA. Gravity measurements using modern relative high-precision meters, suchas Scintrex CG-3Ms or L&R E series, can now be routinely made to anaccuracy of 5 µGal. Such accuracy requires the use of time seriesanalysis at each station, and non-linear instrument drift functions.Modern computerized meters are capable of internally storing a time seriesof measurements for each station; older meters can often be fitted tolog such data to a field computer. This time series, typically of 10-15minute duration in our work, can then be analyzed in several ways toproduce stable estimates of the gravity reading. In particular, ourresearch has emphasized using a weighted arithmetic average (for longoccupations), or a Thiele extrapolation scheme (for shorter stationoccupations). Instrument drift is removed through a superposition ofa linear long-term drift function, and an empirical staircase functionformed from differences between repeated station occupations. To achieve high-accuracy GPS measurements while maximizing the numberof field stations in a survey, rapid-static measurements are necessary.We have tested the effect of occupation time and processing schemeson the absolute accuracy of the resulting GPS position. Using apost-processing differential method with a fixed (but not necessarilycontinuous) base station within 15 km, positioning error of <4 cmvertical is achievable with 30 minute occupations and broadcast orbitalparameters. There is a definite correlation between baseline length andpositioning accuracy. Using precision orbital parameters removes thiscorrelation. Occupations of 60 minutes or more also improve accuracy;combining 1 hour occupations with precise orbital data yields a verticalerror of <3 cm for all stations within 20-30 km of the fixed reference. In both case studies, gravity measurements tracked known mass changesin the reservoir. In the southern Salt Lake valley study, mass changesmeasured along the line of gravity stations qualitatively tracked waterwell level changes, but very complicated local hydrology precluded moredetailed quantitative comparisons. At the Geysers, the station gridshows coherent spatial signals, with gravity changes that are withinmeasurement error of theoretical predictions.

THE EFFECT OF THE GENERATION OF NEW GRAVITY MODELS FROM CHAMP, GRACE AND GOCE ON GEODESY

Reiner RUMMEL, Jakob FLURY, Thomas GRUBER (Institute for Astronomical and Physical Geodesy, Technical University Munich)

It is our expectation that after completion of the missions CHAMP, GRACE and GOCE the static and the time variable part of the earth's gravity field are known with high precision and resolution. For the stationary part a geoid and gravity anomaly precision of 1 cm and 0.1 mGal, respectively, are envisaged with a spatial resolution of somewhere between 70 km or 100 km half wavelength. In combination with geodetic positioning techniques such as VLBI, SLR and GPS height systems could be unified at cm-level, if local short wavelength gravity information is available, too. Thus, once the new generation of global gravity models becomes available, the remaining key question will be, whether systematic distortions in nowadays gravimetry (land and sea), deflections of the vertical and topographic data bases can be identified and eliminated. This would imply, that along with the long and medium wavelength improvements also the short wavelength gravity field material would be significantly improved from these missions.

JSG02/09P/A05-002 Invited 1425

IMPACT OF AIRBORNE GRAVIMETRY ON GEODESY AND OCEANOGRAPHY

Rene FORSBERG (Department of Geodynamics, KMS)

Airborne gravimetry has developed rapidly in recent years, primarily thanks to the development of kinematic GPS. With typical best accuracies at the 1-2 mgal r.m.s. level, with near bias- and drift-free performance, airborne gravimetry is an ideal tool for geoid determination and regional gravity field mapping, allowing vast and inaccessible areas to be quickly and economically covered. In continental areas geoid models from airborne, surface and satellite data, combined with detailed elevation data (e.g., from the SRTM mission) could readily meet most needs of height determination by GPS, reducing or eliminating the need for levelling. In the marine areas, the possibility for seam-less coverage of near-coastal regions, and the ability to detect systematic errors in existing marine gravimetry, would enable the generation of improved geoid models, giving improved direct measurement of dynamic sea-surface topography from satellite (or airborne) altimetry. In the paper a brief overview is given of the current status of airborne gravimetry and some future trends. The applications for land and marine geoid determination are illustrated by a number of KMS cooperative survey projects, spanning from major surveys in the Arctic, over European sea areas, to some experiences in tropical jungle regions.

GEOID HEIGHT TIME DEPENDENCE DUE TO GLOBAL GLACIAL ISOSTASY: A FILTER FOR GRACE DATA ANALYSIS

Richard W. PELTIER (Dept. of Physics, University of Toronto,Toronto, Ontario, Canada)

The Gravity Recovery And Climate Experiment (GRACE) will, within the nextseveral years, deliver an observation of the time dependence of geoid height that will resolve not only the annual cycle of this field with high spatialaccuracy, but also its´ secular component. Although the annual cycle and its´interannual variability will be dominated by atmospheric and surface hydrology effects, the secular component will provide important information concerningthe origins of global sea level rise. However the secular signal will also be significantly influenced by the ongoing impact of the glacial isostaticadjustment process due to the most recent polar deglaciation event which endedapproximately 10,000 years ago. If it were possible to construct a sufficientlyaccurate a-priori model of this contribution to the global secular change signalthat GRACE will observe, then this component could be removed so as to more clearly reveal the modern climate change related influences more clearly. I willdiscuss the considerable further progress that has been made in the constructionof a GIA filter for GRACE, emphasizing the extent to which Holocene relativesea level observations have made it possible to calibrate the model. These datahave recently lead to an improvement in the model of net glacial forcing and toconfirmation of the important role that rotational feedback plays in determining the largest spatial scale characteristics of the expected GIA contribution to the GRACE observations.

JSG02/09P/A05-004 Invited 1515

TIME-VARIABLE GRAVITY: CASE STUDIES OF GEOPHYSICAL AND CLIMATIC MONITORING AND MODELING

Benjamin Fong CHAO (Space Geodesy Branch, NASA Goddard Space Flight Center)

Precise time-variable gravity data from dedicated space missions enable us to study the mass transport processes that occur in the Earth system, from high atmosphere to deep in the Earth interior. This can be done in much higher spatial resolutions than provided by the satellite-laser-ranging (SLR) technique. We will review the quarter-century of SLR observation of low-degree time-variable gravity, which has already led to important discoveries in terms of large-scale geophysical and climatic mass movements. We will then discuss new quantitative aspects accentuated by the high precision of the space missions such as GRACE. For example, the atmosphere pressure field will have to be considered not in 2-D thing-layer approximation but in its full 3-D structure. Certain cases will be raised, where interesting geophysical and climatic mass variations can either serve as ground validations for the space mission observations, or benefit from independent quantitative constraints afforded by the time-variable gravity data, depending on their temporal and spatial resolutions.

JSG02/09P/A05-005   Invited   1555

CAN CONTINENTAL WATER MASS VARIABILITY DERIVED FROM SATELLITE GRAVITY MISSIONSBE USED TO CORRECT FOR THE LONG-WAVELENGTHHYDROLOGICAL LOADING SIGNAL IN GEODETIC TIMESERIES?

Tonie M. VAN DAM[1], John M. WAHR[2] ([1]European Center for Geodynamics and Seismology, [2]Department of Physics, University of Colorado, Boulder)

Model estimates of the annual variations in continental water storage are of sufficientmagnitude to induce peak-to-peak changes in the vertical position of geodetic stationsof up to 3 cm. Signals of this magnitude need to be removed from the geodetic data ifthe geodetic trend is to be interpreted in terms of geodynamic processes.Unfortunately, considerable errors are probably present in the model-derived waterstorage estimates due to errors in the model forcing, parameters and model formulation.If these models are used to correct the geodetic data, it is likely that thecontinental water storage signal is being improperly removed from the geodeticdata sets. A large number of satellite gravity missions have been recently launched, or will comeonline in the near future, that will measure changes in Earth´s surfacehydrology with unprecedented accuracy. Gravity missions such as CHAMP, GRACE and GOCE,and other satellite missions have the potential to significantly improve our understandingof many hydrologic processes, as well as improving ourability to monitor and predict the partitioning of continental water mass intosnow, precipitation, soil moisture and ground water. In this paper, we investigate the possibility that estimates of water storagevariations derived from satellite gravity missions can be used to correctgeodetic data for the long wavelength component of the water storage signal.

JSG02/09P/A05-006   Invited   1620

GRACE - UTILITY AND VALIDATION:MAPPING THE TIME-MEAN CIRCULATION OF THE NORTH ATLANTIC OCEAN

Steven Robert JAYNE (Dept. of Physical Oceanography, Woods Hole Oceanographic Inst.)

The precise measurement of the geoid by the Gravity Recovery andClimate Experiment (GRACE) mission permits the estimation of theocean´s time-mean, three-dimensional, geostrophic circulation. The time-mean sea surface height measured by satellite altimetry includesthe ocean´s dynamic topography (order 1 meter), however this signal isobscured by the much larger signal of the Earth´s geoid (order 100meters). Traditional estimates of the Earth´s gravity field(i.e. EGM96 by Lemoine et al. 1998) incorporated the time-mean sea surface height, heretofore preventing the estimation of permanentocean currents such as the Gulf Stream, the Kuroshio, and theAntarctic Circumpolar Current. The GRACE geoid, measured independentlyof altimeter data, allows for more accurate estimation of the ocean´sdynamic topography. The three-dimensional structure of geostrophic ocean currents isestimated from the combination of dynamic height, computed from aclimatology of temperature and salinity, and the mean sea surfaceheight. This circulation estimate can be independently tested againstthe dynamic pressure estimated from deep float displacements. Thepreliminary results indicate that the GRACE estimate is a substantialimprovement over the EGM96 geoid for calculating the generalcirculation of the North Atlantic Ocean at large spatial scales.

THE GRAVITY RECOVERY AND CLIMATE EXPERIMENT: STATUS AND EARLY RESULTS

Byron TAPLEY[1], Christoph Reigber[2] ([1]University fo Texas Center for Space research, [2]GeoForschungZentrum Potsdam)

The Gravity Recovery and Climate Experiment (GRACE) is a dedicated satellite mission whose objective is to map the global gravity field with unprecedented accuracy over a spatial range from 400 km to 40,000 km every thirty days. The measurement precision will provide a mean gravity field whose accuracy in this frequency range is between 10 and 1000 times better than our current knowledge. The gravity measurements are applicable to studies of the general ocean circulation and ocean-atmosphere heat and mass exchange. Measurements of continental aquifer mass change, polar ice mass change and ocean bottom currents are examples of a completely new remote sensing capability whereby we can use satellite measurements to look into the earth's interior.The GRACE mission involves two identical satellites orbiting one behind the other at an approximate distance of 200 km. The primary measurement is provided by the High Accuracy Inter-satellite Ranging System (HAIRS), which measures range change between the two satellites. The range change will be measured with a precision better than 10 microns. A highly accurate three-axis accelerometer, located at the satellite mass center, will be used to measure the non-gravitational accelerations. Satellite GPS receivers will position the satellites over the earth with sub-centimeter level accuracy. With this set of measurements, the two GRACE satellites will provide highly accurate measurements of the global gravity field once every thirty days. The two satellites were launched on March17, 2002, and are designed to operate for a period of five years. This presentation will summarize the mission status, the satellite and instrument performance, and will describe some of the early results and the impact of these results on global climate change investigations.

SCIENTIFIC ACHIEVEMENTS FROM THE FIRST PERIOD (1997-2003) OF THE GLOBAL GEODYNAMICS PROJECT USING A WORLDWIDE NETWORK OF SUPERCONDUCTING GRAVIMETERS

Jacques HINDERER[1], David CROSSLEY[2] ([1]EOST/IPGS (UMR 7516 CNRS-ULP) Strasbourg France, [2]Department of Earth and Atmospheric Science Saint-Louis University)

The first term of the GGP (Global Geodynamics Project) of a worldwide network of superconducting gravimeters (SGs) started in July 1997 for a duration of 6 years. A special effort was made by all the SG groups to record pressure and gravity to uniform standards of precision and sampling, with standard data acquisition filters. We also agreed to prepare one minute data in an homogeneous way with identical exchange formats before uploading the files to the database hosted at ICET (Brussels, Belgium). This effort has allowed us to collect high quality records of time-varying gravity from about 15 stations with a cluster in Europe and Japan, and individual stations in Canada, United States, Australia, South Africa, Indonesia, Antarctica and in the Arctic (Spitsbergen). We paper is devoted to here review the main scientific results obtained from this set of gravity records. We first emphasize the seismic frequency band (periods below 54 min) where SGs have shown to be better than broadband seismometers for the observations of long-period fundamental normal modes after large earthquakes. A noise comparison from all the stations also shows that these instruments are uniquely suited to study in the best available conditions the sub-seismic band (periods above 54 min and below the tides) where it is predicted there should be the core modes and the Slichter triplet of the inner core. Second, we discuss significant new results that have been obtained concerning the tides: zonal long-period components, ocean

loading, detection of non-linear tides, and Free Core Nutation resonance effects. Third, we deal with the long-term gravity changes and show that SGs, thanks to their extremely low instrumental drift, are also a useful tool for detecting seasonal changes due to various loading effects (hydrological, non-tidal oceanic, atmospheric), as well as the contribution from the pole motion at the Chandler period. Finally we will demonstrate the possibility that a regional network of SGs, such as currently operated in Europe, can validate/calibrate time-varying satellite gravity data from the new space missions, e.g. CHAMP and GRACE.

JSG02/09P/A05-009   1715

MODELLING OCEAN MASS REDISTRIBUTIONS IN THE HADLEY CENTRE CLIMATE MODEL

Keith HAINES, Rory BINGHAM (Environmental Systems Science Centre, Reading Univ.)

Oceanic mass redistribution leads to temporal changes in the Earth's gravitational field. The GRACE satellite mission launched in March 2002 promises the opportunity to observe these changes with unprecedented accuracy.This study is an attempt to characterise the spatial and temporal scales of mass redistribution in the ocean. We further consider gravitational effects of this redistribution. We derive bottom pressure anomaly fields from the output of the one hundred year control run of the Hadley Centre coupled ocean-atmosphere model HadCM3. From the bottom pressure time-series we derive time varying geoid displacements to degree and order 100. Together these two data sets form the basis of our study. We use a variety of mathematical and statistical techniques to separate the time-series into frequency bands. The mean power spectrum reveals that, as expected, the annual harmonic is the dominant bottom pressure signal. Significant power was also found at the semi-annual and third-annual harmonics. Each of the bottom pressure annual and higher harmonics was isolated and it's effect on the geoid calculated.   A comparison of the annual geocenter motion was made between this study and the limited number of other studies for which such a calculation has been performed. Relatively good agreement was found for the x component with much poorer agreement between the models in the two other directions. The oceanic processes leading to the geocenter motion are considered. Empirical Orthogonal Function (EOF) analysis confirmed the dominance of the annual signal. The second mode had a decadal frequency and a spatial pattern suggestive of basin wide transport between the Pacific and Atlantic oceans. We consider the relationship between this mode and observed modes of climate variability. A composite method was also used to characterise the mass redistribution associated with the model ENSO events. Impact on variability of large scale quantities such as J2 are considered.

IMPACT OF NEW GRAVITY MISSIONS FOR SATELLITE ALTIMETRY APPLICATIONS

Thomas GRUBER, Jakob FLURY, Thomas PETERS, Drazen SVEHLA (Institute for Astronomical and Physical Geodesy, Technical University Munich)

The new gravity field missions CHAMP, GRACE and GOCE promise to provide significantly improved global gravity field models of the Earth. Satellite altimetry, which closely links the geodetic and oceanographic areas of research, immediately benefits from improved gravity field information in two ways. Apart from possible improvements in the radial accuracy of altimeter satellite orbits by using better gravity field information, the oceanic geoid and its variations is the quantity of main interest, because it enters into the determination of dynamic ocean topography and into bottom pressure variations. The paper investigates both aspects based on the most recent CHAMP (and if available GRACE) gravity field solutions. (1) Orbits for altimeter satellites based on the new gravity field models are analysed in order to identify the impact of the new gravity field models on their radial accuracy. (2) The ocean geoid, derived from these models is analysed in the spatial and spectral domains in order to identify its impact on newly computed sea surface topography solutions. For this purpose several sea surface topography solutions are computed by subtracting the oceanic geoid from altimetry derived mean sea surfaces and subsequent filtering. Comparisons to oceanographically derived sea surface topography solutions are used to assess the quality of the new gravity field solutions over the oceans.

JSG02/09P/A05-011   1745

CO-SEISMIC GEOID AND GRAVITY CHANGES DETECABLE BY GRAVITY SATELLITE MISSIONS

Wenke SUN, Shuhei OKUBO (Earthquake Research Institute, University of Tokyo)

Recently, a number of dedicated satellite missions is and will be available for gravity field determination from space, such as, CHAMP, GRACE and GOCE. Especially, the primary objective of GRACE is to provide an unprecedented accuracy, global and high-resolution estimates of the constant and time-variable part of the earth's gravity field for every 30 days in 5 years. It can be expected that almost all time change problems in geosciences can be detected and well studied in the near future. The temporal gravity variations causing a global signature is usually considered to result from atmospheric mass redistribution, ocean circulation, sea level changes due to polar ice melting or aggregation, and the visco-elastic response of the Earth´s lithosphere to past and present loads. However, another potential application of the gravity missions is that they provide us with powerful means to detect gravity and geoid changes caused by earthquake, which have never been detected up to the present. A case study of 1964 Alaska earthquake (Sun and Okubo, 1998) indicated that the gravity change could be detected on the earth surface by super-conducting gravimeter even as far as 5,000 km away. A geoid height change due to the earthquake could reach at 1.5 cm. Such gravity and geoid height changes are expected to be detectable by modern space techniques, like Altimetry and gravity missions. However, due to the limit spatial resolution of the gravity satellite missions, co-seismic deformations must calculated with a truncation of the harmonic degrees, i.e., the contribution of higher degree part then the resolution of the space missions should be removed out. This requires a corresponding investigation for individual or group wavelength, i.e., a theoretical work and simulation on truncated co-seismic deformation is necessary. This purpose can be approached by the dislocation theory (Sun and Okubo, 1993) for a spherical model since it is expressed in spherical harmonics. For this purpose, in this research, a concept of truncated co-seismic geoid and gravity changes is proposed and corresponding expressions are presented to compute co-seismic geoid and gravity changes for spherical harmonic degree within the spatial resolution of the gravity satellite missions. So that numerical results of any individual harmonic degree or summation to an interested degree can be used to compare with the precession of the gravity missions, to investigate whether the co-seismic gravity and geoid changes are detectable. A numerical computation of truncated co-seismic gravity and geoid changes is performed for a source equivalent to the fault size of the Alaska earthquake (1964, mw=9.2). Results indicate that both gravity and geoid changes are about two orders larger than the precession of the gravity missions. It implies that co-seismic deformations caused by a smaller earthquake (e.g., m<8) are still detectable.

METHOD OF RESERVOIR STORAGE MONITORING BY SATELLITES

Jun MAGOME[1], Hiroshi ISHIDAIRA[2], Kuniyoshi TAKEUCHI[2] ([1]Graduate Student, University of Yamanashi, [2]Graduate School of Engineering, University of Yamanashi)

More than 41,413 dams over the height of 15m are now in operation in the world serving for various important purposes in their region. Their efficient use is the most important subject in water resources management. Therefore it necessitates the regional monitoring of water storage in reservoirs, especially its seasonal variation. Since the ground observations of reservoir storages are often not available to the users due to lack of proper information transmission network as well as, in some cases, administrative barriers, it is desirable to develop technology to monitor water storage by the use of satellite remote sensing technique. In this study, we propose new methods for estimating water storage in reservoirs based on satellite observations and digitized topographical data. First method is the combination of area of water surface (A) extracted from satellite image and change in water level (dH) measured by satellite altimeter. Second one is the combination of satellite data and relationship between water level (H), area of water surface (A), and reservoir storage (V), i.e. A-V curve, H-V curve, and H-A curve. If these relations are available, satellite measured A or H can be translated into the V. These methods are applied to the Yagisawa-reservoir in Japan and Volta Lake of Akosombo dam in Ghana to verify the possibility of estimating the water storage in reservoir. In order to identify the area of water surface of reservoirs (A), the satellites and sensors used are : JERS-1/SAR, SPOT/HRV, ADEOS/AVNIR and TERRA/MODIS. The radar altimeter system mounted on TOPEX/POSEIDON was used for deriving water revel. For Yagisawa - reservoir, the derived average accuracy based on satellite images and A-V curve estimated form DEM was , in terms of percentage error, 8.3% (SPOT/HRV and ADEOS/AVNIR : semi-automated), 8.2% (JERS-1/SAR : image reading) and 19.7 % (JERS-1/SAR : semi-automated) as against observations at dam site. As for Volta Lake, all proposed methods can provide seasonal to inter-annual variability of reservoir. In comparison with Volta River Authority report, in which the change in water storage from 1999/1/1 to 1999/12/31 was reported as 27.89 km3, the error of estimated results are the less than 10 %. Each method has its advantages and limitations depending upon the availability of data, scale and location of reservoir, and so on. However, these methods have high potential to be used for monitoring the reservoir storage without in-situ observations. Because new satellites and geographic information are being prepared on a global scale, proposed methods are considered to be able to monitor regional water storage in reservoirs more precisely by using these data.

JSG03/09P/A12-002   **1420**

REMOTE SENSING OF LAKE ICE: LAKE BAIKAL, SPRING PHYTOPLANKTON BLOOM STUDIES

Sergei V. SEMOVSKI[1], Nikolay Yu. MOGILEV[2], Petr Yu. PUSHISTOV[3] ([1]Limnological Institute SB RAS, Irkutsk, Russia, [2]Institute of Solar-Terrestrial Physics SB RAS, Irkutsk, Russia, [3]Yugra Institute of Information Thechnologies, Khanty-Mansijsk, Russia)

The state of the ice cover, and the freeze-up and breakup dynamics of lakes are influenced by a climate variability and are good indicators of large-scale climate changes. The spatial distribution and the state of the ice cover of lakes determine in a multitude of ways the occurrence of many processes in lake ecosystems, and the formation of hydrophysical fields. The algal bloom intensity in lakes depends in many respects on the optical properties of ice. Routine observations of the conditions of the snow and ice cover at a stationary hydrometeorological network are usually poorly representative, and the main part of the water surface remains unexplored by researchers. The generation and sample applications of a set of multispectral remotely sensed products for investigations of Lake Baikal´s ice cover variability are described. During the period from mid-January to the end of April, the lake is completely covered with ice, and by analyzing satellite information it is possible to investigate in detail the distribution and dynamics of the main types of ice cover. Different ice cover classes and unfrozen water distributions are estimated from calibrated and navigated NOAA AVHRR 1.1-km imagery of Lake Baikal for January 1994 through May 2002. The processing strategy and characteristics of the products are reviewed. The utility of this type of multiparameter dataset for modeling applications and process studies is discussed. High-resolution Resurs, ERS SAR, ASTER and MODIS images are used for detailed representation of different ice classes distributions. *Aulacoseira baicalensis* diatom is a dominant pelagic endemic species of Lake Baikal during spring. The diatom begins to multiply in February-March under the ice and its concentration reaches a maximum in April-May. The under-ice bloom intensity of diatoms shows a strong interannual variability. The causes of these changes are unclear yet; however, the photosynthetic active irradiance transmission through the ice during the springtime depends largely on ice optical properties. The heat-driven convection intensity, turbulence and stratification structure are also associated with changes in persistence of the ice cover. Both optical and hydrodynamic factors form conditions for diatoms growth. The known spatial and temporal distribution of ice for the whole lake is used in bio-optical model of water ecosystem dynamics for spring bloom simulation. Optical properties of ice classes derived using remote sensing data and available downward irradiance on the water surface are estimated using field observational data. This information is used as external fluxes in the large eddies model of the under-ice convective boundary layer. Bio-optical model of two-component phytoplankton dynamics (heavy diatoms and light picoplankton) coupled with heat-driven hydrodynamics is developed. Equations of the ecodynamics model are based on general principles of population dynamics. The impact in optically active ecosystem components in the underwater spectral irradiance field is simulated.

SURFACE SKIN TEMPERATURE DIURNAL CYCLE OVER LAND FROM COMBINED PASSIVE MICROAVE AND INFRARED SATELLITE OBSERVATIONS - APPLICATION TO SOIL MOISTURE RETRIEVAL

Filipe AIRES[1], Catherine PRIGENT[2], Willian B. ROSSOW[3] ([1]GISS/NASA - Columbia University and LMD/IPSL/CNRS - Ecole Polytechnique, [2]CNRS, LERMA, Observatoire de Paris, Paris, France, [3]NASA/Goddard Institute for Space Studies, New York, USA)

Land surface temperature (Ts) diurnal cycle and its difference with the temperature of the overlying airmass (Tair) govern the exchange of energy fluxes at the land-atmosphere interface. Adequate measurements of Ts over land over the whole diurnal cycle would not only enable model evaluation of coupled land-atmospherec limate model, it would also provide an additional constraint on latent and sensible heat flux calculations. However accurate measurements of Ts over continents are not yet available for the whole globe, for clear and cloudy skies, with a time sampling adequate to resolve the diurnal cycle. Unlike Tair, Ts is not conventionally observed by the meteorological weather stations. Ts are estimated from satellite infrared radiance observations, but are limited to clear conditions because of the inability of infrared to penetrate such clouds. A neural network inversion scheme has been developed to retrieve the surface skin temperature along with atmospheric water vapor, cloud liquid water, and surface emissivities over land from passive microwave from the Special Sensor Microwave / Imager [Aires et al., JGR, 2001; Prigent et al., JAM, 2003]. The results of the neural network inversion are very encouraging, with r.m.s. theoretical error of 1.3K in clear sky conditions and 1.6K in cloudy scenes for Ts over the globe. In the absence of routine in situ surface skin measurements, retrieved Ts values are evaluated by comparison to Tair measured by the meteorological station. The Ts/Tair difference shows all the expected variations with solar flux, soil characteristics, and cloudiness. Microwave Ts retrieval presents a very attractive complement to the infrared estimates in cloudy areas and time record of land surface temperature can be produced. However, the SSMI microwave observations on board the Defense Meteorological Satellite Program (DMSP) polar orbiters do not provide the adequate time sampling for a full description of the surface skin temperature cycle under cloudy condition. A study is underway to reconstruct the complete daily surface skin temperature diurnal cycle over the globe from a limited number of observations for both clear and cloudy conditions, based on a statistical analysis of the observations datasets and excluding model calculations. In a second phase, soil moisture retrieval is examined from combined passive microwave and infrared observations. Surface soil moisture can be derived from passive microwave observations, even at SSM/I above 15 GHz. In addition, analysis of the amplitude of the surface skin temperature cycle can also provide indirect information on the soil moisture content. Soil moisture from NCEP is systematically compared to passive microwave satellite information and to retrieved surface skin diurnal cycle, in order to analyze their sensitivity to spatial and temporal variations of the soil moisture, on a global basis and for a year. This sensitivity analysis will lead to the development of a soil moisture retrieval scheme from combined microwave and infrared observations. It will make use of satellite observations that have been available for more than a decade and will thus enable global scale studies of the intra and inter annual variability of soil moisture.

CLUSTER ANALYSIS OF REMOTELY SENSED DATA FOR DISCRIMINATING SINKS AND SOURCES OF NATURAL ADMIXTURES IN CASE II WATERS

Lioudmila Y. AMETISTOVA[1], Genrikh S. KARABASHEV[2] ([1]Ocean Technology Group, University of Sydney, Australia, [2]PP Shirshov Institute of Oceanology, Moscow, Russia)

Remote sensing is unique in its capabilities for monitoring ocean colour and subsequent assessment of biogeochemical properties of the waters. Sea-viewing Wide Field-of-view Sensor (SeaWiFS) is the most popular sensor for interpreting remotely sensed data from aquatic environments. The basic assumption for chlorophyll retrievals from water-leaving radiances is that there exists a more or less universal relationship between ocean colour and phytoplankton pigment concentration (case I waters). Unrealistically high chlorophyll values obtained with the standard OC4 algorithm in coastal waters of high latitudes (case II waters) is the result of the failure of such an assumption. In turbid waters photosynthetic pigments, coloured dissolved organic matter, organic as well as inorganic solids colour the water. Due to significant river runoff and shallowness of the White Sea (Russian Arctic), it represents typical optically complex case II waters. Cluster analysis was applied to the White Sea L2 SeaWiFS water-leaving radiances in 6 visible wavelengths (λ= 412,443,490,510, 550 and 675 nm) for all dates available from August 1997 (SeaWiFS launch) till October 2001. For total 712 days 10 clusters were identified. Negative values were encountered in over 60% of the cases in the 412 nm band, which indicates atmospheric correction failure in the coastal zone due to particulate matter presence and thus inability to use SeaWiFS standard chlorophyll algorithm. The most abundant pattern has a slightly negative 412 nm band and a radiance peak at 550 nm ranging between 0.3-0.5 mW/cm²/um/sr. Almost parallel is a cluster with more pronounced negative part of the spectra (first three bands have negative radiances). Mentioned spectra are found in the outer parts of the major bays. Due to pronounced 550 nm peak and taking into consideration typical values of particulate matter, chlorophyll and yellow substance concentrations encountered in the White Sea, spectra in the regions of river discharge reflect very high yellow substance concentrations as well as particulate matter presence. Found closer to the shore (but not in the river discharge basins) are the spectra with unrealistically high values in all visible bands – presumably caused by strong bottom reflection in optically pure shallow waters. In these areas Barents sea waters intrusion into the White Sea is observed. In case II waters yellow substance absorption and particulate matter backscatter determine water optical properties. Therefore, only strong chlorophyll blooms can be detected in such waters using SeaWiFS data. The study was supported by the Russian Foundation for Basic Research, project no. 02-05-64680.

ESTIMATION OF SEASONAL PARTIAL PRESSURE CO2 IN NORTH WEST PACIFIC OCEAN BY SHIP AND SATELLITE DATA

Takahiro OHSAWA[1], Keiko HANAWA[1], Chaofang ZHAO[2], Yasuhiro SUGIMORI[1] ([1]Department of Information Science, Chiba Univeristy,, [2]National Laboratory of Ocean Remote Sensing of MOE)

Determination of seasonal and high-resolution partial pressure CO2 (pCO2) in surface seawater is one of the most challenging problems in order to estimate CO2 flux between air-sea interfaces. The new empirical relation among pCo2, different physical and geochemical parameters has been established in the surface ocean using recent WOCE and JGOFS data. This data has been tested in the Northwest Pacific Ocean. Compared with pCo2 investigations, the results show a good agreement in the tropical ocean and subtropical gyres throughout the year, as well as temperate waters in the summer season. The mean value of pCo2 is well-simulated using Levitus climatological dataset. The temporal and spatial variations of pCo2 are dominantly controlled by sea surface temperature, which implies a combination of operational AVHRR dataset. This datasets may produce high resolution of pCo2 and its seasonal variation in the study area. In winter season, when intense upwelling occurs in the subarctic region, a systematic underestimation of about 74 µatm is found for the proposed parameterization method, mainly attributed to the rich nutrients from the deep water and TCo2 accumulated through biological bump. After correcting this bias, the calculated pCO2 coincides well with the historical investigations. Further effort is necessary for modeling the study area where upwelling is active in winter season, especially using remote sensing data (e.g., SeaWiFS, MODIS and GLI).

MAPPING SEA SURFACE SALINITY IN COASTAL WATERS WITH AN AIRBORNE MICROWAVE RADIOMETER

Malcolm Lewis HERON[1], Derek M. BURRAGE[2], Thomas C. STIEGLITZ[1], Arnstein PRYTZ[1] ([1]MARINE GEOPHYSICAL LABORATORY, [2]The University of Southern Mississippi, MS, USA)

A prototype scanning low frequency microwave radiometer (SLFMR), developed by NOAA and NRL and constructed by ProSensing Ltd has been calibrated and validated in deployments on river plumes in the Great Barrier Reef Lagoon in North Queensland, Australia. The spatial resolution, when the aircraft is flying at 3,000 m, is about 1 km and a 6 km swath is mapped across the heading direction of the aircraft. The salinity resolution is about 1 psu. The SLFMR is a null measurement system with a Dicke switch between the antenna and a noise diode which is controlled by a feedback voltage. The compartment is thermally controlled at about 40 OC with thermistors placed at key locations. The calibration of the instrument is sensitive to small differences in the temperatures within the compartment. Also, there is an aging influence on the calibration. We established a calibration procedure which uses the cosmic background and room temperature as two calibration points, and we assume that the correction effects are linear in between. The calibration procedure is performed before and after each campaign (usually for a duration of about two weeks). With careful attention to the calibration, we have successfully mapped river plumes and groundwater runoff from the wet tropics of the North Australian continent, demonstrating that the SLFMR is a valuable tool for coastal oceanography studies.Examples are shown of river plumes from the Herbert River in North Queensland. When the wind speed is low, well formed plumes can be seen being swept alongshore by the prevailing coastal current. Under these conditions there is a strong stratification and the surface layer is highly mobile. When the wind rises to above about 6 m s -1 the plume is rapidly vertically mixed.One of the most pressing problems for the Great Barrier Reef Marine Park Authority (which is a regulatory authority set up by the Federal Government to ensure the sustainable use of the Marine Park) is to determine and manage the effect of river runoff into the main lagoon region. The rivers carry sediments and nutrients into the Lagoon. It has been shown that the sediments predominantly form a coastal wedge and affect only the coastal fringing reefs. The destination and effect of nutrients is less certain and the SLFMR is proving to be a uniquely useful instrument in providing a measure of advective and diffusive mixing of the fresh water into the Lagoon .

JSG03/09P/A12-007   1620

REMOTE SENSING & DECISION SUPPORT FOR ENVIRONMENTAL SUSTAINABILITY

Gilbert L. ROCHON[1], Chris JOHANSSEN[2], Steve MAYO[3], Mohamed MOHAMED[4], Marseyas FERNANDEZ[5], Sarada MAJUMDER[3], Larry BIEHL[2] ([1]Purdue University, Information Technology/Earth & Atmospheric Sciences, [2]Purdue University, Agronomy Dept./Lab. for Applications of Remote Sensing (LARS), [3]Purdue University, Information Technology (ITaP), [4]Pixoneer Geomatics, Inc., [5]Imagine Software, Inc.)

It has been observed that some decisions which have significant impact on inter-generationally prudent management of terrestrial resources are made withoutawareness of the regional historical context (e.g.landcover, landuse, hydrology,biodiversity, human impact, natural geomorphology) and/or with either innocenceor insouciance with respect to the future collateral damage associated with suchdecisions. It has further been observed that the volume and complexity of dataderived from multi-temporal, multi-satellite remote sensing, particularly whencombined with in situ data sources,can be overwhelming for even well-intentionedhighly trained and intergenerationally ethical decision makers.Accordingly, it was determined that a prototype decision support system that wasable to incorporate region-specific legacy data, contemporary input and thecapacity to generate evocative representations of ˝what if˝ scenarios, could bea useful adjunct to both rule-based and quantitative decision support systems. In developing prototypical tools for enabling and monitoring region-specificenvironmental sustainability, the focus advanced herein is the potential benefitof providing the decision maker with virtual hindsight, through real-time rapidexploration of the archival satellite data with on-the-fly change detection,andassociated in situ data, as well as virtual foresight, through visualization of alternative future scenarios. The limitations and contributory roles of remotesensing,GIS,GPS and visualization technologies in such prototyping are examined,within the context of regions within Africa. The complexity of sustainable agri-cultural ecosystems in support of regional food security and the potentialregional impact of climate change provide challenges to effective tool develop-ment. Moreover, the need to establish practical dissemination of the appropriatetechnologies and associated infrastructure in a manner so as to benefit thenutritionally vulnerable segment of the population is of paramount importance. Case studies are presented to illustrate the potential contribution of remotesensing enabled decision support for sustainable development and food securitywithin African contexts and to assess alternative implementation strategies.

INSAR OBSERVATION OF THE AMUNDSEN BAY, ANTARCTICA

Makoto OMURA[1], Katsuaki KOIKE[2], Koichiro DOI[3], Kazuo SHIBUYA[3], Shigeru AOKI[3] ([1]Dept. of Environmental Science, Kochi Women's Univ., [2]Faculty of Engineering, Kumamoto University, [3]National Institute of Polar Research)

InSAR technique is useful method to observe the surface topography and to monitor the Ice sheet and glaciers in the Antarctic region. We selected the Amundsen Bay, Enderby Land, Antarctica as a test site for the InSAR observation. There are some preliminary InSAR researches on the movements of ice sheet (Ozawa, et al., 1998), Glacier (Omura et al., 2000) and topography (Omura et al., 2001). SAR data from JERS-1, ERS-1 and ERS-2 were received at the Showa Station. Some good InSAR pair including the tandem mission of ERS-1/2 data and JERS-1 SAR L-band data were analyzed by three kind of processing system. We will show the characteristics of topography and its changes around the Amundsen Bay and the system dependent difference in interferograms. This study is carried out as a joint scientific research program, [2]of National Institute of Polar Research, Tokyo, Japan.

JSG03/09P/D-002   Poster   1640-010

RESPONSE OF LAKE VOSTOK TO ATMOPHERIC PRESSURE CHANGE

Koichiro DOI[1], Kazuo SHIBUYA[1], Shigeru AOKI[1], Tsutomu YAMANOKUCHI[2], Reinhard DIETRICH[3], Anja POTZSCH[3] ([1]National Institute of Polar Research, [2]2. Remote Sensing Technology Center/The Graduate University for Advanced Studies, [3]3. Institut fur Planetare Geodasie, Technische Universitat Dresden)

More than 70 subglacial lakes were discovered with airborne radio-echo sounding in Antarctica (Oswald & Robin, 1973). The Lake Vostok is the largest one, which locates in east Antarctica around 77°S, 105°E. Ice thickness over the subglacial lake is more than 3km and dynamics of the lake is very interesting. Some geodetical observations like as GPS, SAR interferometry, and gravity measurements will be effective to detect surface displacements over the lake. Schneider and Simon (1976) observed solid earth tides for about 5 month in 1969 with a gravimeter Gs 11 No. 140 at Vostok station, which is on an ice sheet over the Lake Vostok. We reanalyzed the gravity data using a tidal analysis program BAYTAP-G (Tamura et al. 1991) and obtained gravimetric factors for diurnal and semidiurnal tides as well as phase differences of each constituent from theoretical solid tides. The obtained results are consistent with those by Schneider and Simon (1976). We also estimated the response in gravity to atmospheric pressure changes by the program and the obtained value is -3.7 micro-gal/hPa (1 micro-gal = $10^8 ms^2$). Since the response value takes around -0.3 micro-gal/hPa in ordinal observation on the ground, this value is remarkably large. The obtained response value means upward displacement of ice surface under the condition of pressure increment. We suspect that some movements of fresh water beneath the ice sheet affect the surface response to atmospheric pressure changes. We can examine the vertical displacements of ice surface due to atmospheric pressure change by the combination of SAR interferometry and atmospheric pressure data estimated from the NCEP/NCAR reanalysis data. We will detect surface displacements from some interferometric scene pairs observed by ERS-1 and ERS-2 over the lake and discuss the response of the subglacial lake.

LAKE LEVEL MONITORING FROM ALTIMETRY MEASUREMENTS

Jean-Francois CRÉTAUX[1], Anny CAZENAVE[1], Franck MERCIER[2], Alexey KOURAEV[2], Benoit LEGRESY[2], Frederique REMY[2], Gaetan VINAY[1], Fabrice PAPA[1] ([1]CNES/LEGOS-GRGS, [2]LEGOS)

With the recent missions of satellite altimetry (Topex-Poseidon, Jason-1, Envisat, ERS-1 and ERS-2) it is possible to measure with a great precision inland sea level variations that can be interpreted as water mass balance. The Legos laboratory is involved in this field of analysis since many years. In the frame of an INTAS project we have calculated the Aral Sea level variations with the Topex / Poseidon measurements from 1993 to 2002, ERS1&2 from 1991 to 2002, and Jason measurements in 2002. It has been shown that the so called big and small Aral have separate water level variations. Big Aral is continuously drying out with a slope of around 80 cm/year, while in the north, the level of the small Aral fluctuates at an annual time scale (due to climatic seasonal variations) and present also a lower decrease (less than 10 cm/yr). Traditionally lake level variations (that are usually in continental areas) have been measured with Topex / Poseidon mission, but the use of data from ERS satellites is also of a big interest due to their higher spatial resolution than the Topex / Poseidon or Jason satellites. Moreover, sea level variations that result from variation of hydrological parameters such as river discharge, precipitation and evaporation, are very sensitive indicators of regional climate variations. Based on an high spatial resolution bathymetry map which has been digitalized in 2002 we have preferred to compute variations of volume of the small and big Aral seas, which is a parameter more interesting in term of water mass balance than water level.

MICROWAVE REMOTE SENSING OF SOIL MOISTURE IN FIFE FROM 1987 TO 1988

Hiroshi MATSUYAMA[1], Sachiko ICHIKAWA[1], Tosiyuki NAKAEGAWA[2] ([1]Department of Geography, Tokyo Metropolitan University, [2]Meteorological Research Institute)

This study evaluates the possibility of estimating surface soil moisture through passive microwave remote sensing of 19 GHz. Spatial average of the surface 5 cm soil moisture in the grassland of FIFE study area (15 km by 15 km, First ISLSCP Field Experiment, International Satellite Land Surface Climatology Project) from July 1987 to October 1988 are compared with the observation from SSM/I (Special Sensor Microwave / Imager) on board DMSP (Defense Meteorological Satellite Program). Also, LAI (Leaf Area Index) calculated from NDVI (Normalized Difference Vegetation Index) of NOAA/NASA (National Oceanic and Atmospheric Administration / National Aeronautics and Space Administration) pathfinder AVHRR (Advanced Very High Resolution Radiometer) 8-km land data set, is used to investigate the effect of phenology on the soil moisture estimation. The relationship among soil moisture, LAI and the polarization index (PI) is investigated. PI is defined as the brightness temperature of the vertical polarization minus that of the horizontal polarization, which is normalized by the average of these temperatures. By using PI, it is not necessary to consider the variation of surface skin temperature or effective temperature in the ground. The multiple regression analysis is applied to estimate the surface soil moisture by using LAI and PI. The incorporation of LAI into the multiple regression analysis reveals the higher accuracy of the estimation ofsoil moisture (r = 0.53 in 1987 and r = 0.76 in 1988) in comparison with the single regression analysis between soil moisture and PI (r = 0.42 in 1987 and r = 0.73 in 1988). Also, AIC (Akaike´s Information Criteria) of the multiple regression analysis is smaller than that of the single regression analysis. Namely, the importance of phenology on the estimation of surface soil moisture is statistically confirmed. The standard error of the multiple regression analysis (ca. 20-30 % of volumetric soil moisture) is as large as the coefficient of spatial variation of theobserved soil moisture in the FIFE study area.Concerning the transferability of this method, LAI and PI of 1988 (1987) are substituted into the multiple regression equation obtained in 1987 (1988). The estimations are evaluated by the observed soil moisture in 1988 and 1987, respectively. In the United States, it was relatively wet in summer 1987 while it was very dry in summer 1988. Nonetheless, about 50 % of the total variance is explained by this method in both years, which is as accurate as or more accurate than previous studies. From these results, it is possible to estimate surface soil moisture to some extent with the use of SSM/I and NOAA/AVHRR data alone, when the regression equation is once established. Since the method adopted in this study has fairly large generosity, it is possible to transfer this method to other grasslands in the world where soil moisture data are available at least for one year.

GLOBAL SCALE LAND HYDROLOGY MONITORING USING SATELLITE ALTIMETRY

Philippa Anne BERRY, Ralph Allen PINNOCK (Earth And Planetary Remote Sensing Lab, De Montfort University)

The new generation of altimeter-bearing satellites, Envisat and Jason-1, bring enhanced monitoring capability, with currently increased temporal sampling when combined with existing missions, and increased spatial sampling from the three tracking modes on Envisat, which allows data to be retrieved over widely varying topographic surfaces. Combined with the multi-satellite historical record, this provides a unique time-series of water flow over the earth´s land surface. This paper combines data from Envisat, Jason-1, ERS-1, ERS-2 and Topex to investigate the historical record, demonstrate the current abilities of altimeters to monitor the global land surface water flow, and illustrate the future potential of this technique.

THE CLASSIFICATION OF VEGETATION OF WETLAND BASED ON REMOTE SENSING DATA, OVER KUSHIRO MARSH HOKKAIDO JAPAN

Aosier BUHE[1], K. TSUCHIYA[2], M. KANEKO[3], S.J. SUNG[4] ([1]Hokkaido Institute of Environmental Sciences, [2]Hiroshima Earth Environmental Information Center, [3]Faculty of Environment Systems, Rakuno Gakuen University, [4]Agriculture Department, Hokkaido University)

In this research, we proposed the method of the wetland vegetation classification using the Landsat/Enhanced Thematic Mapper (ETM+) multi-band data. A land cover classification map of wetland vegetation in Kushiro Marsh, Hokkaido, Japan was produced from the calculated results of the Normalized Difference Vegetation Index (NDVI), Normalized Difference Soil Index (NDSI) and Normalized Difference Water Index (NDWI), based on the data from Landsat ETM+. The composition of NDVI, NDSI and NDWI value with different proportion in each pixel, the area can be distinctively separated into forest, grassland and water body which exactly match the results of the land cover types from the field research. A comparison of DN value for both ETM+ and Advanced Space-borne Thermal Emission and Reflection Radiometer (Terra/ASTER) in broad-leaved forest, grass (Phragmites australis), soil (riverbank) and clean water shows that RED band reflection of wetland derived from ASTER is significantly higher than Theoretically, others than water body, all the NDVI of woody plants and wetland are larger than zero no matter which sensor is used. With the comparison of the four sensors, Advanced Very High Resolution Radiometer (NOAA/AVHRR), Moderate Resolution Imaging Spectrometer (Terra/MODIS), ETM+ and Terra/ASTER, it is found that the NDVI of MODIS, ETM+ and ASTER have the similar trend except AVHRR due to it relatively large pixel size in comparison to the study site. The statistical analysis of the NDVI computed from the data acquired with the four multi-spectral sensors show that the value computed from the AVHRR data has the largest mean with the smallest standard deviation and the range while that computed from the ASTER data has the smallest mean and the largest standard deviation and the range respectively. The result well reflects the effect of spatial resolutions of the sensors with 1 km for AVHRR and 15 m for ASTER. In one pixel of AVHRR there are nearly 4356 pixels of ASTER. Although the study area is a wet land, there is no negative value in the NDVI computed from the AVHRR data while there are negative values in those computed from other data with the largest absolute value in that computed from the ASTER data.

REMOTE SENSING OF CHLOROPHYLL A DISTRIBUTIONS AND WATER CONDITIONS IN THE GULF OF TONKIN, SOUTH CHINA SEA

DanLing (Lingzis) TANG, Hiroshi KAWAMURA, Ming-An LEE (Tohoku University)

The Gulf of Tonkin is a semi-closed gulf northwest of the South China Sea, experiencing reversal seasonal monsoon. Previous studies of water conditions have been conducted in the western waters of the gulf, but very few studies of the Chlorophyll-a (Chl-a) distribution have been carried out for the entire gulf. The present study investigates seasonal and spatial distributions of Chl-a and water conditions in the Gulf of Tonkin by analyzing Sea-viewing Wide Field-of-View Scanner (SeaWiFS) derived Chlorophyll-a (Chl-a), in situ measurements, sea surface temperatures (SST), and other oceanographic data obtained in 1999 and 2000. The results show seasonality of Chl-a and SST in the Gulf of Tonkin, and reveal phytoplankton blooms in the center part of the gulf during the northeast monsoon season. In summer, Chl-a concentrations were relatively low (< 0.3 mg m-3) and distributed uniformly throughout most of the area, with a belt of higher Chl-a concentrations along the coast, particularly the coast of Qiongzhou Peninsula; in winter, Chl-a concentration increased (0.5 mg m-3) in the entire gulf, and phytoplankton blooms offshore-ward from the northeast coast to the center of the gulf, while Chl-a concentrations reached high levels (0.8-1 mg m-3) in the center of the blooms. One peak of Chl-a concentrations was observed during the northeast monsoon season in the year. SST were high (27-29 oC) and distributed uniformly in summer, but lower with a large gradient from northeast (17 oC) to southwest (25 oC) in winter, while strong northeast winds (8-10 meters/second) were parallel to the east coast of the gulf. Comparison of Chl-a values shows that SeaWiFS derived Chl-a concentrations match well with in situ measurements most parts of the gulf in May 1999, but SeaWiFS derived Chl-a are higher than in situ data in river mouth waters. The seasonal variation of Chl-a concentrations and SST distribution were associated with the seasonally reversing monsoon; the winter phytoplankton blooms were related to vertical mixing and upwelling nutrients drawn by the northeast wind.

INFLUENCE OF WATERS OF DIFFERENT OPTICAL DOMAINS ON THE PHOTOSYNTHETICALLY ACTIVE RADIATIONS

Harilal Bhaskara MENON (Department of Marine Science and Biotechnology, University of Goa)

Results from both field measurements and Laboratory simulations are used to asses the effects of turbidity on the optical properties of water column. For this two regions of differing optical domains have been considered. The coastal and estuarine regions. The lambertian reflectance (remote sensing reflectance - Rrs), optical properties such as absorption and diffused attenuation coefficients of different water constituents at wavelengths 400 - 700 nm are examined in relation to turbidity. In addition the specular reflectance at the sea surface have also been examined in the wavelength range. The optical properties have been generated spectrophotometrically while remote sensing reflectance has been derived through measurement of Eu λ (Upwelling irradiance) and (Downwelling irradiance) Ed λ. As the remote sensing reflectance has been computed for every 1 nm, it differentiate the effect of individual constituent, such as chlorophyll, sediment and yellow substances (Dissolved organic matter DOM), on Rrs. From the data it's clear that DOM decreases reflectance in the blue part of the spectrum (450 nm). Moreover the decrease of reflectance is a non-linear function of wavelength λ within the 400 - 580 nm range while in the range 580 - 700 nm, the reflectance is linear. This is due to the overlapping of reflectance due to DOM, chlorophyll and sediment in the shorter part of the wavelength. The computed values of Rrs agrees with the measured values within rms error of ± 10 %, ± 14 %, ± 23 %, ± 15 %, ± 14 %, and ± 10.2 % at wavelengths 412 nm, 443 nm, 490 nm, 510 nm, 555 nm, 670 nm and 683 nm respectively.

EFFECTS OF THE TROPOSPHERIC DUST ON THE SEA SURFACE TEMPERATURE DERIVATION FROM SATELLITE OBSERVATION

Myoung-Hwan AHN, Ja-Min GU, Ju-Yong CHUNG, Jae-Chul NAM (Remote Sensing Research Lab/METRI)

The effect of the tropospheric dust on the derived sea surface temperature (SST) from the satellite observation is investigated. To analyze the effects, we use a set of simulated radiance using the vertical profiles of temperature and humidity with and without the aerosol presence as an input of a radiative transfer model. The simulation results show that the presence of dust aerosol reduces the upwelling radiances at the top of atmosphere at the infrared window channel, as much as 15 K of brightness temperature at high dust loading. The presence of dust aerosol also reduces the dual channel difference in the split window channels, which also introduces error in the derived SST, mainly toward cold bias. The overall effect of dust aerosol on the derived SST is determined mainly by the single channel deficit of radiance due to the dust loading. The simulation results are further validated by using the actual observation of the GMS-5 data for two cases, for a very heavy and a moderate dust loading. When the dust amount is very high, the cloud screening and quality control procedures used for the operational derivation of SST could detect and remove the dust-loaded data. However, when the dust loading is moderate or weak, the dust-affected data pass through the two procedures and remains as the final products. The dust effect is clearly shown by the comparison between the SST value derived from satellite data and measured by buoy. Most of cases, the error due to the dust loading is only about 3 K in the hourly SST value and is further reduced in the weekly averaged SST. However, this is only true for when the dust does not occur for a long time period during the week and sufficiently large number of clear sky SST values is available at a given position.

REGIONAL ACE ANALYSIS OF SEA LEVEL, SEA SURFACE TEMPERATURE, AND SEAWIFS OCEAN COLOR DATA IN THE NORTH SEA

Per KNUDSEN[1], Klaus B. HILGER[2], Allan A. NIELSEN[2], Ole B. ANDERSEN[1], Thomas KNUDSEN[1] ([1]National Survey and Cadastre, Geodesy, [2]Informatics and Mathematical Modelling)

Alternating Conditional Expectations Algorithm (ACE) is used to estimate canonical variates (CV) that describes the highest correlation between altimetric sea level height, ocean surface temperature and ocean colour data from SeaWIFS during 1999. ACE can handle arbitrary mixtures of continuous and categorical variables. The method is data-driven and non-parametric with minimal assumptions concerning the data distribution and the form of the optimal transformations. In this investigation, the ACE analysis have been set up to create the best fitting additive model to model the relationship between altimetric sea level height, ocean surface temperature and ocean colour data from SeaWIFS during 1999. Time series of SeaWiFS ocean colour, AVHRR sea surface temperature and TOPEX/POSEIDON and ERS sea surface height have been used for the present investigation. The SeaWiFS data are level 3 processed sets of CHLO, CPIG, K490, and L555. Tidal and meteorological contributions to the altimetric sea surface height is modeled and removed by the Mike 21 hydrodynamic model. The residual heights used for the simulations are applied in a multiple regression setting using the SeaWiFS and AVHRR measurements as predictors. When predicting the sea surface height in the Skagerak region in the easternmost part of the North Sea from the SeaWiFS and the SST data a reduction in the residual variance of 39% is obtained by means of linear ACE based CV. If (noninvertible) nonlinear transformation of the SSH residual is introduced the residual variance reduction amounts to 51%, demonstrating that a non-linear relationship between changes in sea level height, sea surface temperature and amount of biological substance can be established empirically.

A MESOSCALE FEATURES OF THE SOUTH PACIFIC CURRENT OBSERVED FROM SATELLITE ALTIMETRY AND IN SITU OBSERVATIONS

Alexander M. SIROTA[1], Sergey A. LEBEDEV[2] ([1]Department of Fisheries Oceanography, Atlantic Research Institute of Fisheries and Oceanography, [2]Geophysical Center, Russian Academy of Sciences)

In September 2002 oceanographic expedition had been sent by the Atlantic Research Institute of Fisheries and Oceanography to the region of the Southeastern Pacific. The main purpose of the expedition is investigation of oceanographic conditions in the region. These investigations were supported with data of satellite observations. Processing of satellite data and mapping were carried out in the AtlantNIRO. To improve the spatial coverage beyond that available from in situ data from CTD survey, satellite SST and surface dynamic topography data were being prepared and transmitted to the vessel. Data source for SST, derived from AVHRR, was the NOAA Satellite Active Archive. Surface dynamic topography derived from the TOPEX/POSEIDON Quick-Look GDR v.1 data. Preliminary results of analysis of mesoscale variability of that region as well as comparison of in situ observation with satellite data are presented. Efficiency of use altimetry products for support of exploratory researches is estimated.

OCEAN TIDE MODELING IN THE SOUTHERN OCEAN

Yuchan YI[1], C.K. SHUM[1], Sangho BAEK[1], Yu WANG[1], Ole ANDERSEN[2] ([1]Dept. of Civil/Env. Engineering & Geod. Sci., Ohio State Univ., USA, [2]National Survey and Cadastre, Denmark)

Ocean tides play a significant role in the complex interactions between the atmosphere, ocean, sea ice and floating glacial ice shelves. Tidal currents create turbulent mixing at the bottom of the ice shelf contributing to the creation of rifts for the possible detachment of part of the icebergs and can influence heat transport between the ice shelf and seawater. Tides near and, in particular, under floating ice shelves and sea ice influence grounding line locations. And, depending on surface and basal slopes, grounding line migrates with time within a grounding zone. Improved knowledge of the grounding line is inherently necessary to study ice mass balance and its contribution to the global sea level change. Even with the availability of most recent suite of global tide models based primarily on TOPEX/POSEIDON data, e.g., GOT00, NAO99, FES99 models, extreme southern ocean tides (below 60S) are limited both in accuracy and resolutions, especially in regions near Antarctica, seasonally or permanently sea-ice-covered oceans. In SAR tidal deformation analysis using ERS-1/-2 tandem missions over Ross Sea and in a test region over the Sulzberger Ice Shelf (77.5S, 210E), Ross Sea, will be presented. In our initial study with the objectives to improve tides in Antarctica oceans for accurate prediction of grounding line locations to enhance ice mass balance studies, we provide an assessment of accuracy of tide models in the region. In addition to global models, finer resolution regional models in the Antarctica Ocean such as the Padman model are available. Coarse resolution tidal models using available over-ocean and over sea-ice/ ice-shelf data from T/P, JASON, ERS-1, ERS-2, GFO, and ENVISAT in

the Southern Ocean below 50S will be presented. In particular, retracked altimeter data over ice-shelf (IGDR) from GSFC's Ice Pathfinder Data Center, and altimeter data from GFO and ENVISAT are used. Analysis of tidal aliasing will be discussed. Finally, initial results for a fine-resolution test ocean tide model using combined radar altimeter and ERS tandem mission InSAR data over the Sulzberger Ice Shelf will be described.

JSG03/09P/D-013	Poster	1640-021

CROSS-CALIBRATION OF ENVISAT RANGE USING MULTI-SATELLITE ALTIMETRY AND TIDE GAUGE DATA

Luciana FENOGLIO-MARC (Darmstadt University of Technology, Institute of Physical Geodesy)

Envisat altimeter data are compared during the calibration phase against data from other satellites (ERS-2, T/P, Jason-1) using crossover and collinear track techniques in order to identify systematic, time variant and geographically correlated differences between the data from the various satellites and to cross-calibrate the Envisat range. The Mediterranean Sea is selected for the regional analysis, where tide gauge data from selected stations are used to cross-calibrate the various altimeters over the same short calibration period. The long-term monitoring of the Envisat altimeter range stability using the identified stations is discussed based on the preliminary three months results and on the long-term monitoring of the Topex/Poseidon mission. The differences between the sea level heights observed by the altimeter and by the tide gauge are analysed over the ten years at a few locations taking into account effects due to instruments, corrections, coast and circulation.

OCEANIC FRONTS AND EDDIES ON THE SYNTHETIC APERTURE RADAR IMAGES

Andrei Yu. IVANOV (Department of ocean remote sensing, P.P.Shirshov Institute of Oceanology, Russian Academy of Sciences)

Oceanic fronts are boundaries between water masses with different physical-chemical properties, while eddies are vortical dynamic ocean structures including fronts at their peripheries. Typical oceanic fronts andeddies includes large-, meso-, and small-scale ones of different origin.Synthetic aperture radar (SAR) signatures of oceanic fronts, as well as eddies,are mainly action result of 3 mechanisms affecting the sea surface roughness. The most important are: (1) surface wave-current interaction modulating spectrum of surface waves, (2) damping short wave due to oil film accumulationsin convergent zones, and (3) difference in atmospheric boundary layer stability due to air-sea temperature differences across front. Eddies are usually visible in the SAR imagery as a result of wave/current interaction or indirectly due to the presence of natural films trapped within spiraling lines, associated with spiral motion; they outline the shape of eddy. However the role of these mechanisms is still poor known and there're no general models describing observed SAR signatures. The paper gives a review of frontal and vortical ocean dynamic fetures on the basis of analysis of the SAR images collected by Almaz-1, ERS-1/2 and Radar sat satellites over the ocean. As recently shown by Ivanov & Ginzburg (2002) ocean frontal/vortical features can be easily classified (by type of surface manifestations and generation mechanisms) on the basis of SAR imagery analysis. Having classified, the expected behavior of phenomenon can be predicted. Author´s classification of oceanic fronts, detected in the SAR imagery, includes large-scale fronts of climatic origin, mesoscale fronts reflecting synoptic processes, and small-scalefronts of local origin. Current fronts and coastal fronts of different scales usually represent them in the ocean. Author´s classification of oceanic eddies includes the ocean rings (generated by meandering currents), associated vortices, open ocean eddies, eddies due to coastal line or bottom topography heterogeneity (so-called wakes and von Karman vortex streets), mushroom-like eddies (dipoles) etc. The analyzed SAR images also represent combination of the above mentioned types forming both frontal meanders and wakes or chains of eddies. Examples of SAR images showing the fronts/eddy of different types are presented and discussed.It is concluded that the spaceborne SAR gives valuable information on ocean dynamical features, such as fronts and eddies, allowing to extract temporal andspatial characteristics. Moreover, an accurate analysis allows to retrieve both kinematic parameters and responsible generation mechanism. However, furtherprogress in their studying will be associated with regular access to multi-sensor satellite imagery combined with contact measurements.

INVESTIGATIONS OF SPACE-TIME VARIABILITY OF THE SEA LEVEL IN THE BARENTS SEA AND THE WHITE SEA BY SATELLITE ALTIMETRY DATA AND RESULTS OF HYDRODYNAMIC MODELLING

Sergey A. LEBEDEV[1], Oleg I. ZILBERSTEIN[2], Sergey K. POPOV[2], Olga V. TIKHONOVA[2] ([1]Geophysical Center, Russian Academy of Sciences, [2]Hydrometeorological Center Research, Russian Federation)

The problem of retrieving of the sea level anomalies in the Barents and White Seas from satellite can be considered as two different problems. The first one is to calculate the anomalies of sea level along the trek taking into account all amendments including tidal heights. The second one is to obtain of fields of the sea level anomalies on the grid over one cycle of the exact repeat altimetry mission. Experience results show that there is preferable to use the regional tidal model for calculating tidal heights. To construct the anomalies fields of the sea level during the exact repeat mission (cycle 35 days for ERS-1 and ERS-2), when a density of the coverage of the area of water of the Barents and White Seas by satellite measurements achieves maximum. It is necessary to solve the problem of the error minimum. This error is based by the temporal difference of the measurements over one cycle and by the specific of the hydrodynamic regime of the both seas (tidal, storm surge variations, tidal currents). To solve this problem it is assumed to use the results of the hydrodynamic modeling. The error minimum is preformed by the regression of the model results and satellite measurements. As a version it is considered the possibility of the utilizing of the neuronet obtained by the model results to construct maps of the sea level anomalies. The comparison of the model results and the calculation of the satellite altimetry variability of the sea level of Barents and White Seas shows a good coincidence between them. The satellite altimetry data of ERS-1/2 and TOPEX/POSEIDON of Ocean Altimeter Pathfinder Project (NASA/GSFC) has been used in this study. Results of the regional tidal model computations and three dimensional baroclinic model created in the Hydrometeocenter have been used as well. This study also exploited the atmosphere date of the Project REANALYSIS. The research was undertaken with partial support from the Russian Basic Research Foundation (Project No. 01-07-90106).

CURRENT SHEAR MEASUREMENT BY USING SYNTHETIC APERTURE RADAR

Akitsugu NADAI (Advanced Research and Standards Division, Communications Research Laboratory)

The synthetic aperture radar (SAR) is one of the powerful tools to measure ocean features. It can detect oceanic fronts, eddies, waves, and so on. Many spaceborne SAR systems and airborne SAR systems have observed the ocean and their data have been analyzed. The spatial resolution of these systems is not enough to measure the spatial change of ocean wave spectra in about 10km separation.The Communications Research Laboratory and the National Space Development Agency of Japan has developed and operated an airborne high-resolution SAR systems called Pi-SAR. The Pi-SAR is a dual-frequency polarimetric radar operating L-band and X-band frequency. The X-band radar, moreover, has interferometry function to measure terrain elevation with accuracy of 2m. The resolution of L-band and X-band radar is 3m and 1.5m, respectively. Based on this hi-resolution, the Pi-SAR can measure the ocean wave spectra from its data of about 10 square kilometers. This paper presents the spatial change of ocean wave spectra observed by the Pi-SAR and the technique for current shear measurement based on wave-current interaction. The Pi-SAR observed southern ocean off Kii peninsula, Japan. The observation path extended about 200km length from Kii peninsula toward south. The Kuroshio ran just south of the Kii peninsula at the observation time, so the path crossed the Kuroshio current. On the intensity images, there were ocean waves with wavelength of about 80m propagating to/from northwest-southeast direction. Because the low-pressure system existed southeast of the observation area, the swell was estimated to propagate from southeast to northwest. The peaks of swell on ocean wave spectra rotate clockwise with approaching to the Kii peninsula (south to north). This rotation agrees with the effect of Kuroshio based on the wave-current interaction. The clockwise rotation component of Kuroshio changed the swell component.The wave-current interaction model suggests that the swell component parallel to current affected by current shear though that perpendicular to current is conserved. Also the magnitude of spectrum change is proportional to the magnitude of current shear. Based on the wave-current interaction model, the current shear by the Kuroshio was estimated. The result presents that the Kuroshio shear is almost east-west direction and that the Kuroshio becomes faster with approaching to Kii peninsula. These results agree with the real situation at the observation. The result shows the ability of current shear measurement by using the high-resolution SAR system. In these days, there are many plans of the spaceborne high-resolution SAR system. The current shear measurement by using SAR systems will give us more important information about global current system.

DOES OCEAN SURFACE RADAR WORK IN THE SURF BREAK ZONE?

Malcolm Lewis HERON, Thomas C. STIEGLITZ, Arnstein PRYTZ (MARINE GEOPHYSICAL LABORATORY)

Ocean surface radars are being used routinely to map surface currents over tens of kilometres at resolutions typically around 3 km. At higher radar frequencies, in the VHF band, the Bragg wavelength for backscatter is reduced so that at 152 MHz the dominant scatter is from a wave with wavelength 1 m compared to 5 m at 30 MHz. This is about the lower limit of the gravity wave spectrum for wind waves on the sea. At this frequency the Bragg lines still dominate the spectrum but the side-band structure in the spectrum indicates deeper modulation (in the radio communications sense) by the longer waves in the wind wave and swell spectra. The spectral feature which enables surface current mapping is the Doppler shift of the Bragg lines. It is shown that the position of the peak can be identified in VHF backscatter spectra, even in the breaker zone.The COSRAD VHF ocean surface radar has been developed at James Cook University in North Queensland and has been deployed on many occasions to map features in the surface current on a resolution (grid) scale of 100 m and over a spatial range of up to 1.3km. This is useful for evaluating the effects of coastal engineering projects, and identifying rip currents and small scale eddies around obstacles like headlands. A deployment at Coffs Harbour on the North Coast of New South Wales in Australia was carried out in 2000 to assist in the design and location of a new sewerage outfall. An upward-looking acoustic Doppler current profiler was deployed within the area that was mapped by the radar for comparison. The depth at the study site was about 14 m and at times the surface was white with breaking waves. A self-consistency analysis of the ADCP data indicate that the current profiles are of acceptable quality from the bottom of the water column up to about 7-8 m. After that the current values become increasingly scattered. The VHF radar values compare favourably with the ADCP current values 7.8 m above the floor.During the deployment, the wind varied over a wide range and included a southerly storm which drove the whole near-coast body of water towards the north. During the storm the whole bay was white. Data indicate that the deep ADCP current measurements and the surface VHF radar measurements retained their integrity. Our conclusion is that the VHF COSRAD radar can successfully map surface currents even in the presence of breakers and white water. It has clear potential to monitor rip currents and coastal vortices under these conditions when conventional techniques become strained.

JSG03/09P/D-018	Poster	1640-026

MEASUREMENT OF OCEANIC VARIABLES FROM DUO-FREQUENCY ALONG-TRACK INTERFEROMETRIC SAR DATA

Duk-jin KIM, Wooil M. MOON (Seoul National University)

Microwave remote sensing of the ocean surface using Synthetic Aperture Radar (SAR) is effective and of great interest because of the high spatial resolution and the almost instantaneous observation potential of large ocean areas.But it is difficult to retrieve significant ocean wave heights and surface current from conventional SAR data, because the imaging mechanism of ocean waves by a conventional SAR is determined by the three basic modulation processes arise through the tilt modulation, hydrodynamic modulation and velocity bunching, which are poorly known functions.Recently, airborne Along-Track Interferometric (ATI) SAR has been widely investigated, which has the potential of measuring ocean surface currents and wave heights. The ATI SAR employs two antennas that are separated physically along the platform flight path (along track) direction. The phase difference between two ATI SAR antennas is a measure of the Doppler shift of the backscattered signal and thus of the line-of-sight velocity of the scatterers. This interferometric velocity is sum of the orbital motion due to ocean surface waves, phase velocity of the Bragg wave, and ocean surface current.In this paper, we developed a new method for extracting ocean surface currents utilizing duo-frequency ATI SAR measurements. The method is applied to C- and L-band ATI SAR measurements acquired at the Ulsan coast from Korea. In addition, the surface gravity wave information (e. g. wave direction, wave velocity, wave height) is estimated using the ATI SAR velocity measurements.

OCEAN WAVE SPECTRUM MEASUREMENT BY USING AN AIRBORNE INTERFEROMETRIC SAR

Chieko KAMESHIMA[1], Noboru SUDO[2], Haruhisa SHIMODA[2], Yoshiaki MATSUMAE[2], Toshibumi SAKATA[2], Akitsugu NADAI[3], Seiho URATSUKA[3] ([1]Electro Photo Optics, The Graduate School of Engineering, Tokai University, [2]Tokai University, [3]Communications Research Laboratory)

The ocean waves take an important role on the global climate. For example, it affects the gas transfer and momentum exchange between atmosphere and ocean. So, the global measurement of ocean waves is needed to monitoring the global climate. Because the global monitoring of ocean waves by direct measurement is difficult, the remote sensing technique is important. By using the synthetic aperture radar (SAR), the ocean waves can be measure under any meteorological condition. The wave spectrum measurement by using SAR is usually based on the intensity spectra of backscattered radar wave. The interferometric SAR, on the other hand, is able to measure the topography of ocean surface directly and the influence of the geometry of observation is decreased. The Pi-SAR is the high resolution airborne Synthetic Aperture Radar developed by the Communications Research Laboratory and National Space Developing Agency of Japan. The Pi-SAR is a dual frequency radar operating at L-band (frequency: 1.27GHz) and X-band (frequency: 9.55GHz) frequencies with polarimetric functions and can observe high resolution (X-band: 1.5m, L-band: 3m) to a target. Moreover, the X-band system has a cross-track interferometric function that can measure a terrain elevation with accuracy of 2m. The cross-track interferometry technique used in this experiment measures the surface elevation by phase difference of between received signals by two antennas installed at right angles to the flight direction. Two SAR observation were done at the northwest sea off Okinawa (9 November 2001) and southern sea off Hokkaido (13 June 2002). In each observation, the Pi-SAR observed same ocean area from different directions. From the collected data, the intensity image and topography map is produced. The wave spectrum is able to be analyzed by the 2-dimensional spectrum of ocean surface elevation as same as by the 2-dimensional spectrum of intensity image. In the spectrum analysis result of the Okinawa observation experiment, a strong peak on the intensity depended not only to the dominant wave component but to the flight direction, and interferometry spectra had a peak only to the dominant wave component regardless of the flight direction. This result shows that the strength of ocean wave component on the surface elevation spectrum is independent to the geometry of observation, though that on the intensity spectrum depends on the geometry. It is because the intensity image contains tilt-modulation effect and hydrodynamic-modulation effect, and the interferometry image indicates change of surface elevation. Therefore, it was shown that the measurement of ocean wave by interferometric SAR is effective. When the interferometry image compared with the intensity image, however, interferometry images are not clear than the intensity images. Also the topographic spectra are not clear than intensity spectra. Since the interferometric function of Pi-SAR was developed in order to observe terrain elevation, the sensitivity of radar and the accuracy of topographic measurement are nearly critical for ocean wave measurement. As solution, in order to measure the phase difference and spectrum clearly development of interferometric function which improved topographic accuracy is required.

SEISMIC AND SATELLITE IMAGE ANALYSIS IN THE VICINITY OF LAKE PUMA YUMCO LOCATED IN SOUTHERN TIBETAN PLATEAU, SW CHINA

Atsushi IWASHITA[1], Tomohiro KAMOSHITA[2], Yoshifumi MISAWA[3], Liping ZHU[4] ([1]Department of Space and Earth Information Technology, Kyushu Tokai University, [2]Ocean Engineering Co., Ltd., JAPAN, [3]School of Marine Science and Technology, TOKAI University, JAPAN, [4]Institute of Geographical Sciences and Natural Resources, Chinese Academy of Sciences, CHINA)

In April 2001, TOKAI University and Chinese Academy of Sciences carried out scientific exploration at Lake Puma Yumco located in the southern Tibetan plateau in southwestern CHINA. We had acquired the data of geologic and topographic field exploration, remote sensing image analysis by using Landsat ETM+ and ASTER VNIR, and topographic and seismic exploration in lake bottom and sub bottom area by using Bubble Pulser and Echo Sounder in the vicinity of the Lake. Purposes of this study are to confirm, 1) existence of structural relation among lake bottom and neighbor land area, 2) relation among topography and lineaments and its lengths by using distribution of extracted lineaments, 3) relation between the number and the length of lineaments.Seismic sections were interpreted and classified the bottom materials into three acoustic layers. Layer A is the top layer with thickness of approx.10 m, layer B is the second layer with thickness of around 30 m, and the layer C is the third layer as basic rock. The top depth of layer C is approx. 70 m in the center of the channel. We had found the several structural anomalous zones in the seismic sections along northeastern offshore. They are running through north to south along the shoreline. Faults are also found clearly in the survey lines A and 29 corresponding to above structural zones. We have found that the lake bottom acoustic anomalous zones are suggested to continue to land structures. As for remote sensing image interpretation, we had extracted the structural anomalies and lineaments from different types of images. Landsat ETM+ with 30 m ground resolution that can be interpret wide area. ASTER VNIR can be seen detailed surface interpretation with 15 m resolution. ETM+ images indicate clear structural features around the Lake. These are essential information for geologic interpretation of Earth's surface and subsurface. We had extracted lineaments from both ETM+ and VNIR images and analyzed the characters of those lineaments reflecting distribution of the fractures. We can recognized several structural patterns running almost WNW to ESE. The "m ?Evalues in each area are calculated, and may reflect some geological and structural characters of the earth's surface.

LARGE-SCALE DISPLACEMENT CORRESPONDING TO THE 1999 CHICHI EARTHQUAKE, INSIGHTS FROM SPACE GEODETIC OBSERVATIONS

Chung-Pai CHANG[1], Chi-Tien WANG[1], Tsui-Yu CHANG[2], Kun-Shan CHEN[1], Long-Shin LIANG[1], Yuan-Hsi LEE[3] ([1]Center for Space and Remote Sensing Research, [2]Institute of Geophysics, [3]Central Geological Survey, MOEA)

The Chichi earthquake (Mw 7.6), struck central Taiwan on 20th September 1999 (UTC), has caused heavy casualties and widespread damage in Taiwan. During this earthquake, an approximately 80 km long upthrust unit underwent displacement of several meters upward and westward along the range-bounding Chelungpu thrust fault. By means of the SAR interferometric method, ERS2 radar image pairs adopted from the periods before and after the 1999 Chichi earthquake have been used to determine the co-seismic surface displacement of the flat region. In the near field, our interferometric results reveal a relative shortening in the round trip distance between the radar antenna and the ground of the footwall side of Chelungpu fault, during the earthquake. This shortening progressively increases from the west coast to the east and reaches the maximum amount of about 26 cm near the central segment of the Chelungpu fault. Further to the south of the Chelungpu fault, the co-seismic deformation is much slight, whereas a right-lateral movement in EW-trending has been observed to dominate the coseismic deformation of this area during the Chi-Chi earthquake. Furthermore, we projected the GPS coseismic measures to the radar slant range direction and implemented a forward simulation from the ground truth displacement to SAR interferogram, so as to evaluate our phase unwrapping performance. This analysis has confirmed our interferometric result and clarified its relationship with the ground truth displacement.

JERS-1 SAR AND ASTER VNIR INTERPRETATION IN THE VICINITY OF HUA-TUNG LONGITUDINAL VALLEY, EAST COAST TAIWAN

Atsushi IWASHITA[1], Hisatoshi BABA[2], Susumu IIZUKA[3], Yu-Feng LIN[4], Yi-Sheng YANG[2], Hwa-Chu SHEU[4], Toshikazu MOROHOSHI[5], Masanao HARA[6] ([1]Department of Space and Earth Information Technology, Kyushu Tokai University, [2]Research Institute of Science and Tecnology, TOKAI University, JAPAN, [3]Faculty of Marine Science and Technology, TOKAI University, JAPAN, [4]DAHAN Institute of Technology, TAIWAN, [5]National Research Institute for Earth Science and Disaster Prevention, JAPAN, [6]Vision Tech Inc., JAPAN)

Southwestern Ryukyu Arc and Eastern Taiwan region are characterized by subduction or collision of the Philippine Sea plate and Eurasian plate. The Hua-Tung Longitudinal Valley (HTLV) is huge valley running from the cities of Hua-Lien to Tai-Tung about the length of 130 km. This valley is located between Central Mountain Range and Coastal Mountain Range. Since 1990, DAHAN Institute of technology of Taiwan started to measure GPS and EDM (Electro Optical Distance Meter) data to monitor the crustal deformation in the northern part of HTLV. In 2001, Kyushu TOKAI University, Research Institute for Earth Science and Disaster Prevention (NIED) and Vision Tech Inc. had generated the first interferometric fringe pattern in the northern part of HTLV by using JERS-1 SAR dual data acquired 45 days apart in between Central and Coastal Mountain Ranges. Satellite image analysis had carried out by using ASTER VNIR and field excursion data were also acquired conducted by Kyushu TOKAI University. Some specific active faults existing in this area have been studied in the past several decades by international researchers. Image interpretation is one of the most adequate methods to acquire wide distributed geologic information to understand the target area. We have processed and interpreted Terra ASTER VNIR data to clarify the existence of active faults in the northern part of HTLV in East Coast Taiwan and detected several geologic information as well as lineaments. We have confirmed clearly some of these active faults existing in Coastal Range. We were able to confirm boundaries of specific geology, but some of boundaries were not confirmed. As for distribution of lineaments, we have manually extracted lineaments in the entire area of HTLV and found many lineaments existing especially in some part of Coastal Range. As the results, we had confirmed the typical features in HTLV showing colored fringe patterns that means the possibility of movement. We have also confirmed specific active faults along HTLV. For the future study, we continue to measure Long Term period GPS data corresponding to the fringe pattern.

REFINEMENT OF JERS-1'S STATE VECTORS AND CORRECTION OF SAR INTERFEROGRAM FOR THE ATMOSPHERIC DELAY EFFECT USING THE METEOROLOGICAL SIMULATION

Shigeki KOBAYASHI[1], Akira OTSUKA[2] ([1]Department of Space and Earth Information Technology, Kyushu Tokai University, [2]National Agricultural Research Center)

JERS-1 L-band SAR interferograms are easily obtained over the wide range of height despite vegetation or slope. In general, however, remarkable phase patterns due to the atmospheric excess path delay remains near the summit of mountains on differential interferograms, even if errors in the satellite's state vector are precisely corrected. Therefore, it is inevitable to identify and correct for the atmospheric effects to detect surface deformations around high active volcanoes. Atmospheric effect contains two components. **Pattern 1)** Residual topographic phase pattern correlated with height in the first order, which is due to the difference in the static structure of water vapor at two SAR observation times: This pattern can be verified by calculating the relationships between height and the atmospheric delay using data from a radiozonde launched within the SAR scene extent. However, even if this effect is corrected in the first order, there remain complicate and irregular phase patterns in some cases [e.g. Iwate volcano in April, 1998 - July, 1998]. **Pattern 2)** Complicate phase pattern (e.g. mountain wave, foehn phenomenon) which not correlated with topography: For example, strong atmospheric noises, which appeared as phase undulation with about 15 km in wavelength, were observed by using data acquired just passing or approaching of developing cold front [e.g. Izu Peninsula on June 15, 1998; Mt. Fuji on August 20, 1993]. Such wavelike patterns of phase noises may be caused by mountain wave flowing high mountain. We developed a meteorological method to quantify the water vapor effect by 3-dimensional numerical simulation of atmospheric dynamics. Our model has 82x82 grids of 1.5 km square in the x-y plane and 32 layers in the z direction. The model also includes the topography of the same x-y resolution. The initial atmospheric condition was given using the radiozonde data of the nearest weather station. The result shows that a mountain wave, a standing wind, appeared on the lee of the mountain. Also it revealed that the downward (upward) winds in the mountain wave corresponded well to the relatively dry (wet) area of the differential phase pattern. Upward wind increase wet delay, downward decreases. Therefore, the atmospheric correction with the meteorological method is essentially required to prove the subtle crustal movements in particular near the summit of high volcano in the SAR interferometry.

AIRBORNE LASER SCANNING - FOR MAPPING OF SLOPE FAILURE POTENTIAL SPOTS

Hiroshi P. SATO[1], Tatsuo SEKIGUCHI[2] ([1]Geography and Crustal Dynamics Research Center, Geographical Survey Institute, [2]Geographic Department, Geographical Survey Institute)

In order to take effective measures against landslide, it is important to know spatial distribution of stable and unstable slopes in detail. Purpose of this study is to map unstable spots at the foot of landslides by using Digital Elevation Model (DEM). Here, unstable slope means high-potential slope failure spot. Study area is Kuchisakamoto area in Shizuoka City. The area, where landslide moved at maximum rate of 400 mm per day in July 1993, is one of the many landslide areas in Japan. In April 5 and 6, 2003 this area was measured by airborne laser scanner (ALS). ALS is the new technology by which DEM was obtained. An ALS is an active sensor that measures the distance from the sensor to the ground on which the laser beam is reflected. In this study Optech ALTM1225 was used as an ALS. Considering a safety factor, actual measurement specifications were as follows; pulse rate 25,000 Hz; flying altitude: nominally 600 m above the ground; flight speed 180 km/h. DEM measurement accuracy was checked at several checking areas. Discrepancy between the twice measurement was 0.05 m in X, −0.04 m in Y and 0.06 m in Z directions on average. Unstable spots mapping method is as follows. First, contour map was depicted using the DEM. Then, the past slope failure spots, which are as training data, were manually delineated on the contour map. In the delineation aerial photos were interpreted. Next, the past slope failure spots were identified on the grids on the DEM. By using DEM slope θ and drainage area A were calculated on each grid of past slope failure. And liner regression was obtained, $\log_{10}(\tan\theta) = -a \log_{10}A + \log_{10}F$ where, a and F are constant. Correlation coefficient was about 0.3. Slope θ and drainage area A were calculated on each DEM grid of the past non-failure spots. These values were substituted for the above formula when F in the formula was treated as parameter, and F was calculated. Finally, when calculated value was more than the constant value F, the grid was mapped as unstable spots. Correct ratio

was about 55 %, which was calculated by mapped grid counts divided by whole grid counts on the training data. The mapping result shows conformity with on-site condition. In this paper, method and result will be explained and discussed in detail.

FIRST DIGISONDE 256 MEASUREMENTS AND TEC AT TUCUMAN AND COMPARISON WITH IRI PREDICTIONS

Victor Hugo RIOS, Cesar Francisco MEDINA, Blas DE HARO, Francisco SORIA, Enzo GOMEZ, Pascual PADILLA, Antonio Perez GOMEZ, Isabel LOMAS (Department of Physics, University of Tucumán)

The Digisonde first results from Tucuman (26.9 S, 65.4 W) and TEC obtained by Global Positioning System (GPS) are used to compare the observations with IRIpredictions. The data were registered during November-December 2002 day to day.The comparison is made for the F region parameters NmF2, hmF2 and TEC and for true height profiles as well. The analysis, based on quietest days during the data period, shows that while IRI provides realistic profiles during daytime hours, it seems to underestimate the bottomside electron density during the early morning and late afternoon hours. The F-layer peak density obtained are underestimated for most of the nighttime hours during summer months. Comparativestudy of TEC indicates that the IRI underestimate significantly measured TEC during daytime on this period. This discrepancy between the IRI and observationshas been reported at other low latitude stations even for low solar activity. When we look to ionospheric slab thickness, discrepancy between the IRI and observations due to the discrepancy in the topside profile is minus serius thanin TEC.

PLASMA DENSITY ENHANCEMENTS ASSOCIATED WITH EQUATORIAL SPREAD F (ESF)

Guan LE[1], C.-S. HUANG[2], R.F. PFAFF[1], S.-Y. SU[3], H.-C. YEH[3], R. A. HEELIS[4], F.J. RICH[5], M. HAIRSTON[4] ([1]NASA/GSFC, Greenbelt, MD, USA, [2]MIT Haystack Observatory, Westford, MA, USA, [3]Institute of Space Science, National Central University, Chung-Li, Taiwan, [4]William B. Hanson Center for Space Sciences, The University of Texas at Dallas, Richardson, TX, USA, [5]Space Vehicles Directorate, Air Force Research Laboratory , Hanscon Air Force Base, MA, USA)

Large-scale plasma density depletions are typically associated with equatorialspread F (ESF) plasma irregularities in the nightside F region, especially in the post-sunset sector. Data from the Ionospheric Plasma and Electrodynamics Instrument (IPEI) onboard the ROCSAT-1 spacecraft reveal numerous cases of localized, discrete plasma density enhancements associated with regions of regular ESF plasma density depletion structures at 600 km altitude. Within these discrete regions, the plasma density may be enhanced by ~ 2-3 times above the background density. The density enhancement regions have sharp, distinct edges and appear to have similar scale sizes as plasma density depletions. They generally occur at edges of the regular plasma depletion region, poleward in latitudes and either earlier or later in local times. In all of the cases we examined so far, they occur in local times at least three-hours after the sunset. The ion velocity data within the density enhancement regions show upward plasma drifts perpendicular to the magnetic field, similar to those within adjacent plasma depletion regions. The magnetic field-aligned plasma flows are generally poleward within the density enhancement regions. In some cases with nearly simultaneous DMSP observations at 800 km available, similar density enhancements are also seen in the same local time sector. We present observational characteristics of the density enhancements and discuss possible mechanisms in this paper.

APPLICATION OF THE SATELLITE ALTIMETRY AND RADIOMETRY FOR ANALYSIS OF ANTHROPOGENIC POLLUTANTS OF A MARINE ENVIRONMENT

Sergey A. LEBEDEV (Geophysical Center, Russian Academy of Sciences)

Ecological monitoring of a marine environment of last years has shown that alongside with processes of a destruction and deposition of pollutants not last role is played by dynamics of a marine surface, as the basic mass transfer. The models, existing on the present time, of calculation of currents usually use oceanographic and meteorological data obtained by the contact measurement methods. The apparent successes in development of ocean remote sensing methods open a path to creation of operating systems of ecological monitoring of a marine environment. The sea surface or dynamic topography calculated by satellite altimetry data, allows to analyze dynamics of the surface currents, which are not having brightly expressed thermal nature, as for instance, strong jet streams. In turn sea surface temperature, obtained by the satellite radiometry data, was used for more precise count of destruction processes of pollutants. Time-space scale of the satellite data from a ocean surface allow actively to use them in different models, that enables with a split-hair accuracy to make the physically reasonable forecast. Surface temperature and dynamic topography data sharing realized in the automated system "Regional Ecological Monitoring of a Marine Environment — Black Sea", which basis by model of pollutant propagation. The research was undertaken with partial support from the Russian Basic Research Foundation

SYNERGISTIC USE OF NEAR-REAL TIME RADAR ALTIMETRY AND ATSR-2 DATA FOR OCEAN CIRCULATION STUDIES AROUND CAPE VERDE

C. LAZARO, M.J. FERNANDES (Faculdade de Ciências, Universidade do Porto)

The Cape Verde Archipelago lies under the influence of the south-eastern North Atlantic subtropical gyre. Cold and nutrient-rich waters upwelled at the Northwest African coast, one of the major coastal upwelling areas in the world, are transported south-westward by the Canary and the North Equatorial currents. Due to its seasonal migration, the eastward North Equatorial Counter-Current can affect the region around the archipelago and, being responsible for a northward transport of warm water along the African coast, suppress the coastal upwelling. Seasonal changes also occur with respect to extension and position of the Guinea Dome, a cyclonic circulation feature south of the archipelago. The subject of this work is the synergistic use of satellite remote sensing data for the characterisation of the seasonal cycle and variability of the flow field and oceanographic phenomena in the Cape Verde region. Synoptic maps of absolute dynamic topography (ADT) and sea surface temperature (SST) from near real time ERS-2 data were created in order to study the seasonal cycle associated with the flow field and the coastal upwelling for the period from June 2001 to May 2002. Based upon the ADT maps, intensity and direction of surface geostrophic currents were calculated. The methodologies adopted for the automation of the near real time data processing are described and particular emphasis is given to the evaluation of near real time altimetric data, by comparison with the information available with a delay of several months (OPR products). The purpose of this analysis, covering the period from January 2001 to December 2002, is to investigate the confidence level of the oceanographic information extracted from near real time data.

JSG03/10A/A12-003 0910

OCEAN CIRCULATION AND TRANSPORT BETWEEN THE NORTH ATLANTIC AND THE ARCTIC SEA, (OCTAS)

Hans-Peter PLAG[1], Helge DRANGE[4], Arne GIDSKEHAUG[6], Johnny A. JOHANNESSEN[4], Hossein NAHAVANDCHI[5], Ove Christian Dahl OMANG[3], Dag SOLHEIM[2] ([1]Geodetic Division, Statens kartverk, Kartverksveien 21, N-3511 Honefoss, Norway andMathematical Institute,University of Oslo,Postboks 1053 Blindern, 0316 Oslo, Norway, [2]Geodetic Division, Statens kartverk, Kartverksveien 21, N-3511 Honefoss, Norway, [3]Department of Mapping Sciences, The Agricultural University of Norway, Postbox 5034, N-1432 AAs, Norway, [4]Nansen Environmental and Remote Sensing Center (NERSC), Edvard Griegsvei 3a, N-5059 Bergen, Norway, [5]Department of Geomatics, Hogskoleringen 7G, N-7491 Trondheim, Norway, [6]University of Bergen, Institute of Solid Earth Physics, Allegt. 41, N-5007 Bergen,Norway)

The Norwegian OCTAS Project running from 2003 to 2006 focuses on the ocean circulation in the Fram Strait and adjacent sea with the main objective to improve sea surface topography determination and to study the impact on ocean modelling. Up to the expected launch of GOCE in 2005 the gravimetric geoid is not known with sufficient accuracy to allow full use of the massive sea surface height information, which several satellite altimetry missions have regularly provided since the early 90-ies, in global analysis of the ocean circulation. However, in a few marine regions in the world sufficient in-situ information about the Earths gravity field exists to compute a more accurate geoid. The region covering the Northern North Atlantic and the Nordic seas between Greenland, Iceland, Norway and the UK, including the Fram Strait is one of those regions. One goal of the OCTAS Project is therefore to determine an accurate geoid in the Fram Strait and the adjacent seas. Together with the results from the on-going EU-funded project GOCINA, where in a similar approach an accurate geoid is determined for the region between Greenland and the UK, this will create a platform for validation of future GOCE Level 2 data and higher order scientific products. The new and accurate geoid is used together with an accurate Mean Sea Surface (MSS) to determine the Mean Dynamic Topography (MDT). Another major goal of OCTAS is to use this new and accurate MDT for improved analysis of the ocean circulation. The ocean transport through the Fram Strait is known to play an important role in the global circulation. Gulf Stream water flows into the Nordic seas and feeds the formation of heavy bottom water that returns back into the Atlantic Ocean. Recent results have shown that changes in this bottom water transport may cause the inflow of Gulf Stream water to slow down or change into another stable circulation mode over a few decades. Such a change of the Gulf Stream with even a possible shut down of the heat transport towards high latitudes would have a huge impact on the North European climate. The OCTAS project, in coordination with the GOCINA project, attempts to elluvidate the role of the water exchange between the Arctic and Greenland Seas in this process.

JSG03/10A/A12-004 0930

COMBINED REMOTE SENSING OF OCEAN COLOR, RADIATION TEMPERATURE AND RADAR ALTIMETRY IN THE TRANSITION ZONE BETWEEN THE NORTH SEA AND THE BALTIC SEA

Niels Kristian HOEJERSLEV (Niels Bohr Institut for Astronomy,Physics and Geophysics, University of Copenhagen)

In the transition zone between the North Sea and the Baltic Sea hydrographic measurements of both temperature and salinity extending from the surface down to bottom have been performed routinely since 1886 from light vessels together with sea level measurements from the land bordering the sea. In addition optical in-situ measurements of daylight penetration and ocean color have been physically measured since 1922. From all these data the steric effect, the light penetration depth and the heat diffusion in the sea can be modeled. Consequently, from known surface temperatures the bottom temperature can be calculated quite accurately. This implies that remote sensing of the radiation temperature, SST provide useful information about the bottom temperature being important with respect to both steric effects and oxygen depletion in water layers near the bottom. Modeled bottom temperatures deviate typically by less than 1 degree Kelvin compared to the measured ones. During the last 12 years combined remote sensing measurements of ocean color, radiation temperature and altimetry have been daily business. In the transition zone the modeled light penetration depth is of the order of a few meters in accordance with the in-situ measurements and the difference between SST and in-situ surface temperature are typically below 1 degree Kelvin. The annual amplitude of the sea level is around 5 cm on average and the steric effect due to heating and cooling of the water column attains half the value. Radar altimetry in the transition zone demonstrates that the sea level during warm summers systematically is about 1 cm higher than during cold ones due to changes in the steric effect. The measuring accuracy of the radar altimetry is obviously better than 1 cm. During the winter the steric effect can be either positive and negative (and therefore also negligible) because the salinities varies around 24.65 in the surface waters. Radar altimetry as well as water level measurements since 1886 show clearly no steric effets especially at the end of the winter for this reason. Analysis of the radar altimetry data suggest that the measuring precision must be of the order of 1 mm. Remote sensing measurements of ocean color, SST and altimetry in combination are therefore a powerful tool in environmental and climatic studies since even small changes in the water level can be safely detected.

JSG03/10A/A12-005 0950

ICESAT LASER ALTIMETRY GEODETIC RESULTS

Bob Ewald SCHUTZ (Center for Space Research, University of Texas)

The Ice, Cloud and land Elevation Satellite (ICESat) was launched 2003 January 13 00:45 UTC from Vandenberg on a Delta-II into a near circular, 94° inclinationorbit with an altitude of 590 km. The primary instrument carried by ICESat is the Geoscience Laser Altimeter System (GLAS), a new space geodetic tool. The GLAS instrument has been developed by NASA

Goddard and was mated to the spacecraft bus, built by Ball Aerospace, in June 2002. The GLAS altitude measurements collected by GLAS will produce elevation time series of the Greenland and Antarctic ice sheets, which will enable determination of present-day elevation change and mass balance. Additional applications of the altimetrychannel include precise measurements of land topography and vegetation canopy heights, sea ice roughness and ocean elevations. Spacecraft commissioning was conducted during the first 30 days after launch. The spacecraft systems have performed as expected and the spacecraft is being phased into the required 8-dayrepeat track to support calibration/validation activities. Preliminary analysisusing data collected by the BlackJack GPS receiver shows that some minor tuningof the gravity field, provided by GRACE, will be required to meet the better than 5 cm radial orbit accuracy requirement. The GLAS laser is scheduled to be powered up in mid-February and an intense period of GLAS commissioning and calibration/validation will follow. This paper will provide an overview of the geodetic results to date for precision orbit determination, precision attitude determination, verification of the instrument performance and validation of thedata products.

ADVANCE TECHNOLOGY OF REMOTE SENSING, GIS AND GPS FOR SEISMIC HAZARD ASSESSMENT

Trinh Trong PHAN, Hoang Quang VINH, Trinh Hai DOAN (Institute of Geological Sciences)

Satellite image is origin of progress in earth observation and geological mapping. It gives us also a very powerful tool for the prediction and warning of natural hazards. We focus in three applications in Vietnam: seismic hazard assessment, landslide hazard and coastal zone erosion. The most important application is the estimation of seismic risk. We use TM, SPOT, ASTER, RADAR imagery and airborne images to determine active fault length, their characteristics (normal, reverse or strike-slip, slip rate) and measure horizontal displacement accumulated in Holocene. Directional filter of SPOT and TM images in combining with DEM from topographic data and RADA image could make in evidence active fault segment. The parameters are used to estimate maximum credible earthquake magnitude. The result of satellite analysis is combined with other data of geomorphology, topographic DEM, earthquake epicenter, radon distribution, stress field by the Geographical Information System. Some examples in application of spatial technology and GIS for seismic evaluation are presented. Radar interferometry help to create the DEM. Spot Panchromatic and multispectral image allows precise mapping of fault traces and estimate of fault displacement. The offset of landforms such as river and drainage patterns, alluvial fans, terraces can be observed and measured from Spot and Saious images. If the age of landforms is estimated reasonably, a fault slip rate can be estimated. The satellite analysis is combined with field study and other measurement such classic geodesy, Global Positioning System and analysis of earthquake focal mechanism. Our study in Vietnam will illustrate for the application of thematic study of remote sensing. We that if remote sensing technique is associated with other studies of Geology, geophysics and geomorphology, it will be a powerful tool to study active faulting and seismic hazard assessment. From this, if one relate with other results deduced from other works of intermediate prediction of earthquake, this technique will be useful for assessment of seismic hazards.

UPRES-A 8013/CNRS/ Côte d'Opale University, Wimereux, France)

The massif of Maqsad lies in a desertic region of Oman and is a large exposure of mantle rocks, bordered by a sedimentary massif of limestone rocks. Spaceborne, airborne and in situ hyperspectral sensors deliver measurements produced by spectro-imagery and field spectrometry. These data, analyzed by means of advanced processing tools and methodologies relying on multidimensional statistics and unmixing techniques, explore quantitatively the geological surface heterogeneity at different spatial scales, ranging from the centimetric rock-scale to the integrated landscape and remote sensing scale of the observation (10 to 50m). The results demonstrate that for arid environments in all cases where an extensive groundtruth has been acquired with the objective of encompassing all the local vegetal and geological variability at 50-100 m scale, it ispossible to explain the subpixel variability in the images by simple combinations of 3 to 5 key components, generally involving 2-3 mineralogy-driven ones, 1-2 types of vegetation, and/or 1 environmental shade component accounting for the different illumination conditions. From this analysis, one can select the key components present on the field and use them as endmembers in an iterative multiple mixture approach. With the support of field spectrometer and laboratory data, these endmembers can be interpreted in terms of first-order petrology information. It reveals that spatially organized variations do occurwithin the field of peridotites that can be used to produce a new type of lithology / mineralogy maps and it gives potentially access to the synoptic mapping of subtle petrological variations. With the dramatic improvement of the spatial resolution of the present and soon-to-come observations, optical heterogeneities related to the physical properties of the surface have to be taken into account at the subpixel scale and this requires experimental laboratory studies on natural rocky surfaces. Efforts are currently underway for producing quantitative compositional estimates with many applications to terrestrial land surfaces and planetary environments such as the lunar and martian surfaces.

GLOBAL IONOSPHERIC MODELS BEHAVIOR AT DIFFERENT GEOMAGNETIC REGIONS AND AT DIFFERENT LOCAL TIME

Amalia Margarita MEZA[1], Alejandro Raul DIAZ[2], Claudio Antonio BRUNINI[1] ([1]Facultad de Cs. Astronomicas y Geofisicas, Universidad Nacional de La Plata, [2]Instituto Tecnologico de Buenos Aires)

The dual frequency altimeter on board TOPEX/Poseidon satellite allows to measure the vertical total electron content (VTEC) of the ionosphere. Due to the dispersive properties of the ionosphere, subtracting the range measurements in the C-band (5.30 GHz) and in the Ku-band (13.65 GHz), the VTEC is obtained. In this work, we compare the climatologies predicted by a global GPS-derived empirical ionospheric model and the International Reference Ionosphere model IRI95 with TOPEX VTEC measurements. These climatological comparisons are performed in periods of various geomagnetic conditions. The periods taken in this analysis are equinoces and solstices. The comparisons are binned in geomagnetic latitude stripes and in local time stripes, where the mean VTEC differences, weighted by the

cosine of the geomagnetic latitude are computed, as well as the standard deviations. We show a quantitative analysis of the VTEC differences between TOPEX measurements and ionospheric models. From this results we conclude that the GPS-based model gives a better description of the ionosphere than IRI95, in almost all local times. We also show that the equatorial anomaly is one of the main source of discrepancy. At sunset, both models have a worse relative representation at middle latitude wherever is summertime.

MEASURING STRATOSPHERIC AEROSOLS, POLAR MESOSPHERIC CLOUDS AND POLAR STRATOSPHERIC CLOUDS USING THE GOMOS EXPERIMENT ONBOARD ENVISAT

Filip VANHELLEMONT, Didier FUSSEN, Christine BINGEN, GOMOS Cal-Val team (Belgian Institute for Space Aeronomy)

GOMOS (Global Ozone Monitoring by Occultation of Stars), one of the atmospheric experiments onboard the European ENVISAT satellite, uses the technique of stellar occultation to measure the transmittance of starlight through the atmosphere. From these measurements, altitude density profiles for gases such as O_3, NO_2, NO_3, H_2O, OClO, air, and stratospheric aerosol extinction profiles are derived. In addition, the experiment has been able to detect the presence of noctilucent clouds (polar mesospheric clouds, or PMCs) and polar stratospheric clouds (PSCs). First observational results are presented and discussed for the aerosols and clouds.

REVIEW OF TRENDS IN MESOSPHERIC TEMPERATURES

Gufran BEIG (Indian Institute of Tropical Meteorology, PUNE-411008 INDIA)

In recent time, it has become increasingly clear that releases of trace gases from human activity have a potential for causing a change in the upper atmosphere. During the past decade, several attempts have been made to analyze different series of long-term observations and to deduce mesospheric temperature trends. The comparison of the results obtained by different observations separated by several decades is complicated. These are related to maintenance of the same equipment sensitivity, noise level, and the method of data processing. Nevertheless, there are a number of occasions where a majority of the temperature trend results indicate consistency and some of the differences are even understandable. In this talk, a review of the long-term trend in temperature of the region from 50-100 km has been made based on available up-to-date understanding of measurements and model calculations. An objective evaluation of the data sets is attempted and important factors of uncertainties are discussed. There are a growing number of experimental results centered on, or consistent with zero temperature trend in the mesopause region. The most reliable data sets show no significant trend, but with an uncertainty of at least 2K/decade. Most studies recognize negative trends in the lower and mid-mesosphere with amplitude of a few degrees (2-3K) per decade.

JSA01/08A/A12-002   0935

IMPACT OF NATURAL VARIABILITY IN THE 11-YEAR MESOPAUSE REGION TEMPERATURE OBSERVATION OVER FORT COLLINS, CO (41N, 105W)

Chiao-Yao SHE, David A. KRUEGER (Physics Department, Colorado State University)

The Colorado State University Sodium Lidar has measured temperatures in the mesopause region (80-105km) since 1991. Based on 7 years´ observation, an episodic change with a warming of 11.8K in 1993 at the mean mesopause altitude of 98km, attributable to Mt. Pinatubo eruptions, was reported. With 11 years of data to the end of 2001, we observed a maximum solar response of 0.06K/SFU at 99km, which decreases at lower and higher altitudes to nearly zero and appears to change sign at ~82km and ~104km. The phase changes are consistent with earlier mid-latitude observation with incoherent scatter radar above and Rayleigh lidar below the altitudes we observed, providing clear experimental evidence of dynamical influences throughout different layers of Earth´s atmosphere. Along with the reporting of these natural variability, we determine, and discuss their impact on the long-term mesopause temperature trends by re-analysis with one more year of data to the end of 2002.

AN UPDATE ON GREEHOUSE COOLING IN THE MESOSPHERE AND THERMOSPHERE

Rashid A. AKMAEV (CIRES, University of Colorado)

Infrared radiation in the 15-μm band of carbon dioxide is the major cooling mechanism of the middle and upper atmosphere. Increasing amounts of atmospheric CO_2 impose strong anthropogenic influence (˝greenhouse cooling˝) all the way through the mesosphere and thermosphere. Collisions with atomic oxygen are the primary excitation mechanism of CO_2 molecules in the thermosphere. Negative radiative forcing due to the CO_2 increase is roughly proportional to the rate of collisional excitation which in turn is proportional to the rate constant of collisional deactivation. The rate constant is still somewhat uncertain at present with various measurements and estimates varying within about a factor of 4. In light of recent laboratory measurements, two sets of numerical simulations have been performed to estimate the thermospheric response to doubling and a 15% increase of CO_2 for two values of the rate constant that differ by a factor of 2. Surprisingly, the temperature and density changes due to the CO_2 increases are practically independent of the rate constant. Simple diagnostics show that two physical mechanisms are primarily responsible: the strong temperature dependence of the radiative forcing itself in a combination with a strong temperature dependence of molecular heat conduction. Since the scenarios considered for the higher rate constant generally operate at colder temperatures, the two physical mechanisms combined provide sufficiently strong negative feedbacks to entirely offset the

IA

initially stronger radiative forcing. Possible effects of solar heating in the CO_2 near-infrared bands will also be discussed.

TRENDS IN CHEMICAL COMPOSITION OF THE MESOSPHERE INDUCED BY LONG-TERM CHANGES OF ATMOSPHERIC BASIC PARAMETERS (MIDDLE LATITUDES)

Alexei A. KRIVOLUTSKY, Tatyana Yu. VYUSHKOVA, Vladimir N. GLAZKOV (Department of Chemistry and Dynamics of the Atmosphere, Central Aerological Observatory)

The results of temperature and pressure (rocket data at Russian station Volgograd, 50 N, 1970 -1990) regression analysis were used to calculate corresponding changes in chemical composition (first of all concentration of ozone). The data sets based on long-term rocket sounding revealed negative trends in both parameters with increased amplitude in the mesosphere. Corresponding magnitudes of these trends have been used in 1-D photochemical model. This 1-D time-dependent photochemical model used for this study describes photochemical interaction between more than 50 minor compounds in the range 0-90 km. Long-term changes in atmospheric parameters such as the temperature and pressure influence on gas-phase chemistry determining the velocity of ozone production in three molecular reactions and changing the photolysis rates. So, only temperature and pressure (which determine the concentration of the air) had trends in model runs, and there were no any other kind of long term forcing. The annual cycle in the basic parameters have been introduced in the model also. The results of photochemical calculations gave corresponding trends (negative) in vertical ozone mixing ratio distribution. Vertical structure of such trend is very similar to observed trends revealed from SAGE-II observations. Calculated magnitudes of trends in ozone and other minor species content in the stratosphere and mesosphere depends on season. Such annual dependence in the results of photochemical model runs determined by annual variability of air density and by solar UV radiation intensity.

THE INFLUENCE OF INCREASING GREENHOUSE GASES ON THE STRUCTURE AND COMPOSITION OF THE MESOSPHERE AND LOWER THERMOSPHERE

Daniel R. MARSH, Douglas KINNISON, Fabrizio SASSI, Rolando R. GARCIA, Byron A. BOVILLE (National Center for Atmospheric Research)

While it is accepted that concentrations of radiatively active (or greenhouse)gases are increasing in the troposphere, the impact of these changes on theupper atmosphere has yet to be fully assessed. Increases in carbon dioxideare expected to cool the mesosphere and lower atmosphere (MLT), but certainobservational evidence suggests there is no cooling trend near the high-latitude mesopause. Large increases in water vapor, brought about in partby changes in methane, are also observed. These changes significantly impactmesospheric ozone, and may affect the formation of polar mesospheric clouds.Using the Whole Atmosphere Community Climate Model (WACCM), a GeneralCirculation Model that extends from the surface to 140 km, we quantify theresponse of the MLT to recent increases in carbon dioxide, methane, nitrousoxide and chlorofluorocarbons. In particular, trends in both temperature andcomposition between 1980 and 2000 are analyzed and compared with theobservational record.

JSA01/08A/A12-006   **1145**

TRENDS IN NOCTILUCENT CLOUDS - NEW RESULTS

Sheila Catherine KIRKWOOD (Atmospheric Research Programme, Swedish Institute of Space Physics)

For a number of years many scientists have believed that there is strong evidence for a secular increase in noctilucent cloud (NLC) occurrence and explanations have been proposed in terms of decreased temperature from increased carbon-dioxide cooling or increased water vapour from increased methane, or even from space-vehicle emissions. A recent reassessment of the observational NLC record from NW Europe, however, shows that there is no significant trend in the occurrence of NLC during the last 40 years. This is confirmed by the observational record from Moscow. Even the reported absence of NLC observations in Europe before 1885 has been questioned, with the illustration of what appear to be NLC included in a painting from 1837. In this talk the evidence for trends and shorter-term variability in the NLC observations will be first be reviewed. The role of variable upper-atmosphere dynamics in secular and shorter-term longitudinal shifts of the regions where NLC can be observed will be discussed. Finally, possible explanations for a zero secular trend in NLC occurrence despite increasing carbon-dioxide, methane and water vapour, will be presented.

LONG-TERM TREND OF MESOPAUSE SCENERIO

Dipak K. CAKRABARTY (Centre for Environment Survey)

Information about long-term changes of several parameters in the mesopause region is gradually coming out. It is now almost established that in this region the temperature has been going down, the density of major neutral constituents has been decreasing, carbon dioxide content has been increasing and water vapor content has been increasing. The trend of change in nitric oxide density is controversial and the trend of change in electron density is also controversial. There is no information on the changes of atomic oxygen and ozone. Using an ion chemical scheme, in which both positive and negative ions have been considered, we have examined the effect of all these changes on the ionization of this region to arrive at a picture which conform to all these changes. It is evident from this analysis that electron density has been decreasing, percentage of both positive and negative clustered ions has been increasing and both f⁺ (ratio of positive molecular ions to clustered ions) = 1 and λ (ratio of negative ions to electrons) =1 levels have been going up over the years.

TRENDS IN THE MLTI FROM A POLAR PERSPECTIVE

Martin J. JARVIS (British Antarctic Survey)

The middle and upper atmosphere may provide a sensitive indicator that anthropogenic influences are changing Earth's environment. However, such signatures occur against a background variability driven largely by external forcing on a range of time scales. It is essential therefore to be able to differentiate between externally and anthropogenically forced changes. To understand the attribution of trends in the MLTI we need to take a global perspective. In this respect, comparing observations in the polar regions both with those observed at lower latitudes and with those observed at the opposite pole should provide pointers to the causative mechanisms. This presentation will discuss some comparisons using Antarctic and Arctic data and suggest areas to investigate further.

JSA01/08P/A12-002   **1430**

LONG-TERM TRENDS IN THE LOWER IONOSPHERE BELOW 120 KM

Jan LASTOVICKA[1], Juergen BREMER[2] ([1]Institute of Atmospheric Physics, Bocni II, 14131 Prague, Czech Republic, [2]Institute of Atmospheric Physics, Schloss-str. 6, Kuehlugsborn, Germany)

The increasing concentration of greenhouse gases in the atmosphere is expected to modify also the mesosphere and lower thermosphere (MLT region). However, the greenhouse cooling instead of heating at these heights is expected by models and generally confirmed by observations. This should more or less affect various ionospheric parameters at these heights. Observations show that in spite of general cooling, at some altitudes and some latitudes during some seasons we observe no trend (e.g. high latitudes, summer, NLC heights of 82-83 km) or even slight heating, whereas under the majority of conditions the cooling is observed, which is sometimes somewhere quite strong. The spatial and temporal structure of temperature trends in the MLT region is quite complex and, therefore, such structure occurs for trends in the lower ionosphere, as well. In the lower part of the ionosphere below about 90 km, the rocket measurements of electron density and the indirect phase reflection height measurements reveal positive trends in electron density, which correspond to cooling and shrinking of the mesosphere. Above 90 km, the nighttime LF reflection height measurements and the E-region ionosonde data provide trends corresponding to the overall cooling and shrinking of the atmosphere, while sparce rocket data display an opposite trend of decrease of electron density. Ionosonde data show that there is a model-expected trend in the maximum electron concentration of the E region ionosphere. foE is slightly increasing. On the other hand, the height of the normal E layer, h'E, is slightly decreasing. The radio wave absorption and rocket electron density measurements clearly display a substantial dependence of trends on height. The role of the solar cycle and other longer-term variability of natural origin in the observational trends must not be neglected. In spite of a general qualitative agreement with model expectations, there is still some controversy between various observational trend results (hopefully rather apparent than real), which needs to be clarified.

JSA01/08P/A12-003   **1500**

TRENDS IN THE NEUTRAL AND IONIZED PARTS OF THE MLT REGION

Bremer JUERGEN (Leibniz-Institute of Atmospheric Physics)

From long-term phase height observations in the LF range a continuous decrease of ionospheric reflection heights has been detected if the solar and geomagnetically induced variations have carefully been removed. Results of other reflection height observations confirm the lowering of the meso- and lower thermosphere (MLT) region. This shrinking can mainly be interpreted by a general cooling of the strato- and mesosphere caused by an increasing atmospheric greenhouse effect. Beside this cooling due to an increasing infrared radiation to space also long-term changes of the nitric oxide density and/or the effective recombination coefficient may play an important role for the explanation of the observed trends of ionospheric reflection heights. Observation of long-term trends of ionospheric absorption at different frequencies may help to decide if trends of the nitric oxide density and of the effective recombination coefficient have to be taken into account. From the combined analysis of different reflection height, absorption and ionosonde data series mesospheric temperature trend profiles have been derived for summer and winter conditions. Maximum cooling is observed during summer up to about -0.45 K/year and up to about -0.35 K/year in winter. These trends agree reasonable with other experimental trends derived from lidar and rocket experiments. The experimental trends are however stronger than the model results derived from the global circulation model COMMA-IAP if the known trends of carbon dioxide and ozone have been used in these calculations.

JSA01/08P/A12-004   **1520**

SOLAR-CYCLE VARIATION OF BACKGROUND COSMIC RADIO NOISE OBSERVED BY THE IMAGING RIOMETER IN THE POLAR CAP

Masanori NISHINO[1], Hisao YAMAGISHI[2], Jan HOLTET[3] ([1]Solar-Terrestrial Environment Laboratory, Nagoya University, JAPAN, [2]Upper Atmosphere Division, National Institute of Polar Research, JAPAN, [3]Department of Physics, University of Oslo, Norway)

The 30 MHz imaging riometer (IRIS) was installed at Ny Ålesund, Svalbard (76.1° MLAT) in September 1991 in order to study dynamics of auroral particle precipitation in the polar cusp/cap. The IRIS has two-dimensional 8 x 8 multiple-beams and thus can obtain ionospheric absorption image due to precipitation of auroral particles. The IRIS observation has been carried out since September 1991. For the ionospheric absorption measurement, quiet-day-curves (QDC) have been determined from background cosmic radio noise (CRN) in each month. The long-term reduction of the monthly QDC is important for evaluation of it availability. We examined the long-term variation from the monthly QDC data during ten years (1991-2001) in the solar-cycles 22 and 23. As the result, the variation showed seasonal changes during years depending on sunlit condition in the polar cap ionosphere. It was also found that the long-term variation (trend) showed an amplitude change of 0.6 - 1.0 dB during the solar-cycles. This indicates that the specific monthly-QDC could be unavailable in different months in the same year and also unavailable on the same month in different years during ten years. Here it should be remarked that the long-term variation of the background CRN showed a good correlation with the annual variation of galactic cosmic ray fluxes (GCR) measured by neutron counter at Oulu in Finland, which is generally modulated inversely by solar activity. This gives us a conclusion that the long-term variation of the background CRN is governed by precipitation of high-energetic protons due to GCR into the lower ionosphere and the mesosphere in polar region, not by ionization in the ionosphere due to solar radiation. Further discussions are needed for the problem that the observed amplitude change is larger than that calculated change theoretically from the electron density profiles and the collision frequencies.

JSA01/08P/A12-005   **1610**

LONG-TERM TRENDS OF F2-LAYER PARAMETERS INDEPENDENT OF GEOMAGNETIC ACTIVITY

Alexei D. DANILOV (Institite of Applied Geophysics)

A detailed analysis of the foF2 data at the series of ionospheric stations is performed to reveal long-term trends independent of the long-term changes of geomagnetic activity during the recent decades (nongeomagnetic trends). It is found that there is a relative

nongeomagnetic trend of -0.0012 per year (or an absolute nongeomagnetic trend of about -0.012 MHz per year) for the period between 1958 and the mid-nineties. The consideration of the earlier period (1948-1985) for a few stations for which the corresponding data are available provides significantly lower foF2 trends, the difference between the later and earlier periods being by a factor of 1.6. This is a strong argument in favor of an anthropogenic nature of the trends derived. The situation with the hmF2 trends is more complicated, but for the majority of the stations considered positive nongeomagnetic trends of hmF2 are obtained. Presumably these trends are a manifestation of the changes occurring during the recent decades in the upper thermosphere (thermosphere) due to its pollution in the process of space exploration. A possible relation of the ionospheric and termospheric trends is discussed.

JSA01/08P/A12-006   1640

THE MLTI IMPACTS OF SOLAR ACTIVITY TRENDS IN THE 20TH AND 21ST CENTURIES

Mark Andrew CLILVERD[1], Ellen CLARKE[2], Henry RISHBETH[3], Thomas ULICH[4] ([1]British Antarctic Survey, [2]British Geological Survey, [3]University of Southampton, [4]Sodankyla Geophysical Observatory)

The aa index provides the longest geomagnetic data set that can be used in the analysis of magnetospheric and ionospheric phenomena. All phases of the solar cycle show increases in storm activity since the end of cycle 14 in 1915. The activity increase does not appear to be strongly associated with any instrumental, ionospheric or magnetosphericeffects. Small effects have been confirmed in the long-term change in ionospheric Pedersen and Hall conductivities due the changing dipole moment of the Earth, but not due to increasing greenhouse gases. Three instrumental effects have been identified where significant changes in quiet-time conditions can be seen i.e. 1938, 1980, and 1997. These do not account for the majority of the increase in aa. Noise levels for the aa index are now close to those seen at the beginning of the dataset. The prime cause of the increase in storm activity is an increase in solar activity. The average aa in cycle 23 should be about 1~nT less than predicted from previous cycles due to the reduction in baseline noise levels at the start of cycle (1997). We consider the likely levels of solar activity in 2100 AD by analysing the previous history of these long-term solar and geomagnetic activity indexes. In particular, we make use of super-posed periods of similar variations in the DELTA C-14 record that have occurred during the last 11,000 years. This leads us to conclude that we could expect solar activity conditions in 2100 AD to be equivalent to those of about 1900 AD when a small minimum in solar activity took place, rather than increase at the relatively high rates of the last 100 years.

JSA01/08P/A12-007   1700

REGIONAL VARIABILITY OF LONG-TERM VARIATIONS OF MIDLATITUDE E SPORADIC LAYER

Oleg Nikolaevich SHERSTYUKOV, Sergey Vladimirovich MAKSYUTIN (Department of Physics, University of Kazan)

Accumulation of long rows of experimental ionospheric data during last several decades has allowed a number of researchers to conduct a study of long-term variations of various parameters of ionosphere. Thus and so consideration of global climatic variations of E sporadic layer parameters is interesting. These studies were already conducted earlier for number station of South hemisphere, but further consideration of long-term variations of E sporadic layer parameters is necessary for more amount of stations during a long periods. At work presented long-term variations of critical frequency E sporadic layer (foEs) were analyzed for 20 mid-latitude stations of north hemisphere (16 from them is situated within latitude band 45-65N, one-43N and last three stations - within latitude band 65-75N) during a period 1957-1990.For analysis hour values of foEs were averaged for the whole day (00-23 LT), as well as for light (9-15 LT) and dark (21-03 LT) time of a day separately. Before the segregating of trends, values of foEs were averaged for the current year by reason of eliminating an influence of seasonal variability of foEs. Analysis of long-term variation season-averaged values of foEs was conducted also. Linear regression dependencies of year-averaged and season-averaged values of foEs from a time are segregated by way of foEs = A*t+B, where t-is a time. The values of linear regression slope parameter (A) were used as quantitative characteristic of segregated trends (it has dimensionality MHz / year). A significance of segregated trends were estimated for confidential probability 90%. As a result of conducted analysis were discovered significant trends of year-averaged and season-averaged values of foEs, observed during light (09-15 LT) and dark (21-03 LT) time of day and during whole day (00-23 LT). A magnitude of segregated trends of foEs for considered stations is about 0,01 MHz per year. However, the sign of segregated trends is not same for all considered stations. Thus as result year-averaged values of foEs analysis negative trend is observed for 13 stations (and for 7 stations it is significant) but positive trend is observed for the rest 7 station (and it is significant for 6 stations). Difference of segregated trends sign for considered stations conceivably caused by the different geographical situation of stations on continent. Thus for stations situated in the central Europe dominate a positive trend but for stations situated in north region of Europe and at heart of continent dominate a negative trend.The the work was conducted under the support of grant RFBR 01-05-65251.

DENSITY STRUCTURE OF THE UPPER MANTLE UNDER NORTH AMERICA

Walter D. MOONEY[1], Mikhail K. KABAN[2] ([1]USGS, [2]Institute of Physics of the Earth, Moscow)

We present a new high-resolution density model for the lithosphere and upper mantle of North America and analyse its geodynamic and tectonic implications. This model is based on an integrated analysis of gravity, seismic refraction, seismic tomography, drill-hole, and geological data. The thickness of sedimentary cover was determined from geological maps, and the average density-depth relationship was estimated for each specific basin from published data. The density model of the consolidated crust (including Moho variations) is derived from seismic determinations. By removing the effect of the crust we calculate the residual 'mantle' gravity anomalies and the residual topography which are due to density inhomogeneities in the upper mantle. A joint analysis of these results with seismic tomography data (Van der Lee et al., 2000) leads to a construction of a 3D density model of the upper mantle under North America that is consistent with the residual gravity and produces the dynamic topography which is close to the residual one. The obtained density variations in the upper mantle under North America change significantly with depth. We conclude that they can not be explained solely by variations in temperature (Goes and Van der Lee, 2001) but a substantial part of them should be due to compositional differences. Under the Canadian Shield this difference is negative and is equal on the average to -40±5 kg/m^3 which corresponds to 1.2% depletion. The opposite 'compositional' anomaly is found in the southern part of North America adjoining to Gulf of Mexico, it exceeds 30 kg/m^3. The origin of this anomaly is disputable.

JSA07/10A/A05-002   0900

THE ELECTRICAL LITHOSPHERE OF NORTHWESTERN CANADA

Alan G. JONES[1], Juanjo LEDO[2], Ian J. FERGUSON[3] ([1]Geological Survey of Canada, Ottawa, Canada, [2]Universitat de Barcelona, Spain, [3]University of Manitoba, Winnipeg, Canada)

Lithoprobe's SNORCLE transect traverses over 1200 linear km from the Archean Slave craton hosting the oldest rocks in the world, across Proterozoic orogenic terranes then Phanerozoic accretionary terranes of the Northern Cordillera of Canada, to end at the Pacific coast within sight of a currently-active transform fault. Electromagnetic surveys, using the natural-source magnetotelluric (MT) technique, have been an integral component of SNORCLE activities from the outset, and MT data have been acquired along all three SNORCLE reflection transects, plus a supplementary profile connecting two of the Corridors (2 and 3). Additional MT data acquisition, funded by Lithoprobe, industry, Canada's Dept. of Indian and Northern Affairs, the U.S. National Science Foundation and the GSC, extended observations across the whole of the Slave craton. Taken together, these MT data, from over 300 locations, facilitate construction of maps of electrical parameters (resistivity, strike direction, anisotropy) for various depths as well as a 1500-km-long lithospheric-scale, electrical cross-section from Contwoyto Lake, in the northern part of the Slave craton (NWT), to Stewart, on the Pacific coast of B.C. The maps of apparent resistivity display strong lateral variation at all lithospheric depths, with the most resistive lithospheric mantle beneath the Anton complex of the Slave craton, and the most conductive beneath Stikinia. There is a remarkable difference in lithospheric electrical parameters between Corridors 2 and 3 in the Cordillera, attesting to different physical conditions of the mantle beneath those locations. The model displays local features known previously from more detailed study. In addition, it shows regional features that pertain to the protracted tectonic history of the region, including a northeast dipping mantle conductor likely a remnant of the recent Kula plate subduction.

JSA07/10A/A05-003   0920

3-D ELECTRICAL CONDUCTIVITY MODEL OF THE SLAVE CRATON LITHOSPHERE

Pamela LEZAETA[1], Alan CHAVE[1], Alan G. JONES[2], Rob EVANS[1] ([1]Woods Hole Oceanographic Institution, MA 02543, USA, [2]Geological Survey of Canada, Ottawa, Ontario, K1A 0E9, Canada)

The Archean Slave Craton, northwestern Canada, exposed outcrop of the oldest known rocks on Earth over an area of about 600x400 km^2. The discovery of economic diamondiferous kimberlite pipes during the early 1990s motivated extensive research in the region. During the years 1998 to 2000, two magnetotelluric (MT) surveys to determine the regional-scale three-dimensional (3-D) electrical structure were carried out in lakes of the Slave Craton using ocean-bottom instrumentation deployed from float airplanes. Each set of surveys occupied one year since field operations could occur only in the summertime when the lakes were not frozen. During the first month of each survey the data were recorded at a higher sample rate for imaging crustal features. The instruments then switched to the standard lower sample rate (30 s) in the following ten months for the purpose of obtaining long period MT data, permitting deep penetration into the lithospheric mantle. The time series were processed into MT responses using a bounded influence algorithm. An unexpected noise source was found in the magnetic field data, from instrument motion induced by surface gravity waves when the lakes were not frozen. The noise was removed using an adaptive correlation canceler filtering method prior to computing MT responses. A regional 3-D conductivity model was constructed to fit the long period MT data, revealing a NW-SE dipping mantle conductor, which together with other geophysical and geochemical results allowed to build an hypothesis for the evolution of the Slave craton's mantle lithosphere. We extend the 3-D model to utilize all of the MT and induction vector data. We test the major features of the model for uniqueness and resolution, and discuss the implications for the evolution of the Slave craton.

HIGH-RESOLUTION GEOPHYSICAL IMAGING OF A VOLCANIC MARGIN: ISLE OF SKYE (SCOTLAND)

Sophie HAUTOT[1], Pascal TARITS[2], the SIMBA Team[3] ([1]School of Earth, Environmental and Geographical Sciences, University of Edinburgh, UK, [2]UMR CNRS 6538, [3]SIMBA Project)

The characterization of the deep structure of volcanic margins is a problem in conventional seismicimaging because of the thick extruded basalt flows that act as high impedance screens, thusmasking the underlying structures. The SIMBA Project is on integrated geoscience approaches to sub-basalt imaging.In the framework of this project, the Isle of Skye Volcanic Province (North Atlantic Margin) is studied with different techniques (gravity, geology, seismics, magnetotellurics). The results obtained withall these techniques will be integrated in order to obtain a high-resolution 3-D model of a typicalxample of a volcanic margin. Here, we focus on the magnetotelluric experiment. The magnetotelluric method is well suited to sub-basalt imaging: in contrast to seismic methods, MT soundings areinsensitive to the highly electrically resistive volcanic structures, and are sensitive to the moreconductive underlying formations. 21 MT soundings have been collected on Skye in order to obtain a full three-dimensionalmodel of the sedimentary basins beneath the lava flows. The MT modeling resultsand the preliminary integration with the others geophysical results are presented.In the MT model, a high resistivity contrast between the different geologicalformations allow to constrain the geometry of the sedimentary structures beneaththe basaltic layers.

EVOLUTION AND COLLISION RELATED STRUCTURE OF THE EARLY PRECAMBRIAN LITHOSPHERE IN THE EASTERN FENNOSCANDIAN SHIELD: SYNTHESIS OF DEEP REFLECTION PROFILING, GEOLOGICAL AND GEOCHRONOLOGICAL DATA

Michael V. MINTS[1], Robert G. BERZIN[2], Alexander N. KONILOV[1], Vladimir M. STUPAK[2], Arsen K. SULEIMANOV[2], Nadezhda G. ZAMOZHNIA[2], Valery L. ZLOBIN[1] ([1]Laboratory of the Early Precambrian Tectonics, Geological Institute RAS, [2]SPETSGEOFIZIKA, Povarovka)

Recently recorded 1-EU and 4B CDP profiles crossed the main tectonic units of the eastern Fennoscandian Shield (EFS) and together with earlier completed KOLA-SUPERDEEP and EGGI profiles provided image of seismic reflections in the crust and in some cases upper mantle from the surface to about 80 km depth (25 s). The reflectivity of the crust varies significantly, however there is no clear difference between reflectivity of upper, mid and lower crust. The mantle is generally transparent although 4B profile displays two levels of slight subhorizontal events, near 17 and 20 s. The base of crustal reflectivity at 36-40 km depth (Moho discontinuity) is clear obvious. The crustal structure is dominated by low- and moderate-angle surfaces, mostly 20-30° dip. Main tectonic units known from geological mapping can been traced to the depth using reflection image geometry and cross-section (down to 15 km depth) formed by calculated values of the effective acoustic impedance. The Neoarchean Karelian granite-greenstone terrain (KGGT) and Central-Kola granulite belt, the Palaeoproterozoic Pechenga and East-Karelian suture zones and Lapland granulite belt and Neoarchaean-Palaeoproterozoic Belomorian gneiss belt are formed by the systems of tectonic crustal slices some of which can be traced down to the lower crust and in some cases reach Moho discontinuity. Usually their boundaries flatten to lower crustal level, however in the 4B profile eastern flank one of the crustal slices cuts Moho discontinuity. The Moho discontinuity is to be treated as mechanical and tectonic boundary. The system of the Palaeoproterozoic sedimentary-volcanic belts in the eastern flank of the Karelia craton has been interpreted as imbricated thrust and nappe belt that is formed by alternating tectonic slices of the Neoarchaean granite-greenstone and Palaeoproterozoic volcano-sedimentary complexes deformed with creation of the tectonic duplexes. Geological, geochemical and geochoronological data evidence that the EFS Archaean lithosphere has been completely formed to the end of the Neoarchaean and then rifted, disrupted and finally transected by a number of the Palaeoproterozoic volcano-sedimentary suture belts. Geochronological data demonstrate that Neoarchaean KGGT spread out mainly in westward direction resulting from 2.94-2.86, 2.84-2.8 and 2.7-2.6 Ga accretion-collision events. Initial ages of some crustal fragments reach 3.2-3.1 Ga, ancient inclusions were dated at 3.6-3.4 Ga. The Palaeoproterozoic evolution of the EFS included four main stages: 2.51 - 2.44 Ga Superplume Event and Initial Rifting of the Archaean Supercontinent, 2.44 - 2.0 (2.11) Ga Quiescent Within-plate Development, (2.11) 2.0 - 1.95 Ga Superplume Event, 1.95 - 1.75 (1.71) Ga Combined Plume- and Plate Tectonic-related Evolution. They were followed by the late-collisional and anorogenic magmatism. During Paleoproterozoic final collision volcano-sedimentary successions of riftogenic basins and intracontinental oceans were transformed in suture zones. Combined interpretation of seismic and geological data allow to consider the structure of the Early Precambrian lithosphere of the EFS as a combination of folded thrust and nappe and upthrust-underthrust structural ensembles.

JSA07/10A/A05-006   1050

LITHOSPHERIC SOURCES OF MAGNETIC AND GRAVITY ANOMALIES OF THE FENNOSCANDIAN SHIELD

Juha Ville KORHONEN, Heikki SÄÄVUORI, Tapio KOISTINEN (Espoo Unit, Geological Survey of Finland)

The Precambrian geological formations of the Fennoscandian Shield have been divided in 12 major groups on the Geological map of the Fennoscandian Shield 1:2, 000,000, representing evolution from Neoarchaean to Neoproterozoic. Corresponding petrophysical properties, measured from hand specimens and drill cores, have been averaged for the groups, and provide an idea of evolution of bulk density, and induced and remanent magnetisation of the shield in time. Neoarchaean and late Palaeoproterozoic formations exhibit lowest average densities, ranging from 2670 to 2700 kg/m3. These include re-melted Palaeoproterozoic crust, the Rapakivi granites that are visible on Bouguer anomaly map as wide rounded minima. Densities of rocks of the Palaeoproterozoic Svecofennian orogeny, and evolution leading to it, range 2760-2700 kg/m3. Average density of formations on the Archaean craton is 2790 kg/m3 and on Proterozoic craton 2760-2910 kg/m3. Induced magnetisation varies from 0.3 A/m of Archaean to 0.6 A/m of Palaeoproterozoic and to 1.5 A/m of Mesoproterozoic formations. The Q-value of formation averages ranges from 2 to 6 for Archaean and Palaeoproterozoic and from 0.4 to 1.7 for Mesoproterozoic. Q-value changes by stabilisation of the crust after the Svecofennian orogeny. In addition to the upper crustal petrophysical samples some mafic granulite xenoliths of the lower crustal levels of the Archaean Domain have been available. Xenoliths represent three density populations of average grain density 3090, 3240 and 3380 kg/m3, corresponding to total magnetisation of 2.0, 1.9 and 3.6 A/m. Heat flow studies reveal that the Curie isotherm of magnetite is deeper than Moho in the area. Hence these three populations may represent deep crustal sources of both magnetic and gravity anomalies of the shield.

JSA07/10A/A05-007   1110

GIS BASED SATELLITE MAGNETIC FIELD MODELLING RESULTS FOR THE EUROPEAN PLATFORM

Kumar HEMANT, Stefan MAUS (GeoForschungsZentrum, Potsdam)

Satellite missions for last three decades have been a rich source of magnetic data which are used to generate the total field anomaly maps of the lithosphere. The CHAMP satellite in a low-earth orbit is particularly suited for the study of crustal magnetic anomalies. Our aim here is to interpret these maps in terms of known geology and to infer properties of the lower crust. A GIS based modelling technique has been developed to generate a vertically integrated susceptibility (VIS) model at every point on a map by assigning a standard susceptibility value to the known rock types for a particular region and multiplying it with the 3SMAC seismic crustal structure. The Total field anomaly is computed at an altitude of 400 km using this initial VIS model and is compared with the observed CHAMP total field anomaly map. The modelling result in the Baltic shield region and around Kiruna agrees very well with the observed anomaly map for the same region. The high associated with Kursk-Voronezh uplift fits well with the observed map. The extent of the anomaly in the Southern Urals follows the observed map, however, a part of the anomaly further inside the platform region is yet unaccounted for. The NW-SE anomaly following the Tornquist Teisseyre Zone (TTZ) is not directly related to some high magnetic geological body but is a result of the bulk susceptibility increase from the thin crust in the west of TTZ to the thick crust in the east. The basement below the Phanerozoic cover of the East European platform is clearly visible in the magnetic field but it does not cover the entire platform. We show that the basement of the East European platform extends from the southern boundary of the Baltic shield down to the centre of the platform, extending upto the northern edge of the Ukranian Shield in the west and the middle Urals in the east. The results suggest that the platform basement behaves as a single large unit below the Phanerozoic crust.

JSA07/10A/A05-008   1130

MAGNETIC MODELS FOR THE DIFFERENT GEOLOGICAL STUCTURES OF THE SOUTH-WESTERN PART OF THE EAST EUROPEAN CRATON

Mikhail I. ORLYUK[1], Inna K. PASHKEVICH[2], Svetlana V. ELISEEVA[3] ([1]Depatment of geomagnetism, Institute of Geophysics, [2]Depatment of geomagnetism, Institute of Geophysics, [3]Depatment of geomagnetism, Institute of Geophysics)

The comprehensive of the interpretation nearsurface magnetic field, its regional component and MAGSAT anomalies were used for modelling. Petromagnetic data for the upper crust, the depths to the basement and to the Moho discontinuity and other geodata were used also as a priori information. 3D magnetic models of the crust have been compiled for the East European Craton (EEC) (1 : 5 000 000) and its SW part (1 : 2 500 000). A regional 4D magnetic model of the consolidated crust of Ukraine is constructed on the base of geomagnetic and geochronology data.According to 4D magnetic model of the Ukraine the high-magnetic bodies are formed cyclically during the time intervals: 2,90-3,20; 2,25-2,55; 1,90-2,00; 1,60-1,70; 0,90-0,95; 0,35-0,44 Ga. The high-magnetic blocks are related mainly to epochs of extension answering to the tectonic situations as rifts, basic granulite nuclears, subduction zones, while low-magnetic ones are associated with periods of constraction of the crust (collizional orogens and compression structures).The nature of the deep magnetic sources reflects two mechanisms of their formation: riftogenetic and subductional. The first mechanism consists in saturating of the crust by basic magmatic rocks (in oxidation-reduction condition favourable for the realization of iron as ferimagnetic minerals). Such sources form at the early stages of the evolution of major tectono-magmatic cycles in rift zones and the magmatic activization. The subductional type of the magnetic inhomogeneities is considered on an example of the palaeoisland and present aisland arcs. The mechanism of its formation is dual: on the one part it is underthrusting of the magnetic crust of oceanic type (and possible "doubling" in some zones of the lower crust) by subduction and, on the other part, the melting of the subducted crust with the saturration of the upper part of the section by respective rocks according to the first mechanism.

JSA07/10A/A05-009   1150

CRUSTAL MODELS AND EVOLUTION OF THE MARGINS OF EAST-EUROPEAN CRATON IN RUSSIA BASED ON SEISMIC AND POTENTIAL FIELD STUDIES

Sergey Leonidovich KOSTYUCHENKO, Anatoliy Vasilievich EGORKIN, Leonid Nikolaevich SOLODILOV (Center GEON)

The Mezen basin and the Timan Range, in the north-east, the Urals, in the east, and the Pre-Caspian basin and the Karpinsky Swell, in the south, are the tectonic units, which are astride or adjacent to the margins of East-European craton in Russia. The architecture of the crust and upper mantle and evolution of the area of study are imaged by seismic data (DSS, Passive observation and CMP) and by results of interpretation of gravity and magnetic fields. Within the Mezen basin, the rifts developed from Mesoproterozoic to Neopretorozoic 1 and 2 and the post-rift sedimentary cover accumulated since the Neoproterozoic III time. The thickness of the consolidated crust under the basin decreases from 42 km to 36 km and it is about 30-32 km within the rifts. The Timan Range stretches from NW to SE along in the eastern boundary of the Mezen basin. The deep refraction and wide-angle reflection observations give evidences that the crystalline crust of East-European craton underlies the up to 10 km thick Riphean successions constituting the Range. Based on deep geophysical data, the Timan Range overthrusted from east to west onto the East-European craton margin. There are crustal roots under the Urals mounting. The roots are about 50 km under the Northern and Southern Urals and about 45 km under the Middle Urals. Combine study of DSS, CMP and potential field data as well as result of teleseismic tomography experiment give evidences that West-Siberian lithosphere overthrusted onto the eastern margin of the East-European craton. Within the Pre-Caspian basin, the basement dips to 20-22 km while the Moho varies between 42 km and 34 km of depth. Plume tectonics is suggested to explain the evolution of the basin within the area, which is just in the south from East-European craton. The signatures of shortening and overthrusting of the Palaeozoic sedimentary successions which constitute the Karpinsky Swell onto the southern margin of East-European craton occur in the crust of the Swell. The crust-mantle mixture, which is imaged by the velocity of 7.6-7.8 km/s, exist between 37 km and 50 km of depth under the southern portion of the Karpinsky Swell.

JSA07/10A/A05-010   1210

3-D LITHOSPHERE DENSITY MODEL FOR NORTHEASTERN RUSSIA AND ITS GEOLOGIC, PETROLOGIC AND DYNAMIC-KINEMATIC INTERPRETATIONS (GRAVITY AND OTHER GEOPHYSICAL METHODS)

Yury Ya. VASHCHILLOV, Olga V. SAKHNO, Viktor V. LYUBOMUDROV, Larissa I. GUTOROVA (North-East Interdisciplinary Scientific Research Institute FEB RAS)

Mass quantitative interpretation of gravity anomalies for 3-D source block models underlie of 3-D lithosphere density model for northeastern Russia. Gravity anomalies were interpreted by of independent and self-sufficient methods of a ″new interpretative gravity″, which has certain advantages even in comparison with seismic prospecting of deep structures of Earth′s upper layers. In addition to this, results of seismic and electromagnetic studies, and magnetic prospecting were also used. This 3-D density model for northeastern Russia consists of a set of intersecting and interrelated vertical density sections of lithosphere at depths greater than 100 km and density horizontal sections at depths 10, 20, 30, 40 and 60 km (density gravity tomography). Absolute density values were established at different levels using methods of lithosphere density ″probing″ developed by the authors of this paper. Density inhomogeneities and their petrologic analogs change at diverse depth. Areas of well-expressed and reduced (or initially absent) ″granite″ layer are well-defined at 20 km horizontal section. A well-developed ″granite″ layer may have thickness of 15-20 km and more (″mesozoids″). A reduced ″granite″ layer is present in Anadyr-Koryak area featured by Mesozoic-Cenozoic tectonics. In Earth′s crust, having thickness 30-40 km and less, basite-hyperbasite rocks become mainly spread. Vertical faults of Okhotsk-Chukchi Volcanic Belt (OCVB) are separating structures between areas of Mesozoic tectonics and pre-Riphean crystal rock masses (continental zone) and Anadyr-Koryak area featured by Mesozoic-Cenozoic tectonics (near-oceanic zone). According to interpreted gravity anomaly data obtained for Near-Magadan part of OCVB, its faults root usually occur at average depth of about 100 km. The top of asthenosphere occurs at this depth, which is supported, both directly and indirectly, by results of electromagnetic, gravity and seismology studies. The top of asthenosphere throughout northeastern Russia plunges to 160-180 km depth toward eastern edge of Siberian Platform. According to geophysical data, some ″weak″ parts of it are found throughout this area of our consideration at depth less than 100 km (polyasthenosphere) . Within near-oceanic zone featured by a ″reduced″ granite layer, core of some anticlinal uplifts are marked by local positive anomalies and consist of basite-hyperbasite sequences of Late Mesozoic. In continental zone they are marked by local negative anomalies and consist of Late Mesozoic granitoids. It was just upward movement of magma that resulted in anticlinal structures genesis. Some anticlinal uplifts occurring within near-oceanic zone (Talovsko-Mainsky, Murgalsky and Vostochno-Taigonossky) are continuous, as the local linear positive gravity anomalies, within northern area of Sea of Okhotsk.

COMPOSITION OF THE LOWER CRUST BENEATH SOUTHEASTERN MARGIN OF NORTH CHINA CRATON: CONSTRAINTS FROM SEISMIC, THERMAL AND GEOCHEMICAL STUDIES

Yang WANG (School of Earth Sciences and Resources, China University of Geosciences, Beijing 100083, China)

Based on the one by one longitude-latitude grid P-wave velocity structure of southeastern margin of North China Craton (NCC), which was derived from the seismic refraction profiles, we infer crustal composition as a function of depth by comparing the velocities with the results from high-pressure laboratory measurements of P-wave velocity for crustal lithologies. The velocities were corrected to the standard P-T condition (25 degree C and 600 MPa) according to the geotherms constructed by downward continuation calculation of heat flux data under steady state conductive assumption and the relationship between elevation and thermal state. The average velocities are calculated for each position at 5-km depth intervals to Moho depth. Then, the model for crustal composition of southeastern margin of NCC was developed. For the lower crust, the corrected P-wave velocity is 6.7 ~ 7.0 km/s with a gentle tendency of increasingly value with depth. According to geothermobarometric calculation and geochemical study, the granulite xenoliths in the Neogene basalt occurred in Jiashan, Anhui Province, the SE corner of NCC, was considered as a representative of the lithology of lower portion of the crust beneath the region, with the depth range of 20 to 30 km. The estimates on P-wave velocity of these granulites, which are derived from the weighted average of minerals´ velocities, were compared with the seismic velocity model. The estimates are consistent with the seismic observation well. The average chemical composition of the granulites is mafic with ~ 51% SiO2 and 0.74% K2O as well as heat production of 0.16E-6W/m3. This result means a mafic lower crust beneath SE margin of NCC, rather than the intermediate estimate by Gao et al (1998, Geochimica et Cosmochimica Acta, v62, 1959), which obtains ~58% SiO2, 1.86% K2O and heat production of 1.08E-6W/m3.

JSA07/10P/A05-002   1420

ESTIMATION OF WATER CONTENT IN THE CRUST FROM RESISTIVITY STRUCTURE – A CASE STUDY IN BACK-ARC AREA OF THE TOHOKU DISTRICT, NE JAPAN –

Makoto UYESHIMA[1], Yasuo OGAWA[2] ([1]Earthquake Research Institute, the University of Tokyo, [2]Volcanic Fluid Research Center, Tokyo Institute of Technology)

In order to estimate crustal rheology and to synthesize tectonic process such as seismic and volcanic activities beneath the island arc, crustal water content and its connectivity is one of the most important parameters. Owing to significant improvements in instruments, data processing methods and inversion schemes, we are now coming to obtain detailed crustal resistivity structures. On the other hand, dependence of whole rock resistivity versus temperature and water content can be estimated by referring resistivity-temperature dependence for dry rocks and water from laboratory experiments, and by assuming a connection rule of the interstitial water. Then, if we can estimate temperature structure successflly, spatial distribution of crustal water content can be estimated for the connection rule directly from the resistivity cross section. In this presentation, as a case study, we try to estimate spatial distribution of water content from a 2-D resistivity structure beneath back-arc area of the Tohoku district, NE Japan (Ogawa, et al., 2001), and compare the results with a seismic structure (Matsubara et al., 2003). Temperature structure was first determined from thermal parameters such as surface heat flow, thermal conductivity and crustal heat generation compiled by Furukawa, 1995 and Tanaka et al., 2000. Based on this temperature structure, we estimated whole rock resistivity versus depth dependences for various water contents, by referring laboratory experiment results compiled by Kariya & Shankland (1983) (for dry rocks) and Nesbitt (1993) (for crustal fluids). Here, we assumed that upper and lower crust is respectively granitic and gabbroic, and we estimated whole rock resistivities for Hashin & Strikman (1962)´s perfectly connected(HSc) and isolated(HSi) models. For the HSi model, whole rock resistivity takes almost the same value as that of dry rocks unless water content becomes more than 10 %, and more than 90 % water content is necessary almost throughout the crust to explain the observationally determined resistivity range: from 0.1 to 10k Ohm.m. On the other hand, for the HSc model, water content range from 0.01% to several % can explain the 2-D resistivity cross section. Ogawa et al., 2000´s 2-D resistivity cross section contains three remarkable low resistivity portions in the upper crust beneath three tectonic faults in the area (Kita-Yuri thrust fault, Senya fault and Kitakami Lowland West Boundary fault). Depths of these low resistivity portions range 10-20 km and resistivity is as low as 1-10 Ohm.m. In order to explain this low resistivity, interstitial water should be connected and its content is estimated as 0.5-5 %. This estimation is not inconsistent with the water content estimation only from tomographic results for P and S seismic wave velocity perturbations (Matsubara et al., 2003). But joint analysis using both electric and seismic information will reveal more detailed features of the interstitial water and enhance persuasiveness of the estimation.

JSA07/10P/A05-003   1440

A STUDY ON THE CONDUCTIVITY STRUCTURE OF THE KOREAN PENINSULA BY GEOMAGNETIC DEPTH SOUNDING

Seokhoon OH[1], Jun-Mo YANG[1], Duk Kee LEE[1], Yong-Hoon YOUN[1], Byung-Doo KWON[2], Seung-Hwan CHUNG[3], Yoonho SONG[3], Kyung Duk MIN[4], Toru MOGI[5], Masao NAKADA[6] ([1]Marine Meteorology & Earthquake Research Lab., METRI/KMA, Seoul, Korea, [2]Dept. Earth Science Education, Seoul National University, Seoul, Korea, [3]Korea Institute of Geoscience and Mineral Resources, Daejeon, Korea, [4]Dept. Earth System Sciences, Yonsei University, Seoul, Korea, [5]Inst. Seismology and Volcanology, Hokkaido University, Japan, [6]Dept. Earth and Planetary Sciences, Kyushu University, Fukuoka, Japan)

We have performed a geomagnetic depth sounding (GDS) and analyzed the data in terms of induction arrows to investigate the deep electrical structure in and around the Korean Peninsula between Japan, the tectonic boundary of Pacific Ocean, and China, where intra-plate earthquakes have been frequently occurring. The GDS results strongly suggest evidence to elucidate relations between the tectonic tension and the deep electrical structure in this area. The inland anomalous pattern of induction arrows appears to indicate the direction of NE-SW, which is similar to that of the axis of tectonic compression of this area. Especially, the results of observations in the middle of the peninsula imply an anomalous pattern on the tectonic area near the Imjin River Belt, thought of as an extension of the Qinling-Dabie-Shandong continent collision belt of Eastern China. Induction arrows in the mid-southern area appear to be related with the thick sediment layer, called the Ogcheon Belt, that is another tectonic boundary in the Korean Peninsula. The overall pattern of arrows observed in coastal area and islands was affected by the surrounding sea. Nevertheless, the pattern adjacent to the southern coastline of the peninsula and Jeju Island near Kyushu, Japan showed southward highly conductive anomalies for the long period band, similar to

the previous study. This result might suggest geoelectrical anomalies in the East China Sea. A three-dimensional (3-D) magnetotelluric (MT) modeling technique was adopted to calculate the sea effect and infer the deep structure.

JSA07/10P/A05-004   1500

PASSIVE HIGH-RESOLUTION SEISMIC ARRAY STUDY OF THE CRUSTAL AND UPPER MANTLE STRUCTURE BENEATH THE DABIE SHAN REGION

Qiyuan LIU[1], Rainer KIND[2], Jiuhui CHEN[1], Xiaohui YUAN[2], Shuncheng LI[1], Biao GUO[1], Wylegalla KURT[2], Yuangen LAI[1] ([1]Institute of Geology,China Seismological Bureau, [2]2. GeoForschungZentrum Potsdam, Telegrafenburg A17, Potsdam, D-14473, GERMANY)

The Qinling-Dabei orogenic belt through the central China was formed about 240Maago due to the collision between the Yangtze and North China plates.In 1980's the investigation of its orogenic evolution and the ultra-high pressure metamorphyismwas promoted greatly by the discovery of coesite and microdiamond within eclogitesin the Dabie Shan mountain. Since that, many results from geological study havebeen published. But the geophysical investigations are only limited to some of low-resolution observations. Up to now, the structure and deformation of the collisionmargin in the crust is still unclear. A high-resolution exploration of the crust andupper mantle structure beneath the Dabie Shan region is necessary for a betterunderstanding of its dynamic evolution.For this purpose, in April of 2001, we deployed a passive seismic profile acrossthe Dabie Shan region and north China platform. This profile consisted of 34broadband seismic stations is about 400 km long . The space between stations inthe Dabie Shan region is about 3-8 km and about 20 km in other part. During oneyear field observation, several hundreds events were recorded. In this presentationis given the 2-D receiver function profile as well as the crustal and upper mantlestructure along our profile, which are obtained by using the receiver functionmigration and nonlinear inversion methods, respectively.Our results illustrate that the crust structures beneath the Dabie Shan region andNorth China plate are completely different. Their demarcation is near 32º03´.Thecrust below the Dabie Shan mountain becomes thick. The largest depth of the Mohodiscontinuity reaches 48 km, and the crust thickness in both sides of the mountainarea is only 30-32 km. The crust structure beneath the Dabie Shan mountain is asymmetric.The Moho discontinuity below the mountain on the side to the Yangtze plate has theschuppen structure and there is a clear offset of the Moho discontinuity near 31º24´.The result from the receiver function inversion reveals a low-velocity body in themiddle crust beneath the Dabie Shan mountain. The lowest S wave velocity is only2.5 km/sec. Our observations illustrate that the Yangtze plate was an active aspectand its crust-mantle boundary was smashed in the Dabie Shan collision orogeny. The lowS-wave velocity body in the middle crust indicates that the brittle crust has becomefragmental after the collision. The further investigation of the subcrustal mantle isstill necessary to confirm the deep continental subduction.

JSA07/10P/A05-005   1520

STRUCTURE AND GEODYNAMICS OF THE CRUST AND UPPER MANTLE ALONG THE PROFILE OBLUCHIE - DATTA CAPE ACCORDING TO THE COMPLEX OF GEOLOGICAL AND GEOPHYSICAL DATA

Lev Aleksandrovich MASLOV[1], Valery KUZNETSOV ([1]Laboratory for Mathematical Modeling in Geology and Geophysics, Computing Center of the Russian Academy of Sciences, [2]State Control Department, Ministry of Natural Resources, Khabarovsk, RUSSIA)

The profile Obluchie - Datta Cape crosses the juncture area of the Bureya massif with the Sikhote-Alin fold system and the superposed structures of the Middle-Amur depression. It is a 700 km long profile. Deep structure of the crust and upper mantle was studied using seismological (MECW - method of converted waves from distant earthquakes) and geoelectric (MTS) methods. Seismological and geoelectric models of the section were constructed. Seismological and geoelectric data were added by the gravity and magnetic anomalies along the profile. The density model of the section was constructed as the solution of the inverse gravimetrical problem with restrictions due to seismological data. The density inhomogeneities of the crust were considered as the source of volumetric force and, consequently, mechanical stress in the medium. The solution of the corresponding mechanical problem allows us to obtain mechanical stress distribution in the crust and upper mantle of the profile under consideration. The geophysical observations data, as well as results of geodynamic modeling were combined in a model of the deep section to be analyzed and interpreted. It has been shown that the density and topographicinhomogeneities of the crust are capable of generating stresses sufficient enough to start up different geodynamic processes occurring not only in the crust but also in the upper mantle. It has been shown also that the gravity and magnetic anomalies, the compositional, density and stress inhomogeneities combined with electric conductivity of the section constitute the single structural unity. All the elements of the unity are interrelated and their interaction is feasible in the single conceptual system. The central element of this system is the Earth's crust whose density and topography inhomogeneities, reflected in the gravity and magnetic fields, are capable of generating stresses inducing different geodynamic processes in the upper mantle. The quantitative characteristics of the results of geophysical observations and those of the geodynamic modeling are presented.

JSA07/10P/A05-006   1610

LITHOSPHERIC STRUCTURE AT CONTINENTAL BREAK-UP REVEALED BY MAGNETOTELLURICS ACROSS THE NORTHERN ETHIOPIAN RIFT

Kathryn A. WHALER[1], Sophie HAUTOT[1], Laike ASFAW[2] ([1]School of GeoSciences, University of Edinburgh, [2]Geophysical Observatory, Addis Ababa University, Addis Ababa, Ethiopia)

The transition from fault-controlled continental rifting to magma supply-controlled seafloor spreading is not understood. The Ethiopian rift is one of the few places to study this. Seismic experiments undertaken include a refraction/wide angle reflection line across the rift traversing a magmatic segment, but the melt body has low velocity and its top will give high amplitude reflections. Hence broadband magnetotelluric data will be collected in January/February 2003 along the line to image the crust and upper mantle, specifically to investigate the volume of melt present, how it has modified crustal structure, whether border faults are accommodating extensional strain, and whether there is asthenospheric upwelling beneath the magmatic segment. Preliminary results and interpretation from this experiment will be presented, linking to any results available from the seismic experiments.

JSA07/10P/A05-007   1630

CRUSTAL MODELLING ACROSS THE RENNICK GLACIER AREA (EAST ANTARCTICA)

Fausto FERRACCIOLI[1], Emanuele BOZZO[2], Egidio ARMADILLO[2], Detlef DAMASKE[3], Gernot REITMAYR[3], Nicola AGOSTINETTI[1], Giovanni TABELLARIO[2] ([1]British Antarctic Survey, High Cross, Madingley Road, Cambridge, CB3 0ET UK, [2]Dipartimento per lo Studio del Territorio e delle sue Risorse, Univ. Genova, Viale Benedetto XV,5, 16132 Genova ITALY, [3]BGR, Stilleweg 2, 30655 Hannover Germany, [4]Istituto Nazionale di Geofisica e Vulcanologia, Via di Vigna Murata 605, 00143

IA

Roma, Italy)

During the joint German-Italian campaign 1999-2000 a variety of geophysical investigations were performed over northern Victoria Land, Oates Land and George V Land (East Antarctica). These included aeromagnetics, ground gravity surveys, geomagnetic depth soundings and seismological investigations. As part of these regional studies we shall present the first results derived from crustal modelling across the Rennick Glacier area in northern Victoria Land. Geological evidence suggests that this glacier may conceal a major tectonic feature, namely the Rennick Graben structure. Geodynamic models predict that this graben relates to Cretaceous or alternatively to Cenozoic sea floor spreading between the Australian and Antarctic plates. Just to the east of the Rennick structure, a fossil suture zone between the allocthonous Bowers Terrane and the autochthonous Wilson Terrane has been identified. However, recent brittle-fault studies suggest that this is not a fossil Early Paleozoic structure. Rather, Cenozoic reactivation of the inherited fault zone may have occurred and induced strike-slip faulting along the margins of the Rennick Graben. Prior to our study, no integrated geophysical investigations had been performed neither to test these geologic models nor to assess deeper crustal structure in the Rennick area. Modelling of longer wavelength aeromagnetic anomalies now shows that magmatic arc basement flooring the Rennick Graben is indeed faulted. Modelling of higher-frequency anomalies indicates that Jurassic sills and basalts are also faulted. The down-faulted Rennick Graben is also marked by a prominent Bouguer gravity low. In contrast, the adjacent uplifted Bowers Mountains block features a 100 mGal high. Modelling reveals that this anomaly is caused by a buried high-density body. This body may be a remnant of Early Paleozoic oceanic crust. Whether uplift of this block is due to Early Paleozoic obduction, or to the presence of a Cenozoic(?) horst along the eastern flank of the Rennick structure is unclear. However, apatite fission track data seem to support the latter hypothesis. Deep electrical conductivity models show that the Rennick Graben is a resistive feature, formed by two sub-basins, separated by a structural high. Therefore, there is no clear indication for a prominent thermal anomaly, which should show up as a major conductor beneath the Rennick structure. Finally, seismologic models image the crust beneath the Rennick Graben as being only 26 km thick. Typically, the crust beneath the Transantarctic Mountains is about 35 km thick. Hence, the Rennick structure may represent a major continental rift structure, rather than a mere graben. We speculate that the Rennick rift is a passive rift, which may have formed in response to regional Cenozoic transtension between East and West Antarctica.

INTEGRATED GEOPHYSICAL STUDY OF THE SEISMICALLY ACTIVE BHUJ REGION, INDIA

Anand P. SASHIDHARAN, Mita RAJARAM, Vinit ERRAM (Indian Institute of Geomagnetism)

The catastrophic Bhuj earthquake of 26th January 2001 with magnitude Mw 7.7 (Ms 8) was the most damaging in the last 50 years and was felt in nearly all parts of India. The Kutch rift basin is considered to be a major seismogenic domain (zone V) due to occurrence of four earthquake of high intensity and forms a crucial geodynamic part of the Western Continental Margin of Indian sub-continent. Number of geophysical investigations including Ground Magnetic, Geomagnetic Deep Sounding, Long Period Magnetotellurics, GPS etc were conducted to study the seismotectonics of the Bhuj earthquakes at the Indian Institute of Geomagnetism. The F and Z maps were generated from the collected ground data and the magnetic sources were mainly associated with the exposed and subsurface trap flows and were controlled by Vigodi fault and Katrol hill fault. The magnetic sources, derived by analytical signal method, form four independent structural units related to the neo-tectonic activity of the region and appear to be controlled by faults in the area. The four tectonic blocks delineated, match rather well with the blocks defined by the displacement vectors of Pollitz's visco-elastic model over Bhuj. The induction vectors derived from the thin sheet model (Arora, 2002) of conductance based on surface geology did not reproduce the observed short period GDS. However when the thin sheet model was based on the block structures derived from magnetization (high conductivity for low magnetizations assuming it due to fluids in the sedimentary column) the match between the observed and calculated induction vector for 12min period was remarkable. GPS results (Reddy et al, 2002) showed changes in East-West, North-south and vertical components of the baselines during 21-28 February,2001 that indicated no displacements. N-S compression of about 0.1 micro-strain/year is seen in the region between Ratanpar and Dhamadkapir. The long period magnetotelluric measurements in the period range of 105-16000s have shown evidence of a crustal conductor in the depth range of 10-17 km. Depth sections of the aftershocks of 800 events indicate that the events are mostly generated at a shallow depth of up to 8km and15-38 km depth (Kayal et al, 2002, JGSI, 395-417). The depth range from 8-15 km produced no after shocks and this aseismic layer coincides well with the crustal conductor. The gravity data are also analysed and the common magnetic and gravity sources appear to coincide with the block east of Anjar. A tectonic model has been constructed integrating the geophysical data sets. The deformation has been calculated for the fault parameters of the Bhuj earthquake considering a viscoelastic layer between 17km (from LMT) and 30km (crustal depth derived from MAGSAT) and compared with the GPS results.

JSA07/10P/A05-009   1710
APPARENT DENSITY MAPPING FROM GRAVITY   DATA OF CHINA

Hualin ZENG[1], Deshu XU[2], Tianfeng WAN[3] ([1]Deprtment of Applied Geophysics, China University of Geosciences(Beijing), [2]Institute of Geophysical and Geochemical Exploration, Ministry of Land and Resources, [3]School of Earth Science and Resources, China University of Geosciences (Beijing))

We present an apparent density mapping of China from Bouguer gravity anomaly and a comparison of the mapping with the tectonic outline and geography data of China. Transformation of gravity anomaly into apparent density is carried out by the following methods: (1) A subtraction of upward continuation of gravity anomaly to a height from the anomaly at observation level enhance the gravity anomaly due to an upper layer of the crust with a thickness equal to the height, and attenuate the anomaly due to lower layer. In other words, the upward continuation height can approximate the thickness of the layer, of which an apparent density is evaluated, and it is possible to enhance gravity anomaly caused by the upper crust with a thickness that equals to the magnitude of the upward continuation distance. (2) A preferential upward continuation operator, which is derived from Wiener filter and Green's equivalent layer principles and can attenuate short-wavelength anomaly due to shallow-source while minimally attenuating long wavelength signals due to deep source, is used to separate the anomaly caused by the shallow layer from the regional anomaly due to the deeper layer. (3) An inversion using a series of right rectangular prisms and from computation of the first vertical derivative of the gravity anomaly is applied to transform the anomaly due to the shallow layer yielded by the subtraction and the preferential upward continuation into an apparent density map. By means of the above methods the gravity anomaly due to a layer with a thickness of 10 km within the upper crust is separated from the Bouguer gravity map of China, which was digitalized with a sampling distance of 10 km, and an apparent density mapping of a layer in upper crust with a thickness of 10 km of China is derived. A comparison of the mapping with the tectonic outline map and geography data of China shows that characteristics such as closed maxima or closed minima of apparent density correspond well with the known tectonic units such as boundaries or collisional

suture between plates, tectono-magma belts, basins, stable blocks, granites and mountains. For example, modern mountains correspond to low density areas; the plates and basins to high density areas; and the large magmatic belts to low apparent density.The method is an effective one for the calculation of apparent density of the upper crust with a given thickness from gravity anomaly in an area, and a careful comparison of the apparent density map with tectonic geomorphy must provide interesting new geological inferences. The key of the method is to separate the anomaly due to the layer of which the apparent density is calculated. Depending on the method for calculating the apparent density the calculated density is an average ones of an area, which indicates regional structures. Gravity interpretation is of nonuniqueness so it is important that the interpretation of the apparent density map should be based on the known geological data.

JSA07/10P/A05-010   1730
RESULTS OF DENSITY MODELING OF THE LITHOSHERE IN THE PHILIPPINE-TO-ASIAN PLATE TRANSITION ZONE, AS EXEMPLIFIED FROM THE RYUKYU ISLAND ARC

Gulya Zabirovna GILMANOVA[1], Vladimir Yakovlevich PODGORNY[2] ([1]Pacific Oceanological Institute,FEB RAS, [2]Institute of Tectonics and Geophysics, FEB RAS)

The lithosphere modeling has been carried out along the geophysical profile by R/V "Professor Gagarinsky" in 1993 through 1994. The study area is located east of Taiwan and is considered to be an area of the Eurasian and Philippine plate interaction. Profile crosses the Okinawa Trough, the Ryukyu island arc, the Ryukyu trench, passing out to the West Philippine Basin water area. Three computation models have been constructed: the lithosphere, divided into the water layer and the solid part, the lithosphere, whose solid part is subdivide into the crust and subcrustal part and that with account of the seismic crustal layering. It has been shown, that the lithosphere is clearly divided into three parts: that of low density (2.955 g/M3), with significantly continental crust, the density one (3.3 g/cm3), with significantly oceanic crust, and that of intermediate density, 3.09 g/cm3. The latter covers a part of the section starting from the northern framing of the Okinawa Trough to the Ryukyu Trench. The analogous density subdivision of the crust by types is not seen. A decrease in the density of about 0.10 g/cm3 is established in the subcrustal part of the lithosphere beneath the northern part of the Okinawa Trough. The asymmetric cone-like unconsolidation area, that of the truncated top, is discerned in the northern part of the section to which the location of the Sinji-Taiwan fold belt corresponds. Being expanded downward, the unconsolidated area makes continuation down to the asthenosphere. The southern part of the unconsolidation area is more moderate as compared to the northern one and testifies to a clearly expressed tendency of superimposition of the material layers with higher density from the south as in the crust so in the subcrustal mantle. The inclined boundaries of the density heterogeneities are distinguished also beneath the middle part of the Okinawa Trough and in the zone of juncture of the oceanic crust of the West-Philippine Basin with the island arc one. In the density section the Ryukyu trench is not clearly discerned. This is related to the fact that the profile under consideration crosses the island arc and the Ryukyu trench in the area of their degradation as the morphological structures. Low density is observed for the southern slope of the Ryukyu arc Aeyama Ridge. South of the Ryukyu arc there exists the asymmetrical negative anomaly of the geoid surface as its submerging of the order of 10 m. The area of the maximum subsidence is located between the axes of the Nanao depression and the Ryukyu trench, that is, it corresponds completely to location of the Aeyama Ridge. The lack of compensation masses as in the subcrustal part of the lithosphere, so beneath it, testifies that the gravity instability is mainly related here to the crust and its aqueous loading, and it is not compensated by the subcrustal mantle.

STRUCTURE AND GEODYNAMICS OF THE EARTH'S CRUST AND UPPER MANTLE OF JAPAN AND PHILIPPINE MARGINAL SEAS ACCORDING TO THE COMPLEX OF GEOLOGICAL AND GEOPHYSICAL DATA

Gulya GILMANOVA[1], Ruslan KULINICH[1], Lev MASLOV[2] ([1]Pacific Oceanological Institute Russian Academy of Sciences, Vladivostok, RUSSIA, [2]Computing Center of the Russian Academy of Science, 65, Kim Yu Chen Str.,)

The gravity modeling as well as mechanical stress simulation has been carried out along two profiles: the latitudinal profile (~N21.5°) stretching from the West Philippine Basin to South China Sea and the profile across the Sea of Japan stretching from the Siberia Seamount (NW part of the Sea of Japan) to the Yamato Rise. Density models of deep sections were constructed as the solution of the inverse gravimetrical problem with restrictions due to seismological data. The density inhomogeneities of the crust were considered as the source of volumetric force and, consequently, mechanical stress in the medium. The stress distribution in the crust and upper mantle of profiles was obtained as solution of the corresponding mechanical problem. Geoid's height anomalies and magnetic data have been used for a comprehensive study of the area under consideration. Gravity modeling results, as well as results of geodynamic simulations, has been interpreted on the basis of tectonic, morphostructural, compositional and seismological characteristics of profiles. The results obtained allow us to conclude that numerous peculiarities of recent geodynamics, tectonic structure and geophysical fields are determined mainly by density heterogeneities of the crust and upper mantle in these active areas. It is shown that geodynamics of the Philippine Sea profile is determined by a relaxation process of the mantle bulge of the West Philippine Basin and smoothing out of the deep density and topography inhomogeneities in the gravity field of our planet. In the Sea of Japan the Earth's crust zoning for genetic types is specified. Areas with different modes of mechanical stress and movements of the crust-mantle matter flow are determined. Downward matter flow takes place on the continental shelf edge and slope of the Primorye region. Deep-see Japan Basin is characterized by a descending movement of the crust-mantle masses. Ascending movements of the mantle material prevail in the Yamato Rise area. The lateral component of the vector flow field in the same area speaks in favor of unilateral closure of the Sea of Japan.

LATERAL VARIATION OF THE LOWER CRUST COMPOSITION BENEATH NORTHERN MARGIN OF SOUTH CHINA SEA

Yang WANG (School of Earth Sciences and Resources, China University of Geosciences, Beijing, 100083, China)

The lower crust composition of northern margin of South China Sea (SCS) was inferred from the P-T corrected seismic velocity structure, which is based on the seismic refraction profiles and the geotherms derived from downward continuation of heat flux as well as the cooling plate non-steady heat transfer model. The result shows a significant lateral variation of lower crust velocity beneath the northern margin of SCS. The thick high velocity ($>=7.0$ km/s) lower crust exists in the eastern and middle portions of the margin. Meanwhile, the velocity of lower crust in western portion is in range of 6.5-6.8 km/s. The lithology of lower crust in eastern and middle portions was inferred as mafic garnet granulite, or the mixture of mafic granulite and upper mantle rocks. The composition of lower crust in western portion is the mixture of felsic lithologies and mafic granulite, with a tendency of increasingly mafic component with depth. Since the variation of crustal properties are believed to result primarily from contrasting, pre-rift crustal structure across the margin (Nissen et al, 1995, JGR, v100, 22407), we proposed that the composition-related rheological heterogeneity of lower crust had influenced the basin evolution in northern margin of SCS. The ability of crustal rock to flow affects the style and kinematics of rifted region (Bertotti et al, Tectonophysics, 2000, v320, 195). No flow occurred in the relative rigid eastern portion of the margin, and subsidence affected the extending areas to form the Pearl River Mouth basin. However, the felsic lower crust beneath Xisha Trough of western portion could not prevent the flow to take place. The lower crustal rocks move towards the rifted zone causing isostatically driven upward movements. These may explain why Xisha Trough has thin post-rifting sediment, and failed to develop into the stage of sea-floor spreading.

A STUDY ON THE CHARACTERISTICS OF DIFFERENCE ARROW BY THREE-DIMENSIONAL MT(MAGNETO-TELLURIC) MODELING

Junmo YANG[1], Seokhoon OH[1], Duk Kee LEE[1], Heuisoon LEE[2], Yong-Hoon YOUN[1] ([1]Meteorological Research Institute, Korea Meteorological Administration, [2]Department of Science Education, Inchon National University of Education)

We perform the three-dimensional MT (Magneto-Telluric) modeling to examine the validity of difference arrow of GDS (Geomagnetic Depth Sounding) survey. In this study, we investigate the validity of the difference arrow on three configurations of conductors; which are located 1) at a surface, 2) at a deep part and 3) vertically extended from surface to the deep part, respectively. For conductors located at the surface, the validity of difference arrows is certified by our numerical model when long periods over 40 min are used or the distance between conductor and sea is over 150 km. However, for conductors located at the deep part, mutual coupling between conductor and sea decreases comparing with that of conductor located at surface. And the increase of the buried conductor size reinforces the mutual coupling. Moreover, the conductor vertically extended from surface to the deep part enhances the mutual coupling for all periods, so that this case makes the validity of difference arrow considerably in doubt even for long periods. Therefore, the mutual coupling between conductor and sea must be examined to remove the known conductor effect such as the sea effect from the observed induction arrow. And the difference arrow that certifies the validity in this way can only provide meaningful support for subsurface information.

3-D CRUSTAL VELOCITY TOMOGRAPHY IN SOUTHERN KOREAN PENINSULA

Qinghe LI[1], So Gu KIM, Yuansheng ZHANG ([1]Seismological Bureau of Jiangsu Province, China Seismological Bureau, [2]Seismological Institute of Korean, Hanyang University, Korea, [3]Lanzhou Institute of Seismology)

A new technique of simultaneous inversion for 3-D seismic velocity structure by using direct, reflected, refracted waves and the genetic algorithm for optimization applied to the southern Korea Peninsula. The 1223 of Pg, Sg, Pm, Sm, Pn, Sn arrival times of 197 events are inverted for locations and crustal structure. 10*10 blocks with about 0.5° and 7 layer (4km each layer) model was inverted. 3-D seismic crustal velocity tomography including 7 sections from surface to Moho, 18 profiles along latitude and longitude, Moho depth distribution were got. The results demonstrate: (1). The average velocities of sediment is 5.04km/s, thickness of are 3-4km, the velocity of basement is 6.11km/s/;(2). The velocities fluctuate strongly in the upper crust. The velocity distribution of lower crust under Conrad appears basically horizontal; (3). The average depth of Moho is 30.4km and velocity is 8.01km/s;(4). From the sedimentary depth, velocity of sediment, basement thick and velocity, form of upper crust, Moho depth and form we can find the obvious difference among different geological province. (5). The difference of crust structure between continent and ocean is obvious.. (6). The dynamic process and evolution for eastern Asia was analysed.

SPECIALIZED HARDWARE-SOFTWARE COMPLEX OF GEOPHYSICAL OBSERVATORY

Sergey Eduardovich SMIRNOV, Alexandr Vladimirovich BUZEVICH (Institute of Cosmophysical Researches and Radio Wave Propagation Far Eastern Branch Russian Academy of Sciences)

Specialized hardware-software complex (SHSC) is intended to solve a wide range of tasks, in particular: to study the influence of solar activity on the processes in the upper and lower atmosphere and their connection with the geodynamics of the earth´s crust in the Kamchatka region; to solve the problem of allocation and distinction of short-term and operative electromagnetic earthquakes´ precursors.The kinds of observations were chosen so as to reveal the whole chain of cause and effect connections from the source of disturbance to the litospheric response of the earth. These are the H, D, Z components of the magnetic field of the earth, which allow to reveal the effect, connected with the active sun formations and their reflection in the Earth´s ionosphere. It is the level of space absorption of radio noise at the frequency of 32 MHz, which reflects the reaction of the D-stratum of the ionosphere in connection with the galactic influence and solar cosmic rays.These are the low-frequency barovariations in the atmosphere, which allow to judge about the character and the level of turbulence in the lower atmosphere.It is the vertical component of the electric field in the near-ground stratum of the atmosphere and the electrical conductivity of the near-ground stratum of the atmosphere. These are the measurements of the emanium level of Radon, which allow to reveal geodeformational processes in the possible earthquakes centers. It is the registration of meteoparameters. SHSC can solve the following tasks:Data gathering and processing from 16-channel GSP with the interval from 1 second and more.The removed monitoring of DSP data in real time received from other computers of local computer network (LCN).The organization of the all the received data for the further processing and

archiving.Automatic generation of samples on the given interval of averaging and transformation of the data by E-mail.Automated data processing received by E-mail.The complex includes a set of service programs:1. The program of the operative exchange of messages.2. The program of the notification in case of malfunctions of operation of any kind of measurements.3. The program of the measurements correctness for each kind of measurements.4. The program of data sampling for each kind of measurements.5. The program of data´s visual presentation.6. The program of the measured data correction.7. The program of time shifts correction.8. The program of SMS-message sending to the GSM-phone in case of observations stops.The system has functioned since November, 1996, registering geophysical fields with the interval of 2 seconds on 12 information channels, and it has proved to be reliable and stable. The complex is easily scaled. On the basis of this complex the method of the earthquakes´ forecast ˝The method of the phase picture˝ was worked off. According to this method 6 earthquakes of the energy class more than 13.0 were officially predicted.

JSA07/11A/D-006 — Poster — 0830-006

3-DIMENTIONAL DETAILED MODEL OF THE STRUCTURE OF THE COASTAL SHELF IN THE SOUTH-EAST AQUATORY OF THE EAST-SIBERIAN SEA AND THE ROLE OF PROCESSES OF BASIFICATION IN THEIR FORMATION (INTERPRETATION OF THE GRAVITY DATA)

Yury Ya. VASHCHILLOV, Vladimir Ye. GLOTOV, Tamara P. ZIMNIKOVA, Victor V. LYUBOMUDROV, Olga V. SAKHNO, Irina P. TSYGANKOVA (North-East Interdisciplinary Scientific Research Institute FEB RAS)

The work has been done by the financial support of RFFI (project 02-05-64010). 3-D density and structural-substantial models of lithosphere of the coastal shelf were created by the methods of new gravity interpretation. Maps of gravity anomalies in the Bouguer reduction with the net of observations points on sea ice approximately 2x2 km were use for quantitative interpretation.. The geological and petrological interpretation was given for the 3-dimentional density model. It is represented by the scheme of block tectonics, system of horizontal sections at depths of 1, 6, 10, 20, 30, 40, and 60 km (gravity tomography) and by the three vertical section. On the scheme of faults and blocks (density heterogeneity) calculated depth of roots of most faults and blocks change from 8-10 km down to 65-70 km. Meridional North-Aionsky fault, which is stretched along meridian 168° 35´ e.l., has calculated depth of root not less than 65 km. Density horizontal section at the depth of 1 km is transformed into the geological map-scheme with the age classification of rocks. Diapason of density change on 6-km horizontal section change from 2680 up to 2930 kg/m³. Both weakly metamorphosed sedimentary rocks with the density about 2680 kg/m³ and dense basites are represented within this diapason. To the east of the North-Aionsky fault, roof of basite layer is situated on depth 6 km and more. The thickness of the Earth´s crust is 38-40 km here. Rocks of basite type prevail at horizontal section of 10 km; basites and basite-hyperbasites - 20 km; rocks of basite-hyperbasite type of the lower parts of the Earth´s crust with the calculated density of 3000-3160 kg/m³ prevail at horizontal section 30 km. Undercrust substance with the density more than 3200 kg/m³, that is characteristic for the deep ultramafites, occurs lower than 40 km. The crust with great thickness of basite and basite-hyperbasite layers occurred as a result of the Late Mesozoic basification of continental crust. During the cooling, very density solidified lithosphere undergone lowing as a result of the thermoisostasy. To west of North-Aionsky fault, crust and lithosphere for the depths down to 65 km have less density. The crust has the typical continental character of composition with the developed ˝granitic˝ layer. The lowing of the Earth´s surface took place here because of lower lithosphere parts density increasing.

GEOTHERMAL STRUCTURE OF PRECAMBRIAN CRUST

Svet Yurievich MILANOVSKY (Institute of Physics of the Earth RAS)

In this work we present some results obtained during years of case geothermal study of Precambrian continental crust based on superdeep drilling, DSS and gravity field in Russia. The main objects discussed below are: 1) Results of heat flow study in Superdeep Kola Hole; 2) Investigations of hydro-geothermal regime in the upper crust; 3) Radiogenic heat generation data for Kola Hole; 4) Heat generation model for Precambrian crust based on deep drilling; 5) Geothermal, DSS, petrological and gravity study of the exposed high metamorphic terrains. Presented results are a part of the program to investigate geothermal field in Precambrian crystalline crust. The reason for such study was the possibility to do hydro-geothermal observations in the deepest hole in the world - Kola SG-3 and in many prospecting boreholes surrounding it (in relatively small area 6-7 km2 - on nickel deposit «Verhnee»). It was established: 1) Increasing with depth thermal gradient and heat flow density; 2) Negative-correlation between filtration coefficient and geothermal gradient; 3) Existence of exogenous zone in the upper crust containing free meteoric water; up to 2000m; 4) Space heterogeneity of geothermal and filtration parameters for the upper crust reflecting anisotropy of transport and hydraulic properties of the rocks in the upper crust; 5) Relationship between hydro-geothermal field heterogeneity and stress field in the crust. From the analysis of U, Th and K distribution in the Kola borehole section, the radiogenic heat generation value has been estimated to a depth of 12064 m and, using the calculated composition of deeper zones. The total crustal radiogenic contribution to a depth of 12064 m is estimated at 9.7 mW•m-2. Detailed studies of U, Th and K in Achaean sections from other deep boreholes on Russian Plate as well as data for the Earth´s oldest rocks from the published literature have been incorporated into a heat generation model for the granite - gneiss (12 - 20 km), gneiss-granulite (20 - 30 km) and the lower-most primary crustal or autochthonous restite (30 - 40 km) layers of the Precambrian crust. For the area of Anabar Shield we investigated geology, seismic, gravity and thermal fields. The Earth crust of Anabar presents a relict of most ancient sialic cover of the Earth. Our interest for the study granulitic terrains is coursed by the possibility to see the inner structure of the deep eroded crust from the surface geology and in the same time to study it with geophysical technology. Gravity field of the crust within Anabar is characterized by linear maxima, which are oriented in NW-SE direction and coincide with zones of granulites. 3D analysis of gravity field gives the same direction of inclination of high density blocks in the crust that was found from surface geology and seismic model along DSS profile ˝Shpat˝. Thermal field of the Anabar Shield is characterized by very low heat flow. The average crustal heat generation was estimated to be 0.36 mkWm-3. The present-day crust being a possible model for the consideration of the lower crust.

GEOELECTRICAL DEEP STRUCTURE OF PRIMORYE REGION REVEALED BY MAGNETOVARIATIONAL INVESTIGATION

Sergey Stanislavovich STARJINSKY (V. I. Il'ichev Pacific Oceanological Institute Far Eastern Branch Russian Academy of Science, 43 Baltiyskaya Str., Vladivostok 690041, Russia.)

The magnetovariational studies were carried out in Primorye territory at 10 sites.On the basisof this investigation the geomagnetic coast effect at this region was studied and

geomagnetic transfer functions, real and imaginary induction arrows were estimated. The orientation of the real induction arrows in a short period range reveals a linear conducting zone in upper crust extended from Khanka lake to the Amurskiy bay. All sites are characterized by strong geomagneticeffect. In order to find the reason of geomagnetic effect we have used the forward digital 2D electromagnetic TE mode modeling for two dimensional data and found that this effect can not be explained only by the conductivity of the sea water layer. Then we test a different models of the deep geoelectrical structure (GS) in the vicinity of the site in order to minimized the misfit between calculated and observed geomagnetic transfer functions. The model with minimum misfit was accepted as a final result. Using a such approach we have taken a three models of deep GS: two for coastal sites and one for shore-inland profile, including a third shore site located near Vladivostok city. The last model is characterized by a presence of conductive layerunder sea at 15 to 140 km depth relative a sea level with resistivity ρ = 5 Ohm.m, dippingin inland direction. At a depth greater than 140 km under sea it was necessary to allow a block with ρ = 1000 Ohm.m to minimize a misfit at long periods. In north-east direction fromthis profile on a shore site Kiyevka bay model includes a conductive layer at 47 to 140km depth with ρ =10 Ohm.m and a roof at 7 km depth. In shelf field this layer has a vertical border with two land layers having resistivities 1000 Ohm.m and 10 Ohm.m, from up to down . The thickness ofthe first layer is 140 km. The general property of all models is a powerful conductive layer beneath the sea bottom near the coast of Primorye territory. It is in accordance with the anomalously high heat flow at a sea floor this region while at the continent it is normal.

JSA07/11A/D-009 Poster 0830-009

3-D SHALLOW CRUSTAL SHEAR VELOCITY STRUCTURE AROUND THE SOURCE REGION OF THE 1999 CHI-CHI (TAIWAN) EARTHQUAKE DERIVED FROM SHORT-PERIOD SURFACE WAVE DISPERSION DATA

Guey-Kuen YU[1], Guey-Kuen YU[1], Ruey-Der HWANG[2], Wen-Yen CHANG[3] ([1]Department of Civil Engineering, Van-Nung Institute of Technology, Chungli, Taiwan, [2]Center of General Education, Hsing-Kuo University, Tainan, Taiwan, [3]Department of Natural Science and Mathematics, National Science Council, Taipei, Taiwan)

A detailed 3-D shallow crustal shear velocity structure around the source region of the 1999 Chi-Chi earthquake is derived in this study by inversion of short-period Rayleigh-wave dispersion data. The result shows that the Chelungpu and Shuilikeng faults are two main boundaries to clearly divide the source region into three different geological provinces. Shear velocities increase systematically from west to east, reflecting the geological features around the source area. Velocity heterogeneity on the eastern side of the source region is stronger and more complicated than that on the western side. This result agrees fairly with the thin-skinned thrust model interpretation. Furthermore, this study may also imply that the Chi-Chi earthquake is probably initiated not only near the border on which large velocity gradient varies, but at the position where the dip-angle of the fault is changed from sharp to gradual.

JSA07/11A/D-010 Poster 0830-010

VELOCITY STRUCTURE OF NORTHERN PART OF ATERA FAULT SYSTEM, CENTRAL JAPAN

Makoto OKUBO[1], Harumi AOKI[1], Masazumi ONISHI[2] ([1]Tono Research Institute of Earthquake Science, Association for the Development of Earthquake Prediction, [2]JGI, Inc.)

The Atera fault system, extending more than 70km northwesterly in central Japan is knows as a prominent active fault with left-lateral offset of 7km, a vertical of 700m and crush zone width of 300m at maximum. According to the strip map of Atera fault system (GSJ, 1973), the northern part of the fault system consists of three parallel active faults, Kowachi, Yugamine and Gero fault. However the southern extensions of Yugamine and Gero are not clear. Therefore, TRIES (Tono research institute of Earthquake Science) directed the reflection/refraction survey across these faults in 2000. Along with the general reflection survey with vibrator, a new technique, named ˝ground-level tomography˝, was tried along two parallel observation lines, across the faults. The velocity distribution near the surface between two observation lines can be analyzed using a *cross-well tomography* technique. In same experiment, clear side-reflections from the fault plane were frequently observed on field records. The inclination of fault plane could be suggested from the appearance and disappearance of side reflections. A refraction survey was also executed with explosive sources for the survey of deep structure. Some of field records were used for the simultaneous determination of time-terms and basement velocities. A new graphic method was successfully adapted in this case. The velocity distribution deduced from ground-level tomography, the distribution of time-terms / shallow reflectors and the faults location provided us with a model of faulting. A sharp velocity contrast between fault zone and outside of it suggests a pull-apart structure in the northern part of Atera fault system.

3D CRUSTAL DENSITY STRUCTURE AND ITS GRAVITY ANOMALY OF CENTRAL TAIWAN

Jian ZHANG[1] ([1]The Graduate School of the Chinese Academy of Sciences, [2]Department of Earth and Planetary Science University of California, Berkeley, [3]The Graduate School of the Chinese Academy of Sciences, [4]Department of Geophysics Peking University, [5]Department of Earth and Planetary Science University of California, Berkeley)

Taiwan is a mountainous island that rises locally to ~4 kilometers. It wasformed since the late Cenozoic, with the oblique collision between the Luzonvolcanic arc on the Philippine Sea plate and the China continental margin.The prevailing structural trend in Taiwan is that of an elongated arc convexto the west. Northeast of Taiwan, the Philippine Sea plate subducts northwardbeneath the Ryukyu arc-trench system. South of Taiwan, the oceanic crust ofthe South China Sea is subducting eastward beneath the Philippine Sea plateat the Luzon arc. Our study focuses on the central section of Taiwan becauseit is away from the subduction zones and thus offers a simpler picture on thecollisional mountain-forming tectonics. We construct a 3D crustal density model in central Taiwan from theavailable seismic velocity. Since density and seismic velocity of crustalrocks are closely related (e.g., Birch, 1961; Christensen and Mooney, 1995),it is reasonable to construct the 3D model for the crustal density in centralTaiwan on the basis of the available seismic velocity and an empiricalvelocity-density relation. 3D tomographic P-wave velocity structures forTaiwan have been published by Rau and Wu (1995) and Cheng (2000). Our studyuse Cheng´s tomographic velocity model because it was specifically designedfor central Taiwan. The model was based on a simultaneous inversion of24,230 P-wave travel times from 2,582 events, as recorded by the CentralWeather Bureau seismic network. This velocity model is converted to a densitymodel by using an empirical relationship between velocity and density.The empirical relationship is obtained by fitting the experimental datapresented by Ludwig et al. (1970) for both crystalline and sedimentary rocksat Vp > 2 km/s. Next, we calculated the gravity anomaly of the 3D densitymodel. The contribution of the 3D-density

model to the gravity anomaly iscalculated with the finite element method. In this study we represent thecrustal block in central Taiwan by a finite-element mesh of 76,500 elements,each 2x2x2 km3 in size. Since the average density does not contribute togravity anomaly, we subtract the average density of each horizontal layerfrom the initial density model, leaving only the density difference. The result shows that the calculated gravity anomaly for the densitymodel are negative values on the western side of the island, reflecting therelatively low density of the sedimentary rocks, and positive values on theeastern side, reflecting the relatively higher density of the metamorphicrocks and the crystalline basement. Beside, there is a curstal root beneaththe Central Range. Southern of Taiwan, the crustal root trends NNE and liesdirectly beneath the Western Central Range. At higher latitudes, however, thecrustal root turns clockwise towards NE to lie beneath the Eastern CentralRange.Acknowledgement. This work was supported by NSFC (No.40074022, 40174027) and NSF (No.EAR-01-06802).

CORRELATION BETWEEN STRONG EARTHQUAKE ACTIVITY AND ACTIVE CRUSTAL-BLOCK IN CHINA MAINLAND AND ITS ADJACENT REGIONS

Hongsheng MA, Guomin ZHANG, Jie LIU, Li LI (Center for Analysis and Prediction, China Seismological Bureau, Beijing 100036, China)

By the hypothesis of the active crustal-block and based on the research of the active crustal-block, the correlation between strong earthquake activity and active crustal-block, in China mainland and its adjacent regions, has been discussed in this paper. The results show that large tectonization and strong earthquakes mainly occur on the active crustal-block boundaries. All the huge earthquakes over Ms 8 and 86% strong earthquakes over Ms 7 cluster on the active crustal-block boundaries which only occupy 17% space of the whole area. The active crustal-block boundaries have controlled almost all the strong earthquakes in China mainland and its adjacent regions. In general, not only strong earthquake activity shows notable rhythm, but also the active and low phases are similar to those of China mainland. Sometimes, the active periods of strong earthquake in some cycles are longer than those of China mainland. The main areas of strong earthquake activity for each seismic cycle show that active crustal-block moves differently in different seismic cycle. Based on present crustal movement, the potential correlation between active crustal-block movement velocity and strong earthquake activity has been discussed in this paper. Key words: hypothesis of the active crustal blocks active crustal-block boundaries strong earthquake activity active crustal-block movement velocity.

JSA07/11A/D-013 Poster 0830-013

LITHOSPHERE ELECTROMAGNETIC WINDOWS: SPATIAL DISTRIBUTION, CONSTUCTION, PROPERTY

Yuri Buddich BASHKUEV, Valery Bazheevich KHAPTANOV, Darima Garmaevna BUYANOVA, Mikhail Georgievich DEMBELOV (Buryat Scientific Center SB RAS)

The report is devoted to the detail study of electrical properties, construction and spatial distribution of lithosphere electromagnetic windows on the earth. We call the electromagnetic windows as areas of the upper part of the earth crust with very low electric conductivities ($10^{-4} \div 10^{-6}$ Sm/m) that have sizeable squares. As a rule, they correspond to crystal massifs of the rocks on the earth surface. The crystal massifs as prominences on daytime surface of the high-resistance fundament are studied very insufficiently because of difficult of soundings on direct current and limited frequency range for MTZ method. In this time regions that have low electric conductivities ($10^{-4} \div 10^{-6}$ Sm/m) occupy sizeable territories (on our estimations - up to hundreds kilometers in length and width). These spots with low electric conductivities are commensurable with ionosphere conductivity and can play an important role in the global electric chain, in particular, when we consider mechanisms of the lithosphere-atmosphere-ionosphere interaction. Our investigations and fund materials on electric exploring in the East part of the Russia (Zabaikalie, Aldan and Anabar shields and etc.) show that crystal massifs with very low electric conductivity are least studied objects as a white spot. In the report an approach based on registration in calculating models of an essential inhomogeneity of electrical properties of the earth crust in the depth direction and on square (3-dimensional geoelectrical model) is developed. We decided the problem of research of electric properties of crystal massifs by means of methods using artificial and natural fields in more high frequency range from ULF-ELF to LF-HF. A possibility to study of electric conductivity and dielectric permeability of the medium and higher precision of its measurements when radiostation fields and other artificial sources are used is as an advantage of such approach. It is necessary to note that methodology of magnetic telluric and radio impedance soundings are common. Thus, a big volume of experimental and fund materials is obtained, summarized and analyzed. An elaboration of models that describe electric condition of the upper high resistance part of the earth crust (maps and sections) is made. The main results: 1) a method of search of earth crust areas with assigned electric characteristics is developed to discover territories with high resistance of upper part of the earth crust; 2) a spatial disposition of the lithosphere electromagnetic windows on the globe is defined; 3) electromagnetic sounding and profiling of crystal massifs of the east part of Russia in ELF-VLF-LF ranges is made; 4) geoelectric models of upper high resistance party of the consolidate earth crust for some regions of Zabaikalie, Aldan shield and Bureya massif are created; 5) a method of definition of dielectric permeability of the crystal rocks in conditions its natural dispositions is created; 6) geoelectric maps with different scales are created for studied crystal massifs.

DEEP GEOPHYSICAL MODEL FOR THE AREA OF THE KURILE-KAMCHATKA AND ALEUTIAN ISLAND ARCS JUNCTION

Yuri F. MOROZ, Larisa I. GONTOVAYA (Institute of Volcanic Geology and Geochemistry, FEB RAS)

The results of magnetotelluric sounding (MTS), seismic tomography and theircomplex interpretation are described. The MTS interpretation has been made by application of the present-day approaches taking into consideration the effect of local and regional near-surface geoelectrical heterogeneities. Using 3-D numerical modeling of the magnetotelluric field, the inversion of the MTS curves was carried out. As a result, a 3-D model of deep electrical conductivity of the region has been obtained. Based on the DSS and seismological data and using seismic tomography method, a 3-D velocity model for lithosphere has been obtained. Based on the complex analysis of geoelectric and seismic models and other geologic-geophysical information, the following peculiar features have been revealed in the deep structure of the junction area of the arcs. At depths of 100-200 km, the upper mantle hosts the astenospheric layer associated with partial melting of the ultrabasic rocks. The roof of this layer forms a riseup to the depth of 80 km beneath the zone of the present-day volcanism of the Kurile-Kamchatka island arc including the Klyuchevskay group of volcanoes and the Shiveluch volcano. The rise is located above the seismofocal zone. It is connected with a mantle source feeding present-day volcanoes. The lithosphere contains transverse conducting zones of the Aleutian direction. Conducting zones are suggested to represent

deep faults with hydrotherms. The faults are the result of the arcs' interaction. They may serve as channels for the fluids supply from the Major Kamchatkan deep fault and from the Pacific Ocean. One of such zones is distinguished within the earth crust at the depths of 10-30 km. It goes through the Klyuchevskaya group of volcanoes. In this region this zone forms a projection with anomalously low electrical resistivity. The low velocity anomaly of the seismic waves continuing down to the astenospheric rise is confined to it. The anomalies are connected with the crust magmatic source that is approximately 50 x 50 x 25 km³ in size. The occurrence of this source is a consequence of the magmatic melts supply from the astenospheric rise and the result of the additional rock melting within the crust fault. By rough estimates, the melt content in the crust source attains about 2%. The total volume of melt ranges from 20 to 60 m³. Another lithosphere transverse zone of low electrical resistance is found at the extension of the Aleutian island arc. It is probably more than 100 km long. Low electrical resistance may be due to the hydrothermal solutions filling rock fissures. The low velocity anomaly within the low parts of the earth crust is confined to the western area of the zone. This anomaly is associated with the crust magmatic chamber feeding the Shiveluch volcano.

THE RELATION BETWEEN MOVEMENTS AND DEFORMATIONS OF ACITVE CRUSTAL-BLOCKS AND SEISMOLOGY IN EAST ASIA

Hui WANG[1], Guomin ZHANG[1], Yun WU[2] ([1]Center of Analysis and Predict, China Seismology Bureau, [2]Seismology Intitute, China Seismology Burear)

Based on the hypothesis of active crustal-blocks in China and its adjacent region, used GPS (Global Position System) survey results and the method of DDA (discontine deformation analysis) on spherical surface, the present-day movements and deformations of each active crustal-blocks were calculated. The results show that although the movement and deformation of each active crustal-block in east region and in west region were different, the blocks in the same region were coherent.For the boundary zones of active crustal-blocks were consisted of rupture zones, the relative velocities of boundary zones can be looked as rupture zones´ velocities. The model results were coherent with geological results.From the kinetic character of boundary zones, the rupture zones can be classed to three type: creep rupture zones, locked rupture zones and mixed rupture zones. When the strong earthquakes in last ten year in this region were considred, the conclusion can be drew that the most strong earthquakes occupied in rupture zones and although the velocitied of mixed rupture zones were not the biggest, the strain energy can concentrated easily in that region, the strong earthquake occupied more offently.

GRAVITY ANOMALIES OF THE HOKKAIDO ISLAND, NORTH JAPAN

Masao KOMAZAWA[1], Hiroshima TOSHIO[1], Yasuaki MURATA[1], Masahiko MAKINO[2], Rie MORIJIRI[1], Kazunari NAWA[1] ([1]Institute of Geoscience, Geological Survey of Japan, AIST, [2]Research Center for Deep Geological Environments, Geological Survey of Japan, AIST)

Bouguer gravity anomaly map of the Hokkaido Island that has been compiled from about 84,000 land gravity measurement data and a lot of shipborne gravity data of surrounding area. All measured gravity data were referred to the International Gravity Standardization Net 1971 (IGSN71), and the normal gravity values were estimated according to Gravity Formula 1980. Terrain corrections were conducted with respect to the distance range up to 60 km by approximating the real topography to an assemblage of annular prisms interpolated by mesh terrain data and random terrain data of gravity points. The effect due to the earth´s curvature was taken into consideration. Bouguer corrections within the range of 60 km in arc-distances were made using a spherical cap crust formula. The features of gravity anomalies, Bouguer anomalies, are as follows. In the central part of Hokkaido, a remarkable high gravity anomaly runs north to south along a line that extends from the Hidaka Mountains through the district of Asahikawa and east of the Teshio Mountains to Hamatonbetsu. This gravity anomaly coincides with the collision zone between the Kurile Arc and the Northeast Japan Arc and is associated with exposures of high-density mafic igneous and metamorphic rocks derived from the deep crust. The gravity high is paralleled on the west by a north-south-trending gravity low that extends from the Hidaka Basin through the Ishikari Lowland, Yubari Mountains, Takikawa Lowland and Teshio Mountains to the Teshio Plain. This low gravity anomaly is associated with deep basins that are filled with Neogene to Quaternary age sediments. The Hidaka basin occurs in a large-scale crustal downwarp that formed in advance of a thick sheet of deeper crustal rocks which were thrust over the surface by the westward movement of the Kurile Arc. The negative gravity anomaly associated with this basin reaches -100mGal, which value is similar to the gravity low associated with a large depression on the backside of the uplifted crust along the coast of Tokachi. Another distinctive gravity high is observed over the Kabato Mountains and the west side of the Ishikari Lowland. This high anomaly is associated with widely distributed high density Late Oligocene to Quaternary volcanics. The complicated patterns observed in this gravity anomaly are associated with uplifted and downthrown areas within the underlying basement. Northeast-southwest-trending oval-shaped gravity lows are observed around Obihiro and along the Daisetsu Range in central Hokkaido. The gravity low around Obihiro is interpreted to be result from a 2-km-thick sequence of relatively low-density sediments. However, Mts. Daisetsu, Tomuraushi and Tokachi-dake, which constitute the Daisetsu Range, are volcanoes composed largely of andesite. Thus, the low gravity anomaly is interpreted to result from subsidence of the basement beneath these volcanoes. A positive gravity anomaly that reaches 200mGal in value extends from the district of Kushiro to the Habomai Islands. The region coincides with Cretaceous sedimentary rocks distributed along a fore-arc highland. However, the region is also associated with a high magnetic anomaly, which implies that high-density mafic igneous rocks probably underlie the Cretaceous sediments.

HIGH BOUGUER ANOMALY MEASURED NEAR AND AROUND THE YAMASAKI FAULT, SOUTHWEST JAPAN

Fumiaki TAKEUCHI, Kazuo MATSUMURA, Kajuro NAKAMURA, Kunihiko WATANABE (Disas. Prev. Res. Inst., Kyoto Univ.)

We measure gravity values near and around the Yamasaki fault, Hyogo, Okayama and Tottori, southwest Japan, from 1984 to 1999, to develop the regional structure. The total length of this fault is about 90 km, some of the longest ones in Japan. However, it is divided into some sub-faults, Ohara, Hijima, Yasutomi and Kuresaka-toge from west to east. The regions of these faults are some 10 km northwest of Kobe Earthquake in 1995 (Mj7.2) and about a hundred km southeast from the Western Tottori Earthquake 2000 (Mj7.3). It is also said that Harima-Yamashiro Earthquake 868 (M >7) near the faults. So many microearthquakes are occurring nowadays along the strike (WNW - ESE), especially a M5.6 earthquake with many aftershocks occurred in 1984 very near the Kuresaka-Toge fault. Almost all microearthquakes occur in depth from 0 to 20 km. The Yamasaki fault is left lateral, and the horizontal displacement is totally 50 - 400 m depending upon the region. Our

first aim is to decide the structure of the fault by gravity measurement data. We mainly use G615 LaCoste-Romberg gravimeter (G615) for observation. The measuring point intervals are usually set as 500-2000 m, and in many cases they make traverse lines to the fault. The observation points are usually selected from the points where the latitude, longitude and height values are shown in the 1/25,000 maps (Geographical Survey Institute). However, if such kind of data is unable to obtain, we use maps from local governments. Then we obtain data from 968 points, and other 987 data from Metal Mining Agency of Japan. Then our data cover almost 20 km width through the fault. Using these data, we calculate the Bouguer anomaly by setting density to be 2.67 g/cm³. The result shows that the Bouguer anomaly is somehow bigger near the fault than other regions, which is anomalous to other faults. In order to make this fact clear, we collect 35 stones from points around the fault, mainly from the stream beds or slopes of mountains. After carrying back them to our laboratory, we saturate them with water to measure the density. The values show 2.44 - 3.04 g/cm³. By using these values, we calculate the upper crustal structure by 2-dimensional Talvani method. It shows a similar results as the upper one (density 2.67 g/cm³), however, this makes much clear the depth and width of high density areas. The widths of high density areas are a few km and their depths distributes 500 - 5,000 m depending on the fault location.

LOWER-CRUSTAL REFLECTOR BENEATH THE TAMBA PLATEAU, CENTRAL JAPAN

Hiroshi KATAO (Disaster Prevention Research Institute, Kyoto University)

Distinct later phases following direct S wave are observed in the Tamba Plateau, which is an active microearthquake swarm area in northern Kinki District, Japan. These phases are interpreted as reflected S wave from the reflector in the lower crust. The amplitude ratios of reflected S waves to direct S waves are estimated to be 0.1-0.4. Even though the radiation pattern is considered on the focal mechanisms, this amplitude ratio is vary high. In order to explain such high amplitude of the reflection phase, S wave velocity contrast across the reflector surface must be large, suggesting that the reflector is a surfaces of fluid layer. The locations of reflectors are derived from more than 200 reflection phases. Depth of the inclined reflector is about 20-25 km in the lower crust. The reflector is not parallel to the horizontal cut-off boundary of shallow seismicity, and is dipping toward the north. The shape of the reflector is related strongly to the deep structure and tectonic movement of the large active fault: Arima-Takatsuki Tectonic Line. Since no Quaternary volcanic activities exist around this region, these features of the reflector beneath the Tamba Plateau are different from that of other mid-crustal reflectors found at volcanic regions in Japanese Islands.

COMPLEX MODEL OF THE ONEGA REGIONAL MAGNETIC ANOMALY (RMA) IN THE FENNOSCANDIAN SHIELD

Victor A. ZEMTSOV (Institute of Geology, Karelian Research Centre, RAS, Petrozavodsk, RUSSIA)

Continental RMA are caused, as a rule, by unknown magnetic field sources located at various depths and are interpreted in different ways. Deep-seated rocks are known to have high magnetization values in the extension zones of the Precambrian earth crust (to 5 A/m on the Canadian Shield). On the contrary, RMA in fold belts, which are younger (for example, in the Urals), are explained by subsurface magnetic sources, and the magnetization of the lower crust approaches zero. The Onega RMA was filtered by means of transformation of the total vector of the anomalous magnetic field at an altitude of 25 km. Its center is located in the southeastern Fennoscandian Shield on the Zaonezhsky Peninsula of Lake Onega. It has a round shape, slightly extended in a northwestern direction, and a diameter of about 200 km. There is a local maximum at the altitude of transformation, and the total RMA value can be as high as + 400 nT. This anomaly is presumably caused by several magnetic sources distributed in two plutonic levels. One of them plunges to a depth of 10 km and the other is deeper and more spacious. If the Curie boundary of magnetite here coincides with the crust base (35 km), the magnetization of the upper column of the crust would be 8.8 A/m. For the lower layer it would be 4.4 A/m, which seems unlikely. The Onega RMA spatially overlaps the minimum heat flow anomaly (less than 20 mW per square metre), which is unique in Europe. In this case, the Curie surface will always be deep in the mantle. Available DSS data show a considerable rise in seismic velocity (to 8.4 km/s), which begins here at a depth of 60 km. Also occurring in this area are the largest mafic rock intrusions, breccia pipes and the Suisari plutonic volcanogenic complex. The complexity of the crust-mantle boundary here is due to a special structure (SS) between the apparent crust and the real mantle surface. Based on geological and geophysical data, a magnetic model of the Onega RMA was developed. If we assume that the average magnetization of the lower layer of the crust and (SS) rocks to a depth of 50 km is identical and homogeneous here, then the magnetization of this block would be 0.7 A/m, provided the concentration of magnetite in the rocks is about 0.05%. The model developed is, of course, an approximation to real conditions.

AN ATTEMPT OF INTERPRETATION IN PETROLOGICAL TERMS OF THE P- AND S-WAVE MODELS ON THE SEISMIC REFRACTION LINE VRANCEA 99, ROMANIA

Victor RAILEANU[1], Franz HAUSER[2], Andrei BALA[1], Claus PRODEHL[2], Werner FIELITZ[3] ([1]National Institute for Earth Physics, Bucharest, Romania, [2]Geophysical Institute, University of Karlsruhe, Germany., [3]Geological Institute, University of Karlsruhe, Germany)

A seismic-refraction line was recorded in 1999, in the southeastern part Romania, to study the crustal and uppermost mantle structure underneath the Vrancea epicentral region. It is a contribution to the joint German-Romanian research programme ˝Strong Earthquakes - A Challenge for Geosciences and Civil Engineering˝ installed by the Co-operative Research Center 461 at the University of Karlsruhe, Germany, in collaboration with various research institutions in Romania. Data quality is very variable along the seismic line: it is better on the southern half with signal-to-noise ratios decreasing towards north. In a first step of data processing and interpretation, a P-wave velocity model was developed. It shows a multi-layered crust with velocities increasing with depth. The upper part of the model delineates the velocity structure of the sedimentary cover composed of the Carpathian Nappes, the Neogene sediments of the Foredeep and the autochthonous cover of the Moesian Platform. The upper and lower crustal layers are marked by constant velocities along their interfaces and by a variable thickness. The model displays a thickened upper crust in the central part of the seismic line, decreasing towards both ends. In a second stage a S-wave velocitymodel is achieved. It displays about the same crustal structure as the P wave model as it keeps the same depths of the crustal interfaces. Based on the Vp/Vs ratio a Poisson´s ratio model is computed. It shows a larger variation of this parameter for the sedimentary cover (0.22-0.35) and a narow range (0.22-0.25) for the crystalline crust. An interpretation in petrological terms of the Poisson ratio model indicates the most probable rock types that could make up the crustal section. Clay, marl, sand, sandstone, limestone for the sedimentary cover, granite-gneiss and granodiorite for the upper crust and gneiss, greenschist facies basalt and amphibolite for the lower crust. In the upper mantle Poisson ratio´s is 0.28. This value is well

IA

matched for the rocks in eclogite facies.

NEW TRANSECT ACROSS MOSCOW SEDIMENTARY BASIN: DEEP STRUCTURE AND HISTORY OF FORMATION REVEALED BY JOINT ANALYSIS OF GEOPHYSICAL DATA AND SUBSIDENCE CURVES

Robert G. BERZIN[1], Arsen K. SULEIMANOV[1], Yury N. ANDRYUSCHENKO[1], Nadejda G. ZAMOJNAYA[1], Elena A. KISELEVA[2], Valentin O. MIKHAILOV[2], Ekaterina A. PSHECHENKOVA[2], Sergei A. TIKHOTSKI[2], Dina Yu. SHUR[2], Mikhail V. MINTZ[3], Tatyana N. KHERASKOVA[3] ([1]Spetsgeofizika enterprise, Moscow, Russia, [2]United Institute of Physics of the Earth, RAS, Moscow, Russia, [3]Geological Institute RAS, Moscow, Russia)

Joint analysis of CDP reflection seismic data and data of gravity, magnetic and telluric measurements has been performed for the new transect 1EV running across the Moscow sedimentary basin. Obtained structure of sedimentary cross-section and crystalline basement as well as new information on position and structure of Riphean grabens were compared to the subsidence history from the Late Riphean to Carboniferous. Dense net of seismic refraction and reflection profiles, numerous boreholes and other data have been collected for the East European platform to perform a correction of the Bouguer anomalies for known inhomogeneities, including corrections for the gravity effect of sedimentary layers (taking into account laterally variable and depthdependent density of sediments), gravity effects of the Moho discontinuity and Riphean grabens. As a result a set of gravity maps has been constructed. These maps demonstrated fairly good correlation with crustal structures revealed by 1EV transect. The density model of the deep crustal structure was constructed, taking into account magnetic anomalies and telluric data. Joint analysis of this data set results in tectonic and compositional interpretation of the crustal structure. In particular, seismic data imaged a synform (syncline type) structure in the central part of the Moscow basin. An outer layer of this synform has lower density and composed of very low resistivity and weakly magnetized rocks, while its core is composed of dense and strong magnetized rocks. We interpret this as a result of high fluid and (or) carbon content in the outer layer. For the analysis of the subsidence history we used the data from 23 boreholes situated in the vicinity of the transect. The study of regional and local components of tectonic subsidence and their comparison to the model of crustal structure demonstrated that the Moscow sedimentary basin has been formed in result of two main tectonic events. The first tectonic event took place in the period from Late Riphean to Early Vendian. The style of extension had been strongly controlled by crustal structure formed before Late Riphean. During the second tectonic event, which took place from Middle Devonian to Late Carboniferous, crustal control was not so strong. Amplitude of uplift and subsidence were almost the same all over the basin. The second tectonic event was probably result of uplift of a mantle plume (e.g. Wilson, Lyashkevich, 1996). This plume supposed to be formed in deep mantle and later separated into several smaller plumes when it moved trough the upper mantle. This plume initiated strong tectonic activation of all East European Platform resulted in opening of 2500 km-long system of rift basins at its periphery and differential, mainly downward movements in its central part.

HEAT FLUX FROM LUNAR CORE AND CONTINENTAL MASCONS ON THE MOON

Alexander GUSEV, Natasha PETROVA (Geophysics, Kazan University)

The question of lunar core existence is still an open question. Nevertheless, many modern observational data, such as the noticeable free librations in the presence of great dissipation, involve the appropriate consideration of active lunar internal stratigraphy, including elliptical liquid core and rigid or viscose mantle. According to calculation of Konrad and Spohn (1997), the lunar core composed of Fe, FeS and Fe-FeS has a melting temperature from 1950K (for pure Fe) to 1250~K (for eutectic proportion). By this means the presence of a fluid core with a turbulent or convective layer at the CMB (Yoder, 1981) appears to be the plausible source not only for great dissipations, but also for exciting and maintaining of free librations. The differential rotation of the rigid mantle and liquid core in the Moon, the interaction between them is responsible for the formation of specific transition zone - core-mantle boundary that plays an important role in the lunar dynamics (Petrova & Gusev, 2001). Extensive discussion of seismic, magnetometric andlibration data were performed by Dickey et. al. (1994) for the parameters (sizes, shape, rheological properties etc.) of the lunar core and CMB. From additional LLR data and an improved gravity field from Lunar Prospector have found four dissipation terms, that can be explained with the combined effects of tide plus core: 2/3 of the 0.26″ term comes from a tidal friction and 1/3 comes from the CMB friction without considering the CMB ellipticity. As result Q~37±5 at a one month period and Q=60(-15,+40) at one year (Williams, 1999). Dissipative effects arising from the core-mantle interaction are responsible for additional heating of the planet′s interior, causing convective motion in the mantle and grows of the early lunar lithosphere; for the exciting and maintaining of free librations in the Moon; for arising of plumes that are responsible for the formation of ancient hot spots and ″mascons″ in the crust (Gusev & Petrova, 1999). With the Yoder′s boundary layer theory, approximate estimation of the heat flow from lunar CMB was made. For a liquid iron core with a radius of 350 km and kinematical viscosity η=3300St and differential velocity $\Delta\omega$= 1.37·10^{-9}rad/sec the estimation of the heat flux from the core to the mantle is 1.5· 10^{10}W. In this connection many new cosmic experiments - Lunar~A, SELENE, SMART, ILOM - will give a possibility to determine the size and composition of a lunar core, the magnetic and heat characteristics of the Moon.

GRAVITY AND MAGNETIC MEASUREMENTS ON THE BLACK SEA ROMANIAN CONTINENTAL SHELF AND THE SIGNIFICANCE OF THEIR RESULTS

Constantin Stefan SAVA (National Institute of Marine Geology and Geoecology - GeoEcoMar, Bucharest - Constanta, Romania)

In the past years, Romanian offshore has attracted much attention because of the oil and gas discovery. The major regional study required an important effort for the seismic acquisition. Interpretation of seismic data had provided a good image of stratigraphy and tectonics, but many explanations are still necessary. In view of improved knowledge on the geological structure at depth under the Black Sea Romanian Shelf as well as to gather more data about the continuation of land geological structures into the sea, gravity and magnetic measurements have been made in addition to seismic. Gravimetric research was done by the use of underwater and onboard marine gravity meters produced in Russia. At the same time magnetic research was carried out. An original method, which made possible the use of land magnetometers at sea, was first applied. Later, marine proton magnetometers were used. All the magnetic equipment used at sea was made in Romania. We have also drawn up all the programs for the marine gravity and magnetic data processing as well as the 2D and 3D geophysical modelling. The first results of marine gravity and magnetic surveys were presented in maps on scale 1:500,000. Then the territory was mapped systematically on the scale 1:200,000. At this scale, the gravity map could be interpolated at intervals of 2.5 mGals and the magnetic map at the intervals of 50 nT. Further, we started detailed work on several

maps on the scale 1:50,000, particularly in the coastal zone, in order to clarify the detailed relations between the land and the marine geological structures. These maps were interpolated at intervals of 1.0 mGal for the gravity one and 10 nT for the magnetic one. Initially, the geological data obtained onshore was correlated to offshore geophysical surveys and drillings in order to obtain a better understanding of the offshore geological structure. Later, offshore geological data was used for establishing a more detailed model of the onshore Dobrogea geological structure. This idea is clearly illustrated by the evolution of the conceptions regarding the geological structure of the on- and offshore areas of the Constanta sector of the Moesian Platform. We have to emphasize the necessity of drawing up the gravity and magnetic maps of the entire Black Sea in a unitary system, through international cooperation, in order to improve the contribution of these geophysical methods to the geological knowledge of the area. To conclude, we could say that the completed magnetic and gravity surveys bring an important contribution to the worldwide knowledge of the Earth magnetic and gravity fields.

SEISMIC ANISOTROPY AND MANTLE CREEP IN YOUNG OROGENS

Rolf MEISSNER[1], Irina M. ARTEMIEVA[2], Walter D. MOONEY[3] ([1]Kiel University, [2]EOST, [3]USGS)

We discuss the origin of anisotropy in the crust and uppermost mantle in terms of processes that are controlled by temperature, rheology, and deformation. Wedisregard anisotropy within sedimentary basins and instead concentrate on anisotropy owing to the lattice preferred orientation (LPO) of anisotropic minerals. We focus on young mountain belts that have thick crustal roots and high geothermal gradients.We compare the orientation of this Pn anisotropy with the direction of compressive stress, which nearly always shows a mountain-perpendicular component in the upper crust. From the discrepancy of directions between the fast axis of mantle anisotropy and compressive crustal stresses, we therefore postulate the existence of a decoupling layer. This layer is generally found in the middle or lower crust in all areas with high geothermal gradients and especially in young and warm mountain belts. A decoupling layer corresponds to a low-viscosity layer capable of creep owing to tectonic stress. Tectonic escape or "lateral extrusion" was first suggested for southern China by Molnar & Tapponier (1975). It is today considered to be a lithospheric process and not limited to the crust.

SHEAR WAVE VELOCITY, SEISMIC ATTENUATION, AND THERMAL STRUCTURE OF THE CONTINENTAL LITHOSPHERE

Irina M. ARTEMIEVA[1], Magali BILLIEN[1], Jean-Jacques LEVEQUE[1], Walter D. MOONEY[2] ([1]EOST, [2]USGS)

Theoretical models based on laboratory studies of dissipation of energy in the crystalline rocks typical for the Earth's mantle suggest a temperature dependence of attenuation through the activation energy. We therefore compare global maps of the thermal structure of the continental lithosphere with the inverse attenuation of seismic shear waves Qs and seismic velocity Vs as determined from surface wave dispersion and amplitudes. Our study is based on recently available global databases.We compare the values of Qs, Vs, and temperature T at the depths of 50, 100, and 150 km in the continental lithosphere. We find that qualitatively (by the sign of the anomaly) the maps of Qs closely correlate with lithospheric temperatures. The best correlation is observed for the depth of 100 km, where the resolution of the attenuation model is the highest. At this depth, the contour of zero attenuation anomaly approximately corresponds to the 1000°C contour of lithospheric temperature, in agreement with laboratory data on a sharp change in seismic attenuation and shear velocities in upper mantle rocks at 900-1000°C. The correlation between Vs and two other parameters (T and Qs), though present, is less distinct.We find that most cratonic regions (the Siberian Craton, the East European Platform and the Baltic Shield, the North American Craton, West Africa, western Australia) show high lithospheric Vs, Qs and low T. In contrast, the South African craton has neither high Qs, nor low temperatures. Several prominent low Qs regions correlate with high lithospheric temperatures; this includes the Paleozoic West Siberian Basin, the Cenozoic-Paleozoic structures of the Western Europe, and western North America. We calculate correlation coefficients between Vs, Qs and T and find that at any depth, for any pair of the parameters the correlation is less than 0.42. It implies that even if temperature variations in the lithosphere are the main cause of seismic velocity and attenuation variations, the relation between temperature and seismic properties is non-linear and the concept of the compositionally homogeneous lithospheric roots is not true.

HOW THICK IS THE EARTH'S CRUST?

Walter D. MOONEY[1], Gary S. CHULICK[2], Shane T. DETWEILER[1] ([1]US Geological Survey, [2]St. Xavier University)

Thorough knowledge of the Earth's crustal structure is necessary for understanding continental evolution and other geological processes. We present a recently updated contour map of the thickness of the Earth′s crust using a 10-km contour interval, and the 45-km contour. This contour map was created from over 5000 individual crustal data points that have been acquired during the past 60 years. The contour map honors all available seismic refraction measurements for features with a dimension greater than 2 degrees. Crustal thickness in Eurasia, North America, and Australia is well constrained by seismic refraction data, while Antarctica, South America, Africa, and Greenland are less well constrained. To a first approximation, the continents and their margins are outlined by the 30-km contour. The part of the continental interior enclosed by the 40-km contour and regions with crustal thickness of 45 to 50 km are found on all well-surveyed continents. Continental crust with thickness in excess of 50 km is exceedingly rare and accounts for less than 10% of surveyed continental crust. These observations, now available on a global basis, provide important information to be used for numerous scientific studies.

ARE THE CRATONIC MARGINS VERTICAL? THE CASE STUDY FROM THE TESZ FROM THERMAL AND SEISMIC DATA

Irina M. ARTEMIEVA[1], Walter D. MOONEY[2], Maria A. KRASNOVA[3] ([1]EOST, [2]USGS, [3]Institute of Physics of the Earth, Moscow)

We use joint interpretation of seismic and thermal data for the transition region from the Precambrian to the Paleozoic Europe (the Trans-European Suture Zone) to refine some new insights into the evolution of the sub-continental upper-most mantle beneath the western margin of the East-European Platform (EEP) and to examine how the tectonic boundaries expressed in surface geology continue in the upper mantle and either the cratonic boundary is vertical or the structure, composition and the age of the uppermost mantle in the transition

region do not correlate with the properties (age) of the overlying crust. In the absence of reliable data on the age of the upper mantle of the region, this question can be addressed by analyzing seismic data and distinguishing the effects of temperature and composition on seismic velocities. We compiled available seismic data on the structure of the upper mantle down to the depth of 100-150 km in the transition region. Data on the thermal regime of the lithosphere of the region (Artemieva and Mooney, 2001) were used to correct observed seismic velocities for the temperature effect. At the cratonic margin (i.e. across the TESZ) Moho temperature can change by 300 °C at a distance of less than 500 km, while the lithosphere thickness varies by more than a hundred km. We find that at the top of the mantle the sharp NW-SE boundary between low and high temperature-corrected Pn velocities approximately coincides with the surface manifestation of the TESZ. However, at the depth of 100-150 km the transition zone shifts eastwards both in N and S parts of the TESZ. Precambrian crust of the SW EEP overlies the mantle with the properties similar to the mantle of the Paleozoic Europe, while the subcrustal lithosphere of the SW Baltic Shield was thermally modified during Proterozoic tectonic activity of the region when the marginal part of the cratonic lithosphere was either detached or metasomatised.

CORRELATION OF POTENTIAL FIELD ANOMALIES, PETROPHYSICAL PROPERTIES AND EVOLUTION OF THE FENNOSCANDIAN SHIELD

Juha Ville KORHONEN[1], Sven AARO[3], Tarmo ALL[9], Seppo ELO[1], Tapio KOISTINEN[1], Anatoli KULINICH[8], Jussi KÄÄRIÄINEN[5], Jan Reidar SKILBREI[2], Dag SOLHEIM[6], Rein VAHER[10], Ludmila ZHDANOVA[4] ([1]Espoo Unit, Geological Survey of Finland, [2]Geological Survey of Norway, [3]Geological Survey of Sweden, [4]State Company Mineral, [5]Finnish Geodetic Institute, [6]Norwegian Mapping Authority, [7]National Land Survey of Sweden, [8]Virg-Rudgeofizika, [9]Geological Survey of Estonia, [10]Institute of Geology, Tallinn Technical University)

Grids of magnetic DGRF-65 and Bouguer IGSN-71 anomalies of the Fennoscandian Shield and nearby area have been compiled as a joint venture between Finland, Norway, Sweden and Russia. Information from Denmark, Estonia, Latvia and Lithuania has been included. Anomaly maps derived from grids have been printed on a scale of 1:2 million. The aim was to provide an overall view of the anomaly structure of the Shield and its margins, and especially assist in correlating Precambrian geological formations across seas, state borders and areas covered by younger formations. Insert maps on a scale of 1:15 million are aimed to correlate anomaly components in different source scales: pseudogravimetric anomaly with Bouguer anomaly, DGRF-65 anomaly with pseudomagnetic anomaly, magnetic vertical derivative with second derivative of Bouguer anomaly. Sample level data on bulk density, induced magnetisation, total magnetisation, Q-value and lithology has been presented as scatter diagrams and averages on maps to delineate variation and evolution trends of properties in space and time. The lithospheric anomaly sources are illustrated in interpreted 2.5-D sections across the western lobe of the Fennoscandian land uplift area and across a rapakivi area of age 1550. Apparent susceptibility and depth-integrated magnetisation have been compared with averaged bulk density and total magnetisation. Major source areas, shallower than 5 km include granites of Central Finnish Lappland and Central Finland, and Estonian high-grade rocks. Depth extent class of 5 - 10 km includes rapakivi granites of 1650 Ma and 1550 Ma groups, and the northern Fennoscandian magnetic high. Unexposed long wavelength sources locate below central part of the Gulf of Bothnia and Caledonian front. Both exposed and unexposed anomaly sources continue across the present Shield Boundary, with exceptions of Oslo and Kandalaksha rifts and NE coast of Kola Peninsula.

CRUSTAL MODEL FOR SOUTHERN AND CENTRAL FINLAND (FENNOSCANDIAN SHIELD)

Koslovskaya ELENA[1], Juha Ville KORHONEN[2], Seppo ELO[2], Sven-Erik HJELT[3], Jukka YLINIEMI[4], Markku PIRTTIJÄRVI[1] ([1]Finnish Academy, C/o Oulu University, [2]Espoo Unit, Geological Survey of Finland, [3]Oulu University, [4]Oulu Unit, Sodankyl Geophysical Observatory)

The paper presents the first version of a crustal and upper lithospheric 3-D distribution model of P- and S-wave velocity, bulk density and magnetisation for the southern and central Finland. The model is intended for reduction of teleseismic travel times prior to the tomographic inversion of the SVEKALAPKO seismic array data and correction for regional magnetic and Bouguer anomalies in upper crustal studies, plus as a background for crustal - lithospheric evolution studies.The main part of the geological evolution of the area took place from Mesoarchaean to Palaeoproterozoic. The bedrock stabilised after the Svecofennian orogeny, rapidly developing to a peneplane where later sedimentary rocks accumulated. Anorogenic magmatic activity, like rapakivi events, intrusion of mafic dykes, alkaline rocks and kimberlite pipes continued until Mesozoic. Erosion of sedimentary cover since Cambrian exposed the present Fennoscandian Shield. The model will be based on joint interpretation of Bouguer anomalies and seismic P- and S-wave velocities from previous DSS-studies, combined with interpretation of magnetic total field anomalies and reflection seismic profiles. The boundary values of density and magnetisation at the upper surface of the Shield will be adapted from the petrophysical data base of Finland. The co-ordinate system is national KKJ that can be transferred to ETRS89, when eventually extending the model to nearby areas. In this case the difference of anomalies in the planar model to an ellipsoidal model is to be estimated. As a preliminary stage we present a stepwise, planar model of P-wave velocity and density on a 2 km x 2 km x 2 km grid. The P-wave velocity model, compiled from previous DSS profiles in the area, consists of upper, middle, lower, and lowermost crust plus upper mantle with P-wave velocities of 5.9 - 6.4 , 6.4 - 6.8, 6.8 - 7.0, 7.0 - 7.9, and 7.9 - 8.2 km/s. Depths to velocity boundaries vary between limits of 10 - 20, 27 - 30, 34 - 39, and 38 - 64 km (Moho). The densities for the P-wave velocity layers were found by inverting the Bouguer anomaly in IGSN 71 gravity system. The inversion algorithm is based on stochastic quasi-linear relationship between P-wave velocity and density. The interpreted densities are correspondingly: 2620 - 2900, 2800 - 3000, 2800 - 3000, 3050 - 3250 and 3250 - 3450 kg/m3. The model demonstrates that the high velocity lower crust does not completely compensate the gravity effect of the Moho depressions. Mass compensation may be achieved by adding mafic rock densities in the upper and middle crustal model.

MAGNETIC PETROLOGY DATABASE FOR INTERPRETATION SATELLITE MAGNETIC ANOMALIES. STATUS OF DEVELOPMENT

Katherine A. NAZAROVA (NASA/GSFC Raytheon ITSS)

A Magnetic Petrology Database (MPDB) is now being developed at NASA/Goddard Space Flight Center in cooperation with Russian and Ukrainian Institutions. The purpose of this database is to provide the geomagnetic community with a comprehensive and user-friendly method of accessing magnetic petrology data via Internet for more realistic interpretation of magnetic anomalies. Recently MPDB has been redesigned and now it can be found on the Geodynamics Branch web server of Goddard Space Flight Center at http://core2.gsfc.nasa.gov/research/terr_mag/php/MPDB/frames.html. User submission forms have been developed. To submit new data one can use Data Entry Forms in EXCEL

---

format at http://core2.gsfc.nasa.gov/research/terr_mag/php/MPDB/doc.html Data on Iron Quartzites (10000 samples) from the area of Kursk Magnetic Anomaly , serpentinized rocks from all around the world (670 samples), volcanic sedimentary rocks recovered by Kola and Krivoy Rog Deer BoreHoles (703 samples) are included into database. More data on xenoliths, granulites and Archean Proterozoic sequences are coming. The database searchable engine was utilized to perform a magnetic study of rocks recovered by Kola and Krivoy Rog deep boreholes. A fully working database is expecting in July 2003.

JSA07/11A/D-031	Poster	0830-031

MAGNETIC STUDY OF ROCKS IN THE KOLA AND KRIVOY ROG DEEP BOREHOLES

Katherine A. NAZAROVA (NASA/GSFC RAYTHEON ITSS)

Magnetic properties of rocks from Kola superdeep borehole and Krivoy Rog deep borehole have been compared. These data can be found on the Magnetic Petrology Database which is now being compiled at the Geodynamics Branch of NASA/Goddard Space Flight Center and published on the web at http://core2.gsfc.nasa.gov/research/terr_mag/php/MPDB/frames.html Extremely high values of remanent magnetization (NRM), magnetic susceptibility (K) and Konigsberger ratio (Qn) are found at approximately the same depths of about 2000 m for both boreholes. Highly magnetic serpentinized peridotites and sedimentary rocks affected by sulfide mineralization were recovered at the Kola borehole for a depth interval of 1540-1940 m. The Krivoy Rog borehole recovered highly magnetic iron quartzites of Band Iron Formations at depths of 1853-2040 m. There is no obvious reason why high magnetizations should occur in two boreholes with different lithologies at the same depth. Magnetic surveys and surface sampling in the nearby Krivoy Rog and Kursk Magnetic Anomaly areas have revealed iron quartzites with high magnetization, similar to values given here. AF demagnetization tests suggest that hard and stable NRM component which is caused by hematite occurred in iron quartzites in different forms and grain sizes ranges. Hematite deposits recently discovered on Mars in western equatorial areas of Aram Chaos crater and Sinus Meridiani layered topography formation could be of hydrothermal origin and can cause magnetic anomalies registered by Mars Global Surveyor.

GRAVITY AND MAGNETIC STUDIES IN THE PORCUPINE BASIN, OFFSHORE IRELAND: INSIGHTS INTO BASIN FORMATION

Brian M. O'REILLY, Peter W. READMAN (Dublin Institute for Advanced Studies, 5 Merrion Square, Dublin 2, IRELAND)

The Porcupine Basin lies west of Ireland on the edge of the west European continental margin. It developed in response to multiple late Palaeozoic and Mesozoic continental rifting episodes. The gross crustal structure can be derived using potential field techniques after removing the effects of the sediment fill using the shallow seismic velocity structure. The resultant structure is integrated with deep seismic profiles to constrain the depth to the Moho and the crustal structure of the surrounding region. The results from gravity and magnetic modelling of five transects along seismic reflection profiles are presented. These cross the entire Porcupine Basin between 50°-53° N. The results indicate that sedimentary basin and crustal structure change abruptly along the axis of the basin at around 51.6° N. In the north a dense and reversely magnetized body extends from acoustic basement to the Moho(?). The basin broadens to the south where an axial gravity low is flanked by highs similar to the anomaly pattern in the neighbouring Rockall Trough where it is due to a seismically imaged thickening of the crust towards the basin centre. This change in crustal geometry is marked by a set of NW-trending gravity lineaments which are interpreted as a cross-basin transfer fault system that control large-scale segmentation of the extensional deformation. Currently published models for the opening of the Porcupine Basin involve a clockwise rotation of the adjacent crustal block leading to a southward broadening of the basin. The results of our gravity studies suggests that the sense of rotational deformation was different on either side of the interpreted transfer fault system. Correlations with the deep seismic structure in the region suggest that this fault system was important in controlling fluid flow in the sub-crustal lithosphere during syn-rift deformation. The modelling results used in this presentation were undertaken on behalf of the Irish Petroleum Infrastructure Programme.

AN APPRAISAL OF GRAVITY SIGNATURES IN THE SOUTHERN PART OF BOMBAY OFFSHORE BASIN, WESTERN INDIA

Subba Raju Venkata LAKAMRAJU, Krishna Sri KOLLURU, Anil K. CHAUBEY, Subrahmanyam VANDRAPU, Gopal Chandra BHATTACHARYA (National Institute of Oceanography, Dona Paula, Goa 403 004, INDIA)

A 2-mGal Bouguer gravity contour map is prepared from ship-borne gravity data of the southern part of Bombay offshore Basin, located on shelf and upper slope region between 10 and 1000 m water depths.The Bouguer gravity map reveals four prominent zones related to tectonically controlled igneous bodies emplaced during northward motion of Indian plate over the Reunion hotspot during Early Tertiary. The upper slopes in 1000-400 m water depths show relatively high gradient indicating fault-controlled structures.A significant gravity closure of +34 mGals on the outer shelf reveals the presence of igneous rock, which may represent one of the vents of Reunion hotspot. In the mid shelf region, the gravity reduces smoothly from +34 to -20 mGal indicating i) absence of basaltic formations and ii) the gravity effect due to the Archaeans and the overlying Tertiaries. The inner shelf is significantly characterised by several gravity closures ranging from -8 to -62 mGals.These low gravity closures are interpreted as several depot centers of Tertiary period. In the southern portion of the study area, a spur-like formation running from the coast toward shelf edge is observed. The structure is terminated due to the existence of NNW-SSE trending basaltic formation related to Reunion hotspot. The seismic profiles over the region from shelf edge to the deeper waters and along the shelf edge show the dissection of the Archaean formations with horst and graben structures indicating the block faulting and igneous intrusions covered with Tertiary sediments. The prominent structures observed in seismic profiles are well reflected in the Bouguer gravity map. A density model of the southern part of Bombay offshore basin is generated using the forward gravity modeling under available seismic constraints. The limits of the basaltic formations with the help of density model in the study area is interpreted and spur-like structure as well as the vent of the hotspot are

2-D CRUSTAL THERMAL STRUCTURE OF THE NARMADA- SON LINEAMENT IN CENTRAL INDIA ALONG UJJAIN-MAHAN DEEP SEISMIC SOUNDING PROFILE

S. N. RAI, S.0. THIAGARAJAN, D. V. RAMANA (National Geophysical Research Institute, Uppal Road, Hyderabad 500 007, India)

The ENE-WSW trending Narmada- Son Lineament (NSL) in the central India extends

eastward for about 1600 km from the west coast of India and lies approximately between 72-88E longitudes and 21.5-24N latitudes. It is characterized by the presence of numerous hot springs, feeder dykes for Deccan traps, and seismicity all along it's length. In order to understand the crustal structure of this region Deep Seismic Sounding (DSS) surveys were carried out along five profiles. Interpretation of seismic data along these profiles indicate that the NSL is divided into two parts by Baswani- Sukta Fault (BSF. To the west of this fault a graben exists while to the east basement uplift is found in the form of horst. The horst structure is bounded by Narmada North Fault (NNF) and Narmada South Fault (NSF). The present work deals with the two-dimensional thermal modeling for the delineation of crustal thermal structure along a 220 km segment of the Ujjain-Mahan DSS profile which is located just east of BSF fault traversing the horst structure. P-wavevelocity distribution obtained from DSS studies has been used to estimate the heat generation values in the middle and lower crust. For the upper part of the crust we use exponential heat generation model to estimate the distribution of radiogenic sources. Numerical results indicate that the Moho temperature varies between 500 to 550°C which more or less coincideswith the Curie isotherm. The estimated surface heat flow varies between 46.3 to 47.1 mW/m², with the maximum between Ujjain to Dorwa and the minimum over the Tapti basin. Although measured heat flow values in the study area along the profile are not available for comparison, these values are found to be in close agreement with the measured surface heat flow values at Mohpani(49 mW/m²) in the NSL zone east of this profile and Lonar and Yavatmal area (47 mW/m²) south of NSL in the Deccan traps. The present study reveals that the upper mantle in this part of NSL is relatively cooler than the north Cambay region on the western margin of India. The lowervalue of the mantle heat flow in this region can be used to infer the brittle nature of the lower crust which is supported by the occurrence of deep crustalSatpura (1938) and Jabalpur (1997) earthquakes of NSL region.

ANCIENT COLLISIONAL CONTINENTAL MARGINS IN THE COUTHERN INDIAN SHIELD: GRAVITY SIGNATURES AND DERIVED CRUSTAL TRANSECTS

Anand P. SINGH, D. C. MISHRA (National Geographycal Research Institute, Hyderabad)

The southern Indian shield is one of the areas of the world, which had preserved the earliest formed crust. Litho-tectonic diversity, missing threads of Precambrian record and for the most part obliterated by imprints of later tectonic events have made it unique in the study of the early evolutionary history of the earth crust. Earlier it was widely believed that the southern Indian shield forms a singular crustal domain. In contrast, a mosaic of smaller litho-tectonic domains, which were once separate but brought and welded together during their evolutionary history, is another notion. Demarcation of these original crustal domains that welded together during the geological past is first and foremost important task in order to understand the evolutionary processes operative at that point of time It has been suggested that the paired (positive and negative) gravity signature characterizes deep crustal breaks along the boundaries between ancient crustal domains. This gravity signature for Late Archaean to Late Proterozoic plate tectonics is analysed/reviewed and a case is presented for the role of plate tectonics in developing reactivated Precambrian terranes with discussion centring on the Dharwar craton of the southern Indian shield. Further support is provided by geologically analogues terranes of the Canadian shield.

INVESTIGATION OF EFFECTS OF EXPLOSIONS ON THE OIL PIPES AT MARVAK DAM SITE IN LORESTAN REGION(IRAN)

Shayesteh MEHRABIAN, Ahmad SADIDKHOI (Department of Earth Sciences, University of Tehran)

In this study the effects of vibrations due to 25 performed explosions on the oil pipes by using the delay time are investigated. Vibrations are recorded by four seismographs (PDAS, L4-3D seismometer). The obtained data are analysed and processed by using suitable methods and available soft wares. According to the obtained relationships between the particle velocity and scaled distance, acriterion for reduction the effects of vibrations on the oil pipes is proposed.Finally these geophysical data are used to describe a regional crustal model which can lead to robust geophysical interpretations.

ESTIMATION OF LITHOSPHERIC THICKNESS BENEATH SEISMICALLY ACTIVE REGIONS OF THE DECCAN VOLCANIC PROVINCE OF INDIA

Venkata Ramana DRONAMRAJU (National Geophysical Research Institute)

Thermal evolution of the lithosphere is primarily governed by heat conduction and plays a key role in deforming the lithosphere and controlling its structure. Surface heat flow is major observation for estimating the temperature field of the lithosphere. It consists of two parts (i) contribution from the mantle, and (ii) heat generation within the lithosphere due to radiogenic heat sources. In continental lithosphere, radiogenic sources account for about 40 percent of the total surface heat flow. Previous models for the estimation of thermal structure of the Indian continental lithosphere used exponential/ step model of radiogenic heat sources distribution. Since continental crust consists of rocks having very different concentration of these radiogenic sources, it is important to consider the vertical heterogeneity in the thermal parameters to construct the thermal structure. The vertical distribution of the radiogenic heat sources is obtained by direct measurements of the heat generation in different rock types or by estimating it from the observed seismic velocities using an empirical relationship between the heat generation and P-wave velocities. In the present work the radiogenic sources in the mid – and lower crust for Killari and Koyna locations of the Deccan Volcanic Province have been estimated by using deep crustal seismic velocity information and the thermal structure is obtained by treating the lithosphere as an n-layered model. The results reveal a relatively thick thermal lithosphere for these locations.

SEISMOLOGICAL CONSTRAINTS ON CRUSTAL EVOLUTION IN SOUTH INDIA

S. S. RAI, Sandeep GUPTA (National Geophysical Research Institute, Hyderabad, INDIA)

Receiver function analysis of teleseismic waveforms from 32 broadband seismic stations in South India suggest significant difference in the crustal structure. The eastern Dharwar Craton, Deccan Volcanic and Cuddapah basin show very similar crustal thickness 33-39 km. The western Dharwar Craton (WDC), however, has thicker crust (42-51 km). The crustal thickening in WDC occurs in step fashion, Moho offsets coinciding with surface expression of N-S elongated shear zones. The thickest crust (~ 60 km) is observed beneath the Nilgiri hills. Elsewhere, in the Southern Granulite Terrain (SGT), crust is 40-53 km thick. Considering 20-30 km crustal exhumation in the southern part of WDC and SGT, we speculate possibly 70-90 km thick crust across WDC-SGT during Archean. This suggest of a Himalaya type geodynamic frame work for the evolution of granulite terrain.

CRUSTAL STRUCTURE IN THE SIKKIM HIMALAYA FROM NEW GRAVITY AND MAGNETIC DATA

Virendra Mani TIWARI, M.B.S. VYAGRESWARA RAO, R. S. RAJESH, D. C. MISHRA (National Geophysical Research Institute)

Recently, we have recorded gravity and magnetic data in the Sikkim Himalayas to elucidate the subsurface structure in this part of Himalayas. The recorded profile starts from Gangetic plain and runs across main tectonic features like MBT and MCT. Data are recorded at 1 km spacing and location and elevation of the stations are determined using differential GPS. All the main tectonic features are reflected in the gravity and magnetic data. The gravity and magnetic anomalies are modelled for subsurface structures.

SOME PROPERTIES OF THE MAGNETOTELLURIC ROTATION INVARIANT TENSORS

Suman DEY[1], Shashi Prakash SHARMA[1], Kalyan Kumar ROY[2], Someshwar SRIVASTAVA[3] ([1]Department of geology and geophysics, IIT(Kharagpur), India., [2]Department of Geological Sciences, Jadavpur University, Calcutta-700032, India, [3]AFPRO, IC/262, Ashoke Nagar, Ranchi-834002, Jharkhand, India)

Rotation Invariant Tensors (RITs) can be used for interpretation of magnetotelluric field data. Three RIT apparent resistivities and their phases, viz, rho-determinant, rho-average and rho-central generate much more closer apparent resistivities than the conventional Cagniard TE and TM mode Swift rotated apparent resistivities and their phases near prominent geological lateral heterogeneities. RITs generate perfect rotation invariance with noisy field data with larger error bar. RITs generate stable apparent resistivities and phases for longer period signals where TE and TM mode values may show instability and fluctuations. Field data from Archean and Proterozoic terrain may generate best 2D model with 1D inverted data using RITs. Even 2D Rapid Relaxation Inversion algorithm using RITs generates much more stable models than those obtained using TE and TM mode data. Two eigen values of the impedance tensors are also rotationally invariant and generates respectively higher and lower apparent resistivities in comparison to rotated and unrotated apparent resistivities. In a complex domain the tensor elements Zxx, Zyy, Zxy and Zyx generates ellipses of widely variable ellipticities where as RITs describe just one point. The diagonal elements of the impedance tensor are nonzero and nontrivial even after optimum rotation for a 3D structure. Therefore RITs will have a role in the interpretation of MT data because through determinant and central RITs, information from diagonal elements enter into interpretation.

MAGNETIZATION MODELING OF THE MAUD RISE CRUST IN THE SOUTHWEST INDIAN OCEAN

Hyung Rae KIM[1], Ralph R.B. VON FRESE[1], Alexander V. GOLYNSKY[2], Patrick T. TAYLOR[3], Jeong Woo KIM[4] ([1]Dept. of Geological Sciences, The Ohio State Univ., [2]VNII Okeangeologia, 1, St. Petersburg, Russia, [3]Code 921 Geodynamics branch, GSFC, NASA, Maryland, USA, [4]Dept. of Earth Science, Sejong Univ., Republic of Korea)

We produced a crustal magnetization model for the Maud Rise in the southwest Indian Ocean off the coast of East Antarctica using magnetic observations from the Ørsted satellite and near-surface surveys complied by the Antarctic Digital Magnetic Anomaly Project (ADMAP). New inversion modeling of the two anomaly fields suggests that the magnetic effects due to crustal thickness variations and remanence involving the normal polarity Cretaceous Quiet Zone (KQZ) dominate at satellite altitude (≥700 km).The crustal thickness effects were modeled in the Ørsted data using crustal thickness variations derived from satellite altitude gravity data. Modeling of the residual Ørsted and near-surface magnetic anomalies supports extending the KQZ eastwards to the Astrid Ridge. The remaining near-surface anomalies involve crustal features with relatively high frequency effects that are strongly attenuated at satellite altitudes. The crustal modeling can be extended by the satellite magnetic anomalies across the Indian Ocean Ridge for insight on the crustal properties of the conjugate Agulhas Plateau. The modeling supports the Jurrasic reconstruction of Gondwana when the African Limpopo-Zambezi and East Antarctic Princess Astrid coasts were connected as part of a relatively demagnetized crustal block.

GRAVITY ANOMALIES AND ASSOCIATED TECTONIC FEATURES OVER THE INDIAN PENINSULAR SHIELD AND ADJOINING OCEAN BASINS

Dinesh Chandra MISHRA, K. ARORA, V. M. TIWARI (National Geophysical Research Institute, Hyderabad, India)

A combined gravity map over the Indian Peninsular Shield (IPS) and adjoining oceans brings out well the inter-relationships between the older tectonic features of the continent and the adjoining younger oceanic features. The NW-SE, NE-SW and N-S Precambrian trends of the IPS are reflected in the structural trends of the Arabian Sea and the Bay of Bengal suggesting their probable reactivation. The Simple Bouguer anomaly map shows consistent increase in gravity value from the continent to the deep ocean basins, which is attributed to isostatic compensation due to variations in the crustal thickness. A crustal density model computed along a profile across this regionsuggests a thick crust of 35-40 km under the continent, which reduces to 22-24km under the Bay of Bengal. Large crustal thickness and trends in the gravity anomalies similar to the structural trends of the southern part of IPS suggest a transitional crust in the Bay of Bengal. The crustal thickness under the Laxmi Ridge and east of it in the Arabian Sea is 20 and 14 km respectively. The crustal density model in this part of the Arabian Sea (east of Laxmi ridge) and the structural trends similar to the Indian Peninsular Shield suggest a continent-ocean transitional crust (COTC). The COTC may represent down droppedand submerged parts of the Indian crust evolved at the time of break-up along the west coast of India and passage of Reunion hotspot over India during late Cretaceous.

UPPER MANTLE HETEROGENEITY BENEATH THE CAMBAY RIFT BASIN, INDIA:INSIGHT FROM GRAVITY MODELLING

Bijendra SINGH, D. C. MISHRA (National Geophysical Research Institute)

The Camaby rift basin, which is one of the major petroliferous basins of India indicates anomalous gravity signatures. The Bouguer anomaly map of basin and the adjoining regions depicts number of large amplitude circular gravity 'highs' related to high density intrusive/extrusive igneous plugs resulting from Deccan Volcanism. The small wavelength gravity 'lows' are caused by Tertiary and Mesozoic sediments and are superimposed on a

large wavelength small amplitude gravity 'low' suggesting source at deeper level. Modeling of gravity anomalies across the basin incorporating constrains from seismic and borehole information requires a low-density (3.04 g/ cm3) upper mantle and a high-density (3.10 g/cm3) underplated lower crust with Moho at a shallow depth (32 km) beneath the basin. This low-density upper mantle extends over hundreds of kilometres on either side of the basin. These features are typical of continental rift evolved from a thermal source. Presence of high heat flow, extremely thin thermal lithosphere, Deccan volcanism and low velocity zone associated with low-density body probably indicate region of elevated temperature suggesting partial melting condition in the upper mantle. This might have resulted due to interaction of Reunion plume with the Indian lithosphere during the northward migration of the Indian plate in late Cretaceous after the break up of the Gondwana land.

LITHOSPHERIC STRUCTURING OF THE TUNISIAN NORTHEASTERN AFRICAN PLATE MARGIN

Mourad BÉDIR[1], Fouad ZARGOUNI, Chokri JALLOULI, Badiaa CHULLI-ZENATI ([1]Department of Georesources,Institute of scientific and technic research of Tunisia, [2]Facult des Sciences de Tunis. Campus Universitaire, 1060 Tunis. Tunisia., [3]Facult des Sciences de Bizertes. Tunisia.)

Key Word : Tunisia, Geophysics, CrustGeological and geophysical data from the different regions of the Tunisian Atlassic and Mediterranean zones permit the reconstruction of the structuring and the evolution of the crustal margin and its tectonic and sedimentary cover mechanisms. Reflection and refraction seismic investigations, geothermal studies and gravimetric Bouguer and residual anomalies had highlighted the deep tectonic framework of the Eastern Tunisian margin. This domain is characterized by a deep structural discontinuities trending North-South, East-West, Northeast-Southwest and Northwest-Southeast corresponding to a deep-seated flower fault corridors. These discontinuities bound the main tectonic blocks of the margin. The Mohorovitchi discontinuity depth evolutes from the South to the North-East from forty to twenty kilometres. The upper levels are respectively to the North at the Galite granitic Island latitude and to the North-East along the Tunisian- Sicilian Pantellaria and Linosa volcanic islands straight. This rising of the Moho corresponds to the important magmatic activity in these zones since the Triassic until the Neogene times and the high geothermal rates encountered in the petroleum wells of these areas. From the South to the North the margin is subdivided in three main geotectonic blocks. The Eastern-Northeastern Sahel-Pelagian block. From the Triassic to Cenozoic times these blocks evolutes progressively across a mosaic of tilted platforms and grabens.This area is affected by an important tectonic activity of transtensional and transpressional deep-seated faults that create a mosaic of Mesozoic and Cenozoic Grabens, Horsts, Platforms and folds. During the Mesozoic times, took place marine to deep marine carbonate basin and platform deposits intruted by magmatic volcanic basaltic rocks. Triassic halokinetic movements are also active. A great subsidence occurs in the Tertiary where the horizons are composed by thick deposits of Paleocene marls, Eocene platform carbonates, deep-marine marls and black shales. The Oligocene consists on deltaic and fluvial sandstones deposits. Paleocene to Eocene series are intercalated by volcanic alcaline explosive rocks. Miocene deposits comprise deep-marine to thick deltaic series marked by an alternations of marls, platform carbonates and clay packages with sandstone turbidites. Burdigalian to Langhian series are interbedded in some offshore wells by basaltic rocks. To the offshore basins Pliocene deposits are formed by a thick deep marine marls and sandstone turbidites. These Neogene deposits are engaged in a claykinesis and clay intrusives along the strike-slip fault corridors. The treatement of these data had permitted to propose a geodynamic model for this particular margin.

GRAVITY CONSTRAINTS ON THE CRUSTAL THICKNESS OF NORTHERN AFRICA, WESTERN MEDITERRANEAN

Chokri JALLOULI[1], Kevin L. MICKUS[2] ([1]Department of Geology, FST, Univ. Tunis El Manar, [2]Department of Geosciences, southwest Missouri State Univ., Springfield, MO 65804, USA)

The evolution of western Mediterranean region of northern Africa involves several complex tectonic environments controlled by the interaction between the Eurasian and African plates. As a result of this interaction, two orogenic belts (Atlas and Tell Mountains) were formed in northern Africa. Most workers are in general agreement on the tectonic events affecting northern Africa however, the general crustal and upper mantle structure of this region remains relatively unknown due to the lack of deep seismic data and regional geophysical analyzes. To provide insights on the deep crustal structures under the Atlas and Tell Mountains and the African northern margin, gravity data were analyzed in conjunction with available drill hole, geologic and deep seismic data. Bouguer, free-air, isostatic residual gravity anomaly maps and two 2D gravity models across the Tell and Atlas mountains in Algeria and Tunisia were constructed. The gravity models provide estimates of the crustal thickness (37 km in Algeria and 30 km in Tunisia) and the amount of crustal shortening caused by the collision of the African and Eurasian plates. The isostatic residual gravity anomaly maps and the gravity models provide evidence of a thick crustal root under the Atlas Mountains in Algeria, while a thin crustal root is suggested under the Atlas Mountains in Tunisia. The Atlas Mountains are partially to fully compensated implying crustal shortening. However, based on the gravity models, and the amplitude and width of the Bouguer gravity anomalies over the Saharian Atlas in Algeria and the Tunisian Atlas Mountains, the amount of crustal shortening was greater in Algeria than in Tunisia.

MAGNETIC INTERPRETATION OF THE ONSHORE GEBEL EL-ZEIT AREA, GULF OF SUEZ, IN EGYPT USING INTERPRETATION TECHNIQUES

Essam Aboud ABOUD, Keisuke USHIJIMA, Ahmed SALEM (Essam Aboud)

This paper documents the result of an integrated interpretation technique of magnetic data carried out on the onshore of Gebel EL-Zeit area, Gulf of Suez, in Egypt of magnetic data carried out on the onshore of Gebel EL-Zeit area, Gulf of The objective of this study is to identify the possible subsurface structure framework that may assist in delineation of promising areas for hydrocarbon reservoir Gradient techniques including Euler Deconvolution and analytic signal have been applied to the observed magnetic data by National Research Institute of Astronomy and Geophysics, Egypt Then the result of this study geological trends and depths of subsurface geologic structures are defined. The central portion of the area is characterized by basin block forming a graben bounded by major uplifting faults striking in the NW-SE direction Depth to the basement of basin structure ranges about 1.5 km in the eastern and western parts of the study area and gets deeper toward the central part up to 4.5 Km Moreover, gradient interpretation techniques supplied by geologic and drill hole information enabled delineation of promising areas which are highly recommended for further hydrocarbon exploration in the area.

MAGNETIC AND GRAVITY MODELLING ON FUEGUINIAN FOLD-AND-THRUST BELT. ARGENTINE

Alejandro Alberto TASSONE[1], Juan Francisco VILAS[2], Maria Alejandra COMBA[3], Horacio Francisco LIPPAI[4], Emanuele LODOLO[5], Marco MENICHETTI[6], Jose Luis HORMAECHEA[7] ([1]18270, [2]9848, [3]18277, [4]18273, [5]19228, [6]19233, [7]19220)

The studied area is localized in the central northern side of the Fueguian Andes, where the structures of the external thrust front propagate through to the Magallanes thin-skinned foreland fold-and-thrust belt. A system of Oligocene-Quaternary E-W (the Magallanes-Fagnano Fault System, MFS) left-lateral strike-slip faults with an extensional component overprints the contractional structures and is responsible for the main depression of the Lago Fagnano. A Quaternary system of N-S faults with right-lateral strike-slip attitude crosses all the previous structures and probably constitutes the present day deformation strain field in the eastern part of the Island. Geophysical field surveys allowed to acquire 440 DGPS-fixed data points where gravity, magnetic and magnetic susceptibility measurements were performed. In the surveyed area, the MFS segments have clear morphological expression, and are associated with localized gravity minima in correspondence of their unconnected ends. At the ESE tip of Lago Fagnano, the magnetic data suggest the existence of several intrusive bodies in the subsurface. The magnetic anomaly for each of these bodies indicates a rotation in relation to the N-S direction. The geophysical modeling of an outcropping monzodioritic body revealed a piston shape. A 2D numeric modeling was performed (employing the IGMAS software) with the data of total Bouguer anomaly. The model displays a N-S section of about 40 km through the upper 10 km. A 2D numeric modeling was performed with the data of total magnetic anomaly using the Geomodel software. The model N-S cross-section through the area combines the acquired gravity data with the field geological information and the geometry of the deep structures derived from industrial seismic reflection lines. A very good fitting was observed between the measured and computed values for the basement depth whose modelized geometry indicates a southward deepening from 5 km to 7 km. The model geometry of the deep duplex with buried leading edge is geometrically similar to the structures exposed in the western part of the Island. The model geometry of passive roof thrusts and back-thrust that develop the triangle zone north of the Lago Fagnano area is well constrained with the geological field data and well marked by the seismic reflectors of the shear zones. The lower detachment levels have up to 40% of shortening, while the upper structures display less than 20% of contraction. In the modelized section the MFS is related to a -49 miliGal minimum. The offset of the strike-slip faults toward the plane of the section constitutes one of the main incertitude for lack of geometrical tags. Field geological data and regional considerations indicate that the offset could be about few tens of km.

JSA07/11A/D-048   Poster   0830-048

RELATION BETWEEN TECTONICS FEATURES AND EPICENTER SEISMIC DISTRIBUTION PATTERN (ARGENTINE CENTRAL ANDES

Guillermo Hector RE[1], Maria Silvia JAPAS[2], Silvia Patricia BARREDO[1] ([1]Dpto. Geologia - Universidad de Buenos Aires, [2]CONICET - Argentina)

The Cordillera de los Andes system lies parallel to the Peruvian-Chilean trench, which delineates the meet zone between the subducted oceanic plate (Nazca Plate) and the continental plate (South American Plate). This active margin shows numerous and important tectonic changes along its entire strike. One of the most conspicuous characteristics is the significant change in the subduction angle along the South American Coast. It is thus that two sub-horizontal subduction segments are observed (between 2° S and 15° S and between 27° S and 33° S). Anomalies located in the convergence process along the west margin of the South American plate would be caused by the subduction of aseismic ridges and chains of submarine foothills dragged by the Nazca Plate during its descent. Another effect caused by the change in the subduction angle is the displacement of the different tectonic fronts several hundred kilometers towards the East, and the subsequent rise of numerous mountain systems in the West sector of Argentina since Miocene up to the present times (Precordillera, Western Sierras Pampeanas, Sierra de Famatina, Eastern Sierras Pampeanas). These rises have conditioned the development of important continental sedimentary basins. Where the epicentres of South America margin are plotted two types of distribution patterns can be noticed: between 17° S and 23° S the fabric shows a bending design parallel the continental margin; from 24° S onwards there is an earthquake alignment tendency with depth following NNE, NNW and ENE-WSW directions. Taking into account only those of shallower depths a persistence of the alignments previously defined can be observed. In addition, it is outstanding the good correspondence between the northern NNE lineament observed with respect to the present volcanism boundary. Another striking point, is the correspondence (localization and orientation) between the NNE and NNW lineaments and those which, for this particular zone, can be defined from the localization of the seismic epicenters. This latter would not only certify the kinematic importance of the major lineament already described but would also provide the scale thereof as a direct consequence of the involvement of the continental lithosphere deeper portions. In the case of the ENE – WNW seismic epicenters alignment the orientation permits to suspect the incidence of the subduction of the Juan Fernández ridge.Another significant characteristic is the correspondence between those lineaments defined in surface on the basis of the above mentioned elements and the deep earthquake alignments in the subducted plate. This apparent correspondence is major for the flat-slab subdution zone, probably due to the interplate coupling.

MEASUREMENT OF COMPARATIVE TERRESTRIAL STRESS AT XIAN AND NEARBY AREAS AND EARTHQUAKE FATALNESS STUDY

Wen-xiang WANG, Wu-yang YANG (China Coal Research Institute, Xi'an Branch)

Through studying the distribution-configuration and variation-characteristics of deep underground depth terrestrial stress, the on the ground location of where the earthquake will occur can be determined, the magnitude of the future earthquake can be calculated, and the timing of the earthquake occurrence could be held.With the DYL Type Terrestrial Stress Measurement Instrument, installed on a vehicle or on a train, using a natural electromagnetic wave field source, can directly and rapidly measure the comparative terrestrial stress magnitude of which geological bodies are subjected to at deep underground depths of 5km, 7km and 10km. Through the study method of terrestrial stress issoline analysis, can determine the configuration and size of future earthquake source zones, explain locations of deep and major faults and terrestrial heat abnormal zones. In accordance with the background data, detected and measured by the MDCB Instrument, indicating that damaging earthquake underlies dormant in areas nearby Xian, as well as the Xian Seismology Bureau's consultation and study opinion on situation of earthquakes nearby Xian for the year 2001, the Xian Municipal Government and the Xian Municipal Science Committee approved to establish the project for studying the conditions of terrestrial stress at deep underground depths at Xian and nearby areas. This paper is the resulting report of the

completion study on this project.Upon review and examination by concerned specialists from the State Seismology Bureau of China, it was concluded that this report provides important seismological and geological basis for determining the on the ground location for where damaging earthquake(s) could occur nearby Xian in the future, and for the Xian area to establish earthquake resistance, earthquake prevention measures and earthquake precursor monitoring and measurement measures.

THE ROLE OF EXTRATROPICAL WAVE FORCINGIN DRIVING POSSIBLE SOLAR CYCLE VARIATIONS IN THE TROPICAL LOWER STRATOSPHERE

Lon L. HOOD[1], Boris E. SOUKHAREV[2] ([1]Lunar and Planetary Laboratory, University of Arizona, [2]Dept. of Climatology, University of St. Petersburg)

Records of column ozone, temperature, and geopotential heightwith lengths greater than 20 years are consistent with the existenceof a long-term, quasi-decadal oscillation (QDO) of the tropicaland subtropical lower stratosphere. This long-term variation has beenapproximately in phase with the 11-year solar cycle during theperiod for which accurately calibrated data are available.Two-dimensional models demonstrate that direct solar UV photochemicaland radiative forcing in the lower stratosphere is unlikelyto produce a QDO of the observed amplitude. We have thereforeinvestigated whether solar UV variations inthe upper stratosphere may modulate extratropicalwave forcing. The latter is an important driver of the Brewer-Dobsoncirculation, which influences the tropical lower stratosphere bychanging the rate of vertical transport. For this purpose,daily and monthly mean meridionaleddy heat fluxes have been calculated at a series of lowerstratospheric pressure levels over a 23-year period usingNational Centers for Environmental Prediction (NCEP) Reanalysis data. Adecadal variation of the low-pass filtered extratropical eddy heat fluxis present in both hemispheres with an amplitude that increases withincreasing altitude. A simplified model of the contribution ofextratropical wave forcing to long-term variations in tropical lowerstratospheric ozone and temperature is then formulated based on theozone chemical continuity and thermodynamic energy equations. Usingthis model together with empirically derived regression relationshipsbetween short-term changes in extratropical eddy heat flux and tendenciesin both tropical column ozone and lower stratospheric temperature, itis found that decadal variations of extratropical wave forcing in bothhemispheres are sufficient to explain approximately both the amplitudeand the phase of the observed QDO of the tropical lower stratosphere.

EVIDENCE OF THE SOLAR CYCLE IN THE GENERAL CIRCULATION

Murry L. SALBY[1], Patrick F. CALLAGHAN[2] ([1]The University of Colorado, [2]Atmospheric Systems and Analysis)

NCEP reanalyses are used to isolate systematic variations in the stratospherethat operated coherently over the last 4 decades with the 11-yr variation of UV irradiance. A systematic variation is scarcely visible at low frequency,which would reflect a simple linear response that drifts with solar flux, F_s. However, a systematic variation manifests itself clearly at high frequency,which involves changes between neighboring years. Corresponding to interannual variability, the systematic variation at high frequency reflects amore complex, nonlinear response to the 11-yr variation of UV irradiance. It is analogous to a similar variation found earlier in the QBO of equatorial wind, u_{EQ}. Interannual variability undergoes a frequency modulation that systematically alters its phase during winter, when planetary waves couple the polar and equatorial stratosphere. The polar-night vortex is then sensitive to equatorial wind,which itself varies systematically with F_s. Monte Carlo simulations indicate that the systematic variation of wintertime phase is highly significant. The systematic variation appears prominently in the wintertime tendencyof temperature, which is coupled directly to the residual mean circulation.In fact, the anomalous wintertime tendency operating coherently with F_s has the same basic structure as that operating coherently with anomalous forcing of the residual circulation. Each reflects anomalous downwelling over the Arctic that is compensated at lower latitude by anomalous upwelling.The structural similarity of these anomalies suggests that the systematic variation at high frequency enters through changes of the residual circulation. Accompanying the variation of zonal-mean structure is a systematic amplification and decay of wave-number 1 at high latitude.It represents a poleward advance and retreat of the critical region, or surfzone,where planetary waves experience strong absorption that forces residual motion. This variation of wave structure, along with anomalous residual motionit forces, parallels the systematic variation of equatorial wind.Wintertime-mean u_{EQ} suggests a reversal in anomalous downwelling between solar min and solar max, one broadly consistent with the observed reversal in anomalous temperature.

JSA08/09A/A08-003 — 0945
SOLAR ACTIVITY AND GLOBAL/REGIONAL WARMING AND COOLING

Hengyi WENG (LASG, Institute of Atmospheric Physics, Chinese Academy of Sciences)

The coherence between the solar activity and global and North Pacific winter sea surface temperature (SST) variation on centennial timescales such as the Gleissberg cycle (~80-90 yrs) and the Suess wiggles (~200 yrs), may be a manifestation of solar impacts on global and regional warming trend since the beginning of the 20th century. The additional harmonics of the Gleissberg cycle (~40-45yrs and 27-30yrs) and the subharmonics of the 11-yr solar cycle (33yrs and 44yrs) may be related to the SST variability on interdecadal timescale with two warm periods in the 1940s-50s and 1980s-90s, and the cool period in the 1960s-70s. The sunspot number may be a rather good predictor for global and North Pacific SST variation on interdecadal timescale. If the predicted sunspot number published by NOAA/NGDC is reliable, then the global and the North Pacific winter SST may undergo a cooling decade at the beginning of the 21th century based on the reduced solar activity up to 2007, compared with the last decade in the 20th century.

WINTER NAO VERTICAL STRUCTURE PROFILE CHANGES IN ASSOCIATION WITH THE SOLAR ACTIVITY, GEOMAGNETIC ACTIVITY AND THE QBO

Pavel HEJDA, Josef BOCHNICEK (Geophysical Institute, Academy of Sciences, 141 31 Prague, Czech Republic)

The aim of the paper is to analyse the association between the solar activity,geomagnetic activity and the QBO phase on one side and the changes of NAO vertical structure profiles going through eastern part of North America continent, eastern Atlantic, middle Europe, western part of Asia continent and eastern Pacific on the other. For this purpose, corresponding NAO meridional cross-sections were created on the series of pressure, temperature and prevailing wind distribution in the levels between sea level and 100 mb level. Changes in the meridional cross-sections observed in winter (January+February) periods 1952-2001 were investigated by the composite method. The occurred changes seem to be associated with both the activities as well as the QBO phases. Statistical significance of the composite maps were tested using Student`s t-test. Meteorological data in the winter periods 1952-2001 for pressure and temperature, and in winter periods 1964, 1967-1969, 1971-2001 for prevaling winds were taken from the NCAR Research Data Sets.

JSA08/09A/A08-005 — 1015
THE IMPORTANCE OF STRATOSPHERIC DYNAMICS IN DETERMINING THE RESPONSE OF THE TROPOSPHERE TO SOLAR FORCING

Michael Anthony PALMER[1], Lesley GRAY[1], Myles ALLEN[2] ([1]Rutherford Appleton Laboratory, [2]University of Oxford)

In order to quantify the potential impact of anthropogenically inducedclimate change, it is vital to understand the natural variability of theclimate system. A crucial, unresolved question involves the climatic effectof changes in total solar irradiance (TSI), and in particular the role thatthe stratospheric circulation plays in inducing anomalous flow at lower,tropospheric levels. Using the Unified Model, in a configuration with amixed-layer ocean and a well resolved stratosphere, we investigate the roleof stratosphere/troposphere coupling in governing the response to solarforcing. The importance of realistically simulating the natural variabilityof the stratosphere is studied, by comparing model runs both with andwithout a scheme to account for the vertical propogation of gravitywaves. The implications of our results for climate change detection studies,which have tended to use models without a well resolved stratosphere, isdiscussed.

JSA08/09A/A08-006 — 1030
STUDY OF LONG TERM CHANGES IN THE GEOMAGNETIC FIELD, CUTOFF RIGIDITIES, COSMIC RAYS, AND POSSIBLE RELATION TO CLIMATE CHANGES

Don Frederick SMART, Margaret Ann SHEA (CSPAR, University of Alabama in Huntsville)

The possibility of a connection between cosmic radiation and climate has intrigued scientists for the past several decades. The studies of Friis- Christensen and Svensmark have reported a variation of 3-4% in the global cloud cover between 1980 and 1995 that appeared to correlate with the change in galactic cosmic radiation flux over a solar cycle. We present results of a study of geomagnetic cutoff rigidity changes over a 400-year interval. These results show that the change in cutoff rigidity over the last 400 years results in a change of the cosmic radiation flux impacting the earth that is approximately equal to the relative change in flux over a solar cycle. These changes in cutoff rigidity are non-uniform over the globe with both significant increases and decreases at mid-latitude locations. We suggest that in long term studies of possible cosmic ray correlations with climate, not only the solar cycle modulation of cosmic radiation be considered, but also the changes in the cosmic radiation impinging at the top of the atmosphere as a result of the long term evolution of the geomagnetic field.

JSA08/09A/A08-007 — 1045
THE POSSIBLE CONNECTION BETWEEN IONIZATION IN THE ATMOSPHERE BY COSMIC RAYS AND LOW LEVEL CLOUDS

Enric PALLE[1], John C. BUTLER[2], Keran O'BRIEN[3] ([1]Big Bear Solar Observatory, [2]Armagh Observatory, [3]Northern Arizona University)

Recent analysis of monthly mean cloud data from the International SatelliteCloud Climatology Project (ISCCP) have uncovered a strong correlation between lowcloud and the cosmic ray flux for extensive regions of the Earth. New data has been recently released up to September 2001. With it, we have made a new study of the geographical variation of the correlationbetween low cloud and predicted ionization level from cosmic rays at 2kmaltitude. We find a latitude dependence of the correlation that does notcorrespond to that expected from the geographical variation in cosmic ray flux.In addition, we find that there is an unexplained longitude dependence. Moreover,the fact that satellite monitoring of low cloud must frequently be made throughintermediate higher level cloud gave rise to a concern that the result may havebeen influenced by the presence of higher clouds. Here, by excluding days whenmid-level and higher clouds are present, we provide evidence that the low cloudvariation over the period 1983-1994 is real and not due to overlapping higherclouds. Thus, some evidencesupports the connection between cosmic rays and low cloud whilst other evidencemitigates against. We use a toy model to calculate the climatic impact should the correlation be confirmed.We show that, under the most favorable conditions, a reduction in low cloudfactors since the late 19th century, combined with the direct forcing by solarirradiance can explain most of the global warming over the past century but not all.However, this computation assumes that there is no feedback or changes incloud at other levels.

JSA08/09A/A08-008 — Invited — 1130
A LIKELY DECADAL SOLAR-CYCLEEFFECT IN THE TROPICS

Harry VANLOON (Colorado Research Associates)

The availability of global precipitation data after 1978 enables an examinitation of the influence of the 11-years solar cycle on the rainfall associated meteorological elements in the tropics during three solar maxima and two minima. In July-August the mea rainfall in solar maxima was higher than in the minima from India southeastward to the Pacific warm pool in the ocean and in the Intertropical Convergence Zones of the North Pacific and Atlantic Oceans. The mean difference between solar maxima and minima in tropospheric vertical motion and in the mean outgoing long-waveradiation was consistent with the difference in the rainfall: the vertical motion was more upward / less downward and the OLR was from higher cloudtops in the areas higher rainfall in the solar maxima than in the minima. The signal is found in the tropical centers of action. The difference in vertical motion

between maxima and minima of the solar cycle suggests a solar influence on the Hadley and Walker cells. Similar signals are found between extremes in the Southern Oscillation in July-August of the year° in the extremes; but the signals is larger by the factor of two to four.

JSA08/09A/A08-009   1200
THE GLOBAL SIGNAL OF THE 11-YEAR SUNSPOT CYCLE IN THE ATMOSPHERE: WHEN DO WE NEED THE QBO?

Karin LABITZKE (Institut fuer Meteorologie, FU Berlin)

The global structure and the size of the signal of the 11-year sunspot cycle (SSC) in the stratosphere and troposphere was examined in earlier studies. The correlations between the solar cycle and heights and temperatures at different pressure levelswere mainly carried out with the whole data set and only during the northern winters the Quasi-Biennial Oscillation (QBO) was introduced. Here, this work is expanded and it is shown that the QBO must be introduced especially during the northern summers, because the solar signal is very different in the respective phases of theQBO, particularly over the tropics and subtropics. The structure of the solar signal in (northern) summer appears to indicate that the mean meridional circulations (Hadley and Brewer-Dobson Circulations) are influenced by the SSCespecially during the east phase of the QBO. This result may help to find the mechanism through which the solar cycle (and the connected variation of the UV radiation)can influence the atmosphere.

OSCILLATIONS IN THE SUN-EARTH SYSTEM AS MANIFESTATION OF FORCES OF ASTRONOMICAL ORIGIN

Tamara V. KUZNETSOVA, Lev B. TSIRULNIK (IZMIRAN, Russian Academy of Sciences)

Spectra of interplanetary magnetic field (IMF) modulus and solar wind velocity V used measurements in space during 1963-1998 years at 1 AU near the ecliptic plane has been calculated by a method of a non-linear spectral analysis (MGM). The most power (in short-periodic part of the spectra) non-stationary (with varying phase and amplitude) oscillations at periods T=1.3 years detected both in spectrum of B and V are discussed, their parameters are described (time intervals of damping, building up, and regime change of oscillations, time changes of amplitude and phase etc.). It is shown that time changes of the non-stationary oscillations does not depend on 11-year solar cycle that allows placing the source of the oscillations under the convection zone of the Sun. Additional arguments are presented (such periodicity was detected in the spectrum of neutrino flux, in variations in the rate of the Sun near the base of the convection zone with the same period etc). Remarkable feature of the cycle at T=1.3 yr. is that the regime change (from damping to building up) of the oscillations (marked by phase shifts called by phase catastrophes) took place simultaneously both in solar and interplanetary data. Besides, time intervals marked by extreme points of the second derivatives of phase with respect to time of the cycle at T=1.3 yr. coincide with the time intervals of well-known geomagnic jerk events (secular variation impulse). Periodicity 1.3 yr. was extracted from different geophysical data. Possible sources of the Sun-Earth oscillations are discussed. Thorough analysis of the spectra shows that its periods can be interpreted as periods (and overtones) of astronomical periods reflecting dynamics of the external planets of the solar system (starting from the Earth). In particular, oscillations at T=1.3 yr. are forced by perturbed tide forces (this component of the tide force is connected with motion of the Sun relative to the mass center of the solar system) of Mars, Jupiter, Saturn and Uranus. Amplitude of oscillations at T=1.3 yr. is increasing for now. Long-periodic changes in the IMF and V have essentially different character. It is shown determining contribution of the long-periodic parts of the spectra to the changes of velocity and IMF at the Earth's orbit.

TREND DISCOVERED IN TOTAL SOLAR IRRADIANCE DURING SOLAR CYCLES 21-23

Richard Clayton WILLSON (CCSR Columbia University)

Results from a series of satellite total solar irradiance (TSI) observationscovering the period 1978 - 2003 can be combined in a precise composite TSIdatabase by determining the relationship between two non-overlappingcomponents: SMM/ACRIM1 and UARS/ACRIM2. An ACRIM composite TSI time series uses Nimbus7/ERB results to relate ACRIM1 and ACRIM2 demonstrates a significantsecular upward trend of 0.05 percent-per-decade between consecutive solaractivity minima. The PMOD TSI composite of Frohlich and Lean uses ERBSresults to relate ACRIM1 and ACRIM2 and differs from the ACRIM composite in twosignificant respects: a negligible trend between solar minima and lower TSIduring solar maxima. These differences are shown to be artifacts of ERBSdegradation and modifications of Nimbus7/ERB and ACRIM1 published results thatproduce better agreement with the predictions of TSI/solar proxy models.

DYNAMICAL RESPONSE TO THE SOLAR CYCLE

Kunihiko KODERA (Meteorological ResearchInstitute)

The dynamical impact of the 11-year solar cycle is investigated with the focus on the stratopause region where solar ultraviolet heating is greatest. The results of the analysis suggest that in a climatological mean state, the stratopause circulation evolves from a radiatively controlled state to one dynamically controlled during winter in both hemispheres.The transition period is characterized by a poleward shift of the westerly jet. The solar cycle effect appears as a change in the balance between the radiatively and dynamically controlled states.The radiatively controlled state lasts longer during the solar maximum phase and the stratopause subtropical jet reaches a higher speed. The large dynamical response to relatively weak radiative forcing may be understood by the bi-modal nature of the winter atmosphere due to interaction with meridionaly propagating planetary waves and zonal-mean zonal winds. It is suggested that the solar influence produced in the upper stratosphere and stratopause region is transmitted to the lower stratosphere through (i) modulation of the internal mode of variation in the polar night jet and (ii) a change in the Brewer-Dobson circulation. The first process is significant in the middle and high latitudes, whereas the latter is prominent in the equatorial region.

A MODEL OF SOLAR SPECTRAL IRRADIANCE NEAR MG II

Jeff Stanley MORRILL[1], Kenneth P. DERE[1], Clarence M. KORENDYKE[1], Linton E. FLOYD[2], Judith

L. LEAN[1] ([1]E. O. Hulbert Center for Space Research, Naval Research Laboratory, [2]Interferometrics Inc., Chantilly, Virginia, USA)

We are currently developing an empirical model of solar spectral irradiance varaibility near Mg II that combines areas and locations of plage and sunspots with wavelength dependent contrast factors in order to estimate the solar spectrum. These areas are derived from full disk solar images of Ca II K. At UV wavelengths, earlier models have relied on estimated or calculated contrast factors that are often at low resolution. Using quiet sun, plage, and sunspot spectra near 280 nm measured by the NRL HRTS instrument, we have recently derived the wavelength dependent contrast factors for plage and sunspots. We have also examined wavelength dependent limb darkening. In this presentation we will discuss the details of the current model including the use of measured high resolution contrast factors and limb darkening in the 276.5 - 288.5nm region. A preliminary comparison of model results with SUSIM observations will be presented. These comparisons will examine spectral irradiance variations on solar rotational and solar cycle timescales.

WAVELET TRACING OF SOLAR, GEOMAGNETIC AND CLIMATE CHANGES

Dmitri I. PONYAVIN (Institute of Physics, University of St.Petersburg, 198504, Russia)

Wavelet technique was applied to the sunspot, geomagnetic and air surface temperature records in the Northern hemisphere. Patterns of reconstructed wavelet coefficients were compared to find their similarities and coherence at different time and time-scale. We found a quasi 11-year oscillation in theregional temperature time series established since 1930. It was also founda quasi three-cycle periodicity in all studied data. Predictions of the current and future solar cycles, geomagnetic activity and climatic regional changes were made using trends discovered.

JSA08/09P/A08-005   Invited   1550
MODELLING THE INTERACTION OF THE SOLAR AND QUASI BIENNIAL INFLUENCE ON THE STRATOSPHERIC WINTERTIME CIRCULATION

Lesley J. GRAY[1], Simon CROOKS[2] ([1]Meteorology Dept., Reading University, [2]Oxford University, U.K.)

The equatorial quasi biennial oscillation of wind direction in the lower stratosphere is known to influence the propagation of planetary waves in the Northern Hemisphere winter-time. Recent model and data studies have suggested that the equatorial wind direction in the upper stratosphere is also influential on the frequency of sudden stratospheric warmings. The equatorial upper stratosphere is a region that is highly influenced by solar variability and current estimates of the zonal wind anomalies associated with the 11-year solar cycle are of the same order of magnitude as the QBO anomaly in this region. It is possible that these two upper equatorial influences may explain the observed interaction of the solar and QBO signals in northern high latitudes. The recent model and data studies will be summarised. New experiments using both a stratosphere-mesosphere model and a full GCM will then be described. In all studies a zonal wind anomaly at the equator is imposed and the response of the northern polar vortex variability is analysed. Experiments range from a simple comparison of the influence of the upper versus the lower equatorial stratosphere through to simulations that have an imposed QBO throughout the stratosphere and also an imposed 11-year solar cycle.

JSA08/09P/A08-006   Invited   1620
REALISTIC SOLAR SIGNAL IN THE FUB-CMAM

Katja MATTHES, Ulrike LANGEMATZ (Institut fuer Meteorologie, Freie Universität Berlin)

So far, GCM studies have not been able to capture the magnitudeand characteristics of the observed 11-year solar signal in thestratosphere satisfactorily. Here, results from model experimentswith the ″Freie Universität Berlin Climate Middle Atmosphere Model(FUB-CMAM)″ are presented which are for the first timecomparable with observations. The experiments usedrealistic spectral solar irradiance changes, ozone changes from a2D chemical model, and a relaxation towards observed equatorialwind profiles throughout the stratosphere. The results suggest that irradiance and ozone changes alone arenot sufficient to reproduce the observed solar signal in a GCM. Theyemphasize the important role of equatorial winds in achieving amore realistic wind climatology and therefore a more realisticsolar signal. Interestingly, only the magnitude of the anomaliesduring the dynamically active season improves, whereas the summersignal as well as the signal at low latitudes are still too weak. It will be shown that not only the solar signal is reproduced inthe model experiments but also the interaction with the QBO.Similar to observations, major stratospheric warmings occurrpreferentially in the west phase of the QBO during solar maximum years.

JSA08/09P/A08-007   1650
A MECHANISM FOR SOLAR VARIABILITY EFFECTS ON SURFACE CLIMATE

Mark P. BALDWIN (Northwest Research Associates)

Despite the observational, theoretical, and modeling evidence in favor of a solar cycle influence on climate, a coherent mechanism (that amplifies the solar signal in the upper stratosphere and brings it to the surface) is not well understood. I will discuss one possible mechanism that involves wave, mean-flow interaction and would be capable of transmitting circulation anomalies in the upper stratosphere to Earth's surface. In observational data zonal wind anomalies in the stratosphere tend to progress northward and downward through the stratosphere on a timescale of a few weeks. The process of wave, mean-flow interaction in effect amplifies the anomalies as the progress downward from ~1 hPa to below the 100 hPa surface. This mechanism does not appear to be capable of propagating the anomalies from just above the tropopause to Earth's surface, but in observations the anomalies do descend. Once annular mode anomalies are just above the tropopause, they are observed to bias the tropospheric annular mode to be, on average, the same sign as that in the lowermost stratosphere. To date, specific mechanism to couple the stratosphere and troposphere has not been identified. Although several mechanisms could be at work, I will show that most of the evidence points toward an interaction between anomalies in the lowermost stratosphere and synoptic-scale waves in the upper troposphere. Once the waves (specifically, the wave momentum fluxes) are affected, the tropospheric response is a combination of zonal-mean flow adjustment and zonal-mean surface pressure changes. These surface pressure changes are seen as shifts in the surface annular mode, or Arctic Oscillation. The mechanism described above operates on an intraseasonal timescale, but would presumably operate consistently with interannual (or long-term) changes to forcing in the upper stratosphere. Observationally, a considerable difficulty is that the 11-year solar cycle is not the only forcing, and its effects seem to be dwarfed by the QBO and other natural interannual variability. Since the observational data record is less than 50 years,

IA

other effects (the QBO, ozone loss, greenhouse gas increases, etc.) make the signal difficult to see. This mechanism is not specific to the solar cycle, and would also allow for the downward propagation of any other signals from the stratosphere. This mechanism may help explain why the climate system is sensitive to circulation anomalies in the upper stratosphere, regardless of their origin.

JSA08/09P/A08-008   1710

THE MANIFESTATION OF SOLAR ACTIVITYIN CLIMATE CHARACTERISTICS OF THE BAIKAL REGION

Gelii A. ZHEREBTSOV, Vladimir A. KOVALENKO (Institute of Solar-terrestrial Physics)

Long-term ground air temperature (GAT) variations have been analyzed. It is shown that the main meaningful GAT variations in the Baikal region for the period 1881-1960 were caused by solar variability, and the amplitude of these variations was 1 degree. Since the 1960s, with the persisting solar variability influence, the effect of another factor has been observed, the role of which was steadily increasing, and in the last decade it has already exceeded the contribution from solar variability. During the period from 1960 to 1997, the temperature rise, not associated with solar variability, was 1.5 degree. Analysis of the seasonal GAT variations showed that the ongoing variations are most clearly pronounced in the winter-spring period and are associated with the reduction of the stationing time of the Siberian anticyclone. This indicates that the mechanism of realization of the regional climate variability is the global atmospheric circulation rather than a local change in the atmospheric energy balance. It is most likely that this new factor are the global changes in the thermal regime of the atmosphere caused by the anthropogenic effect. An analysis of the data characterizing the forms of atmospheric circulation confirms the assumption made about the determining role of the influence of the global circulation on the Siberian anticyclone's stationing time and characteristics. Since solar cycle 20 (end of the 1960s) there has been a substantial change of the correlation between the zonal and meridional circulation in favor of the latter. Thus the region's ground air temperature is very sensitive to global variations of the atmosphere because of the enhancer: in the form of atmospheric global atmospheric circulation influence on the Siberian anticyclone characteristics An analysis is made of the atmospheric radiation balance elements from stations located in the Baikal region of east Siberia, and from the network of other stations. It is established that in the overwhelming part of the territory, the last 50 years have seen a statistically significant decrease in direct and total solar radiation making up, respectively, 6.3% and 2.5% for 10 years. It is established that the scattered radiation distribution spanning the period 1939-1986 reveals a clear 11-year periodicity. Scattered radiation maxima that are clearly pronounced in the spring-summer period correspond to the minima of solar activity and to maximum intensities of galactic cosmic rays. Since the 1960s-1970s, this correlation has been disturbed. A possible physical mechanism of solar-tropospheric couplings is discussed.

JSA08/09P/A08-009   1730

ABSORPTION PHENOMENA OF SOLAR XUV-RADIATION BY UPPER EARTH ATMOSPHERE IN THE NUMERICAL MODEL OF THE NEUTRAL ATMOSPHERE WMA01

Kirill A. BOYARCHUK[1], I.A. ZHITNIK[2], G.S. IVANOV-KHOLODNY[1], A.V. KARELIN[1], O.P. KOLOMIITSEV[1], A.S. TRUSHIN[2] ([1]Institute of Terrestrial Magnetism, Ionosphere and Radiowave Propagation, [2]Lebedev Physical Institute)

The numerical model of a neutral Earth´s atmosphere - working model of atmosphere 2001 (WMA01), designed in Institute of the Terrestrial Magnetism, Ionosphere and Radiovawe Propagation, was corrected on the basis of the data of atmospheric sounding in X-ray range. The absorption phenomena by a Earth´s atmosphere of solar XUV-radiation observed in the Sun´s images obtained by a telescope TEREK-K (Space Vehicle ˝Koronas-I˝) in May-June 1994 at low activity of the Sun and instrumentation SPIRIT (Space Vehicle ˝Koronas-F˝) in October - November 2001 in a maximum of activity are studied in this research. The images of the Sun were registered on orbit segments when satellites moving in a shadow of the Earth and en satellites moving out of a shadow. So the upper Earth´s atmosphere was sounded at altitudes 100 - 500 kms .The telescope TEREK-K was tuning on spectrum range 175 A and 304 A. The scientific equipment SPIRIT were tuning on spectrum range 175, 304 and 8,42 A. Integral value of absorption, direction of a density gradient of atmosphere, the local variations of absorption on an altitude to scale 1 km can be obtained by using of this technique. This method can essential supplement traditional techniques of research of the upper atmosphere and ionospheres.

THE PHYSICAL MECHANISM OF FAST CHANGES OF SOLAR IRRADIANCE AND CLIMATE

Alexy I. LAPTUKHOV (IZMIRAN, Russian Academy of Sciences)

As known from theoretical hydrodynamics and observations, the rotation of the Sun, stars, atmospheres and liquid nucleuses of planets is differential and unstable. Therefore the Sun fluctuations of angular rotation speed and magnetic field are always observed. It means, that some types of own fluctuations of the Sun (connected to its rotation and internal magnetic field) are unstable. In the established condition amplitudes of fluctuations are such, at which the surplus of energy of fluctuations (generated in unstable types with frequency Fun) is equal to dissipation of energy in all steady modes with frequencies Fsi, i, n=1,2,3, ÅElf, for example, 2Fu1-Fs2=0 (or in more general case in view of a magnetic field: Fun +-Fum +-Fsi +-Fsj=0), then the interaction of modes of fluctuations has resonant character and consequently one is very strong. Let´s speak in this case, that the Sun is in a resonant condition. It is important to understand, that in a resonant condition the amplitude of unstable own (but not forced (!)) oscillations is established minimal (but not maximal). Really, at condition of an almost strict resonance because of strong interaction oscillations modes the surplus of energy (generated in unstable modes) transfers to steady already at SMALL amplitudes of oscillations. Than the condition of a resonance is more precisely executed, the less amplitude established oscillations, the less activity of the Sun and speed of reorganization (change) of his structure, the more time Sun life in such condition. At an exit

---

from a resonant condition (for example, due to slow change of chemical composition as a result of nuclear reactions) the amplitude of fluctuations of unstable modes grows. Activity of the Sun and speed of change of its structure too are increased. Because of it the own frequencies of oscillations change, and the former resonant condition is carried out worse and worse, and the new resonant condition (with other set of own frequencies) is carried out at first poorly, and then it is better and better. In result the Sun passes from one almost stationary and resonant condition in another. The time of such transition is mach smaller then Sun life-time in a resonant condition. More in detail about this mechanism it is possible to read in the published in Russian work:[Laptukhov A.I. A role of nonlinear resonant interactions in fluctuations of the Sun and his evolution // Solar plasma and geomagnetic disturbances. M.1989. p.5-12]. We see, that the evolution of the Sun occurs not to constant speed, but numerous (and already therefore small), short-term jumps. It is quite possible, that now on the Sun begins to occur or already actively there is one of such next jumps. Such transition is accompanied by small changes of all basic characteristics of the Sun, including it energy output. Probably, it explains observable changes of the Earth climate.

SHARP CHANGES AND OSCILLATIONS OF CLIMATE IN SOLAR-TERRESTRIAL DATA IN THE PAST, PRESENT AS BASIS FOR FORECASTING THE FUTURE CLIMATE CHANGES

Tamara V. KUZNETSOVA, Lev B. TSIRULNIK (IZMIRAN, Russian Academy of Sciences)

It is generally recognized that climate regime shifts are connected with sudden changes of other geophysical systems although these systems are controlled by different physical mechanisms. However, this speed and the global synchronicity of climate changes are the major problems in understanding links between the Milankovich forcing of astronomical origin and climate data. Time series of different solar-terrestrial data (on solar activity, geomagnetic field variations, Be-10, C-14, anomaly of global surface temperature, etc) are analysed by a method of non-linear spectral analysis (MGM method) to detect time intervals of appearance of non-stationary oscillations of large amplitude and times of abrupt changes of their oscillation regime. The most power non-stationary (with varying phase and amplitude) sinusoid at mean period T~2230 yr. (and its overtones), reflecting oscillations of non-dipole part of the geomagnetic field in C14 data and variations of long-term solar activity), is connected with climate variability and its abrupt changes. Amplitude of the cycle is increasing for present. It is well-known high correlation between changes of the geomagnetic and gravitational fields. Elements of geomagnetic field are the most sensitive to global changes. In particular, our spectral analysis of the longest data set of the inclination variations on the Earth in Hartland showed: trend described by a polynomial has two extreme points: at t~1815 yr. and at t~1993 yr.; t~1815 yr. is marked by violation of Gnevishev-Ohl rule for solar cycles; t~1993 yr. is marked by the violation of the same rule (1989-1994 yrs is a time interval of deceleration in the Earth's rotation too). Besides, warm phase of SOI lasted during maximal time interval (1990-1995) for all period of observations (140 yr.). Our careful comparative analysis of all results clearly shows that beginning of global changes at present will be marked by global warming, decreasing of the value of the magnetic moment of the Earth, reaching maximum of over-long cycle in sunspot formation and etc; all these features are favourable for abrupt climate changes for the decades after 2012 yr. Analysis shows that the most power cycles of the calculated spectra can be interpreted by periods (and overtones) of astronomical origin. It is possible to separate in orbital motion of each celestial body non-perturbed (Kepler´s) part and perturbed one. The non-perturbed part of tide force characterizes non-evolving orbital motion (analogous to normal part of geophysical fields, for instance, gravitational and geomagnetic); respectively, perturbed part of tide force characterizes evolving orbital motion (analogous of anomalous part that can be extracted from observation). A possible physical mechanism is presented showing a possibility of transformation of signals of perturbed tide forces of astronomical origin (arising during orbital motion of the Earth) to geophysical systems through small variations of dissipative parameters of a dynamo system.

SOLAR AND CLIMATE VARIATION RELATIONSHIP SEARCHED BY STUDYING TREE RING INDEX TIME SERIES FROM CHILE (1588 - 1994 A.D.)

Nivaor Rodolfo RIGOZO[1], Daniel Jean Roger NORDEMANN[2], Heloisa Helena FARIA[2], Ezequiel ECHER[2], Luiz Eduardo Antunes VIEIRA[2], Alan PRESTES[2] ([1]Faculdade de Educaçõ e Tecnologia Thereza Porto Marques (FAETEC) and Instituto Nacional de Pesquisas Espaciais (INPE), [2]Instituto Nacional de Pesquisas Espaciais (INPE))

This work presents a study of the relations between solar and climate variations during the last four centuries by spectral analysis of tree ring index, sunspot number, rainfall and temperature anomalies time series. Trees used for this study were cupressaceous *Pilgerodendron* from Glaciar Pio XI, in Chile. Rainfall and temperature time series from Punta Arenas, in Chile were used. The spectral analysis of tree ring index shows that 11, 22 and 80 year periodicities of the solar cycle were present in tree ring data with 0.95 confidence level. This result suggests a solar modulation of climate variations, as recorded by the tree ring growth. Short-term variations, between 2-5 years, are also present in tree ring data. This spectral analysis shows that both, solar and climate factors, are recorded in the tree ring data.

SOLAR MAGNETIC FIELD AND MASS EJECTIONS DURING CYCLE 23

Ahmed Abdel HADY (Cairo University)

The solar cycle 23 started in 1996 and its maximum was in May 2001. More thanten high energic flares (Proton flares) occurred from solar active region's of large and complex magnetic fields of strength 2500 to 3000 gauss. The mass ejection measured by artificial satellites for proton of energiesmore than 10 Mev. The increased of the solar wind in velocity and density,which occurred after the releasing of the solar eruptive flares was measured by artificial satellites. The geomagnetic storms and the sudden ionospheric disturbance measured by ground stations. The used data will be world-wide solar-geophysical data as that of NOAA, USA and Bejin observatory, China.The results lead to important role of the local magnetic field of the solaractive region in production of high-energetic solar flares and its effect onthe electromagnetic component and dynamic component of the flare. The effect of the magnetic field on the three different phase of the eruptive flare were given (thermal phase , impulsive phase , and recovery phase). Our results in this study, may be help in flare prediction and mass ejection estimation before its reach to the earth and produce geomagnetic storms.

ON THE INFLUENCE OF HELIO-GEOPHYSICAL PARAMETERS ON GLOBAL CIRCULATION PATTERNS

Tomas HALENKA (Dept. of Meteorology and Environment Protection, Fac. of Mathem. and Physics, Charles University)

To represent an objective characteristics of circulation patterns the spectral structure of both stratospheric and tropospheric fields is analysed in terms of spherical harmonics coefficients. The aim of this study is to compare the long-term behaviour of global circulation structures and their connections to some helio-geophysical influence, especially solar activity, solar magnetic field and geomagnetic activity. NCEP/NCAR database of reanalyses is used with appropriate spectral coefficients available for period 1948-2002 four times per day in 28 levels for vorticity, divergence, temperature, etc. Temporal analysis of significant spherical harmonics is introduced as well as the comparison of their changes with respect to the changes of different sets of solar, geomagnetic and global circulation indices. Quite strong connections to a set of extraterrestrial parameters appear for some distinctive shapes of polar vortex. The natural variability connected to the extraterrestrial influence is studied as well as interannual variability with the emphasis to the QBO and ENSO. The systematic review of the appropriate correlations is presented and decadal variability and long-term trends are pointed out for some of wave numbers. The connections between stratospheric and tropospheric circulation is also discussed in terms of coefficients of spherical harmonics affected by extraterrestrial influence. Long-term changes in the variability of the circulation patterns are analysed by means of wavelet analysis as well.

NONLINEARITIES, THRESHOLDS AND SURPRISES: WILL THE FUTURE SURPRISE US?

Michael C. MACCRACKEN (International Commission on Climate)

Climate change can result from external changes in climate forcing and from internal fluctuations that move energy among elements of the climate system. Although changes in forcing can be unexpected and relatively abrupt, it is generally assumed that the large thermal capacities of the oceans and cryosphere are likely to moderate all but the very largest changes (e.g., from asteroid impacts). However, paleoclimatic records suggest that large and relatively rapid shifts in climatic conditions have occurred, at least on scales from regional to semi-hemispheric. As context for this symposium on the potential for large or sudden changes in forcing, this paper will summarize the results of IUGG symposium MC10, which is focused on understanding past and potential future changes in climate that were in the past, or could be in the future, larger, more rapid, or more unexpected than straightforward climate sensitivity analyses would indicate.

LONG-TERM VARIATIONS OF THE MIDDLE ATMOSPHERE SEMI ANNUAL OSCILLATION (SAO)

Dirk OFFERMANN[1], Matthias DONNER[1], Peter KNIELING[1], Annette MENZEL[2], Barbara NAUJOKAT[3] ([1]Department of Physics, Wuppertal University, [2]Department of Ecology, Technical University, Munich, [3]Institute of Meteorology, Free University of Berlin)

Long-term temperature data are available in the upper mesosphere from hydroxyl emission measurements at Wuppertal (5° N, 7° E), in the stratosphere from SSU data, and in the lower stratosphere from the Berlin analysis. Temperatures are influenced by solar forcing from above and by dynamical forcing from below. They are corrected for these effects. The strong seasonal temperature variations in the middle atmosphere allow to define a summer duration by means of a threshold temperature, or by the circulation turn-around. This summer length has changed by a few weeks in the last two decades: it has increased in the mesosphere and decreased in the stratosphere. This will be compared to vegetation data on the ground, where the length of the growing season has increased in a comparable way. The middle atmosphere summer changes are related to considerable changes of the SAO. These changes are found to be anticorrelated in the mesosphere and the stratosphere. Latitude and longitude dependence of the phase changes will be analyzed by means of CRISTA and SSU data. Circulation reversal data in the lower stratosphere go back by more than four decades. They are used to discuss a possible anthropogenic influence on the trends presented, and to give a respective prognosis.

THE EARTHSHINE PROJECT: MEASURING THE EARTH'S ALBEDO. LATEST RESULTS

Enric PALLE[1], Pilar MONTANES RODRIGUEZ[1], Phillip R. GOODE[1], Steve E. KOONIN[2], Jiong QIU[1], Jeff HICKEY[2] ([1]Big Bear Solar Observatory, [2]California Institute of Technology)

Since December 1998, photometric observations of the bright and dark sideof the Moon have been regularly carried out at Big Bear Solar Observatory, withthe aim of determining a precise and absolutely calibrated global albedo of the Earth.The up-to-date synoptic, seasonal and long term variation in the Earth´s albedo are reported in this paper, toghether with comparison with modelled albedo using modern cloud satellite data and Earth Radiation Budget Experiment (ERBE) scene models. The Earth´s albedo has a major role in determining the Earth´s climate. During the past 4 years, a significant increasing trend in the averaged Earth´s reflectance has been detected in the observational data. More scarcedata from 1994 and 1995 allow us to take a longer-term look at the Earth´salbedo variability and the possibility of a response of this parameter to solar activity is discussed. Simultaneously, spectroscopic observations of the earthshine have been carried out at Palomar Observatory. First analysis and comparison betweenthe spectral and photometric observations are also being presented.

VARIABILITY IN SOME NEGLECTED ATMOSPHERIC PARAMETERS

Gufran BEIG (Indian Institute of Tropical Meteorology, PUNE, INDIA)

This talk will briefly touch upon some silent features related to the ´changing atmosphere´ and set the platform for further deliberations. There may be several reasons for such variability some may have long lasting and another may have sporadic impacts. Impact of such effects (natural or anthropogenic) on some of the atmospheric parameters are seldom discussed because they has such slow effects that even their additive results are difficult to perceive. One such example is the ion chemistry of troposphere and stratosphere which gets highly influenced by volcanic eruptions as well as growing level of Human induced greenhouse gases and pollutants led by carbon-dioxide. Emphasis will be placed to such parameters.

JSA09/10A/A08-005   Invited   **1030**

STRATOSPHERIC AND TROPOSPHERIC FORCING OF THE ARCTIC OSCILLATION BY THE 1991 MT. PINATUBO ERUPTION

Georgiy L. STENCHIKOV[1], Alan ROBOCK[1], Kevin HAMILTON[2], V. RAMASWAMY[3], M. Daniel SCHWARZKOPF[3] ([1]Department of Environmental Sciences, Rutgers University, New Brunswick, New Jersey, [2]International Pacific Research Center, University of Hawaii, Honolulu, [3]NOAA Geophysical Fluid Dynamics Laboratory, Princeton University, Princeton, New Jersey)

Observations show that strong equatorial volcanic eruptions have been followed by a pronounced positive phase of the Arctic Oscillation (AO) for one or two Northern Hemisphere winters. To understand the atmospheric processes that cause the AO response, we studied stratosphere-troposphere interaction forced by the explosive volcanic eruption of Mt. Pinatubo on June 15, 1991, which caused the strongest volcanic effect on the atmosphere and climate in the 20th century. Following large volcanic eruptions, the radiative perturbation from stratospheric aerosols exerts a strong influence on the climate system. Volcanic aerosols cool the Earth´s surface because of reflection of solar radiation, and heat the lower stratosphere because of absorption of thermal IR and solar near-IR radiation. The ozone depletion that results from the presence of the stratospheric aerosols also perturbs the radiation. In addition, radiative effects of aerosols and ozone interact with the quasi-biennial oscillation (QBO) that dominates a tropical stratospheric circulation. We implemented volcanic aerosols, observed ozone anomalies, and the QBO in the GFDL SKYHI GCM and conducted a series of control and perturbation experiments to examine the evolution of the circulation in the two years following the Pinatubo eruption. We were able to simulate fairly realistically the observed spatial and temporal structure of stratospheric temperature variations when QBO and aerosol forcings are included. The phase of the QBO appears to modulate climate system sensitivity to a volcanic forcing. The QBO in its westerly phase strengthens the AO response. Because of nonlinear interactions, aerosols and the QBO together produce a stronger response than linear superposition of responses to each of these forcings. Aerosol radiative heating in the tropical lower stratosphere strengthens the equator-to-pole temperature gradient in the lower stratosphere and produces a stronger polar night jet that in turn affects the propagation of planetary waves and tends to cause a positive phase of the AO in winter. Ozone depletion causes a positive phase of the AO in late winter and early spring by cooling the lower stratosphere in high latitudes, strengthening the polar night jet, and delaying the final warming. Aerosol-induced tropospheric cooling in the subtropics decreases the meridional temperature gradient in the winter troposphere between 30N and 60N. The corresponding reduction of mean zonal energy and reduction of amplitudes of planetary waves in the troposphere decrease wave activity flux into the lower stratosphere. The resulting strengthening of the polar vortex forces a positive phase of the AO. We suggest that this mechanism can also contribute to the observed long-term AO trend being caused by greenhouse gas increases, because they also weaken the tropospheric meridional temperature gradient due to polar amplification of warming.

THE GLOBAL CHANGES OF WATER LEVELS IN SOME EARTH SYSTEMS

Nikolay V. SOKOLOV (Water Problems Institute of Russian Academy of Sciences)

There are global changes in Earth Systems that connect with the water intakes for agricultural and industry. The global changes may be seen on regional levels too. Four mathematical models have been created for simulating of these global changes of water levels in earth Systems and it influences on regional levels. The first is a model of simulating to change water´s layers in Dead Sea under influence of men intake water from Jordan River. The creation of this model has been connected with the following. Evolution of water column and the density, salinity and temperature profiles that influenced it were traced from 1960 to 1980. In 1960, as for many years before, a large density difference (caused by a large change in salinity) separated the variable upper layers from the deep fossil waters. By the 1976 the interface between the surface and fossil waters had descended. The upper layers' salinity and density had increased, but in summer warming decreased the surface density. These trends continued in 1977, but there was a new reverse salinity gradient in the summer. In 1978 the salinity was uniform throughout the column; a small temperature difference (arrow) maintained the stability of the fossil water body. In 1979, after the overturn, the fossil water body had been dissipated and the entire column was more saline and somewhat warmer. In 1980 after a rainy winter, there was a new but shallow salinity gradient. These phenomena are study with the aid of a created mathematical model of Dead Sea now. The second environmental model is a model of changes of Aral Sea under influence of men intake waters from rivers that discharge into this Sea. It is well known that the square of this Sea is decreasing now. Salt is moved from squares of former sea bottom to the villages and fields. A socio-economic danger connects with it. The third environmental mathematical model connects with the changes of salinity of Azov Sea. They study process water and salts moving to Azov Sea from Black Sea and rivers of Don and Kuban under influence of increasing of water intakes. They will take into account the change of numbers of fishes in the Azov Sea with the aid of this model. The fourth model is a model of water level decreasing in mountain Sevan Lake. The using of lake´s waters for hydroelectric power stations have led to a decreasing of evaporation and volume of rain´s waters go return to the Sevan Lake. One former island of this lake has been a peninsula under decreased water level. Thus, the changes of water level and some bio-physic characteristics are study in the seas and lakes with the aid of these mathematical models. The socio-economic perspectives are analyzed with the aid of this simulating too.

HORIZONTAL T-S MIXING AND FRONTOGENESIS IN THE WESTERN PACIFIC WARM POOL AREA

Alexander V. SOLOVIEV[1], Roger LUKAS[2] ([1]Oceanographic Center, NOVA Southeastern University, [2]Department of Oceanography, University of Hawaii)

In the western Pacific warm pool, convective rains produce surface ″puddles″ containing salinity and density anomalies. These puddles store significant potential energy, which release plays an important role in the dynamics and thermodynamics of the warm pool area. This effect -- largely ignored by the existing bulk ML parameterizations -- is analyzed here with a nonlinear advection-diffusion one-layer model of Ferrari and Young (1997). Analysis of the nonliner problem allows us to hypothesize the existence of an equilibrium wavenumber range, in which the 1-D spectrum of horizontal T, S, and density inhomogeneity follows a ″k⁻³″ law. A numerical experiment illustrates how nonlinear diffusion transforms initial horizontal density anomalies into the structures with increased buoyancy curvature and leads to a ″k⁻³″ wavenumber spectrum. These structures represent an equilibrium state. The data collected during TOGA COARE demonstrate agreement with the theoretical ″k⁻³″ law, for horizontal wavelengths less than 16 km. The increased buoyancy curvature drives frontogenesis, which requires non-hydrostatic modeling. Incorporation of these results into high-resolution ocean models with bulk ML may improve the simulation of the ENSO cycle.

A PRELIMINARY STUDY OF THE SOFIA FREE TROPOSPHERE/LOW STRATOSPHERE PARAMETERS IN AN ASSOCIATION WITH GLOBAL CHANGES

Staytcho KOLEV (National Institute of Meteorology and Hydrology-BAS,)

Reports in 2001 from the Intergovernmental Panel of Climate Change (IPCC), said unequivocally that human induced climate change was happening and that it was likely to get a whole lot worse. The reports claimed that the carbon dioxide produced from burning fossil fuels was already warming up the world and that if nothing was done it would have all sorts of disastrous consequences. There had been a slight increase in the temperature on the ground. But satellite measurements showed, that higher up in the so-called ″free troposphere″, things didn´t seem to be getting much warmer. Anyhow, the status of the free troposphere became a very big deal. A regionally study of the locally trends of the free troposphere experimental measured parameters will be of great profits to clear up the variability of meteorological conditions controlling the local air pollution dispersion and chemical processes in the atmosphere. The most of the warming predicted in the models came from a feedback involving main meteorological parameters. The aims of the present work are to investigate magnitude changes of the temperatures, dew point temperatures and wind directions at the main isobar standard levels in the free troposphere over Sofia and their tendency.The behavior of these parameters at different altitudes up to 20 km, influenced by the global atmosphere change has been analyzed.

ATMOSPHERIC ELECTRICITY MEASUREMENTS AT MAITRI, ANTARCTICA DURING ANTARCTIC SUMMER

Panneerselvam CHITHIRAIVEL[1], S. GURUBARAN[1], K. JEEVA[1], B.N. RAINA[1], R. RAJARAM[2], A.K. KAMRA[3], C.G. DESHPANDE[3] ([1]Equatorial Geophysical Research Laboratory, Indian Institute of Geomagnetism, [2]Indian Institute of Geomagnetism, Colaba, [3]Indian Institute of Tropical Meteorology)

Simultaneous surface measurements of the atmospheric electrical parameters viz ionosphere to ground currents, electric field and conductivity have been carried out at an Indian station, Maitri (70.75° S, 11.75°E, 117 m above mean sea level), Antarctica, during austral summer for the year of 2001 and 2002. The response of the quality of data to changes in background conditions such as winds, drifting or falling snow; cloudiness, fog effects etc. have been examined and presented in a consolidated form. The measurement shows that atmospheric conductivity is more or less stable during fair weather days at this station. The averaged pattern of diurnal variations in the electric field and vertical conduction current density averaged over fair weather days follow nearly the Carnegie curve, with a minimum at about 03 UT and a maximum near 19 UT. However during magnetically disturbed days, there is a departure from universal diurnal variation in both the electric field and vertical conduction current indicating the influence of solar activity. Day-to-day variation in the diurnal curves of electric conduction current and field, probably due to day-to-day variation in global thunderstorm activity, are clearly evident.

SOLAR AND VOLCANIC EFFECTS ON THE EARTH CLIMATE OVER THE LAST 300 YEARS

Elena A. KASATKINA[1], Oleg I. SHUMILOV[1], Oleg M. RASPOPOV[2], Nils A. MORNER[3] ([1]Polar Geophysical Institute of Kola Science Center RAS, [2]St.-Petersburg Filial of IZMIRAN, St.-Petersburg, Russia, [3]Department of Paleogeophysics and Geodynamics, Stockholm University, Stockholm, Sweden)

The influence of cosmic rays modulated by solar variability and volcanic activity on the aerosol layer is considered. The acidity index obtained from the Greenland ice cores has been used for an analysis. It has been shown that the sunspot numbers correlate with the background value of acidity in Greenland ice, characterizing the variation in the atmospheric aerosol component. This supports the mechanism of the influence of solar and galactic cosmic rays on the aerosol concentration and cloudiness in the atmosphere. The results of the analysis have indicated that acidity records in ice cores can be used to characterize the influence of cosmic rays on climate in the past, after excluding the peaks associated with volcanic activity.

IMPACTS OF THE 11-YR SOLAR MODULATION OF THE SEASONAL CYCLE ON THE GENERIC QBO IN CLIMATE SYSTEM

Hengyi WENG (LASG, Institute of Atmospheric Physics, Chinese Academy of Sciences)

The generic QBO (quasi-biennial oscillation) in climate system, with a cycle-length slightly above or below 2 years, is studied in a simple forced dynamical system. The fundamental cause of the quasi-biennial periodicity of the QBO is the nonlinear subharmonic resonance of the system to the seasonal forcing that is modulated by the 11-yr solar cycle. For a given nonlinearity, the cycle-length and the amplitude of the QBO depend on the intensity of both the seasonal forcing and the 11-yr solar modulation, which may be one of the reasons why the QBO properties in climate vary with time and space.

ENSO - A QUASIPERIODIC FORCED DYNAMICAL SYSTEM

Nadejda Nazarovna IVACHTCHENKO (Hydrometeorological Research Center of Russia)

Several years ago a scenario of the ENSO timing has been proposed connected with an ENSO phase-locking to the annual period.The respective bifurcation sequence from an invariant two-torus, via a resonant limit cycle on this torus, and then either the cycle doubling,tripling, or quadrupling that finishes in chaos is well-known in the mathematical dynamical systems theory for this scenario. Accordinglythis scenario, the shape of the ENSO power spectra must consist of a continuous background with a finite number of power density peakssuperimposed on this background at combinatory harmonics of the annual period. But, the really observed shape of the ENSO spectra isquite different from that. The real ENSO spectra reveal very many peaks within a wide band of frequencies. Many of these peaks cannot be attributed to any sub- and superharmonic of the annual period for certain. Therefore, the proposed phase-locking scenario must be improved.Mention that similar shapes of spectra are inherent to NAO, AO, and NPO too.Thus, it seems there is a common external driver of all of thesephenomena that is more complex than a simple annual periodic forcing.The aim of this report is to show that the shape of the real spectra of ENSO and other above phenomena can be better reproduced if theexistence of a second forcing periodicity at a frequency that is essentially incommensurate to the annual frequency is taken into consideration.In the case of a quasiperiodic forcing, the dynamical systems theory indicates another scenario connected with the arising of an invariantthree-torus, and the subsequent bifurcation of the loss of the three-torus smoothness, and then the arising of the so-called strange nonchaoticattractor(SNA). Typically, the SNA power spectrum consists of innumerable peaks and spikes re-distributed along the frequency axis by a self-similar manner. It is just the shape of the power spectrum that is seen in the real ENSO etc. power spectra.One can suppose that the pole tide excited by the well-known Chandler wobble in the Earth´s pole motion (of the about 14-month-longperiod) may be considered as the second externaldriver of the ENSO etc. dynamics. A parametric excitation seems to be a reason for an enhancement of the ENSO etc. responses to the pole tide force. Because of the ″worst″ incommensurability of the annual and pole tideperiods not only interannual but even interdecadal ENSO, AO, NAO and NPO variability can be excited.Thus, the mystery of the interdecadal variability of these phenomena may be explained.

OBSERVATIONS OF IONOSPHERE TO EARTH CURRENT DENSITY FROM A LOW LATITUDE CONTINENTAL STATION TIRUNELVELI (8.7°N, 77.8°E)

Panneerselvam CHITHIRAIVEL[1], K. JEEVA[1], K.U. NAIR[1], C. SELVARAJ[1], S. GURUBARAN[1], B.N. RAINA[1], R. RAJARAM[1] ([1]Equatorial Geophysical Research Laboratory, Indian Institute of Geomagnetism, [2]Indian Institute of Geomagnetism, Colaba)

The observations of ionosphere to ground current from the low latitude continental station close to the dip equator, Tirunelveli (8.7°N, 77.8 °E), India, are presented in this study. The horizontal long-wire antenna with an effective collecting area of around 140 Sq. Meters is used as a sensor. Results of a comprehensive systematic study of the influence of background winds on the current measurements are presented. It is found that during the summer months no reliable measurements of the air-earth currents can be carried out at the station. On fair weather days during winter and equinox, the mean variations follow the Carnegie pattern except for a clear and persistent sunrise effect. The sunrise effect is observed during fair weather days in both winter and equinox conditions. The measured current starts increase about 30 minute before sunrise and last for nearly an hour and a half. The possibility of the sunrise effect being associated with the sunrise at upper boundary of the global electric circuit in the ionosphere is discussed.

MONITORING OF SCHUMAN RESONANCE AT EQUATORIAL ELECTROJET LATITUDE

C. PANNEERSELVAM[1], C. SELVARAJ[1], K. JEEVA[1], K.U. NAIR[1], S. GURUBARAN[1], B.N. RAINA[1], R. RAJARAM[2] ([1]Equatorial Geophysical Research Laboratory, Indian Institute of Geomagnetism, [2]Indian Institute of Geomagnetism, Colaba)

Using a pair of induction coils, the north-south and east-west components of geomagnetic field have been continuously monitored for more than six months at Tirunelveli (7.8° N, 77.8° E), a station under the equatorial electrojet. The data offers the unique possibility of studying the influence of the equatorial ionospheric conductivity profile on the phenomenon of Schumann resonance. The resonant frequencies were obtained the application of Fast Fourier Transforms on the individual time series. The analysis reveals that the first resonant mode is between 7.75 and 8.0 Hz and the second mode between 14.0 and 14.25 Hz. The strength of individual resonant oscillations averaged over a large number of days reproduces the Carnegie type universal time variations. For further validation the results measured power in the resonances is compared with data of worldwide distribution of the lightning flashes available from the space based observatory (TRMM Observatory). On fairly large number of the days the diurnal variations of strength of the resonance and lightning flashes have a fairly good agreement. The lack of universal agreement is discussed in terms of contamination due to local oscillations not linked with Schumann resonance.

GLACIERS AND SEA ICE

JSH01/07A/C27-001   0940

FORM AND FLOW OF ARCTIC ICE CAPS: REMOTE-SENSING INVESTIGATIONS FROM AIRCRAFT AND SATELLITES

Julian A. DOWDESWELL (Scott Polar Research Institute, University of Cambridge)

The ice caps and glaciers of the Arctic islands make up about 45% of the 540,000 km2 or so of ice outside Antarctica and Greenland. If the small glaciers and ice caps on Greenland and Antarctica are included, there is a global total of 680,000 km2 and about 180,000 km3 of ice, excluding the great ice sheets. In either case, the glaciers and ice caps of the Arctic islands form a significant area and volume of the World's ice. In addition, atmospheric General Circulation Models (GCMs) predict that the Arctic will warm preferentially over the next hundred years or so, relative to lower latitudes, thus making the mass balance of Arctic glaciers and ice caps critical to future projections of global sea level in a warming World. However, the form and flow of many of the larger Arctic ice caps (104 km2) are relatively little known. Satellite investigations of these ice caps, using Landsat and ASTER high-resolution visible-band imagery, yield information on ice-cap area, drainage-basin configuration and, in the case of ASTER, elevation. The drainage basins of Austfonna, Svalbard (8,200 km2) and Academy of Sciences Ice Cap in Severnaya Zemlya (5,500 km2), for example, have been defined in this way. Synthetic aperture radar (SAR) methods have also been used to calculate the ice-surface velocity structure, using phase data, and the distribution of snow and ice on the surface, using backscatter data. The next generation of polar orbiting satellites, IceSat and Cryosat, will provide further opportunities to measure ice-surface elevation to an accuracy of a few tens of centimetres, allowing calculations of change through time. Airborne radio-echo sounding at MHz frequencies remains the only method of acquiring ice-thickness data over large areas, and this method has been used to derive the thickness and ice volume of a number of large ice caps in the Arctic islands of Canada, Svalbard and Russia. Combining data on marginal ice thickness and velocity allows calculation of the mass loss through iceberg production from these ice masses. In some cases, iceberg calving may account for about 40% of total mass loss from marine-terminating Arctic ice caps.

JSH01/07A/C27-002   1000

APPLICATION OF ASTER IMAGES TO ESTIMATE GLACIER SYSTEM CHANGES IN THE CENTRAL TIEN SHAN DURING THE SECOND HALF OF THE 20TH CENTURY

Tatiana Y. KHROMOVA[1], Mark B. DYURGEROV[2], Roger G. BARRY[3] ([1]Department of Glaciology, Institute of Geography Russian Academy of Sciences, [2]Institute for Arctic and Alpine Research (INSTAAR), University of Colorado, Boulder,US, [3]National Snow and Ice Data Center (NSIDC), University of Colorado, Boulder,US)

The optical satellite sensor ASTER (Advanced Spaceborne Thermal Emission and Reflection Radiometer) on board Terra offers new possibilities for worldwide glacier monitoring. We present the results of comparisons of glacier-extent and volume determined by comparison of ASTER-imagery taken in September 2001 with two repeated-mapping surveys by aerial photography in 1943 and 1977 over the Akshirak Glacier system, central Tien Shan. The Akshirak Range reaches 5,100 m asl, or about 1500 m above the central Tien Shan plateau (43°N, 75°E). The range is heavily glacierized with a total ice area of about 400 km2. The ENVI, ERDAS, ARC/GIS, and ARC/View software packages were used to manipulate, transform and overlay the ASTER image and historical data for the Akshirak Range. A substantial change in glacier area is observed to have taken place since the 1977 survey. The changes involve: a decrease in average size of glaciers, an increase in the area of outcrops and in the perimeters of water divides between individual glaciers, the appearance of new glaciers and disappearance of former small ones. The number of glaciers has not changed greatly. A significant loss of glacier area locally has been caused by the direct impact of the exploitation of mineral resources.BRThe changes in climate, based on data from a meteorological station located on the high plateau at 3614 m a.s.l., close to glacier termini of the Akshirak Range, show increases in summer and annual air temperature and decrease in annual precipitation. Moreover, the ratio between summer (June-August) and winter (October-May) precipitation has decreased especially since the mid-1970s accompanied by increased summer air temperature. This presents the most unfavorable climatic conditions for glaciers in Central Asia where summer precipitation plays the crucial role in the annual mass balance. Our findings confirm the results of earlier studies of the regime of Tien Shan glaciers and their sensitivity to summer conditions. BROur study illustrates the value of combining remotely sensed data and historical observations to monitor ongoing changes in glaciers. The disintegration of the compact high-altitude Akshirak glacier system in Central Asia has been identified and the increased glacier wastage quantified.

JSH01/07A/C27-003   1020

DISTRIBUTION OF CRYOCONITE ON THE SURFACE OF A GLACIER DERIVED FROM A LANDSAT TM IMAGE

Nozomu TAKEUCHI[1], Reginald R. MUSKETT[2] ([1]Research Institute for Humanity and Nature, [2]International Arctic Research Center, University of Alaska Fairbanks)

Cryoconite, biogenic surface dust on the glacial surface, can affect the surface albedo of snow and ice thereby accelerating ablation. Distribution of cryoconite on the surface of an Alaska glacier (Gulkana Glacier in the Alaska Range) has been analyzed using Landsat TM band 2 and 5 ratio. The band ratio was relatively lower in the area near terminus and snow line in the ice area, suggesting higher cryoconite concentration in this area. In situ measurement of cryoconite on the glacier agreed with the cryoconite distribution derived from the band ratio. The biological analysis of the cryoconite collected from the glacier revealed that the cryoconite distributed in the area near the terminus mainly consisted of mineral particles, and that the cryoconite near the snow line, on the contrary, contained large amounts of snow algae and dark-colored organic matter. Results suggest that the albedo reduction by biological activity is significant in the area near snow line on the glacier. Depending on the percentage area distribution of the biological activity, the albedo reduction could affect glacier mass balance during the ablation season. A positive feedback may exist between biological activity and abnormally high melt rate years as a consequence of global warming in the northern hemisphere. Research is continuing to investigate the biological activity - albedo reduction with satellite imagery and in-situ field measurements on other glaciers with wide geographic distribution in Alaska and Central Asia.

JSH01/07A/C27-004   1140

ANALYSIS OF ASTER AND PANCHROMATIC IMAGES FOR SURFACIAL CHARACTERISTICS OF THE GANGOTRI GLACIER, GARHWAL HIMALAYA, INDIA

Syed Iqbal HASNAIN, Sarfaraz AHMAD, Meenakshi YADAV (School of Environmental Science, Jawaharlal Nehrij University)

Quantitative and qualitative analysis of the Gangotri glacier surface and various geomorphological features have been carried out by using ASTER (Advance Spaceborne Thermal Emission and Reflection Radiometer) and Panchromatic IRS 1D image and field studies. The area of the main Gangotri glacier is about 77 km2 in 2001 Panchromatic image, while this area is 87 km2 in the toposheet surveyed in 1985. This implies that glacier has vacated about 12% area in last 17 years. The entire glacier area between snout and accumulation has been divided into three zone on the basis of tonal and textural characteristics. Zone 1 ranging between 3975 and 4507 masl is characterised by non-uniform thick debris-cover with highly fractured ice, whereas Zone 2 is less fractured and characterised by uniform thin debris-cover. At junction of Zone 1 and Zone 2 between elevation 4507 and 4663 masl, there are about six ice-dammed lakes varying in size between 25 - 200 m2. Moraine are better identified by ASTER as compared to Panchromatic IRS 1D image, as it provide different spectral signature for dry and ice covered debris.

JSH01/07A/C27-005   1200

APPLICATIONS OF SEA-ICE MOTION AND DEFORMATION DERIVED FROM SATELLITE DATA

Antony K. LIU, Yunhe ZHAO (Oceans and Ice Branch, NASA Goddard Space Flight Center)

QuikSCAT backscatter and DMSP SSM/I radiance data have been used to derive sea ice motion for both the Arctic and Antarctic region using the wavelet analysis tracking method. Both results from QuikSCAT and SSM/I are compatible with buoys and can then be merged by data fusion method to generate composite sea ice motion maps for more complete coverage. Furthermore, based on this merged data set daily sea-ice deformation (shear, and convergence) maps have been produced and show consistent spatial and temporal patterns. Temporal correlation maps between ice deformation and SSM/I ice concentration show interesting results in the Arctic, especially in the coast area. In this study, principal component analysis to both the merged ice tracking result from satellite data and pressure field from buoy has also been examined for the relationship between the principal components and eigenvectors from these two data sets. While the result shows that principal components of modes 1 and 2 from two data sets are highly correlated which confirms that wind forcing is a major factor driving the ice drift, it also reveals that other high-energy modes are not highly correlated which maybe caused by coastal effects. Principal component analysis of sea-ice motion during fall/winter period in different years has also been used to correlate with the results of Arctic Oscillation study.

JSH01/07A/C27-006   1220

IMPROVING THE NEAR-REAL TIME QUIKSCAT/SEAWINDS SEA-ICE EDGE

Joerg HAARPAINTNER[1], David G. LONG[2], Mike L. VAN WOERT[1] ([1]Polar Science Team, National Ice Center, [2]MERS Laboratory, Brigham Young University)

The current QuikScat/SeaWinds sea ice edge is a daily product and part of the operational data set at the National Ice Center in Washington DC. The sea ice edge is extracted from the near-real time resolution-enhanced SIR data that are 36-hour composites of the Polar Regions. Given the highly dynamic nature of the marginal ice zone and the importance of the daily standard deviation in the algorithm to separate ocean from sea ice, the extracted ice edge corresponds to high ice concentration above 50%. The main reason for not detecting low concentrations is that the temporal variability of the location of the ice edge exceeds the effective resolution of the composite by up to an order of magnitude. By reducing the integration time for the composites, we can therefore improve locally the determination of the ice edge to lower ice concentration and new ice. In this paper we study the optimal balance between maximum resolution and minimum integration time to detect the lowest possible ice concentration.

PERMAFROST

JSH01/07P/C27-001   1400

GEOPHYSICAL MONITORING OF HYDROTECHNICAL OBJECTS IN PERMAFROST ZONE

Vyatcheslav Aleksandrovich ISTRATOV[1], Svet Yurievich MILANOVSKY[2], Sergei Aleksandrovich VELIKIN[2] ([1]Radionda Ltd, Moscow, [2]Institute Physics of the Earth RAS, Moscow, [3]Vilui Permafrost Research Station of Permafrost Institute RAS, Chernishevskii)

Frozen rocks in permafrost zone are very sensitive to natural and man-caused influences because of possibility of phase transition from frozen state to thawed and back. Together with temperature field, fluid mineralization and hydrogeological conditions determine durability of the rock massive and it's mechanical properties. We discuss peculiarities of temporal and spatial changes in frozen soils that are primarily conditioned by constitutional ice - pore solution transformations. During these transformations all physical properties of frozen medium change, the most sensitive of which are electrical and mechanical. The hydro technical engineering objects which are carried up in permafrost zone like Western Sakha Yakutia, are exposed to action of a different sort of the negative factors step-by-step resulting some of them in a labile state, down to catastrophic. Owing to these circumstances for last 5-8 years on a number of hydro technical objects of Western Sakha Yakutia are observed thawing-filtration processes, are found out local filtration zones posing under threat their secure exploitation. Due to a difficult and hardly predictable geocryological situation in this area, the geophysical methods were included into the system of local monitoring. Authors present original results of long-term geophysical study on hydrotechnical objects (constructing and exploiting reservoirs) analyzing problems associated with use of geophysical methods for the study of rocks and soils in permafrost area. We present results of complex experimental control observation of the development of filtration process. More and more relevant role in these studies is gained with a georadar study. The georadar observations were carried out on Mirnii region in a complex with electric-prospecting observations and temperature logging. The georadar SIR 2000 (production of the company GSSI, USA) with antennas 40, 200 MHz was applied. The data were processed with software packages RADAN (GSSI, USA) and RadExPro + (GSD Production, Russia). The purpose of inter-well radiowave investigations was, first, to control the frozen rock thawing (talik) within the coastal zone of the reservoir and to assess the dynamics of the process, and second, to identify and to locate places of the most intensive thawing and filtration of

water from the reservoir. Thawing process leads to a decrease of electrical resistivity. Besides, the high saturation of the filtering layer must be reflected in an increase of relative dielectric permittivity within the same interval. As a result of these observations the quite good correlation between applied geophysical methods was established. The most interesting results of observations documented by excavation and visual observations will be presented in the report. On the base of detailed surface and boreholes geophysical observations the 2D-numerical model of the part of right-bank contiguity was done. The model shows temperature evolution of thawing zone as a function of air and water temperature, lithology, thermal properties of the section. Observed geophysical data compared with numerical modeling.

JSH01/07P/C27-002   1420

PERMAFROST MAPPING AND DEFORMATION MONITORING USING SAR INTERFEROMETRY

Zhen LI, Xinwu LI, Xin REN, Qing DONG (Institute of Remote Sensing Applications, Chinese Academy of Sciences)

The interferometric SAR technique has demostrated its capability to measure ground deformation in wide range of application. For the purposes of some applications, especially those that involve engineering projects, a quantitative use of the InSAR results must be required. The seasonal transition of the land surface between frozen and non-frozen codition affect a number of ecological and hydrological processes the cycle between wintertime dormant and summertime active states. At the same time, the freeze/thaw transition will cause the deformation of ground surface, which is the main factor for engineering construction in pemafrost region. At microwave frequencies, freezing results in a dramatic decrease of the dielectric constant of soil, which significantly decreases their radar back-scattering properties. The obvious difference on soil moisture between frozen and unfrozen area can be detected by SAR images. Usually, soil and vegetation are considered as a single medium when single-polarization, single-frequency SAR data is employed. But the vegetation covered on the permafrost will influences the permafrost detection, because of the volume scattering effect of vegetation. The permafrost and the seasonal frozen ground cover respectively 1,272,709 km ^{2} and 1,146,399km ^{2} in the Tibetan Plateau. China begins construction of Qinghai-Tibet railway in 2002. The first handicap will be the permanent frozen earth. About 550km of the railway will pass through such areas. Continuous permafrost and some island permafrost underlie the entire region, and the maximum active-layer depth at the site reached approximately 0.4-1.5m. Extensive areas of frozen ground hold large quantities of moisture in wintertime conditions. Thawing and temperature rising has a great influence on railway stability. In order to study the process of railway building deformation for different permafrost types and geophysical environments, deformation monitoring is very important. In this study, 6 scences SAR SLC images, including Tandem data, are used to produce multiple interferograms. The techniques to classify permafrost using SAR data, conherence analysis, and two typical methods for deformation detection are discussed. One method is the InSAR measure with the high accurate DEM used to reduce the terrain effect, the other is differential InSAR. The results be validated and compared quantitatively base on precise and accurate geodetic data derived from field measurement. We analyzed the precision and reliability of two methods. The suitable technique is chosed for deformation monitoring using ERS-1/2 SAR data in Qinghai-Tibet Plateau. Then, an InSAR monitoring system of frozen ground deformation is proposed for the Qinghai-Tibet railway building.The results showed that multi-temporal SAR data could be used to discriminating permafrost from other targets with high accuracy, and interferometrical SAR are fairly good use to permafrost deformation monitoring.

JSH01/07P/C27-003   1440

REMOTE SENSING DETERMINATION OF THE PERMAFROST THICKNESS

Vil S. YAKUPOV, Sergey V. YAKUPOV (Institute of Space Physic Research and Aeronomy)

The possibility of increasing by factors power potential (PP) of pulsed-tipe radar sounding station (RSS) based on super-conductivity technology magnetic moment generators and SQUID-magnetometers allow to use it for frozen strata thickness determination. For this purpose the remote sensing survey becomes possible both from the ground and the air. Let us estimate the depth to which it might be possible to determine frozen strata thickness at different assumptions about electrical properties of frozen and underlying it thawed rocks considering them homogenous. Let resistivity of frozen rocks ρ be equal 300, 1 000, 3 000 and 10 000 Ω m and resistivity of frozen unconsolidated deposits with massive cryogenic texture — 1 000, 3 000 and 10 000 Ωm. Relative permittivity ε for them be equal 9 and 4 in frozen condition and 15 for thawed ones. Then limits of possible values of Frenel coefficient will be 0,1 (for rocks) and 0,3 (for unconsolidated deposits), with specific absorption 0,18 — 0,05 dB/m (ε = 9) and 0,8 — 0,1 dB/m (ε = 4) accordingly. The possible depth of investigation for lower boundary of permafrost when PP = 560 dB and ε = 4 (unconsolidated deposits) will be for ρ = 1 000 Ω m 410 m, for ρ = 3 000 Ω m — 1 230 m, for ρ = 10 000 Ω m — 3 900 m. When it is possible to accumulate reflected signals to increase PP up to 600 dB these depth estimations will be 450, 1 340 and 4 300 m. For frozen rocks (ε = 9) these values will be 125 (ρ = 300 Ω m), 400, 1 200 and 3 800 m when PP = 560 dB and 135, 440, 1 300 and 4 200 m when PP = 600 dB. Remote sensing from air (PP = 560 dB) decreases these estimates to 370, 1 150 and 3 500 m for unconsolidated deposits and to 120, 380, 1 150 and 3 500 m for rocks due to losses on double passing the air-ground boundary. Simultaneously another important task can be solved: determination of frozen unconsolidated deposits thickness if the resolution of their lower boundary in relation to the ground surface and to the lower boundary of frozen rocks can be achieved. Identification of found interface nature could be made by comparing its depth with drilling and direct current sounding data. Thus, the possibility of remote sensing determination of the frozen strata and, as well, of frozen unconsolidated deposits thickness seems to be real using radar sounding by mighty magnetic pulses both from the ground and the air everywhere when $\rho \geq 1$ 000 Ω m if the resolution of their lower boundaries is possible.

JSH01/07P/C27-004   1500

DETECTING THE NEAR-SURFACE SOIL FREEZE-THAW CYCLE USING A COMBINED FROZEN SOIL ALGORITHM

Tingjun ZHANG, Richard L. ARMSTRONG, Jeff SMITH (National Snow and Ice Data Center, University of Colorado at Boulder)

Better knowledge and understanding of the near-surface freeze/thaw cycle of soils are prerequisite for evaluating the impact of cold season/cold region processes on surface and subsurface hydrology, regional and global climate, carbon exchange between the atmosphere and the land, and the terrestrial ecosystem as a whole. The challenge is to develop new techniques and methodologies to obtain data and information of the near-surface soil freeze/thaw cycle. A combined frozen soil algorithm was developed and validated to detect the near-surface soil freeze-thaw cycle over snow-free and snow-covered land areas. The combined frozen soil algorithm consists of two parts: (i) over snow-free land areas, passive microwave satellite remote sensing algorithm was used to detect the near-

surface soil freeze-thaw cycle; (ii) over snow-covered land areas, a one-dimensional numerical heat transfer model with phase change was used to detect soil freeze-thaw status under snow cover. Using the Defense Meteorological Satellite Program's Special Sensor Microwave Imager (SSM/I) data, the passive microwave satellite remote sensing algorithm utilizes a negative spectral gradient between 19 GHz and 37 GHz, vertically polarized brightness temperatures and a cut-off brightness temperature at 37 GHz with vertical polarization (TB(37V)). A cut-off brightness temperature of 258.2K was obtained based on a linear correlation (r2=0.84) between the soil temperature at 5 cm depth and the TB(37V). Soil temperatures used in the correlation were measured from 26 stations over the contiguous United States for the period from July 1, 1997 through June 30, 1998. Using soil temperature data measured from the same stations for the period from July 1, 1998 through June 30, 1999, the combined frozen soil algorithm provides the accuracy of frozen soil detection of about 76% and the correct classification of both frozen and unfrozen soils of approximately 83% with the percent error of about 17%. The combined frozen soil algorithm was used to investigate the timing, duration and number of days, and daily area extent of the near-surface frozen soils from July 1, 1997 through June 30, 1999 over the contiguous United States. The primary results indicate that the maximum area extent of frozen ground during the winter of 1997/98 was about 4.4 x 106 km2 or 63% of the total land area of the contiguous United States, while during the winter of 1998/99, the maximum extent was about 5.2 x 106 km2 or 74%. The duration of the seasonally frozen ground ranges from less than one month in the south to over eight months in the Rocky Mountains. The actual number of days of soil freezing varies from a few weeks to more than several months. Further validation is needed to improve the accuracy of frozen ground detection and to estimate thickness of the seasonally frozen ground using the combined frozen soil algorithm.

ELECTROMAGNETIC DIAGNOSTICS OF PERMAFROST OF THE NORTHEAST PART OF THE RUSSIA BY MEANS OF GROUND AND REMOTE METHODS OF RADIOIMPEDANCE SOUNDING AND PROFILING

Mikhail Georgievich DEMBELOV[1], Yuri Buddich BASHKUEV[1], Viktor Petrovich MELCHINOV[2], Ludmila Khanharaevna ANGARKHAEVA[1] ([1]Buryat Scientific Center SB RAS, [2]Yakut State University)

The report is devoted to detail research of electrical properties of the permafrost of the northeast part of the Russia. Regions of the Aldan plateau, the central Yakutia and tundra areas that are near the Arctic Ocean coast are objects of investigations. The aim of the research is to define of its electric characteristics and to create geoelectric models of different types of the permafrost. The main results: 1. Detail physical description and classification of electric properties, construction and structure of the permafrost on the depth of skin-layer in the VLF range is offered. 2. According to measurements on typical cryogen rocks systems the season variations of geoelectric sections (GES) parameters, surface impedance and electromagnetic field are discovered. The geoelectric model for a permafrost stratified section that takes into account main climate generating factors and season processes for freezing and thaw of grounds is developed. The model of stratified medium with structure and properties that are changed depending on climate conditions describes season impedance variations of the border surface and ground electromagnetic field. The model allows to predict propagation of VLF-MF electromagnetic waves over permafrost paths in different year seasons with the precision that is enough for practice. 3. It is established that frequency dispersion of the electric resistance of the frozen friable sediments layer between direct current and high frequency currents of VLF-MF ranges is a feature of electric properties of the permafrost. A good conformity between calculated values obtained from data of vertical electromagnetic sounding (VES) and measured values of surface impedance of the horizontally stratified cryogen medium for areas of ˝high temperature˝ frozen layers disposition and for cases of small contrast of GES layers is received. This fact confirms absence of the frequency dispersion of electric properties of frozen layers that are in position close to melted condition. A difference of electric resitivity (ER) on direct and alternating currents for GES that have frozen friable sediments is established. ER values that are reconstructed after the inverse problem solution on data obtained from radioimpedance sounding are less in 3-10 times that on data obtained from VES method. A physical interpretation of obtained results for frozen layers that takes into account the influence of conductive engaging in multi-phase heterogenic medium is offered. 4. A method of physical-statistical prediction of the geoelectric section for main types of permafrost is developed. The predicted map of geoelectric sections of the Yakutia and geoelectric maps of the Aldan plateau with different scales are created. 5. A method of radioimpedance sounding and profiling in VLF-MF ranges for ground electric cartography of Arctic lakes and coastal zone of the Arctic Ocean area of water on resitivity in the framework of multi-sectional model of the ground with high and low conducting foundation is developed. 6. An estimation of efficiency of the vertical electric transmitter in LF-MF ranges of electromagnetic waves is made. It is shown that the efficiency for emitted antennas situated on the permafrost does not exceed 28 per cents.

JSH01/07P/C27-006   1600

COMBINING REMOTE SENSING ADVANCES, DATA RELAY, AND INTERLINKED HYDROLOGIC MODELS TO IMPROVE SNOWMELT RUNOFF FORECASTING IN THE RIO GRANDE BASIN

Albert RANGO[1], Enrique GOMEZ-LANDESA[1], Max BLEIWEISS[2], David DEWALLE[3], Geoff KITE[4], Jaroslav MARTINEC[5], Kris HAVSTAD[1] ([1]USDA/ARS/Jornada Experimental Range, New Mexico State University, 2995 Knox St., Las Cruces, NM 88003, USA, [2]Department of Entomology, Plant Pathology, and Weed Science, New Mexico State University, Las Cruces, NM 88003, USA, [3]Pennsylvania State University, 107 Land and Water Building, University Park, PA 16802, USA, [4]Hydrologic Solutions, Bryn Erthin, Cefn Bychan Road, Pantymwyn, Flintshire, WA CH7 5EN, UK, [5]7270 Davos-Platz, Switzerland)

Remotely-sensed data can be used with modern hydrological models to provide effective snowmelt-runoff forecasts and to evaluate water resource management options. MODIS, on both TERRA and AQUA satellites, is likely the optimum sensor for snow mapping because it has a best resolution of 250m (two bands), it passes over daily, it is free from downloading, and it provides a logical transition from l km NOAA-AVHRR data. Its worth for snow mapping has been proven both in the Rocky Mountains of the United States and the Pyrenees of Spain. Still, research to solve automated and operational problems is ongoing including correction of the ˝ Bow Tie˝ effect, mapping in shaded and heavily vegetated areas, and using bidirectional reflectance distribution functions to retrieve snow albedo. As the remote sensing improvements are made, the data are used in the Upper Rio Grande Basin for improvement of the snowmelt forecasting system. Remote snow water equivalent site data is acquired through the Natural Resources Conservation Service SNOTEL system employing meteor-burst relay. These data can be used for early season (November-December) volumetric forecasts which increase water management flexibility. The MODIS-derived snow cover data are input to the Snowmelt Runoff Model (SRM) for generating daily streamflow forecasts over the entire melt season. Because snowmelt runoff is not significant throughout the entire basin, SRM outflow from snowmelt basins is linked to the Semi-

distributed Land Use-based Runoff Process(SLURP) model as an input. SLURP is a comprehensive distributed model now operating on the entire Rio Grande basin to assist in water management decision-making today and to evaluate future scenarios for improving long range planning. SLURP also uses remote sensing inputs to establish current land cover throughout the basin. Examples of forecasts made from 2001-2003 in the Upper Rio Grande basin are presented.

JSH01/07P/C27-007   1620

THE SNOW WATER EQUIVALENT SCALING EXPERIMENT: OVERVIEW AND INITIAL RESULTS

Chris P. DERKSEN, Chris P. DERKSEN, Anne E. WALKER, Barry E. GOODISON (Climate Research Branch, Meteorological Service of Canada)

Passive microwave snow water equivalent (SWE) retrieval algorithms are influenced by a range of land cover and snowpack state variables that are present at a range of scales. Because of the relatively low levels of naturally emitted microwave energy, pixel dimensions of spaceborne passive microwave brightness temperatures are large (10 to 25 km). A single passive microwave derived SWE estimate, therefore, integrates multiple land and snow cover conditions into a single measurement. Multi-scale brightness temperature datasets with coincident ground sampling are required to quantify the impact of spatially heterogeneous land cover and snowpack properties on passive microwave SWE retrievals.New multi-scale research datasets will be acquired through the Snow Water Equivalent Scaling Experiment, conducted near Prince Albert, Saskatchewan, Canada in February 2003. Passive microwave brightness temperature datasets will be acquired from tower-based sensors, airborne radiometers (100 m resolution), and spaceborne sensors (Advanced Multichannel Spaceborne Radiometer — AMSR ~ 10 km resolution; Special Sensor Microwave/Imager — SSM/I ~ 25 km resolution) for a 25 by 25 km study area centred at the Old Jack Pine Boreal Ecosystem Research and Monitoring Site (BERMS). A coincident ground sampling program will characterize in situ SWE, depth, and density using a land cover sensitive sampling scheme. A suite of micrometeorological variables from seven distributed tower sites will complement the passive microwave brightness temperature and in situ snow datasets, while land and forest cover datasets including land cover type, canopy closure, and forest stem volume have already been obtainedThis presentation will provide an overview of the field experiment, and results of initial dataset analysis. A preliminary investigation of pre-campaign airborne microwave data indicates that a high degree of brightness temperature variability is evident along individual flight lines, with strong associations to forest cover properties. Following full airborne dataset acquisition in February, various scaling techniques will be used to link the variability in small footprint airborne brightness temperatures with the coarse scale spaceborne AMSR and SSM/I data. The degree to which brightness temperature variability is captured by the 10 km AMSR data relative to the 25 km SSM/I data will be determined. The in situ snow measurements will illustrate the variability in SWE, depth, and density that can be found on spatial scales ranging from individual trees and clearings to inter-species stand-to-stand variability. The distributed micrometeorological data will be used to identify physical influences on brightness temperature variability. For instance, species specific relationships between tree temperature and air temperature have clear impacts on measured brightness temperature in forested environments. Ongoing analyses of these datasets will advance our understanding of important scale and process issues related to the remote estimation of SWE.

JSH01/07P/C27-008   1640

ESTIMATION OF SNOW WATER EQUIVALENT AND SNOWMELT WATER USING THE SNOW INDEX -A CASE STUDY IN THE KUROBE BASIN, JAPAN-

Yuichi SHIMAMURA, Takeki IZUMI, Daichi NAKAYAMA, Hiroshi MATSUYAMA (Department of Geography, Graduate School of Science, Tokyo Metropolitan University)

The snow index ´S3´ (Saito and Yamazaki, 1999) is applied to Landsat-5/TM images, to estimate the snow water equivalent and the snowmelt water. This index considers the mixel of snow and plants using reflectance of one visible (Band 3 of TM) and two infrared (Bands 4 and 5), so the index should obtain the distribution of the snow-covered area under the plants more exactly than other indices using only visible band(s). ´S3´=B4*(B3-B5)/{(B4+B3)*(B4+B5)} ´S3´ was developed for ADEOS-II/GLI, but the satellite has just been launched on 8th December, 2002. This research is, therefore, the first case to apply ´S3´ for satellite data. In the Kurobe basin (Toyama prefecture, Japan) in the spring of 1986, the snow-covered area is clustered from ´S3´ with threshold value of 0.0 which is proposed by Saito and Yamazaki (1999). Then, the gross volume of the snow water equivalent is estimated with the relationship that snow water equivalent increases linearly with altitude. When Landsat-5 passed over the study area, the snow water equivalent can be calculated from the altitudinal distribution of the snow-covered area and the increasing ratio of the snow water equivalent; the ratio is called ´altitudinal distribution factor´ and the value in the basin was surveyed by KEPCO (the Kansai Electric Power Co., Inc.) in 1959. The amount of the snowmelt water is calculated as the difference of the snow water equivalent estimated by two scenes (14th and 30th April, 1986). In this study, there are no ground truth data, so results are validated indirectly by the estimation error of snowmelt water. The relative error is based on the difference between the estimated amount of the snowmelt and the observed runoff which flowed into the Kurobe-daiyon-dam (Kuroyon dam) from 14th to 30th April, 1986. When ´S3´ is used for extracting the snow-covered area, the estimation error is -8.2 percent. Even if the effect of rainfall and time lag of snowmelt-runoff are taken into account, the error ranged with in ±10 percent. While the snow-covered area is extracted by the other method which does not consider the disturbance by vegetation, the error is as large as -23.8 percent. Since ´S3´ can capture the ground snow under the plant canopy, the index has higher precision. Namely, this guarantees the snow index ´S3´ as the better method for extracting the snow-covered area.

JSH01/07P/C27-009   1700

STREAMFLOW RESPONSE TO SNOWCOVER EXTENT CHANGE IN LARGE SIBERIAN RIVERS

Daqing YANG[1], David ROBINSON[2], Yuanyuan ZHAU[1], Thomas ESTILOW[2], Baisheng YE[3] ([1]University of Alaska Fairbanks,, [2]Rutgers University, [3]Chinese Academy of Sciences)

The Lena, Yenisei and Ob rivers are the three largest rivers in the Arctic regions. They contribute more than 45% of total freshwater inflow to the Arctic Ocean and have great impacts to the regional/global ocean and climate systems. Snowcover melt and associated floods are the most important hydrologic event of the year in the northern river basins. To better understand the streamflow regime and variation in the high latitude regions, this research uses the weekly NOAA snowcover extent data to study the streamflow hydrology in Siberia. The focus of this research is to examine the streamflow response to snowcover extent change on a weekly basis particularly during the spring melt period. In this analysis, we calculated the basin-mean snowcover extent over the watersheds for the entire NOAA records (1966-present) and generated a weekly snowcover time-series. We used these weekly data to examine the seasonal changes of snowcover extent, such as defining the

weekly snowcover climatology, determining the dates of snowcover formation/disappearance and duration of snowcover, and quantifying the rates of snowcover change during the accumulation and melt seasons. We examined the weekly correlation of streamflow with basin-mean snowcover extent, and determined the consistency between snowcover and runoff changes during the snowmelt period. We also investigated the associations between snowcover and runoff anomalies, identified extreme snowmelt runoff cases, and examined their correspondence with snowcover and climate conditions. Based on these analyses, we defined the weekly relation between snowmelt runoff and snowcover changes for the watersheds.This study explores the potential of using remotely sensed snowcover information to improve our capability of snowmelt runoff modeling and forecasting over large northern river basins. The results demonstrate that the NOAA weekly snowcover extent data are useful for understanding and predicting streamflow changes in the arctic regions. Snowcover water equivalent data obtained from ground and via remote sensing will be examined in further studies.

JSH01/07P/C27-010   1720

STUDY ON SNOWMELT RUNOFF SIMULATION AND FORECAST USING GIS AND REMOTE SENSING DATA IN THE MOUNTAINOUS REGION OF WESTERN CHINA

Jian WANG[1], Yongchao LAN[2] ([1]Cold and Arid Regions Environmental and Engineering Research Institute(CAREERI),Chinese Academy of Sciences(CAS), [2]The State Key Laboratory of Frozen Soil Engineering Chinese Academy of Sciences)

In this paper, the progresses of studying on monitoring the water resource derived from snow cover melting in western of China are introduced amply. Commonly, the Remote Sensing data and Geographic Information System (GIS) techniques are the important methods and tools. The key parameter--snow cover area can be computed through satellite images from Multi-platform, multi-temporal and multi-spectral. Supervised classification filter has chosen to yield clusters of snow cover. Meanwhile, GIS will provide abundantformation in order to obtain the remaining parameters of simulating model. The simulated models and predicting results about snowmelt runoff serving forthe water resource management office and reservoirs will also be mentioned in detail. The samples about successful simulations and predicting snowmelt runoff extracted from two typical mountainous regional covered by snow-coverwill be presented.

JSH01/07P/C27-011   1740

IMAGERY OF SNOW WATER EQUIVALENT FROM SSM/I AND MODIS DATASETS IN QINGHAI-TIBETAN PLATEAU

Tao CHE[1], Xin LI[1], Richard L. ARMSTRONG[2], Rui JIN[1] ([1]Remote Sensing and GIS Lab, Cold and Arid Regions Environmental and Engineering Research Institut, CAS, [2]National Snow and Ice Data Center, University of Colorado)

Snow water equivalent is a key factor in the variable study of snow storage and water resources management. Passive microwave remote sensing data (SSM/I) have a faculty to penetrate clouds and snow cover and to provide dual polarization information at different frequencies. In fact, due to its low spatial resolution and complex topographic condition of the Qinghai-Tibetan plateau region, the estimation of snow water equivalent cannot be obtained a result of satisfaction yet. MODIS data as an important complement has a high spatial resolution. Using the MODIS data to decompose mixed-pixels of passive microwave bright temperature data is an available method to advance the spatial resolution of SSM/I data. After fusion of the two datasets, the snow cover, frozen ground and desert-soils regions are distinguished in the SSM/I sub-pixel scale. Three separate algorithms were developed based on the surface environments (snow cove, frozen ground, and desert-soils). A final snow water equivalent value represents the area-weighted average based on the proportional land cover within each SSM/I pixel. In this study, one day, 5 day, and 10 day averaged passive microwave derived SWE imagery for the winter season (December-February) are compared to in situ data from the Bureau of Meteorology in Qinghai and Tibet, in order to assess algorithms performance. The results have shown that retrieved SWE remains within ±10-20mm of surface observations, independent of fractional within-pixel land cover.

CRYOSPHERIC REMOTE SENSING AND THE NASA COLD LAND PROCESSES FIELD EXPERIMENT

Edward KIM[1], Don CLINE[2], Robert DAVIS[3], Cold Land Processes Working Group ([1]NASA Goddard Space Flight Center, [2]NOAA National Operational Hydrologic Remote Sensing Center, [3]US Army Cold Regions Research and Engineering Laboratory)

The Cold Land Processes Field Experiment (CLPX) has been designed to advance our understanding of the terrestrial cryosphere. Developing a more complete understanding of fluxes, storage, and transformations of water and energy in cold land areas is a critical focus of the NASA Earth Science Enterprise Research Strategy, the NASA Global Water and Energy Cycle (GWEC) Initiative, the Global Energy and Water Cycle Experiment (GEWEX), and many other programs. Quantitative understanding of cold land processes over large areas will require synergistic advancements in (1) understanding the spatial scaling behavior of cold land processes, (2) improved representation of cold land processes in coupled and uncoupled land-surface models, and (3) a breakthrough in large-scale observation of hydrologic properties, including snow characteristics, soil moisture, the extent of frozen soils, and the transition between frozen and thawed soil conditions. Major scientific questions to be addressed through CLPX research, strategies, and expected outcomes will be discussed. The CLPX Plan has been developed through the efforts of over 60 interested scientists that have participated in the NASA Cold Land Processes Working Group (CLPWG). A major product of the experiment will be a legacy data set including satellite, airborne, and ground-based remote sensing as well as comprehensive ground truth. Field observations were conducted in February and March, 2002 and 2003 within a 25,000 km2 domain in Colorado, USA. Participants included researchers from several countries. A detailed description of the field campaigns will be presented along with some preliminary examples of field data.

JSH01/08A/C27-002   0930

PRELIMINARY RESULTS FROM THE VALIDATION OF SNOW COVER PRODUCTS DERIVED FROM AMSR-E

Richard L. ARMSTRONG, Mary Jo BRODZIK, Matt SAVOIE, Ken KNOWLES (CIRES/NSIDC)

The National Space Development Agency of Japan (NASDA) has developed two Advanced Microwave Scanning Radiometers: AMSR-E, built for NASA´s Earth Observing System (EOS) launched on 4 May 2002 on the Aqua platform and AMSR which was launched by Japan on December 14, 2002 on ″Midori-II″ the Advanced Earth Observing Satellite-II (ADEOS-II). The AMSRs provide improved spatial resolution, varying with frequency from 6 km x 4 km at 89.0 GHz to 75 km x 43 km at 6.9 GHz, compared to earlier generations of space-borne passive microwave instruments (e.g., SMMR and SSM/I) and they include more frequencies than their predecessors (horizontally and vertically polarized brightness temperatures at 6.9, 10.7, 18.7, 23.8, 36.5 and 89.0 GHz). Given the large footprint of passive microwave sensors, snow cover within a footprint is seldom uniformly distributed and large differences between station or gauge measurements (a point) and satellite estimates (an area integration) can be expected. Therefore it is necessary to develop schemes to compare areal snow cover with satellite derived snow cover and our present study relies on several such validation data sources. These include comparisons of AMSR-E derived SWE with snowmelt runoff models and stream gauge data for selected large river basins such as the Lena River Basin in Russia, comparisons with SSM/I algorithm output and comparisons of snow extent with Moderate Resolution Imaging Spectroradiometer (MODIS) data. In addition, using data obtained during the NASA Cold Land Processes Field Experiment (CLPX) during February and March of 2003 in northwestern Colorado, we validate the AMSR snow products based on a wide range of measurements from the ground-based and airborne components of this field experiment. Aircraft data will be available from the NASA P3 (radiometers:10-220 GHz), the NASA DC-8 (AIRSAR) and the NOAA AC690 (gamma measurements) combined with ground measurements coming from the University of Tokyo GBMR-7 ground-based AMSR simulator and University of Michigan ground radars (L, C, X, Ku) as well as intensive manual ground sampling. These manual measurements will provide a sampling density that is unprecedented and will include 9,000 snow depth measurements and 288 snow pit profiles (snow water equivalent, snow density, grain size type and size and temperature) to characterize the snow cover over three 25 x 25 km Meso-cell Study Areas (MSAs) providing data at a spatial scale appropriate to the analysis of AMSR-E retrievals. We also present results from our development of enhanced snow cover mapping through blending of microwave (SSM/I and AMSR) and optical (MODIS) satellite data.

JSH01/08A/C27-003   0950

MULTISENSOR REMOTE SENSING OF SNOW COVER

Sverre Thune DOKKEN, Rune SOLBERG, Jostein AMLIEN, Rune ØDEGÅrD, Per-Ove HUSøy, Hans KOREN (Department of Statistical Analysis, Image Analysis and Pattern Recognition, Norwegian Computing Center)

Snow cover has a substantial impact on interaction processes between atmosphere and surface. Our goal is to improve methodologies for remote sensing of snow parameters and the use of snow parameters in hydrological models in order to achieve better water management practices related to snow. This should result in improved climatologic data collection, as well as better flood prediction, management of rivers and dams, and hydropower production planning. Present snow algorithms are developed using a number of satellite sensors, data formats, programming languages as well as being of variable quality. In view of new satellite sensors recently launched, we endeavour to improve the understanding of how satellite-measured microwaves and light interact with snow cover in mountainous areas, and thereby develop new and improved algorithms for snow parameter retrieval. A multisensor and multitemporal approach is applied in order to utilise the complementary sensor characteristics of optical and radar data. The methods are particular suitable for Envisat's Medium Resolution Imaging Spectrometer, Advanced Along Track Scanning Radiometer and Advance Synthetic Aperture Radar as well as the EOS AM-1's Moderate Resolution Imaging Spectroradiometer and Multi-angle Imaging SpectroRadiometer. We have developed a snow retrieval algorithm laboratory environment including both single and multisensor algorithms under the Environment for Visualizing Images. The main parameters are snow water equivalent, snow cover area, snow wetness, albedo and snow surface temperature. The presentation will focus on the applicability and the quality of the different selected methods and how they can be used to make seasonal and decadal snow trend analyses.

JSH01/08A/C27-004   1030

USE OF THE TOPEX-POSEIDON ALTIMETER OVER LAND SURFACES AN APPLICATION TO ESTIMATE TERRESTRIAL SNOW DEPTH

Fabrice PAPA, Benoit LEGRESY, Frederique REMY (legos/OMP)

The capability of Topex-Poseidon radar altimeter data for land surface studies at regional or global scale has been investigated. The analyzed data, available since mid-1992 consist of dual-frequency backscattering coefficients values (Ku and C band) estimated at the nadir pointing angle along the satellite tracks between 66 S and 66N. Over the snow covered areas of the Northern Hemisphere, backscatters particularly exhibit a strong seasonal variability and in that context, the use of T-P is investigated to recover snow depth evolution through winter. Snow pack thickness and extent, and the duration of the snow period are important parameters to characterize and to understand climate changes. Global average surface temperature has increased by approximately 0.5°C since the last half of the nineteenth century and climate models suggest that an anthropogenic global warming should manifest itself most strongly over the land in high latitudes. In that context, changes in snow cover characteristics take a special significance. Active and passive microwave measurements obtained from the Northern Great Plains of the United States are used to develop a snow pack radar backscatter model, based on the decreased of the mean value of the backscattering coefficient as the snow cover thickened through the winter. The model results are compared to daily time series of surface snow observations made by the U.S. National Weather Service, especially during the extreme winter 1996-97. First the beginning and the end of the winter snow pack are accurately determined with in the repeat cycle of the satellite. Then, the model results show that Ku band provides more accurate snow depth determinations than does C band. Comparing the snow depth determinations derived from the Topex-Poseidon nadir looking passive microwave radiometers with the oblique looking SSM/I passive microwave observations and surface observations shows that both instruments accurately portray the temporal characteristics of the snow depth time. While both retrievals consistently underestimate the actual snow depths, the Topex-Poseidon results are more accurate. We will also enlarge study area from local to global scale, presenting mean global backscatter images of the entire land surfaces in Ku, C band and the difference C-Ku, which exhibit a strong dependence with classical global vegetation and surface slopes maps. Statistics and major temporal signals over nine entire years are presented.First results of the use of T-P data over continents at global or regional scale look very promising and indicate the high capabilities of Topex-Poseidon radar altimeter data for

land surfaces monitoring and its complementarities for future synergy with passive microwave radiometer data over continents or other active sensors such as wind-scatterometer.

JSH01/08A/C27-005   1050

INTERANNUAL VARIABILITY OF BRIGHTNESS TEMPERATURE OVER SNOW COVERED REGION

Ramesh P. SINGH[1], V.D. MISHRA[2], P. MATHUR[2], Netramani HARIJAN[3], Sagnik DEY[3], Nitin KATIYAR[3], S.P. SINGH[3], Y.P. SINGH[3] ([1]Professor, Department of Civil Engineering, Indian Institute of Technology, Kanpur, [2]SASE, Chandigarh, India, [3]Department of Civil Engineering, IIT Kanpur)

The snow cover in the northern part of India controls the climatic conditions of Indian continent and also snow is considered as one of the important natural resources. The northern part of Indian region where immense snow resources lie is often covered by clouds and in winter the sun is not seen. The knowledge of the snow cover and the thickness of the snow is very important in understanding the radiation budget and also useful in estimating the surface runoff in the Indo-gangetic plains, flood conditions and recharge of ground water. The visible remote sensing data has limitations due to the cloud cover and it also fails to provide any quantification estimate of snow cover. In high altitude and cloud cover regions, the microwave remote sensing data have been proved to be one of the important tools in quantification of snow cover and also studying the snow covered characteristics. we have carried out detailed analysis of SSM/I data over northern part of India covered wht snow for various frequencies and polarizations for the year 1989-1998. the brightness temperature variations show cyclic nature with minimum value in winter season and maximum value in summer season. The brightness temperature shows a linear trend with small variations during 1989-1998. From the brightness temperature data emissivity of the snow covered region for seven locations have been extracted. At these seven locations, ground parameters have been routinely recorded by the scientists from SASE, Chandigarh. In the present paper, the characteristics of the brightness temperature, emissivity ror the period 1989-1998 will be presented. The interannual variabiltiy of brightness temperature and emissivity in view of the nature of the snow cover. The use of SSM/I data in monitoring of snow avalanches will be presented.

MONITORING OF IMJA GLACIER LAKE IN THE EAST NEPAL USING THE SATELLITE IMAGE

Hironori YABUKI (Frontier Observational Research System for Global Change)

The research of the glacial lake in the Nepal Himalaya region is carried out since 1990´s (Ex. Yamada, 1998). The glacial lake has been stopped in the unstable moraine. The size of the lake expanded by the melting of the glacier ice in mountain region by the global warming. GLOF (Glacier Lake Over Flood) occurred by the moraine can not sustaining and collapsing quantity of water of glacial lake. However, unclear points such as glacial lake forming condition and process of the glacial lake extension have been left. In this study, the quantitative evaluation was carried out using satellite image in respect of the extension of glacial lake of Imja glacial lake in East Nepal of which a risk of a glacial lake collapse is high. The analysis was carried out on climate change and glacial lake formation using global temperature data. The analysis period was from 1962 to 2000, 10 scenes (1962, 1964, 1968, 1975, 1977, 1987,1991, 1993, 1995, 2000) in this period were analyzed. Used satellite image was used in 4 types. One is high-resoluble military affairs reconnaissance satellite CORONA image that the U.S.A. of which the resolution is 7.6m photographed was used in 60´s. And LandsatMss of which the resolution was 83m was used in 70´s. And SPOT of which the resolution was 10m was used in 80´s and 90´s. And Landsat ETM+ of which the resolution was 15m was used in 2000. Each image carried out the geometric correction using the map. Climetological data used Global Historical Climate network Ver.2 of National Climate Data Center (NCDC).The glacial lake was formed around 1960, and that the area expanded after it at the almost fixed speed clarified. Glacial lakes were four small ponds at the initial stage in 60´s. Next, glacial lakes spread during around 70´s to the downstream direction by the expansion of those ponds. Those ponds expanded, and it became one lake. The end in the glacial lake did the extension by 1991, and it was stabilized after it. The glacial lake expanded to the upstream direction from the middle of 70´s. ICIMOD (2000) is said that many glacial lakes of Himalayas would rapidly develop in here 1960´s. The Imja glacial lake is also similar. The global warming is being caused from before formation of glacial lake with the mean deviation of annual mean temperature of the Northern Hemisphere. The shrinkage of the glacier by the global warming occurred before formation of glacial lake. The glacial lake might be formed by the glacier shrinkage process.

GIS-BASED GLACIER INVENTORY OF CHINA

Zong Li WU, Xin LI (Cold and Arid Regions Environmental and Engineering Research Institute)

The project of the Glacier Inventory of China initialized in 1979 was just accomplished in 2000. This inventory was complied based on numerous LandSat TM images, aerial photographs, and topographic maps. More than 40 Chinese glaciologists made their great

efforts in this work. With the newest statistics from the inventory, there are total 46388 glaciers in China; the total area is 60050 km2 and the ice volume is 5591 km3.The largest glacier locate in Tianshan Mts.(length: 63.5m,area:392.84km2,code: 5Y673K1).The highest latitude of moraine is 6560 meter and the lowest latitude of moraine is 2240meter.Comprehensive statistics of glaciers in China are followed as:

Unit	Area(km2)	number	Ice Volume (km3)	source
Qilian Mts.	1931	2751	94	1981
Altai Mts.	293	416	16.5	1983
Tianshan Mts.	9196	8908	1011	1986,1987
Pamirs	2448	1147	232	2001
Karakorum Mts.	5925	3059	684.5	1989
Kunlun Mts.	8737	5947	848	1992,1994
Changjiang River	1895	1332	147	1994
Huanghe River	213	176	12	1981,1992
Tibetan Plateau	7814	5213	698	1988
Langquanjiang River	316	380	18	2001
Nujiang River	1730	2021	115	2001
Ganga River	18101	13005	1620	2002
Indus River	1451	2033	94	2002

We launched a new project to digitize the 11 volumes of published glacier data and all the distribution maps of glaciers in China. Large-scale topographic maps were also used as reference to reconstruct a more accurate geographic coordinate system of the inventory. We paid particularly attention to the data quality control. The properties of both the spatial and attribute data were carefully examined with a few operations by manual and computerized checks. We will discuss the comparison of the areas between the books and digital data in this paper.Since the digital inventory lays a baseline for the monitoring of glacier change, we are going to release the database on the Internet and with CD-ROMs. In additions, the second glacier inventory in Pumqu River drainages(Tibet) was carried out. New generation remote sensors such as ASTER and LandSat ETM+ were used to identify glacier change in many areas. Preliminary results showed that the change is significant.

JSH01/08P/D-003   Poster   1400-041

INVENTORY OF GLACIAL LAKES AND IDENTIFICATION OF GLACIAL LAKE OUTBURST FLOODS IN THE PUMQU BASIN, TIBET

Tao CHE, Xin LI, Rui JIN, Zong Li WU (Remote Sensing and GIS Lab, Cold and Arid Regions Environmental and Engineering Research Institut, CAS)

There are 999 glaciers in the Pumqu basin in total, covering a large area of 1,556 square kilometers. However, these glaciers are retreating in the face of accelerating global warming. They are particularly vulnerable to climate change, and the resultant long-term loss of natural fresh water storage will have as yet uncalculated effects on communities downstream. More immediately, as glaciers retreat, glacial lakes form behind some of the now exposed terminal moraines. Rapid accumulation of water in glacial lakes, particularly in those adjacent to receding glaciers, can lead to a sudden breaching of the unstable *dam* behind which they have formed. The resultant discharges of huge amounts of water and debris, namely a glacial lake outburst flood (GLOF), often have catastrophic effects downstream. These GLOFs have resulted in many deaths, as well as the destruction of houses, bridges, fields, forests and roads. The lakes at risk, however, are situated in remote and inaccessible areas. The study's major objective was to identify areas where GLOF events had occurred and lakes that could pose a potential threat of a GLOF in the near future. First, we digitalized glaciers and glacial lakes based on the topographic maps published three decades ago, and remote sensing images (ASTER) acquired in 2001/2002. Secondly, the inventory of glaciers and glacial lakes was obtained according to the spatial and attribution data. Thirdly, we analyzed the change of glacial lakes in the two periods. Finally, on the basis of actively retreating glaciers and other criteria, the potentially dangerous glacial lakes were identified using the spatial and attribute database composed by multi-temporal remote-sensing data sets. The final results have shown that there are 225 glacial lakes with a total area of 1,062 square kilometers, and there are 24 glacial lakes were identified as the potentially dangerous lakes in Pumqu basin. However, due to the influence of the acquisition seasons of remote sensing images, the field survey is necessary to more soundly identify the potentially dangerous glacial lakes.

SEQUENTIAL ESTIMATION OF MESO-SCALE SEA ICE MOTION FROM SATELLITE IMAGES OF MULTIPLE RESOLUTIONS

Tsuyoshi WAKAMATSU[1], Motoyoshi IKEDA[2] ([1]Institute of Ocean Sciences, DFO, Canada, [2]Graduate School of Environmental Earth Science, Hokkaido University, JAPAN)

We will propose new approach to extract meso-scale sea-ice motion from satellite images with multiple spacial resolutions. In order to merge data from different sources, we construct simple sea-icemodel consist of Lagrangian equations, which forecast locations of sea-ice particles, and interpolation kernel, which simulate the gridded value of signal intensity corresponding to observed data. The estimation system is designed to correct forecasted ice particle positions using sea-ice images as input data based on optimal interpolation technique. Then sea-ice motion is reconstructed from the estimated ice particle positions. Preliminary result from simple numerical experiments shows that merging several data with different resolution helps to correct ice positions when error distributions of each data and forecasted positions are given.

SEA ICE CLASSIFICATION USING QUIKSCAT SEAWINDS SCATTEROMETER DATA

Rasmus T. TONBOE[1], Joerg HAARPAINTNER[2] ([1]Danish Meteorological Institute, [2]Polar Science Team, National Ice Center)

The Ocean and Sea Ice Satellite Application Facility project (O&SI SAF) from the European Organisation for the Exploitation for Meteorological Satellites (EUMETSAT) is now entering the operational phase. A data fusion sea ice product (O&SI SAF ice product) is issued daily. The supervised Bayesian classification method is used to combine microwave radiometer data, visual/infrared and microwave scatterometer data. The derived sea ice parameters are: ice cover concentration, ice type and ice edge. The aim of this study is to establish statistical values for selected ice classes in order to implement SeaWinds scatterometer data in the operational and automated O&SI SAF sea ice product. These ice class signatures are produced by co-location of two years (2000-2002) SeaWinds data and ice charts around Greenland from the Danish Meteorological Institute (DMI).Our results show that SeaWinds data are useful for sea ice classification during the cold season (September-May). Four SeaWinds parameters are used in the classification: 1) horizontally and 2) vertically polarised backscatter, 3) the polarisation ratio, and 4) the daily standard deviation of the backscatter. The backscatter separation between first year ice and multi year ice is most effective for high ice concentrations ($>70\%$), but SeaWinds ice class parameters are also separated for intermediate ice concentrations (30-70%). Ice types can not be separated for

---

low ice concentrations ($<30\%$) and these classes also overlap ocean backscatter parameters at high wind speeds ($>15m/s$). In summer (June-August) it is impossible to discriminate ice types because of ice surface melt. However separation between ice and water is still possible. Initial results will be presented at the conference.

ASSESSMENT OF AMSR-E SEA ICE PRODUCTS USING IN-SITU OBSERVATIONS AND MODELING

James Andrew MASLANIK[1], Julienne STROEVE[1], Matthew STURM[2], Thorsten MARKUS[3], John HEINRICHS[4], Don CAVALIERI[3] ([1]University of Colorado, [2]USA CRREL, [3]NASA GSFC, [4]Fort Hays State University)

As part of the validation effort for AMSR-E onboard the EOS Aqua platform, in-situ measurements of a variety of sea ice and snow cover parameters were collected on shore-fast ice areas near Barrow, Alaska, USA in March 2003. These measurements were carried out in conjunction with NASA P-3 aircraft flights over the in-situ locations as well as P-3 flights over portions of the Beaufort and Chukchi sea ice pack. Coincident atmospheric data were obtained using flights of Aerosonde unpiloted aerial vehicles. The in-situ measurements and P-3 observations are used to assess the performance of AMSR-E sea ice product algorithms through direct comparisons of data sets and via forward modeling of microwave radiances using MWMOD and MEMLS. Results to be presented will highlight the performance of the AMSR snow depth and ice temperature algorithms, and will address the effects of snow properties on AMSR-E retrievals of snow and sea ice information.

SATELLITE INVESTIGATIONS OF FAST ICE BREAKUP IN EAST GREENLAND FJORDS

Evelyn K. DOWDESWELL (The Scott Polar Research Institute, University of Cambridge)

Landsat satellite imagery is used to provide a record of the breakup of fast ice in several major fjord systems in East Greenland (68-74 deg N). The areas considered are Kangerdlugssuaq Fjord, Scoresby Sund, Kong Oscars Fjord and Kejser Franz Josephs Fjord. Thematic Mapper and Multispectral Scanner QuickLook images from 1979 indicate that the breakup of fast ice generally occurs by a regular pattern of thinning and polynya development prior to the breakup and disappearance of landfast ice. Interannual variability in timing of breakup is compared with climate records for these years. The spatial and temporal pattern of fast-ice breakup places constraints on iceberg calving and the potential sediment flux into these fjord systems.

SATELLITE OBSERVATIONS OF SEA ICE TRANSPORT IN THE SEA OF OKHOTSK

Hiroyuki ENOMOTO[1], Kazutaka TATEYAMA[2], Takashi KUMANO[3] ([1]Department of Civil Engineering, Kitami Institute of Technology / FORSGC, [2]Institute of Low Temperature Science, Hokkaido University, [3]Kitami Institute of Technology)

The dominant pattern of sea ice drift was analyzed in the Sea of Okhotsk using DMSP SSM/I data. Dominant ice drift along the Sakhalin Island was apparent in the satellite derived ice drift map in the Sea of Okhotsk. The flow pattern was indicated by the trace lines appeared on the vector field of ice drift. The flow pattern shows a dominant stream along the east coast of Sakhalin. Many flow path of sea ice were converged in the coastal zone of Sakhalin. Recurring polynya area in the northeast of Sakhalin was indicated as absence of steady flow lines. In the southern part of Okhotsk Sea, ice flow was highly variable due to mesoscale eddies. Ice group of almost same path can follow different paths due to affecting different eddies. Seasonal and local variations of ice drift were analyzed along the Sakhalin and Hokkaido. The alternative patterns of convergence and divergence along the ice drift zone affect ice deformation and thickness change. There are convergence zone along the Sakhalin Island. The convergence in this zone can cause significant compacting, rafting and deformation of sea ice. Interannual variations of ice mass transport in this stream were estimated by applying an algorithm of ice thickness estimation by satellite. Large amount of freshwater and latent heat can be transported as a form of sea ice by the dominant ice stream. Sea ice coverage decreased between 1989 to 1996. The ice area was minimum in 1996 during the last 20 years. The mean ice thickness in the ice stream zone was also estimated to be minimum, and then recovered in the recent years. However, the ice transport was not increased since the ice drift speed was remained in the lower range. For the evaluating sea ice change concerning energy and mass, combinations of ice coverage, thickness and drift are required. This study introduced available approach of estimation and recent fluctuation of sea ice in the Okhotsk Sea.

REMOTE SENSING OF SNOW GRAIN SIZE AND SNOW IMPURITY CONCENTRATIONS AND THEIR IMPACT ON THE RADIATION BUDGET

Teruo AOKI[1], Masahiro HORI[2], Knut STAMNES[3], Hiroki MOTOYOSHI[4], Tomonori TANIKAWA[5], Akihiro HACHIKUBO[6] ([1]Meteorological Research Institute, [2]National Space Development Agency of Japan, [3]Stevens Institute of Technology, [4]Space Service Inc., [5]University of Tsukuba, [6]Kitami Institute of Technology)

Snow grain size and concentration of snow impurities are vitally important snow physical parameters required to determine the spectral snow albedo. According to radiative transfer simulations of spectral snow albedo, it depends sensitively on the concentration of snow impurities in the visible, and on snow grain size in the near infrared. The remote sensing of these snow physical parameter will be operationally made with ADEOS-II/GLI data since 2003 by National Space Development Agency of Japan. We conducted preliminary performance tests of the algorithm using global data set of TERRA/MODIS in 2001-2002. The algorithm worked well except for melting areas in sea ice. We also made a validation experiment in northern Hokkaido, Japan in February, 2002. The snow physical parameters retrieved from TERRA/MODIS data agreed with the ground truth data within operational uncertainties. In addition, we have made continuous radiation budget observations and semi-continuous measurements of snow pit work on the snowfields in northern Japan. The effects of snow physical parameters on the visible and the near infrared albedos are calculated using a radiative transfer model for the atmosphere-snow system and compared with the measured ones. The measured broadband albedos were close to the theoretically calculated ones as functions of these snow physical parameters. These results suggest the possibility to develop a physically based snow albedo scheme for describing land-surface processes in climate models. Furthermore, the snow albedo scheme could be validated with the satellite remote sensing data mentioned above.

SNOW ACCUMULATION STUDIES IN ANTARCTICA WITH GROUND PENETRATING RADAR USING 50, 100 AND 800 MHZ ANTENNA FREQUENCIES

Anna Katariina SINISALO[1], Aslak GRINSTED[1], John MOORE[1], Eija KärKäs[2], Rickard PETTERSON[3] ([1]Arctic Centre, University of Lapland, [2]Division of Geophysics, Department of Physical Sciences, University of Helsinki, Finland, [3]Department of Physical Geography, Stockholm University)

Snow radar profiles were measured in Dronning Maud Land in the vicinity of the Finnish research station Aboa during the austral summer 1999-2000. The aim was to study the annual layering in the upper 50 meters of the snow pack and to compare the results obtained by three radar antenna frequencies. The radar profiles measured by three antenna frequencies (50, 100, and 800 MHz) are compared with each other, and some internal layers shown to be visible with different antennas. Sparse accumulation rate data from stake measurements and snow pits are compared with layer depths and exhibits a great deal of scatter due to the larger inter-annual variability in accumulation patterns. Using the radar layers as isochrones together with a model of depth-density-radar wave velocity allows the individual accumulation data to be integrated and a better estimate of accumulation patterns obtained. Using the radar layering seems to be a much better method of estimating accumulation rate than short series of stake measurements in this region, even in the absence of deep ice cores to directly date the radar layering.

JSH01/08P/D-011   Poster   1400-049

A PROCUDURE FOR CLASSIFING DRY SNOW, WET SNOW AND FROZEN SOIL BY USING MICROWAVE REMOTE SENSING

Xin LI[1], Tao CHE[1], Richard L. ARMSTRONG[2], Lizong WU[1] ([1]Cold and Arid Regions Environmental and Engineering Research Institute, CAS, [2]National Snow and Ice Data Center, University of Colorado)

The purpose of land classification by using microwave remote sensing is not only to discriminate different landcover types such as snow, soil, and vegetation but also to identify surface status such as melting or dry snow, frozen or unfrozen soil, precipitation or cloud liquid water. This kind of classification, with the help of other ancillary information as DEM, can be used to improve the accuracy of retrieval models. We developed a decision-tree classification procedure for classifying a wide range of surface and atmospheric features by using the (Defense Meteorological Satellite Program) DMSP Special Sensor Microwave/Imager (SSM/I). Main foci were put on those features have similar scattering/absorbing properties since it significantly affects the quantitative retrieval of geophysical parameters. For example, snow water equivalent is overestimated in some areas because snow and frozen soil are not discriminated. The first step of the procedure is to classify the absorbing and scattering materials using the combination of 85 GHz and 22 GHz vertical polarization channels. Then, using some rules between 22 GHz and 85 GHz, precipitation can be discriminated from other scattering materials. Sand is identified when $Tv19\ Th\ 19 > 20$. For dry snow and frozen soil, their scattering properties are very similar. We use the equation given by Robinson and other a priori information to classify them. After the classification, different models can be used to retrieve different geophysical parameters according to the different surface features.

SPECTRAL CHARACTERISTIC-BASED VEGETATION AND SNOW INDICES ON VARIOUS SURFACES IN THE AIRBORNE MULTI-SPECTRAL SCANNER (AMSS) TWO-ALTITUDE OBSERVATION IN 2001

Ken MOTOYA (Frontier Reserch System for Global Change)

Spectral characteristics and spectrum-based snow and vegetation indices from one visible and two near-infrared bands, on various surface categories were evaluated, using an Airborne Multi-Spectrum Scanner (AMSS) in 2001. The AMSS was improved in sensitivities of near-infrared channels compared with those in 1998. Interrelations between the indices (or visible-to-near-infrared albedo) and vegetation density were also discussed with field observations of forest density in a high spatial resolution. In addition, differences of atmospheric effects on both the AMSS data and the snow and vegetation indices were estimated with observations at two altitudes and compared with the result of a radiative transfer model. From observation at the higher altitude (13200ft), radiances at bands less than 490 nm in wavelength were strongly affected by the Rayleigh scattering. However, the visible (625 nm) and short (865 nm) near-infrared channels of the snow and vegetation indices, were not affected so much by the atmospheric effects and long (1650nm) near-infrared also has only a small effect of the water vapor absorption. The indices were little affected by the atmosphere in general. Moreover, viewing-angle dependencies of detectors on near-ultraviolet (380 nm), visible (625nm), and short and long (865 nm and 1650 nm) near-infrared channels were investigated. As a result, fore-scattering was representative on snow surface in its viewing-angle dependency and forest has a Lambert-like dependency. The dependency at wavelengths of more than 1000nm was approximately half of that in the AMSS of 1998 because the IFOV of those channels was expanded from 2.5 mrad to 5 mrad.

MICROWAVE AND MICROMETEOROLOGICAL OBSERVATIONS OF WINTER SNOW IN ROCKY MOUNTAIN

Haoyu GU, A. W. ENGLAND, R. DEROO, H. PHAM, D. BOPRIE (Department of Atmospheric, Oceanic and Space Sciences, University of Michigan)

Snow plays an important role on earth's hydrology cycle, and significantly interacts with global weather and climate. However, snow melt processes and their interaction with soil, vegetation and atmosphere are still not well understood. Microwave radiometry is a technology which promises to enable space-based remote sensing of snow pack wetness. To understand the radiometric signature of a wet snow pack, we are participating in the NASA Cold Land Processes Field Experiment (CLPX) in the Rocky Mountains of Colorado during winter and spring of 2003. We are using our Truck Mounted Microwave Radiometer System (TMRS3) and our Micrometeorological Station (MMS). TMRS3 includes dual-polarized 1.4, 6.7, 19 and 37 GHz radiometers. The MMS measures air temperature, relative humidity, soil heat flux, two soil temperature and moisture profiles and a snow temperature profile. These MMS data complement the meteorological data collected as part of CLPX. This presentation will cover both radiometric and meteorological observations made during the experiment. These data will be used to test and improve a Soil Vegetation Atmosphere Transfer (SVAT)/Radiobrightness Model coupled with SNTHERM, a one-dimensional snow energy budget model. The coupling of the two models is underway. The observational data will be archived in National Snow and Ice Data Center for access by other researchers.

SNOW PROCESSES: REPRESENTATION IN ATMOSPHERIC AND HYDROLOGICAL MODELS (IAHS/ICSI, IAMAS)

EXPERIENCE OF APPLICATION OF PHYSICALLY-BASED MODELS OF SNOWMELT RUNOFF GENERATION AND ASSIGNING OF MODEL PARAMETERS

Lev S. KUCHMENT (Water Problems Institute, Russian Academy of Sciences)

Experience of application of physically based models of snowmelt runoff generation for different physiographic conditions is analyzed. Case studies have carried out for three river basins in the central part of the European Russia and for two basins in the Far East part of Russia. The models are based on the finite-element schematization of river basins and include a detailed description of snow processes, soil freezing and thawing, infiltration into the frozen and thawed soil, overland and subsurface flow, water movement in the river channel system. It is assumed that the snow water equivalent, the saturated hydraulic conductivity and the depth of frozen soil have subgrid stochastic variability and the ways of taking into account this variability have suggested. The structure of the models is chosen on the basis of results of sensitivity analysis and analysis of runoff generation mechanisms in given river basins. The part of parameters are the measured basin characteristics, several parameters are determined on the basis of empirical dependencies including the measured characteristics, and the rest of parameters are calibrated against runoff or other water balance component measurements. Comparisons of measured and calibrated model parameters as well as the empirical formulas obtained for determination of parameters for different river basins are given. Possibilities of using different empirical dependencies and transferability of these dependences and model parameters between basins are considered. Numerical experiments have been carried out to test ability to apply the suggested physically based models of snowmelt runoff generation for the poorly gauged river basins. It has been showed that only 2-4 of most important parameters should be calibrated using comparatively short series of runoff measurements, whereas the values of the rest 10- 12 parameters can be regionalized.

JWH01/09A/C30-002   0920

WATER AND ENERGY TRANSFER IN SNOW AND FREEZING SOIL IN EASTERN HOKKAIDO, JAPAN

Tomoyoshi HIROTA, Yukiyoshi IWATA (National Agricultural Research Center for Hokkaido Region)

Eastern Hokkaido is one of the largest agricultural regions in Japan. Low air temperature (annual minimum air temperature is — 30 ° C) and relatively thin snow covers on the ground cause the topsoil to freeze over the winter in this region. But recently, trends in maximum frozen soil depth in a year tend to decrease due to timing of snow covers earlier. Despite the importance of frozen soil and snow for agriculture, very few comprehensive meteorological and hydrological studies were conducted in this region until recent years. The study objectives are to 1) conduct a detailed and long-term field study under snow and soil freezing condition, 2) identify key parameters affecting the water and energy transfer at the ground surface and in the soil, and 3) develop predictive tools for assessing the impacts of farming practices and climate change on the frozen soil. The field study has been conducted in agricultural experimental field located Memuro, Tokachi, Hokkaido since October 2001. We have observed atmospheric factors (temperature, humidity, wind speed, precipitation, short and long wave radiation (upward and downward)), soils factors (vertical temperature profiles, vertical water content profiles by TDRs, water potentials beneath frozen layer by tensiometeres, surface soil heat flux, frozen depth by frost tube filled with 0.03% methylene blue solution), snow factors (snow depth, snow water equivalent (SWE) by pressure sensor measurement, snow temperature vertical profiles) and a weighing lysimeter for measuring evaporation and snowmelt. Almost sensors have measured automatically and continuously every 10 to 60 minutes. In 2001-2002 years winter observation period, maximum frozen soil depth was 20 cm however maximum snow depth was relatively thick; 80 cm, maximum SWE was 225 mm. Seasonal variations of the soil water status was characterized into four stages; 1) beginning of winter (December); Due to thin snow layer (less than 20 cm), frozen soil depth was increased, surface soil liquid water content was decreased rapidly, direction of soil water flux was upward from deeper soil layer to surface layer, 2) mid of winter (January to February), After thick snow layer covered (over 40 cm depth) , developing of frozen soil depth stopped, soil liquid water content was almost constant, direction of soil water flux was changed from upward to downward, 3) beginning of snow melt season (from begging to mid of March), occurring following phenomena simultaneously; starting snowmelt, snow temperature raised rapidly near 0 °C, frozen soil was partially thawed. 4) End of snowmelt season (end of March), snowmelt water moved into subsoil by gravitational flow though frozen soil depth was still 10 cm. We also discuss new snow and soil temperature model developed by Hirota et al., 2002 in JGR called the extended force-restore method using detailed our field datasets.

JWH01/09A/C30-003   0940

A MODEL OF ANNUAL HYDROLOGICAL CYCLE FOR ARCTIC TUNDRA

Hiroyuki HIRASHIMA[1], Tetsuo OHATA[1], Yuji KODAMA[1], Hironori YABUKI[2] ([1]Institute of Low Temperature Science, Hokkaido University, Kita 19, Nishi 8, Kita-ku, Sapporo 060-0819, Japan., [2]Frontier Observational Research System for Global Change, Tokyo 105-0013, Japan.)

In arctic region, it is remarked that rising of temperature by the effect of global warming is most serious. The influence of global warming to annual hydrological condition can be usually estimated by one-dimensional model. However, in arctic tundra region, snow is distributed non-uniformly due to low vegetation and strong wind. Thus, discussion on hydrological condition distribution must be considered for simulation to such a place. Distributed hydrological model for warm period and snow distribution model for cold period have been developed in recent years. In the present study, distributed annual hydrological cycle model was developed to simulate thermal condition and hydrological term for such a non-uniform snow distributed region. This model consists of snow and subsurface multi-layer model, snow distribution model and distributed hydrological model and simulates energy and hydrological processes in cold and warm period. The model is spatially distributed model and simulates using meteorological and topographical input data. In cold period, this model simulates snow redistribution by calculating blowing and drifting snow amount. Snow depth and profiles of snow temperature, density and water content are simulated simultaneously

using one dimensional snow multi-layer model for each grid. In warm period, this model estimates snowmelt amount by energy balance method. The snowmelt water contributes to the hydrological process (e.g. soil moisture, evaporation and river runoff) with liquid precipitation. Vertical water movement and horizontal water movement by subsurface flow and surface flow are calculated by multi-layer diffusion model, Darcy´s law and Manning´s equation, respectively. Permafrost is assumed to be impermeable layer. Since hydrological process in permafrost region depends on thermal condition, ground temperature profile and thaw depth was calculated simultaneously. In this study, numerical simulation with this hydrological model was carried out in Siberia tundra region, Tiksi. The simulated result was validated using observational data obtained under the GAME-Siberia project. Simulated soil temperature was compared with observed one obtained at the meteorological station and agreed well. The snow distribution observed by helicopter, suggested that the snowdrift was mainly formed at the hollow region such as river, and the model reproduced this characteristic. However, simulated river runoff was too much in melt period and too little in the latter half of warm period than observed river runoff. This result suggests the infiltration of melt water to frozen soil is important process here. The simulation results of hydrological cycle model considering this process are going to be discussed as well.

JWH01/09A/C30-004 — 1000
A COMPLETE MODEL FOR SNOW DRIFT PROCESSES IN STEEP ALPINE TERRAIN

Michael LEHNING, Judith DOORSCHOT, Norbert RADERSCHALL (Swiss Federal Institute for Snow and Avalanche Research SLF)

Since blowing and drifting snow is a major factor influencing avalanche danger and the local micro climate, a high resolution, objective and quantitative assessment and forecast of snow transport by wind is of great practical value. Wind transport of snow is governed by three components: the erodability of the snow pack, the current snowfall and the wind field. A snowdrift model has been developed that combines an atmospheric model analysis of the high resolution wind field over steep topography, a novel formulation for snow drift and a snow cover model. For modeling snow drift, the transport modes saltation and suspension are distinguished. The flow field over steep topography is modeled using the meteorological model system ARPS (Advanced Regional Prediction System). It is shown that important features of the wind field such as speed-up over the crest and flow separation in the lee can be reproduced by the flow model using a high resolution computational mesh. Also discussed are the turbulence fields, which are important for the simulation of the drift modes saltation and suspension. A novel model for snow saltation is presented, which is suitable for steep terrain. Based on a computationally efficient equilibrium approach, the description of saltation uses explicit trajectory calculations to estimate mass fluxes on steep slopes. The snow cover is represented by the model SNOWPACK. SNOWPACK is a detailed model of the snow cover development and simulates the erodability of deposited snow as well as metamorphic changes, heat and mass fluxes and phase changes. Emphasis of the presentation is further on the coupling between the snow cover, the drifting and blowing snow and the wind field. For a correct description of the erosion and deposition pattern, the formulation of the coupling functions is of major importance. The full model system is applied to predict snow loading in avalanche slopes. Results for the avalanche winter 1998 / 1999 are presented. The evaluation of the results show that major characteristics of snow redistribution are captured by the model. In steep terrain, saltation appears to contribute less to snow redistribution than previously assumed. Preferential deposition during snow fall events appears to be a major factor influencing snow distribution in small scale steep terrain. Preferential deposition is the process that during snow fall events the snow is already inhomogeneously distributed, even when the wind velocities are too small for saltation and thus erosion of deposited snow to happen. This process is not represented in other snow drift models. Remaining uncertainties of the model system concern the formulation of suspension and the accuracy of the flow simulation. Suggestions for improvements are made. Finally, the importance of an adequate representation of snow processes for improvements in meteorological prediction models and climate models is pointed out.

MODELLED AND OBSERVED REDISTRIBUTION OF SNOW ACROSS AN ANTARCTIC ICE RISE

John C. KING[1], Phil S. ANDERSON[1], David G. VAUGHAN[1], Graham W. MANN[2], Stephen D. MOBBS[2] ([1]British Antarctic Survey, [2]School of the Environment, University of Leeds)

The ice sheets of Antarctica provide ideal, simple environments for testingmodels of the redistribution of snow by the wind. Between January 2000 and January 2002 we carried out a detailed campaign of measurements along a transect of Lyddan Ice Rise (LIR), Antarctica (74ºS, 22ºW). LIR is an approximately two-dimensional ridge about 15 km wide which rises 125 m above the surrounding ice shelves. The local prevailing winds blow approximately perpendicular to the axis of the ridge. Snow accumulation variability along the transect was determined from a ground penetrating radar survey and snow stake measurements. The survey revealed variations in accumulation of up to 50% of the area mean, both on the scale of the LIR itself and on scales of a few hundred metres. The broad-scale pattern ofredistribution is consistent with estimates of snow transport made using wind measurements from 3 automatic weather stations installed along the transect line. In order to test whether the small-scale variability in accumulation was also due to redistribution, the surface wind field over the LIR was modelled using a simple airflow model. The model was forced using radiosonde observations from nearby Halley station and the computed surface stress field was used to calculate snow transport using a simple parametrisation. The modelled snow redistribution matches the observed spatial variations in accumulation extremely well. This confirms that the observed spatial variability in accumulation is driven by variations in snow transport which are, in turn, caused by rather small topographic variations on a variety of scales.

DISTRIBUTED SNOW ACCUMULATION AND MELT MODELING - ROLE OF SNOW DRIFT, VALIDATION AND UNCERTAINTY OF THE SIMULATIONS

Juraj PARAJKA, Ladislav HOLKO, Zdeno KOSTKA (Institute of Hydrology, Slovak Academy of Sciences)

Distributed snow modelling in seasonaly snow covered areas is potentially very important for proper assessment of the amount of water contained in snow and its release into river network during the snowmelt. However, many uncertainties may appear in practical applications of distributed snow models. How to obtain true distributed input data and model parameters? Can the spatial predictions be validated and how? What is the value of a distributed snow model compared to the lumped one? We have tested modified distributed version of the energy based Utah Snow Accumulation and Melt Model (UEB-EHZ) in small mountain catchment of the Jalovecky creek, Slovakia (area 22,2 km2, mean elevation 1500 m a.s.l.). Special attention was paid to distributed parametrization of snow drift. Values of snow drift based on snow survey measurements performed in winters 1989-2001 were

combined with theoretical distribution of wind speed and topographic features of the catchment. Produced snow drift map was used to simulate the spatial distribution of snow water equivalent in two winters - the snow rich winter of 2000 and the snow poor winter of 2001. The results were validated against snow surveys and ground photographs of the catchment. Synchronisation between modelled snowmelt and measured catchment runoff and comparison of snowpack development in the forest and at open areas served as additional qualitative validation measures of the model. The simulations confirmed that there is essential difference in model parameters for forested and open areas. Consideration of spatially distributed drift factor resulted in prolonged snowmelt. However, there is high uncertainty in the estimation of snow drift. While spatial patterns of snow erosion and deposition areas can be easily estimated from DEM and other analyses, the concrete values of drift in mountains can only be estimated from field measurements.

MODELING REGIONAL AND GLOBAL SCALE SUBGRID HETEROGENEOUS SNOW COVER

Glen E. LISTON (Department of Atmospheric Science, Colorado State University)

To improve the depiction of autumn through spring land-atmosphere interactions and feedbacks within regional and global weather, climate, and hydrologic models, a Subgrid SNOW Distribution (SSNOWD) submodel that explicitly includes subgrid snow-depth and snow-cover variability has been developed. From both atmospheric and hydrologic perspectives, the subgrid snow-depth distribution is an important quantity to account for within large-scale models. In the natural system, these subgrid snow-depth distributions are largely responsible for the mosaic of snow-covered and snow-free areas that develop as the snow melts, and the impacts of these fractional areas must be quantified in order to realistically simulate grid-averaged surface fluxes. SSNOWD's formulation incorporates observational studies showing that snow distributions can be described by a log-normal distribution and the snow-depth coefficient of variation. Using an understanding of the physical processes that lead to these observed snow-depth variations, a global distribution of nine subgrid snow-depth-variability categories was developed, and coefficient-of-variation values were assigned to each category based on published measurements. In addition, SSNOWD adopts the physically realistic approach of performing separate surface energy balance calculations over the snow-covered and snow-free portions of each model grid cell and weighting the resulting fluxes according to these fractional areas. Using a regional atmospheric model (ClimRAMS) over a North American domain, SSNOWD was compared with a snow-cover formulation similar to those currently used in most general circulation models. The simulations indicated that accounting for snow-distribution variability has a significant impact on snow-cover evolution and associated energy and moisture fluxes.

FEATURES OF SPATIAL DISTRIBUTION DYNAMICS OF SNOW COVER DURING SNOW MELTING PERIOD IN SUBARCTIC TUNDRA OF EASTERN SIBERIA

Georgiadi GEORGIADI, Vladislav MALYSHEV, Alexander ZOLOTOKRYLIN, Nikolai OZEROV (Institute of Geography, RAS)

Low mountains (up to 300 m above sea-level) and piedmont plains with big enoughnumber of lakes are the main features of subarctic tundra relief of Eastern Siberia in the vicinity of Tiksi polygon of GAME/Siberia program. Mentioned features as well as strong wind during winter period redistribute of snow and as a result non-homogeneous snow cover is formed. Main part of territory is characterized by relatively thin snow depth. Much snow is accumulated in river valleys,depressions etc. These features of snow spatial distribution determine character of snow clearing of territory. Snow disappears during several days of active snow melting in main part of territory while snow is melting rather long time in the places of accumulation of much snow. In 1999-2001 a complex remote sounding of the Suonannakh river basin (in vicinity of Tiksi) was fulfilled. It was aimed to investigate of spatial-temporal distribution features of areas covered by snow, their spectral brightness, surface temperature, albedo before and during snow melting period. Remote sensing measurements were conducted by a complex of equipment from board MI-8 helicopter from a height of 400-2000 m along special routes. The equipment complex included: spectrometer recording reflecting characteristics of underlying surface in absolute values of spectral density of energy brightness within 0.4-0.85 micrometers of electromagnetic wave band with 450 spectral channels; digital video camera working in RGB channels; radiometer working over 8-14 micrometers for recording of surface temperature as well as piranometer.Results of analysis of spatial distribution dynamics of snow cover during snow melting period based on remote sensing data are presented.

SNOWMIP, AN INTERCOMPARISON OF SNOW MODELS: COMPARISON OF SIMULATED AND OBSERVED INTERNAL STATE

Charles G. FIERZ[1], Pierre ETCHEVERS[2], Ross BROWN[3], Michael LEHNING[1], Yves LEJEUNE[2], A. BOONE[4], Y. GUSEV[5], Rachel JORDAN[6], E. KOWALCZYK[7], R.D. PYLES[8], T. YAMAZAKI[9] ([1]Swiss Federal Institute for Snow and Avalanche Research SLF/WSL, [2]Centre d'Etudes de la Neige, CNRM Météo-France, Grenoble, France, [3]Canadian Meteorological Service, Dorval, Qc, Canada, [4]Météo-France, Toulouse, France, [5]Laboratory of Soil Water Physics, Institute of Water Problems, Russian Academy of Sciences, Moscow, Russia, [6]CRREL, Cold Regions Research and Engineering Laboratory,Hanover, U.S.A., [7]CSIRO Atmospheric Research, Aspendale, Australia, [8]Cooperative Institute for Research in the Environmental Sciences, Boulder, U.S.A., [9]Frontier Observational Research System for Global Change, Tohoku University, Sendai, Japan)

Snow-cover models are now widely used for various applications such as hydrology, snow ecology, global circulation models, snow monitoring, snow physics research and avalanche forecasting. The degree of complexity of these models is highly variable, ranging from simple index methods to multi-layer models simulating the snow-cover stratigraphy and texture. The main objective of the project SnowMIP (Snow Model Intercomparison Project) is to identify key processes for each application. Four sites have been selected as representative of typical snowpacks and because of the availability of both input and verification data. 26 models have participated in SnowMIP by simulating the snow-cover with the observed meteorological parameters. However, comparison should not only deal with bulk energy and mass budgets but also with the internal state of the snow-cover. Indeed, both the structure (layering) and the microstructure (shape and size of both grains and bonds) of the snow-cover are relevant to many important processes and properties of the snow-cover such as albedo, liquid water content or microwave emissivity. With varying degree of complexity, 8 of the 26 models participating in SnowMIP simulated the internal state of the snow-cover too. This paper focuses on the comparison of observed snow pit profiles to model profiles according to a simple and standardised evaluation procedure. The method provides a quantitative statistical similarity measure between either snow pit and modelled profiles or numerical results from different models. In particular, special care is given to the varying degree of complexity shown by the different models. Finally, in light of this comparison of internal state simulation, sensitivity of selected key processes to input parameters such as either albedo or new snow density are presented.

SNOWMIP (SNOW MODELS INTERCOMPARISON) : MAIN RESULTS OF THE MASS AND ENERGY BUDGETS SIMULATIONS

Pierre ETCHEVERS[1], Eric MARTIN[1], Ross BROWN[2], Charles FIERZ[3], Yves LEJEUNE[1], E. BAZILE[4], A. BOONE[4], Y.-J. DAI[5], R. ESSERY[6], A. FERNANDEZ[7], Y. GUSEV[8], R. JORDAN[9], V. KOREN[10], E. KOWALCZYK[11], N.O. NASONOVA[8], R.D. PYLES[12], A. SCHLOSSER[13], A.B. SHMAKIN[14], T.G. SMIRNOVA[15], U. STRASSER[16], D. VERSEGHY[2], T. YAMAZAKI[17], Z.-L. YANG[18] ([1]Centre d'Etudes de la Neige, Météo-France, [2]Canadian Meteorological Service, [3]Swiss Federal Institute for Snow and Avalanche Research (SLF), [4]Météo-France, CNRM, Toulouse, France, [5]Institute of Atmospheric Physics; Chinese Academy of Sciences, Beijing, China, [6]Met Office, Bracknell, Berks. U.K., [7]Instituto Nacional de Meteorologia, Madrid, Spain, [8]Laboratory of Soil Water Physics, Institute of Water Problems, Russian Academy of Sciences, Moscow, Russia, [9]CRREL, Cold Regions Research and Engineering Laboratory, Hanover, U.S.A., [10]NOAA/NWS/OH1/HRL, Silver Spring, MD 20910 U.S.A., [11]CSIRO Atmospheric Research, Aspendale, Australia, [12]Cooperative Institute for Research in the Environmental Sciences, Boulder, U.S.A., [13]COLA/IGES, Calverton, U.S.A., [14]Laboratory of Climatology, Institute of Geography, Russian Academy of Sciences, Moscow, Russia, [15]Forecast Systems Laboratory, Boulder, USA, [16]Dept. of Earth and Environmental Sciences, University of Munich, Munich, Germany, [17]Frontier Observational Research System for Global Change, Yokohama, Japan, [18]Dept of Hydrology and Water Resources, The University of Arizona, Tucson, U.S.A.)

Many snow models have been developed for various applications such as hydrology, global circulation models, snow monitoring, snow physics research and avalanche forecasting. The degree of complexity of these models is highly variable, from simple index methods to multi-layer models simulating the snow cover stratigraphy and texture. The main objective of the intercomparison project SnowMIP (Snow Model Intercomparison Project) is to identify key processes for each application. Four sites have been selected for the representativeness of their snowpack and the quality of the collected data. Two of them are situated in the European Alps, the two others in North America. 26 models have participated in intercomparison by simulating the snowpack using the observed meteorological parameters. A precise analysis of the models results has been done. The paper focuses on the variability of the results quality for the mass and energy budgets, which can be explained by the sites specificities and the models features. A particular attention is paid to the model complexity impact. The mass balance simulations are validated by comparison with local observations (snow depth, snow pits, snow bottom runoff). The models performances are interpreted using the results of the energy budget simulation. The paper also presents the sensitivity of the models results to physical processes parametrization like the snow albedo or the fresh snow density. Lastly, a general classification of the models is proposed, based on the application field and the required complexity level.

JWH01/09P/C30-002   1420

DEVELOPMENT OF MRI/JMA-SIB AND ITS IMPACT ON GLOBAL FORECAST BY GSM

Mitsuo OH'IZUMI[1], Masahiro HOSAKA[1], Masayuki HIRAI[2], Park BYOUNG-KWON[3] ([1]Meteorological Research Institute, [2]Japan Meteorological Agency, [3]Korea Meteorological Administration)

New land-surface model (MRI/JMA-SiB) has been developed under a cooperative project between MRI (Meteorological Research Institute), JMA (Japan Meteorological Agency) and KMA (Korea Meteorological Administration). Its aim is to improve a performance of GSM (JMA operational global weather forecasting model) and MRI/JMA98 (MRI climate community model) in mid and/or high latitudes. MRI/JMA-SiB consists of three sub-models, Canopy, Snow and Soil. Canopy sub-model treats momentum, heat and moisture transfer between a surface boundary layer and ground vegetation/bare soil. It is basically the same as the operational SiB implemented in GSM (Sato, 1989), except dependency of stomatal resistance on soil water. Snow sub-model is newly designed, and Soil sub-model is extended from three layers SiB implemented in MRI/JMA98. They are incorporated into MRI/JMA-SiB to simulate precisely cryosphere. **S**now sub-model deals with snow mass evolution from snow accumulation to melting, with taking account of the following; initial fallen snow density, compactive viscous flow, low heat conduction, albedo change due to aging, and water holding of snow. Snow cover is classified into two categories, partial snow cover or full snow cover. Partial snow cover (snow patch) coexists with ground grass/bare soil, and has only one snow layer in constant depth with changing a grid fraction of occupation. Full snow cover is discretized into some snow layers, with changing from one to three according to snow water equivalent. Uppermost snow layer is intended to reproduce diurnal change. Lowermost is provided for snowmelt at the bottom. Mid snow layer is expected as a buffer of heat and mass. **S**oil sub-model consists of three layers, where heat conduction, soil water diffusion due to unsaturated Darcy's flow and soil ice freeze/thaw are formulated. Heat conductivity of a frozen (or an unfrozen) soil layer of dry soil, soil water, (soil ice,) and air, is assumed to be that of a mixture by Farouki(1981). Soil ice is presumed to decrease the effective porosity of the soil layer, so that coexistence of soil water and soil ice in the soil layer increases both the effective soil water degree of saturation and the soil matric potential, but on the other hand decreases the soil water permeability. **O**ffline sensitivity experiments on snow depth, forced by surface meteorological data in Hokkaido, show that, 1) snow albedo affects weekly on snow depth, 2) snow compactive viscosity has an effect during all winter season, and 3) snow heat conductivity is a dominant factor in melting season. **O**nline preliminary forecast experiments in April 2002 with GSM indicate that snow cover evolution in Tibetan Plateau is better simulated by MRI/JMA-SiB than by the operational SiB which gives too early snowmelt compared with SSM/I. However, too fast retreat of the southern edge of snow cover in Siberia and negative bias in 850 hPa temperature in mid latitudes are generally not improved by MRI/JMA-SiB. This implies that further improvement and tunings of Snow/Soil sub-model are required.

JWH01/09P/C30-003   1440

UNDERSTANDING SNOWMELT MECHANISMS OVER THE SIERRA NEVADA REGION USING THE NCAR/PSU MESOSCALE MODEL (MM5)

Jiming JIN, Norman L. MILLER (Lawrence Berkeley National Laboratory)

Snowmelt is essential to climate and water resource variabilities in the Sierra Nevada region. The Penn Sate-National Center for Atmospheric Research fifth generation Mesoscale Model (MM5) has been used to investigate snowmelt mechanisms in this region. The model with a one-way nested 48km-12km domains was driven by a 6-hourly reanalysis dataset from the National Centers for Environment Prediction during the 1998 snowmelt season (April-June). The results showed that the snowpack was substantially underestimated due to the lower initial snowdepth and the faster snowmelt, which resulted in higher surface temperature and stronger convective precipitation because of the unstable atmospheric structure. Although the assimilation of observed daily snowpacks in the model collected from the automated Snowpack Telemetry system dramatically alleviated the warm bias and the exaggerated

precipitation, the simulated snowmelt was still not significantly improved. Further investigations indicated that the faster snowmelt resulted from intensified solar radiation absorption on the snow surface, which is caused by a lack of simulation of the effects of vegetation fraction in MM5's land-surface scheme, the Oregon State University canopy-atmosphere-plant-soil model. The lower simulated albedo also had contributions to the stronger snowmelt. The results from a sophisticated land-surface model driven by the MM5 output over the region emphasized that the realistic descriptions of the vegetation fraction and surface albedo gave rise to an accurate simulation of snowmelt, which implies that a physically-based land-surface model is critical to the mesoscale model´s predictability. In the meantime, the variations of snowmelt in the region are also strongly correlated with atmospheric patterns because of their influences on the incoming radiation and the air temperature above the snow surface.

JWH01/09P/C30-004   1500

UNCERTAINTY IN MEASUREMENT AND MODELLING OF LONGWAVE RADIATION AND IMPLICATIONS FOR SNOWMELT

John W. POMEROY[1], Alexander N. GELFAN[2], Richard L.H. ESSERY[1], Jean E. SICART[1], Raoul J. GRANGER[3], Janet P. HARDY[4] ([1]Institute of Geography & Earth Science, University of Wales, Aberystwyth, [2]Water Problems Instiue, Russian Academy of Sciences, Moscow, Russia, [3]National Water Research Institute, Environment Canada, Saskatoon, Canada, [4]US Army Cold Regions Research and Engineering Laboratory, Hanover, NH, USA)

Net longwave radiation fluxes can have an extremely important role inproviding the energy to melt snow, however their observation remainsparticularly difficult and models often have a high degree of uncertainty.Longwave radiation measurements over snow from standard and experimentalsensors were examined from sites in Russia, Canada, USA and Bolivia. Theuncertainty in some standard radiation measurements is large and can result in longwave flux estimates in error by over 100%. Where a vegetation canopy is present, there is a substantial spatial variability to thedownward longwave flux, which depends upon the energetics of the canopy aswell as atmospheric conditions. There are several methods used inhydrological modelling to estimate incoming longwave to snow from theatmosphere (Kuz´min, Satterlund, Gray), the transferability of theseregionally-derived relationships is examined. Standard methods formodelling sub-canopy downward longwave radiation are assessed in light ofrecent measurements of the spatial variability of longwave. Net longwaveflux is discussed with respect to the difficulty in diagnosing the radianttemperature of snow from its internal energetics. Finally, the sensitivityof snowmelt to the uncertainty in longwave radiation in various environmentsis demonstrated from a combination of observations and modelling.

JWH01/09P/C30-005   1520

WATER AND ENERGY BUDGET IN THE SOUTHERN MOUNTAINOUS REGION OF WETERN SIBERIA

Jumpei KUBOTA[1], Kazuyoshi SUZUKI[2], Tetso OHATA[3], Varely VUGLINSKY[4] ([1]Research Institute for Humanity and Nature, [2]Frontier Observational Research System for Global Change, [3]Institute for Low-Temperature Sciences of Hokkaido University, [4]State Hydrological Institute, St Petersburg, Russian Federation)

Siberia, which is located in the northern part of the Eurasia continent, has the widest permafrost area on earth. The runoff provided big rivers in Siberia, like Lena River, plays an important role as fresh water supply to the Arctic Sea, affecting not only the hydrological and thermal conditions of the Arctic Sea, but also the polar region climate. In order to understand water and energy cycle in Siberia, An intensive field campaign was carried out at a small forested watershed in the southern mountainous region, which is the main source of the Lena River. The Mogot watershed is located at 55.5N, 124.7E and its basin area is 30.2km2. The elevation ranges from 550m to 1150m. The dominant species are larch, birch and pine. Both the catchment scale hydrological study, including time and spatial distribution of thawing depth and soil moisture, and the observation of water, heat and CO2 fluxes between land surface and atmosphere using a tower were carried out in the Mogot watershed. The amounts of precipitation, discharge, evapotranspiration by flux measurement and interception loss, in the warm period from April 19 to October 13, 2001 (178 days)were 434.5mm, 204.1mm, 127.5mm, and 82.6mm, respectively. According to measurements of transpiration by the sap flow method and the evaporation from forest floor by the pan method, the contribution of the evaporation from forest floor was significant, around 80% of the total. The Bowen ration after the snowmelt, in the middle of April, was around 2.0. Just after the opening leaves at the beginning of June, it decreased due to transpiration, then began to increase at the end of August with falling leaves.

JWH01/09P/C30-006   1540

SPATIAL ENERGY BALANCE SNOWMELT MODELING OF THE ECHAURREN AND TOKOPAH WATERSHEDS

Constance M. BROWN-MITIC, Noah MOLOTCH, Roger BALES (SAHRA, Department of Hydrology and Water Resources, University of Arizona)

Describing the spatial distribution of snow water equivalent (SWE) as well as the space-time characteristics of snowmelt in alpine/subalpine basins is important for water resources management. Distributed SWE is critical for forecasting seasonal runoff and provides the initial condition for forecasting the timing of runoff. A spatial energy balance snowmelt model was used in two alpine watersheds: the 4.7 km2 Echaurren basin of the Chilean Andes (33.58° S, 70.13 °W) and the 19.1 km2 Tokopah basin of the Sierra Nevada, California, U.S.A. (36.60° N, 118.66° W), to melt snow from peak SWE accumulation to the end of the melt season. The model utilizes peak SWE accumulation maps generated from remotely sensed snow covered area and ground observations of snow depth and density, digital elevation models, gridded meteorological data generated from meterological stations within the watersheds, and incident solar radiation images. Binary regression trees were employed to distribute point observations of snow water equivalent (SWE) and snow depth across the study areas. Four annual peak-SWE accumulation snow surveys consisting of an average of 77 depth measurements and two density measurements from snow pits were used to estimate SWE in the Echaurren basin. An average of 319 depth measurements and 53 density measurements were collected in the Tokopah basin in April, May and June 1997. The snowmelt analysis was conducted on an hourly time step from peak-accumulation. Unrouted meltwater generated by the model were then used to create simple hydrographs for the watersheds, which were then compared to the observed basin hydrograph. The model run for the Tokopah basin was also evaluated at several stages during the snowmelt season. Modeled snow ablation was compared to observed SWE during the May and June snow surveys. The modeling approach applied in this research calculates the energy flux occurring at the snow/ atmosphere interface and therefore has low input requirements and computational expense relative to more complex models.

JWH01/09P/C30-007   1630

COMPOSITE MODELLING OF SNOWMELT AND WATER EQUIVALENT OF SNOW

Shigeo SUIZU (Geosystems Inc.)

The state of deposited snow and snowmelt is deeply related to human life and it would be useful to grasp its conditions quantitatively. The purpose of this study is to develop a practical snowmelt and water equivalent snow model for water resource management. A simplified heat balance method has been developed and daily snowmelt can be calculated based on heat balance method with a few meteorological elements. The model has been further developed and it can provide the distribution and time series of snowmelt and water equivalent of snow in an extensive area. Daily amounts of solid precipitation are predicted with the data of precipitation and air temperature. Daily amounts of snowmelt are predicted with only the data of precipitation, sunshine duration, air temperature and K_{SL} by calculating all heat balance components over snow cover. K_{SL} is the coefficient of sensible and latent heat transfer and its value can be decided with the data of precipitation, sunshine duration, air temperature and snow depth. Daily amounts of solid precipitation and snowmelt lead to a calculation of water equivalent of deposited snow. All meteorological data that are used for the calculation are collected by Automatic Meteorological Data Acquisition System (AMeDAS), operated by Japan Meteorological Agency. AMeDAS is the most densely meteorological network in Japan. The calculation has been further developed to be capable of being applied to everywhere in an extensive area. The model uses a digital elevation model (DEM), meteorological data and vegetation. Precipitation, sunshine duration and air temperature are related with topography so these values at any site are estimated with observed AMeDAS data and topographic factors of the site. The topographic factors express topographic features such as elevation, the distance from the sea, slope and so on. All topographic factors are calculated by the use of DEM. The analysis of K_{SL} has shown its dependency on topographic features and its value also can be estimated with the topographic factors. Topographic shading, slope and aspect angles influence snowmelt because they change short and long-wave radiation on the snow surface. These influences are estimated with DEM. Trees also influence snowmelt because they reduce wind speed and short-wave radiation and change long-wave radiation. Trees—covered influence is estimated with those reduction ratios that depend on the type of vegetation. The model was applied to northern and central parts of Japan. The estimates of snowmelt and water equivalent of snow are compared with observed data and the model is successfully verified.

JWH01/09P/C30-008   1650

THE ANALYSIS OF THE SNOW WATER EQIVALENT DISTRIBUTION USING SNOW MODEL AND SATELLITE INFORMATION OF SNOW IN TOHOKU DISTRICT IN JAPAN

Takehiro TOTSUKA, Yoshihiro ASAOKA, So KAZAMA, Masaki SAWAMOTO (department of civil engineering , school of engineering, Tohoku University)

Spatial and temporal SWE (Snow Water Equivalent) distribution in the Tohoku district in Japan was estimated using elevation, meteorological and satellite data. The estimation terms were from December 1998 to April 1999 and from December 1999 to April 2000. Digital elevation data was made by Geographical Survey Institute Japan (GSLJ), and its mesh size was restructured from 250m to 1100m resolutions. As meteorological data, Daily mean temperature and daily total precipitation from AMeDAS (Automated Meteorological Data Acquisition System) provided by Japan Meteorological Agency (JMA) were prepared.Observation points of AMeDAS are about 250 points in the Tohoku district. As the satellite data, eastern Japan images of JAIDAS (Japan Image DAtabaSe) were compiled from NOAA (National Oceanic and Atmospheric Administration) Satellite data. The time variation of snow water equivalent was simulated from snowfall and snowmelt models. Explanation on estimation method of the amount of snowfall is as follows.Snowfall model is based on temperature discriminating between snowfall and rainfall.Then, the temperature at each mesh was interpolated with observed data using weighted average distance method.The temperature at each mesh was corrected by temperature lapse rate, 0.6°C/100m, with digital elevation data. The amount of snowfall was interpolated with observed data using weighted average distance method with consideration for altitude dependency data of snowfall. Secondly, snowmelt distribution was estimated.The amount of the snowmelt on each mesh was calculated by degree-day method.Snow melt rate factor was decided comparing snow covered area by snow model involving the certain snow melt rate factor with the snow area map composed with the JAIDAS images. After some snowmelt rate factors were tried, the highest correlation coefficient in degree-day method was selected to estimate snow water equivalent variation. Snowmelt factor was determined using snow area maps in every month. The snowmelt rate factors were about 4(mm/day) in most months during estimation terms. As the results, this algorithm could show as better SWE distribution than previous models. As the most interesting results, almost uniform snowmelt rate factor were obtained during winter.

JWH01/09P/C30-009   1710

A NEW SNOW COVER PARAMETERIZATION FOR USE IN GCMS

Andreas ROESCH (Institute for Atmospheric and Cliamte Science)

Snow cover fraction (SCF) has a significant influence onthe surface albedo and thus on the radiation balance and surface climate. Long-term three dimensional simulations withGeneral Circulation Models (GCMs) show that the SCF greatly affects the climate in the Northern Hemisphere.By means of both ground observations and remotely sensed data, several deficiencies in the SCF simulated by the current ECHAM4 GCM were identified: over mountainous areas a substantial overestimation in the SCF was found whereas flat areas showed a distinctly underestimated SCF. This paper proposes a new parameterization of the SCFfor use in GCMs. Evaluations illustrate that it is beneficial todistinguish between the following three terrains: (i) flat, non-forested areas, (ii) mountainous regions and (iii) forests. The modified SCF parameterization for flat, non-forested areas was derived byusing global datasets of ground-based snow depth and remote sensingobservations of snow cover data. A 3-dimensional ECHAM4 simulation showedthat this modification raises the SCF by up to approximately 20%,mainly in areas with a relatively thin snow cover.The comparison between remotely sensed and simulated mean monthly surface albedorevealed a significant overestimation of the surface albedo in snow-coveredmountainous areas. An extension of the current SCF parameterization in ECHAM4to take into account mountain effects, based on the French climate model Arpège, yielded a close agreement with satellite-derived surface albedo.The adoption of the submodel for snow albedo, as used in the Canadian Land Surface Scheme (CLASS), combined with a newly-developed simple snow interception model, demonstrated the ability to capture the main physical processes of snow-covered canopies, including the albedo. The validation of thenew parameterization with Boreal Ecosystem-Atmosphere Study (BOREAS) field data showed that the modification is appropriate to capture the main features of the albedoover snow-covered forests during and after heavy snowfall events.

JWH01/10A/C30-001   0830

TESTING THE IMPACT OF PARAMETERIZATIONS IN INTERNAL SNOW PHYSICS AND INTERFACE PROCESSES ON THE SIMULATION OF SNOW COVER AND RUNOFF AT VEGETATED AREAS

Yongkang XUE[1], Shufen SUN[2], Daniel S. KAHAN[3], Yanjun JIAO[3] ([1]Department of Geography, Department of Atmospheric Sciences, University of California, Los Angeles, [2]Institute of Atmospheric Physics, Chinese Academy of Sciences, China, [3]Department of geography, University of California, Los Angeles (UCLA), USA)

To improve the prediction potential in snow cover regime in vegetated environment, a biophysical model, SSiB, has been coupled with a comprehensive snow model, SAST, which includes important physical processes for simulation of seasonal snow cover change. Base on analyses of diurnal and seasonal variations of snow temperature, SAST includes an efficient snow cover layering system for better prediction. The volumetric specific enthalpy is used as the prognostic variable instead of temperature, which simplifies the formulations in phase change processes. The coupled SSiB/SAST model includes the vegetation regime, snow cover regime and ground surface regime. Snow cover interacts with both vegetation cover above and ground surface below. In the coupled model, the snow surface temperature and canopy temperature are solved simultaneously to ensure the energy and water conservation in the vegetation-snow interface, which is crucial in the study of snow effects in global as well as regional climate models. A series of numerical experiments have been designed to understand the physics at the soil-vegetation-snow-atmosphere interface and to find the major parameterizations/parameters, which are crucial to simulate cold season processes. Observational data sets from Col de Porte of France, Ovre Lansjarv of Sweden, and Gander of Canada were used to help interpret the results. This study shows that snow layering and compaction are important to properly simulate snow depth, snow water equivalent, surface temperature, and surface runoff. The fixed snow density could produce as high as 100 percent error in estimating the snow depth and cause significant biases in SWE simulation mainly during the melting period. Furthermore, with a bulk snow/soil layer, the simulated surface temperature would persistently be close to the freezing point and its variability is substantially hampered, and the variability and the amplitude of the runoff during the snow-melting season could be severely underestimated. The experiments also show that the proper snow albedo is crucial during the ablation period and affects the magnitude and timing in both SWE and runoff simulations. Furthermore, this study indicates that the parameterizations in the surface aerodynamic resistance in the stable regime play an important role in determining the sensible and latent heat fluxes during the winter season, and then affect the snow depth simulations and prediction of snow melting as well as runoff timing. Although the snow may fully cover the ground in cold regions during the winter, numerical experiments in this study show the vegetation still exerts a substantial influence in the snow depth and runoff simulations. Numerical experimentation shows that with two ground conditions: bare soil and forests, less downward sensible heat flux on the bare ground condition produces thick snow cover and extremely high peak runoff, which leads to a typical deforestation scenario in cold regions.

PARAMETERIZATION OF SNOW PROCESSES WITHIN BOREAL ECOSYSTEMS

Yeugeniy M. GUSEV, Olga N. NASONOVA (Institute of Water Problems, Russian Academy of Sciences)

The boreal zone determines significantly the rate of climatic processes on the planet, plays an important role in the formation of hydrological cycle and influences the stability of the Earth as a global ecological system. For these reasons, problems related to studying and modelling heat and water exchange within boreal ecosystems are of a great interest and importance. The goals of the present work are to develop parameterizations of snow processes occurring within boreal ecosystems (especially evergreen coniferous forests), to include new parameterizations into one of the land surface models, namely SWAP (Soil Water - Atmosphere - Plants) model, previously developed by the authors, and to validate the new version of SWAP. Evergreen coniferous forest represents tall vegetation intercepting significant part of precipitation (both liquid and solid). That is why two active surfaces were used to schematise heat and water exchange within the forest during the cold season: the surface of forest crowns and the surface of forest floor. Modelling of heat exchange between these two surfaces and the atmosphere is based on the Monin-Obukhov similarity theory with accounting for the specific features of energy exchange within a forest. Thus, it was taken into account that trees extinguish incoming solar radiation and produce longwave emission in all directions, in particular, toward the forest floor, and that turbulent heat exchange between the forest floor and the forest crowns exists. When the water balance of the boreal forest was calculated, interception of solid and liquid precipitation by vegetation, as well as snowmelt and water freezing on the forest crowns were taken into account. Snowpack formation at the forest floor was modelled with considering phase changes of water within snow cover as well as water yield of snow on the forest crowns during melting. The developed blocks of snowpack formation on the forest crowns and on the forest floor were added to the main module of SWAP. The developed new version of SWAP was validated against a vast set of intensive observations obtained by the Valdai Scientific-Research Hydrological Laboratory during 18 years (1966-1983) at forested and grass experimental catchments located in the central part of the Valdai Hills (the boreal zone, Russia). The validation data included, in particular, intercepted solid and liquid precipitation, snow density, snow depth, snow water equivalent, snow sublimation, soil water storage, and runoff. In addition, the validation of simulation of snow processes by SWAP was performed using the observed data on snow depth (1986-1989) for 24 sites located in the French Alps. The results of validation allow us to conclude that the land surface model SWAP parameterizes heat and water exchange processes (including snow processes) which occur in the boreal zone quite reasonable.

A STUDY ON HYDRO-METEOROLOGICAL EFFECT OF INTERCEPTED SNOW USING A ONE-DIMENSIONAL LAND SURFACE MODEL

Takeshi YAMAZAKI[1], Hironori YABUKI[2], Reiko OKUBO[3], Tetsuo OHATA[4] ([1]Frontier Observational Research System for Global Change /Tohoku Univ., [2]Frontier Observational Research System for Global Change, [3]NEC Soft, Ltd., [4]Frontier Observational Research System for Global Change /Hokkaido Univ.)

In order to simulate full-year water and energy exchange between the atmosphere and land surface, snow interception is one of the least known processes. Hydro-meteorological effect of intercepted snow has been studied using a one-dimensional land surface model with a snow-interception model recently proposed by Okubo and Yamazaki (2000). The land surface model includes three submodels; vegetation, snow cover, and soil. It can calculate water and energy fluxes above and within forest, if meteorological data over the forest are

given as input. The interception model has been developed to consider both liquid and solid water on forest, melting and freezing, changing transfer coefficient of sensible and latent heat fluxes, and albedo changing. Since vegetation submodel has two layers of crown space, difference of evaporation timing between top and lower branches can be simulated. Preliminary study shows that the model can simulate intercepted snow mass and snow depth on forest floor observed previously at Morioka and Sapporo in Japan. When snow-interception is considered, we can find large differences on energy and water budgets compared with the cases of no interception or same treatment with rain. For example, the forest works as a heat source for no interception, however, latent heat is dominant and sensible heat is almost transferred from the atmosphere to vegetation when the intercepted snow is considered. Moreover, the snow cover on the forest floor strongly depends on the treatment of interception. On the other hand, the effect of albedo increasing is transient; it does not produce obvious differences of energy and water budgets in winter average. As a result, we find that it is important to heat and water budgets that snow interception is more in quantity and cooler than rain interception, and it is essential to need much energy for melting and evaporating the intercepted snow. The model is also applied to a taiga forest in eastern Siberia, Russia. Meteorological and hydrological observations were carried out there as part of GAME (GEWEX Asian Monsoon Experiment). The effect of snowfall interception is discussed quantitatively in intensely cold region such as Siberia. Since the dominant species is larch, which is deciduous, in the taiga in eastern Siberia, branch/stem area density is important especially in winter. Frost or condensation is also considered in this model, although sometimes remarkable frost is observed in the site in winter.

JWH01/10A/C30-004   0930
DEGREE-HOUR MODEL OF MOUNTAIN SNOW WATER EQUIVALENT AND EVALUATION USING SNOW LYSIMETERS BENEATH THE FOREST CANOPY

Andrew C. WHITAKER, Hironobu SUGIYAMA (Graduate School of Science and Technology, Niigata University)

Snow modeling issues are examined through the application of a degree-hour model in the Asahi Mountains of Niigata Prefecture on the Japan Sea coast. In the study basin, average annual precipitation is >2900mm with snowfall December to March and seasonal snow cover December to May in elevations up to 950m. Vegetation is mainly natural mixed beech and planted cedar and larch. Model evaluation is achieved by using three lysimeter plots of which two are located beneath the forest canopy: (a) large opening, (b) cedar stand, and (c) larch stand. Air temperature, relative humidity, snow depth and albedo, snow surveys, and snowmelt discharge are measured at each lysimeter plot. Snow surveys and air temperature are also measured at high elevations of 550m and 750m. Remaining uncertainties in modeling snow water equivalent in mountain areas include; under-catch of snowfall by precipitation gauges, variable threshold temperature to distinguish rain/snow, variability in air temperature and lapse rates, and orographic enhancement and spatial variability of precipitation. In forested areas there is additional uncertainty regarding interception and sublimation losses in the forest canopy, and the influence of the forest canopy on the energy balance and snowmelt process. This study addresses the critical lack of data on snow water equivalents and snowmelt dynamics beneath the forest canopy within a simple modeling framework.

JWH01/10A/C30-005   0950
SNOW PROCESSES IN THE SOUTHERN MOUNTAINOUS TAIGA OF EASTERN SIBERIA. I. SNOW ABLATION PROCESS UNDER A LARCH FOREST CANOPY

Kazuyoshi SUZUKI[1], Jumpei KUBOTA[2], Yinsheng ZHANG[1], Tsutomu KADOTA[1], Tetsuo OHATA[3], Varely VUGLINSKY[4] ([1]Frontier Observational Research System for Global Change, [2]Research Institute for Humanity and Nature/ Frontier Observational Research System for Global Change, [3]Institute for Low-Temperature Sciences of Hokkaido University/ Frontier Observational Research System for Global Change, [4]State Hydrological Institute)

An intensive field campaign in the spring of 2002 was carried out at southern mountain taiga region of Siberia where it is the headwater of the Lena River and Baikal basins, in order to clarify the water and energy balance of snow and soil under larch forest canopy. More than 90% percentages of these regions are covered by forest, which is composed mainly of larch tree. There are many study of snow ablation under forest canopy (e.g. Suzuki et al. 1999). In this study, we focused on the snow ablation process beneath a sparse larch forest canopy, which included the effect of snowmelt water on the forest floor evaporation. Three sites with different topographic and surface conditions were selected to observe meteorological elements, snow water equivalent and snow surface energy balance. A sparse larch forest covers Site LF at the bottom of valley (610m asl.), and Site OP was covered by grassland (608m asl). Site ES contains a sparse larch forest of east slope (635m asl.). We applied the snow and soil model (SNTHERM, Jordan 1991) to evaluate the water and energy balance within a snowpack and soil layers at the three sites and directly observed water and energy balance above snow surface by eddy covariance method at Site LF. Our study obtained the following results, 1) According to eddy covariance method, the contribution of snow surface evaporation to the snow ablation at Site LF was about 8.7% during a thaw of 2002. Whereas the large portions of snowpack melted, river discharge was insignificant during a thaw period because the river water still had frozen. 2) The most effective energy to snowmelt was net radiation because the most of turbulent fluxes were negative value to the snowmelt energy. 3) When snowcover disappeared on 7 May 2002 at Site LF, sensible and latent heat fluxes increased quickly and both values were mostly equivalent. The daily mean evaporation on forest floor with free snow in May 2002 was 0.94 mm/day. This value was similar with a value of evapotranspiration above forest canopy during a summer season in this region. This result showed the melt water contributed to the large evaporation from forest floor because our previous study showed a roughly half of melt water infiltrated into the frozen ground.

DYNAMIC CHARCTERISTICS OF SNOW COVER IN THE LENA RIVER BASIN, SIBERIA

Tetsuo OHATA[1] ([1]Institute of Low Temperature Science, Hokkaido University, [2]Frontier Observational Research System for Global Change)

Snow cover is the important component in climate system determining the winter water storage and thermal response of the earth surface. Many studies has been made to characterize their structure, find process related to their accumulation and ablation. In the present paper, summary of characteristics of seasonal variation, structure and further issues will be discussed in relation to the behavior of snow cover in the northern continental region of Siberia studied during the GAME-Siberia Project phase 1 (1996-2002). Additional information will be added from past studies. The local research sites in GAME-Siberia were Tiksi (71N, 129E), Yakutsk (62N, 130E) and Tynda(55N, 125E), expanding in the range of 16 degrees north-south. Tiksi is tundra facing the Arctic Sea, Yakutsk is in a region of forest called taiga and Tynda is also taiga area but the topography is hilly with higher summer precipitation. The discussions will made on the (1) Seasonal variation of snow cover depth and SWE.(2) Process related to accumulation and ablation of snow cover.(3) Snow-cover vegetation interrelation.(4) Satellite derivation of snow cover using microwave sensors.(5)

Future issues on the snow studies in this regions related to modeling.

THE REPRESENTATION OF SNOW IN THE UPPER DANUBE CATCHMENT AREA - A MODELLING APPROACH

Heidi ESCHER-VETTER[1], Michael KUHN[2], Wolfram MAUSER[3], Stefan NIEMEYER[3] ([1]Commission for Glaciology, Bavarian Academy of Sciences, [2]Institute of Meteorology and Geophysics, University of Innsbruck, AUSTRIA, [3]Department of Earth and Environmental Sciences, University of Munich, GERMANY)

In 2001, the research programme GLOWA-Danube was started with the aim to investigatewater-related issues in the catchment area of the upper Danube including alpinetributaries. GLOWA incorporates DANUBIA, a decision support system for a widerange of ecologic as well as socio-economic problems. DANUBIA is anetwork-based, distributed system, designed in UML (Unified Modelling Language)and implemented as a cluster of Java-programmes. Within DANUBIA, the spatialresolution is 1 km², the time step varies from fifteen minutes to one year. Thewatershed of the upper Danube is distributed over five countries and comprisesea multitude of terrains: lowland agricultural regions, pastures in the lowerand meadows in the upper pre-alpine part, rocks and glaciers in the highermountains. The whole area covers nearly 77000 km², the altitudes range from288 m to 3770 m a.s.l.. Snowfall occurs in the whole basin with a highlyvariable space and time spectrum. For the representation of snow withinDANUBIA, different surface types had to be combined with different modellingapproaches. While generally a 1 km grid was used, sub-gridcalculation was required in areas of strong relief. The presentationstarts with a short overview of the whole GLOWA-Danube programme andconcentrates on the first results of two modelling approaches, one with anenergy balance concept and one with a hydro-meteorological model.

JWH01/10A/C30-008   1120
ANALYZING THE EFFECT OF SNOW STORAGE ON BASIN-WIDE RUNOFF

Makoto NAKATSUGAWA[1], Kiyoshi HOSHI[2] ([1]Civil Engineering Research Institute of Hokkaido, [2]Foundation of Hokkaido River Disaster Prevention Research Center)

To secure water for irrigation, hydroelectric power and drinking, the dam reservoirs in cold, snowy regions need to be maintained at high water levels in spring, because snowmelt is the predominant water resource in these regions. For this reason, heavy rainfall combined with snowmelt, an event that has become increasingly likely with the acceleration of global warming, is problematic to flood regulation of dam reservoirs in early spring. The Hoheikyo Dam basin in southern Sapporo, Hokkaido Prefecture has been threatened twice by unseasonably heavy spring rainfall. In mid-May of 2000, heavy rain combined with snowmelt to cause a particularly large and unexpected inflow, and flood regulation of the dam became temporarily impossible. In late April of 2000, about 1.7 times as much rain fell as during a similar number of days in mid-May of the same year. However, the peak inflow in the mid-May event was 300 m3/s, versus 210 m3/s for that in late April. This means that outflow in late April was 0.7 times that in mid-May. To properly quantify the above situation, the storage effect of soil and snow cover on runoff should be considered, which requires the modeling of long-term hydrologic processes. These processes must be clarified not only for flood prediction under heavy rain combined with snowmelt but also for adaptive water management throughout the watershed. Hydrologic processes related to snow play a particularly important role in cold, snowy regions such as Hokkaido, northern Japan, so the snow accumulation condition and the snowmelt amount need to be properly estimated, as does evapotranspiration according to the conditions of ground surface and vegetation, in order to clarify the basin-wide water budget. The Two-layer model proposed by Kondo et. al. that considers the heat balance in the atmosphere, in the vegetation layer and at the ground surface was applied to estimate hydrologic processes, and the long-term runoff was calculated by the Tank model. The model evaluates hydrologic processes in relation to the conditions of snow pack and snowmelt amount. Based on the calculated snow accumulation condition and snowmelt amount, the snow storage amount was provided as the initial condition of a flood runoff model to reproduce the relationship between rainfall and runoff. In this way, the storage routing relating to snow processes was evaluated and its modeling was found to have promise toward rational and practical estimation of the hydrologic processes in cold, snowy regions.

JWH01/10A/C30-009   1140
SNOW COVERED AREA AND VEGETATION DATA CONSIDERATIONS IN MODELING SNOWMELT STREAMFLOW FOR TWO SOUTHWESTERN US HEADWATER BASINS

Kevin Andrew DRESSLER[1], Steven Richard FASSNACHT[2], Roger C. BALES[1] ([1]Department of Hydrology and Water Resources, University of Arizona, [2]Department of Forest, Rangeland, and Watershed Stewardship, Colorado State University)

Seasonal, snowpacks in mountains of the Southwestern USA contribute the major source of water for streamflow, typically over 85% in the Colorado River basin, and groundwater recharge. Modeling of streamflow for forecasts depends on accuracy of snow condition inputs and on parameters, particularly vegetation. To examine implementation of improved inputs for modeling snowmelt streamflow, sub-pixel Advanced Very High Resolution Radiometer (AVHRR) satellite-derived snow-covered area (SCA), interpolated snow water equivalent (SWE), and several vegetation cover types are used as input and parameterization data for the USGS Precipitation Runoff Modeling System (PRMS). The spatial distribution of modeled (1989-1999) and AVHRR-derived SCA is significantly different both in the White River (Arizona) and Upper Rio Grande (Colorado) basins. The SCA data are fractional representations of snow-covered extent within a 1-km² pixel, and are illustrated to provide a significant improvement over the snow versus no snow representation (binary SCA). The SWE data are derived from snow telemetry (SNOTEL) point data and also compare differently to modeled results. Several vegetation/land cover data sources are compared for the two basins and indicate differences in the amount and distribution of cover types. Since the majority of the spatially extensive datasets are derived from composite AVHRR imagery, the datasets and simulated streamflows are also compared to Landsat Thematic Mapper (TM) land cover maps. Several simulations are run using the various vegetation sources, including TM, and results are compared in relation to cumulative observed streamflow over a 10-year (1989-1999) simulation.

JWH01/10A/C30-010   1200
ESTIMATION OF SNOW WATER EQUIVALENT IN THE MOUNTAINOUS REGION OF JAPAN

Hiroshi ISHIDAIRA[1], Kuniyoshi TAKEUCHI[1], Zongxue XU[1], Naoki YAMAMOTO[2], Tomomi ISHIHARA[2] ([1]University of Yamanashi, [2]Graduate School, University of Yamanashi)

Japan is a country enriched with abundant snow resources. Although a heavy snow can be a

cause of the disaster such as avalanches, a large quantity of freshwater resulted from the snowmelt in the mountainous regions is a valuable resource, which can be provided to satisfy the water demands in the agriculture, industry, municipal water supply and power generation. In order to effective use this kind of resources, it is important to ascertain the spatial and temporal distribution of snow. However, it is very difficult to measure and observe snows because of geographic conditions. Fortunately, it is possible to obtain various meteorological information through the network of weather stations, and the progress of data processing technology in recent years has also provided useful means to obtain some basic data in this respect. With the meteorological data and the snowmelt model, the distribution of the snows and its equivalent water quantities can be estimated. In this paper, a method to estimate the spatial and temporal distribution of snows and its equivalent over a basin is presented. The extent of snow-covered area is detected from satellite images, and the snow water equivalent over snow-covered area is estimated by using a snowmelt model with the meteorological data. The proposed method is applied to the upper Tone-River basin, which is the second longest main river (322km) with the largest catchment area (16,840km²) in Japan. The spatial distribution of snow-covered area, snow water equivalent, and the amount of snowmelt water are estimated for past 10 years, and the correctness of the estimation by the model was confirmed by the test at observational snow water equivalent (SWE) station. The result of application shows that snowmelt water occupies about 40% of total discharge from April to June, and it shows the importance of snowmelt for water resources in the basin.

BREAKUP OF INVERSION LAYER OVER SNOWY FORESTED BASIN

Toru IWAKURA[1], Yuji KODAMA[2], Nobuyoshi ISHIKAWA[2] ([1]Hokkaido Gijutsu Consultants Inc., [2]Institute of Low Temperature Science, Hokkaido University)

Breakup of inversion layer over snowy forested basin was observed using tethered balloon and its seasonal characteristics was obtained by analyzing the surface and volumetric heat balances. In summer season (no snow), the inversion layer was destroyed by the development of mixing layer. In winter (dry snow) the inversion layer of the basin was diminished by lowering the top of the inversion layer and no mixing layer was observed. In the snowmelt season, both the lowering of the inversion layer top and the development of mixing layer was observed. The analysis of volumetric heat balance suggested that the heat source of the breakup is the sensible heat flux from the basin bottom in summer, in winter the sum of sensible heat flux at the basin bottom and radiative flux divergence was negative, suggesting some heat flux from other than the basin bottom, and in snowmelt season the same sum was positive but small. In snowmelt season the string contrast of albedo of snow at the flat basin bottom to the forest at the surrounding slopes would cause the differential heating between the basin bottom and the surrounding slopes and the anabatic situation on the surrounding slopes. These conditions of the basin could form a local circulation, which might be responsible for the breakup of the inversion layer in snowmelt season.

JWH01/10P/C30-002   1420
PHYSICALLY-BASED HYDROLOGICAL MODEL OF SNOW ACCUMULATION, SUBLIMATION AND MELT EVALUATION IN NORTHERN RUSSIA

Alexander GELFAN[1], John W. POMEROY[2], Lev S. KUCHMENT[1] ([1]Water Problems Institute, Russian Academy of Sciences, [2]University of Wales, Aberystwyth)

A comprehensive, physically based model of snow accumulation, redistribution, sublimation and melt for open and forested catchments was assembled, based on algorithms derived from hydrological process research in Russia and Canada. The model includes full radiation and multiphase mass balance, blowing and intercepted snow redistribution and sublimation algorithms. The model calculates sublimation terms explicitly and includes the canopy effect on long and shortwave radiation and on turbulent transfer. Model parameters were derived from the results of snow process experiments in both Russia and Canada. The model was used to evaluate the long-term snow mass balance of a forested and an agricultural catchment in north-western Russia using a 17 year dataset. The model was used to provide an uncalibrated simulation of snow water equivalent during both accumulation and melt periods in both forest and agricultural catchments. Mean errors in snow water equivalent were less than 5 mm over the 17 years. Blowing snow redistribution was minimal due to low wind speeds. Intercepted snow storage in the forested catchment ranged up to 18.6 mm; some of this snow sublimated resulting in a cumulative loss of 30 mm per season on average. Surface sublimation losses were small ranging from 10 mm per season in the forest to 20 mm in the open. Mid-winter melting was greater in the agricultural catchment than in the forested. Because of typically cold winter conditions, losses due to intercepted snow sublimation from the forest overcame greater surface snow sublimation and mid winter melting in the agricultural catchment in 14 seasons out of 17, resulting in an average 15% greater maximum snow water equivalent in the agricultural catchment. Because this model does not require calibration, it has potential to help estimate the water resources of poorly-gauged cold regions catchments.

JWH01/10P/C30-003   1440
SOLAR VARIABILITY BENEATH OPEN AND DENSE CONIFER CANOPIES

Janet P. HARDY[1], Rae A. MELLOH[1], Geoff G. KOENIG[1], John W. POMEROY[2] ([1]Cold Regions Research and Engineering Laboratory, [2]University of Wales, Aberystwyth)

Snow dynamics under forest canopies are strongly influenced by the large spatial variability of energy transfers in this environment. Incoming solar radiation is an important transfer that has a particularly high degree of spatial variability. Transmission of solar radiation through a canopy varies with the size and location of the canopy gaps and with canopy leaf area. Modeling this transmission has proven challenging due to the highly variable structure of forest canopies. This study aims to describe and simulate the solar variability incident on the snow surface beneath an open, discontinuous canopy and a relatively uniform, dense conifer canopy. The objectives are 1) to evaluate the variability of incoming solar radiation data with respect to canopy structure and cloudiness, and 2) to correlate measured solar radiation data with measured canopy gap fractions and predicted solar transmission based on analysis of hemispherical photographs. Observations were made during winters of 2002 and 2003 in predominately lodgepole pine (Pinus contorta) stands, one open and one dense, at the Local Scale Observation Site (LSOS) in Fraser, Colorado USA as part of the Cold Land Processes Mission. The canopy structure of all trees in a 100 ´100-m2 plot was measured in detail (species, tree location, height, crown height, diameter at breast height). Incoming global solar radiation at the snow surface beneath the open and the dense canopies was measured using arrays of upward looking radiometers (10 pyranometers, 2 pyrgeometers at each site). Incoming global solar radiation was also measured above the canopy. Hemispherical photographs were taken with a Nikkor 8mm/f2 lens at each radiometer

location in both canopies, and were analyzed with Gap Light Analyzer (GLA) software. Measured mean transmissivity for the dense pine canopy was 0.27, while the mean transmissivity in the open canopy was 0.46, with large spatial variations. The point transmissivities determined at each individual radiometer location, using above and below canopy solar incidence data, compared well with predicted transmissivities using hemispherical photographic analysis.

JWH01/10P/C30-004   1500
A SENSITIVITY STUDY OF SNOWMELT TO THE DENSITY OF THE FOREST CANOPY

Jean E. SICART[1], John W. POMEROY[1], Raoul J. GRANGER[2], Richard E. ESSERY[1], Alexander N. GELFAN[3] ([1]Institute of Geography and Earth Sciences, University of Wales, Aberystwyth, UK, [2]National Water Research Institute, Canada, [3]Water Problems Institute, Russian Academy of Sciences, Russia)

This study deals with the relations between the snowmelt in forested environments and the radiative properties of the canopy. Due to low wind speeds, turbulent fluxes under the canopy are generally of secondary importance and snowmelt strongly depends on the radiative fluxes. As the canopy density increases, two competitive processes affect the snowmelt rate: the solar irradiance decreases and the long-wave irradiance is enhanced compared to an open environment. The decrease in solar transmissivity of the canopy is generally the dominant effect and melting is reduced. Here, we used a simplified one-dimensional radiative model to describe the dependence of the surface net radiation to the canopy characteristics in terms of solar transmissivity and sky view factor. The model results are compared with measurements taken from Canada and Russia.

REPRESENTING SNOW-COVERED SURFACES IN ATMOSPHERIC MODELS : WHICH PROCESSES AND PARAMETERS MATTER ?

Richard ESSERY[1], Pierre ETCHEVERS[2], Eric MARTIN[2] ([1]Centre for Glaciology, University of Wales, [2]Centre d'Etudes de la Neige, CNRM Météo-France)

Among other applications, snow models are required for calculating surface heat and moisture fluxes as boundary conditions for atmospheric models over snow-covered surfaces. The computational demands of large-scale models, however, mean that the complexity with which snow processes are represented may be limited and snow parameters may be poorly defined. In this study, an adjustable snow model is used to investigate the influence of common snow process representations and parameter ranges on simulations of snow depth, surface temperature and fluxes. Features examined include albedo, thermal conductivity, snow hydrology and discontinuous snow cover. Results are compared with the range of results produced by 26 different models in the Snow Model Intercomparison Project (SnowMIP).

JWH01/10P/C30-006   1630
COMPARISON OF SNOW COVER ENERGETICS DURING SPRING AT OPEN AND FORESTED SITES

Danny G. MARKS, Adam WINSTRAL (Northwest Watershed Research Center, USDA-ARS)

A forest canopy modulates precipitation, meteorological conditions and energy available for warming and melting the seasonal snowcover. A detailed evaluation of meteorlogical conditions and snow cover energy balance at a site on an exposed ridge, in a protected grove of trees, and below a dense fir canopy is presented. In general the ridge site accumulates the least snow with meltout in early spring, while the grove site accumulates nearly twice as much snow and melts nearly a month later. At the fir site snow accumulation is restricted by interception so the site accumulates only a little more snow than the ridge site, and meltout occurs only a week later than the ridge site. At the ridge site energy for snowmelt is primarily from sensible heat exchange, because net solar radiation is not large enough to overcome longwave heat losses at night so net allwave radiation is generally negative. At the grove and fir sites energy for snowmelt is primarily from net radiation because wind speeds are low, and turbulent fluxes are small. At the forested sites thermal radiation is enhanced by the canopy, and net solar radiation increases with higher sun angles in spring. As melt begins, debris on the snow surface decreases snow albedo, enhancing net solar radiation. Though net thermal radiation is small or slightly negative, net all-wave radiation is positive because of input from net solar radiation. This research will improve our understanding of the effect forest cover has on snow surface energy balance.

THE SNOW COVER MODEL SNOWPACK-ECO: RADIATION AND SOIL MODULES TO STUDY PLANT GROWTH AND PERMAFROST

Michael LEHNING, Martina L. SCHG, Ingo Meirold-MAUTNER, Charles FIERZ, Perry BARTELT (Swiss Federal Institute for Snow and Avalanche Research SLF)

The snow cover model SNOWPACK represents many physical processes within the snow cover, at the interface snow atmosphere and at the interface snow soil. It is therefore suitable to give a detailed description of the snow cover development for avalanche warning, which is its original purpose. However, because the snow cover is an important part of the land surface ecosystem, many additional problems can be addressed. One aspect of growing importance is the interface between the snow cover and the soil, from the point of view of both plant ecology and permafrost development. In this context, this presentation discusses two innovations implemented in SNOWPACK: First, a new radiation transfer scheme and its application to plant ecology and second, a model module describing underlying soil layers for permafrost studies. The very sensitive and spectrally selective response of plants to radiation requires an adequate description of radiation transfer into the snow cover. This is achieved by a novel radiation transfer scheme based on Mie theory and the ?-Eddington model, which treats multiple scattering. It predicts the flux densities for

wavelength intervals. The new scheme is evaluated against laboratory measurements and data collected on summit in Greenland. As an application, the response of snow covered plants to radiation via photosynthesis or photoperiodism is modeled. In addition, plants that reach into the snow cover are an effective trap for radiation and can create their local microclimate. These three mechanisms influence the survival and growth of plants under harsh alpine conditions. The soil snow interface has a major influence on the development of permafrost. Changes in permafrost in Alpine areas can lead to slope instability and melt water release. SNOWPACK has been extended to simulate a variable number of soil layers and its physical processes heat conduction, phase change and water transport. The new model module is tested against laboratory behavior of different soils. The model is applied to predict permafrost behavior under climate change scenarios.

CHEMICAL PROPERTY OF SNOW IN THE JAPAN ALPS

Keisuke SUZUKI, Katsutaka YOKOYAMA (Department of Environmental Sciences, Shinshu University)

A chemical study of the new snow was conducted in the Japan Alps during 2000-2003 winter seasons. The samples were filtered, and conductivity and pH were measured with a conductivity meter and pH meter, respectively. Anions and cations were determined by an ion chromatography (DIONEX: DX-500). A relationship was observed between ion concentration of the new snow and the height of sampling site.

SNOW PACK IN THE SWISS ALPS UNDERCHANGING CLIMATIC CONDITIONS:AN EMPIRICAL APPROACH FOR CLIMATEIMPACTS STUDIES

Martin BENISTON, Franziska KELLER, Stephane GOYETTE (Department of Geosciences, University of Fribourg)

In many instances, snow cover and duration are a major controlling factor on a range of environmental systems in mountain regions.When assessing the impacts of climatic change on mountain ecosystems and river basins whose origin lie in the Alps, one of the keycontrols on such systems will reside in changes in snow amount and duration. At present, regional climate models or statistical downscalingtechniques, which are the principal methods applied to the derivation of climatic variables in a future, changing climate, do not provide adequateinformation at the scales required for investigations in which snow is playing a major role. A study has thus been undertaken on the behavior of snowin the Swiss Alps, in particular the duration of the seasonal snow-pack, on the basis of observational data from a number of Swiss climatologicalstations. It is seen that there is a distinct link between snow-cover duration and height (i.e., temperature), and that this link has a specific˝signature˝ according to the type of winter. Milder winters are associated with higher precipitation levels than colder winters,but with more solid precipitation at elevations exceeding 1,700 - 2,000 m above sea-level, and more liquid precipitation below.These results can be combined within a single diagram, linking winter minimum temperature, winter precipitation, and snow-cover duration.The resulting contour surfaces can then be used to assess the manner in which the length of the snow-season may change according tospecified shifts in temperature and precipitation. While the technique is clearly empirical, it can be combined with regional climate modeinformation to provide a useful estimate of the length of the snow season with snow cover,for various climate-impacts studies.

SECOND PEAK OF THE SOLUTE CONCENTRATION IN SNOW MELTWATER

Gaku YAMAZAKI, Yoshiyuki ISHII (Institute of Low Temperature Science,Hokkaido)

A hydrochemical study of the meltwater from the base of the snowpack was carried out using snow lysimeter during the snowmelt seasons at Moshiri, northern Hokkaido, which is known for severe cold and deep snow depth. Two snow lysimeters (13 square meters) were installed at 290m(Site A) and 535m(Site B) above mean sea level. Discharge of the meltwater was measured by a tipping bucket gauge with a pulse counter. Specific electrical conductivity of meltwater was monitored automatically. Samples of meltwater were collected by automatic water samplers. Snow stratigraphies beside the snow lysimeters were observed just prior to the snowmelt season in 2002, and snow samples were collected from each snow layer. Many studies reported that solute concentrations were highest in the initial meltwater flux and decreased in subsequent days. This pattern was also observed at our stage sites in 2000 and 2001. However, in 2002, the solute concentrations in the middle of snowmelt season increased again after they had decreased from high concentrations in the early snowmelt season. The onset of this increase at Site A was 4 days earlier than Site B. If dry or wet deposition to the surface of snowpack had caused this increase, both sites would start to increase simultaneously. On the other hand, the solute concentrations of the meltwater in each site increased when the snow depths decreased to the thick granular snow layers at each site. These layers were formed when the daily average temperature exceeded zero degree-Celsius in the middle of January. Anion concentration in snow layer samples and meltwater samples were compared. The anion concentration of an upper snow layer sample was different from a lower sample, because atmospheric deposition of northeast Asia occurred intermittently in March and April. Before the increase, the anion concentration in meltwater samples were close to the concentration in an upper snow layer sample. And then the concentration in meltwater samples changed remarkably as the solute concentration started to increase. After the increase, the concentration in meltwater samples were close to the anion concentration of a lower snow layer sample. These results indicated that the chemical substances in lower snow layers were retained until the snow depths decreased to the thick granular snow layers in each site. As the chemical substances are generally released from melting snow, we posutulated that the meltwater from the near surface snow flowed through preferential channels in deeper snow layers and the meltwater didn't flow in the part of deeper snow layers outside of the preferential channels. The part of deeper snow layers outside of preferential channels retained the chemical substances until the snow depths decreased to the thick granular snow layers.

LAND - OCEAN INTERACTION FOR INTEGRATED COASTAL ZONES MANAGEMENT

Lalitkumar Pandit CHAUDHARI (Institute for sustainable development and research)

Water is the key to development of the agricultural as well as social and economic development of the world. Considering the shortage of water , cost involved in water storage and conveyance to the users end , it is necessary to adopt the innovative methods of conjunctive use of water for agricultural production using water effectively and efficiently. Aquaculture is such a innovative tool in the urban and also in rural agriculture to use and reuse the water as well as waste water . Aquaculture has emerged as one of more promising industries in the world with considerable growth potential and excepted to contribute around a quarter a global fishery harvest of year 2000.Availablties of water is a constraint in nonirrigated agriculture system. The Aquafarming has a multidimensional context in perspective agricultural growth . It is tool for utilizing land and water more economically and optimally for increasing productivity, of both, land and water ,through sustainable agriculture .The countries in the Asia-Pacific region have vast and varied Aquafarming resources Oftenly these are the main source of irrigation , coastlines , bays, marshy land along coast lines reservoirs etc in this region .The overuse of water ,the saline water intrusion from the coast line causes salinity problems in many countries reducing the cultivable area resulting reduction in agricultural production. An attempt has been made in this poster to develop the plan for water management for the agriculture , aquaculture and horticulture using innovative technologies from Indian experience .The poster also evaluates the waste water quality criteria for increasing the aquacultural productivity along the coastal zones of the Maharashtra state . The poster also explain the innovative small scale methods and technologies for food production using non conventional source of water in the coastal zones for increasing the productivity.

FRESHENING OF COASTAL GROUNDWATER SYSTEMS DURING SEA REGRESSIONS:EXAMINING THE TRANSITION ZONE THROUGH NUMERICAL EXPERIMENTS

Michele R. MINIHANE[1], Henk KOOI[2] ([1]Environmental Fluid Mechanics & Hydrology, Stanford University, [2]Faculty of Earth and Life Sciences, Vrije Universiteit, the Netherlands)

The salinity distribution in coastal aquifer systems plays a key role in water resource development and land use issues. Groundwater salinity patterns are often very complex due to sea-level changes and the associated shifts in coastlines on time scales of many tens of thousands of years and the more recent impact of human activities on coastal groundwater systems. Most research focuses on the latter influences; notably that of sea-water intrusion. The influence of sea transgressions and regressions has received very little attention, but is of prime importance to understand and predict offshore occurrences of fresh and brackish groundwater that are known to extend up to 100 km from the coast. This study uses numerical modeling experiments to gain insight into the way in which freshening of groundwater systems occurred during sea regressions and determine critical factors impacting the shape and salt distribution of the saltwater-freshwater transition zone. A finite-element, variable-density flow and transport code (Metropol3) is used that incorporates advection, diffusion and dispersion. It is found that for slow but steady regression of the sea, the transition initially becomes wider, and then reaches a stable width. The observed stability in transition zone width and salt distribution suggests that, for these scenarios, the transport processes reach a dynamic balance causing the transition zone to maintain a stable shape and follow the withdrawing sea. The steady width of the transition zone increases with increasing regression rate and decreases with increasing topographic (subaerial and seafloor) gradient. It is anticipated that at higher regression rates (beyond a certain threshold value), the dynamic balance cannot be attained, causing the transition zone to become ever wider. These results can be used as a starting point for analysis of the extent to which offshore sediments on continental shelves and other shallow seas were freshened during periods of sea-level fall during glacials.

SALINIZATION ALONG PARTS OF THE EAST COAST OF INDIA IN THE CONTEXT OF CLIMATE CHANGE

U. ASWATHANARAYANA (MAHADEVAN INTERNATIONAL CENTRE FOR WATER RESOURCES MANAGEMENT)

The biophysical and socioeconomic fluxes in the coastal zones along parts of the east coast of India are studied in order to evaluate the extent of perturbation of coastal systems by human activities. Saline incursions may arise from natural causes (such as, tides, floods, cyclones, storm surges, etc., as has happened due to the supercyclone in Oct. 1999 along the Orissa coast) or may be anthropogenic (such as, excessive drawdown of freshwater for use in drinking, irrigation and industry, as has happened in the Krishna river delta). An attempt is made to delineate how rising sea levels as a consequence of global warming would affect the interlinked geomorphic, pedogenic and hydrologic elements in the evolution of the lowlands of the east coast of India. Saline incursions would not only salinize the soils, but would also degrade the groundwater resources. There is little doubt that sea level rise and possible increase in the frequency of extreme weather events will undoubtedly exacerbate the coastal salinization. The structure of the saline / fresh water interfaces is studied on the basis of the geomorphic evolution of the coastal zones, geophysical methods (e.g. self-potential and resistivity logs), geochemical (contents of Ca^{2+}, Mg^{2+}, Na^+, K^+, Cl^-, SO_4^{2-}, HCO_3^-, etc.) and isotopic methods (tritium profiles, isotopes of H, O, C and S), etc. Infiltration of excess quantities of freshwater (river water or rain water) to flush the salt water backwards, and the construction of artificial recharge structures, are some of the ways employed to roll back the coastal salinization. It is now widely realized that mitigation methodologies for climate change developed on the basis of the biophysical studies alone have very little chance of success, unless they have been drawn up in consultation with stakeholders right from the beginning. We need to find out how the socioeconomic factors in the developing countries such as India, are contributing to the global change, and how the global change is feeding back into the system and affecting the communities. Studies are needed for the economic valuation of ecosystem services, integration of biophysical and socioeconomic approaches, and developing adaptation scenarios (e.g. saline agriculture) to mitigate the consequences of the salinization. A case history is presented in regard to the adaptation measures (hydraulic methods, biological methods, and engineering structures) through stakeholder participation to keep in check the salt water intrusion in the Krishna River delta (Dr. I. Radhakrishna, person. commun.).

VERTICAL AND HORIZONTAL STRUCTURE OF THE ATMOSPHERIC BOUNDARY LAYER OBSERVED BY A MOBILE AIRPLANE (AEROZONDE) OVER SUB-TROPICAL OCEAN UNDER THE SUPPRESSED CONDITION

Atsushi HIGUCHI, Tetsuya HIYAMA, Taro SHINODA, Hiroki TANAKA, Hiroshi UYEDA, Kenji NAKAMURA (Hydrospheric Atmospheric Research Center (HyARC), Nagoya University, Japan)

For the better understanding of internal structure within the atmospheric boundary layer (ABL) over the ocean, a mobile airplane measurement was carried out near the Shimoji Island, located East China Sea, Japan. A mobile airplain (Aerosonde, operated by Aerosonde Inc., Australia) can measure air temperature, relative humidity, air pressure, and wind speed and its direction with the flight. This overall ABL field campaign was conducted as a part of Lower Atmosphere and Precipitation Study (LAPS) project, supported by Core Research for Environmental Science and Technology (CREST), Japan Science and Technology Corporation (JST). The mobile airplane flight was designed to achieve dataset for both horizontal and vertical profiles internal and above the ABL, thus we set the ˝flight pass˝ with approximately 4 km length (from 24.80 N to 24.85 N in latitude, and parallel to the line of 125.08 E in longitude) over the ocean near the Shimoji Island. Flight pass was fixed as the seven-height (100m, 200m, 400m, 600m, 800m and 900m) a.s.l. A mobile airplane measurement was carried out in five days (21, 22, 24, 25 and 26 August, 2002). Measurement period was characterized synoptically as; northern wind phase (phase I) from 21 to 23 with dry-air suppression above ABL, and southern wind phase (phase II) from 24 to 26 with relatively wet within ABL, obtained from radiosonde profiles in the same period (once par 3 hours). We focus on the phase I, the mobile airplane observed the many plumes (corresponding to same phase change both potential temperature and specific humidity, usually, opposite sense) at the height of 100 m flight pass, however, significant upward transfer of the plume could not confirmed within the ABL (200m, 400m, sometimes 600m). Since entrainment and detrainment between the top of ABL and lowest free atmosphere were observed frequently at the height of 600m, 700m and 800m. We found the shallow convective type clouds in phase I, from the aerosonde path measurements, cloud (low potential temperature & high specific humidity) and downward suppression (high potential temperature & low specific humidity) with the horizontal scale of around two kilometers.

SIMULATIONS OF THE SUBTROPICAL SEA BREEZE

Kevin WALTER, John W. NIELSEN-GAMMON, Craig EPIFANIO (Texas A&M University, College Station, Texas USA)

Theoretical and numerical studies of the sea breeze have progressed from idealized linear, two-dimensional models to fully realistic simulations of actual events with few intervening studies of intermediate complexity. As a result, there are significant gaps in our understanding of the sea breeze, despite the common view that the sea breeze is a solved problem. In this study, we use a sophisticated two-dimensional model to examine fundamental aspects of the subtropical sea breeze that are not explained by conventional theory. These aspects include: the behavior of the sea breeze near the critical latitude on a beta-plane; the observed upward phase propagation over land; the dependence of the critical latitude and the inertia-gravity wave response on the background flow; and the interaction of the sea breeze and a coastal nocturnal low-level jet.

JSM03/08A/A13-006   1100

GAP WIND-INDUCED SUMMER UPWELLING IN THE SOUTH CHINA SEA AND ITS INTERANNUAL VARIATIONS

Qiang XIE[1], Shang-Ping XIE[1], Haiming XU[4], Dongxiao WANG[2], W. Timothy LIU[5] ([1]International Pacific Research Center, University of Hawaii at Manoa, Honolulu, Hawaii, 96822, USA, [2]LED, South China Sea Institute of Oceanology, Chinese Academy of Sciences, 510301, China, [3]Department of Meteorology, School of Ocean and Earth Science and Technology, University of Hawaii at Manoa, Honolulu, Hawaii, 96822, USA, [4]Department of Atmospheric Sciences, Nanjing Institute of Meteorology, Nanjing, China, [5]Jet Propulsion Laboratory, California Institute of Technology, Pasadena, CA, 91109, USA)

Seasonal and interannual variations of the summer upwelling off the Vietnamese coast and the eastward spread of the cold water are investigated using high-resolution satellite measurements. The development of this cold jet disrupts the summer warming of the South China Sea (SCS) and causes a pronounced semi-annual cycle in SST. In summer, as the southwesterly winds approaches a north-south running mountain range, a strong wind jet occurs at its southern tip along the 10-11°N. The strong curl of this wind jet appears to be the dominant mechanism for upwelling on the Vietnam coast. In July and August an ocean anti-cyclonic eddy develops to the southeast and advects the cold jet toward into the open ocean. The maximum wind speed is located consistently south of the maximum surface cooling, indicating that the open-ocean upwelling also helps to cool the SST. Further evidence for the cold jet can also be found in chlorophyll data as the upwelled water has higher nutrients for the growth of phytoplankton. Furthermore, the cold jet is a key element to interannual variability in summer SCS. In 1998, this mid-summer cooling never took place because of the decreased wind speed, which led to the strongest surface warming on records in SCS. Interannual SST variance has a local maximum over the cold jet, and is much greater than the variance over the adjacent Indian and western Pacific Oceans. A cold jet index is constructed, which displays significant correlation with SST in the East Pacific and Indian Oceans at a lag of 5-6 months, suggesting a teleconnection from ENSO.

JSM03/08A/A13-007   1120

THE APPEARANCE OF PROUDMAN RESONANCE AND HARBOUR SEICHES IN THE AREA OF SPLIT (ADRIATIC SEA)

Ivica VILIBIC, Hrvoje MIHANOVIC (Hydrographic Institute)

The paper examines the occurrence of Proudman resonance in front of Split harbour (Adriatic Sea) and harbour seiches, including the possibility of their coupling. The dataset comprises air and sea pressure (sea level) data collected in August-December 2000, characterized by rather strong synoptic disturbances that took place over the harbour. The analyses encompass empirical tools such as time-series analysis, high- and band-pass filtering, spectral and wavelet analyses, whereas the theoretical approach includes the conceptual model of the resonance and barotropic 2D numerical model of the harbour seiches. The resonance seems to be generated in front of the harbour and then propagates inside, covering the periods between 7.7 and 28.5 min as a result of a complex atmospheric gravity wave structure and having a gain between air pressure and sea level equaling 5-40 cm/hPa. The seiches were documented to occur at the periods of 6.5, 3.0, 1.6 and 1.15 min, and were verified by the barotropic 2D numerical model. In addition, two model runs were executed: the first one with present topography and the second one with the nautical marina removed (built in 1972). The comparison quantify the influence of the marina on the seiche

characteristics. Namely, the leading seiche modes of 7.1-min and 5.0-min periods, calculated for the present topography, were probably joined in the 6.2-min mode before 1972. On the other hand, the numerical model showed that the 3.0-min seiche mode keeps its period, having the maximum amplitude at the north end of the harbour calculated for both runs. Finally, the seiches and resonance may endanger the navigation near the entrance and within the marina during the enhanced seiche episodes.

MECHANISMS OF NIGHT-MORNING RAINS OFF A MOUNTAINOUS TROPICAL COAST

Brian E. MAPES[1], Thomas T. WARNER[2], Mei XU[2], Andrew NEGRI[3] ([1]Climate Diagnostics Center, [2]National Center for Atmospheric Research, [3]NASA Goddard Space Flight Center)

The rainiest place in the Americas, and arguably the rainiest on Earth, is in western Colombia. Here the western slopes of the Andes mountains face the Pacific ocean across a ~100 km coastal plain, just north of the Equator. The rainfall climatology in this region exhibits a complex geographical pattern and an interesting diurnal cycle. We explored diurnal rainfall processes in this region using the MM5 mesoscale model with nested domains, with a finest resolution of 2km to resolve convection explicitly. Many modeling issues arose in this exercise, especially regarding cumulus parameterization. In the end, the model simulated the diurnal cycle well enough to permit a detailed investigation of physical processes. The sea breeze is the most familiar aspect of diurnal variation in coastal regions. An analogous ˝land breeze˝ has been invoked to explain nocturnal events, but is unsatisfying in this setting for two reasons:1. Nocturnal cooling of land is much weaker than daytime heating.2. Cooling a fluid from below is inefficient at driving circulations. We show that the eruption of convection offshore after midnight is caused not by a land breeze, but rather by gravity waves radiated from the diurnally varying heat source of the mixed layer over land, which is raised up into the stratified layers of the adjacent marine atmosphere by the mountains.

STUDY OF AIR TEMPERATURE MULTI-YEAR VARIATION AND ITS RELATION TO SEA ICE IN THE BOHAI SEA USING EMD METHOD

Jie SU[1], Jinping ZHAO[1] ([1]Oceanography Department, Ocean University of China, [2]2. First Institute of Oceanography, State Oceanic Administration)

In this paper, Empirical Mode Decomposition (EMD) method was adopted to analyze air temperature multi-year variation and its relation to sea ice. The data was obtained from marine stations along the seashore of the Bohai Sea. EMD method can give new information of data's multi-year variation which other data statistics method can't present. This will provide some ideas of acquiring information that implied in data's frequency. The analysis result shows that the first mode of EMD presents seasonal variation. And air temperature shows obvious regional difference among the stations. The last mode presents long-term variation. Winter contributes to warm trend mainly. The other modes present multi-year variation. Intrinsic relation exists between air temperature and sea ice feature in the Bohai Sea.

JSM03/08P/A13-002   1420

EFFECTS OF STABILITY WITHIN SPARSE CANOPYS ON AERODYNAMIC RESISTANCE IN ROUGHNESS SUBLAYER OBTAINED BY WIND TUNNEL EXPERIMENT

Susumu KURITA (Atmospheric Environment and Applied Meteorology Research Department, Meteorological Research Institute)

Under neutral and weakly stable conditions, effects of stability within sparse canopies on aerodynamic resistance in roughness sublayer above it were studied systematically by wind tunnel experiment using Laser Doppler anemometer and cold-wire thermometer. Two types of canopy were utilized. One is block canopy and the other is pole canopy. The frontal indexes of them are 0.36 and 0.12, respectively. They belong to sparse canopies. The heights of the elements were 95mm for block, and 100mm for pole, respectively. Fetch was 13.9 m. Stable stratification was established by cooling the floor of the wind tunnel. Including neutral condition, five stabilities were utilized. The stability indexes of the canopies defined by H/L0 ranged from 0 to 0.15. The H is the height of the canopy and L0 is the Obukhov's stability length just above it. One of the purposes of this experiment is to obtain stability dependent feature of horizontal area average in the roughness sublayer above the canopy. The horizontal average of the results were compared with the conventional log-linear treatment, which assumes fixed (neutral) values of roughness length (z0) and zero-plane displacement (d). Following results were found. (1) The aerodynamic resistances obtained show a considerable difference from the conventional treatment for both canopies. (2) Introduction of stability dependencies of the roughness length and zero-plane displacement can compensate the differences. (3) Horizontal average of wind speed and temperature profiles can also be fit by the conventional treatment using the stability dependent parameters in the roughness sublayer. (4) For example, using the conventional log-linear form and the constants recommended by Hogstrom (1996), the zero-plane displacement increased and the roughness length decreased under the stable stratifications. To realize the stable conditions in the wind tunnel of MRI, wind speeds were required to be weak (from 0.85 m/s to 1.5 m/s in inflow). This means that the Reynolds number of the canopies in wind tunnel becomes small compared with that of canopy under atmospheric boundary layer. So there is a possibility that effects of the Reynolds number change caused the results, because the stability change was accompanied by wind speed change at canopy height. To estimate contributions of Reynolds number dependence, wind speed dependencies of the resistances were also obtained under neutral condition. It was found that the effect of wind speed change is very small compared with stability effects. So far effects of a canopy have been parameterized by its geometry only in an atmospheric surface layer. Stability effects within a canopy have not been paid much attention independently. But this is not *a priori* thing as pointed out early. The results of this experiment suggest a possibility that thermal stratification within a canopy may affect on the canopy-atmosphere interaction independently.

JSM03/08P/A13-003   1440

THE COASTAL OCEAN DRAG COEFFICIENT

Gerald L. GEERNAERT (Los Alamos National Laboratory)

During the past four decades, the air-sea interaction community has reached a general consensus that the drag coefficient is larger for steep wave conditions and smaller for older wave states. The predictability of the drag coefficient for swell conditions is less certain.

These tentative conclusions, in most part, are based on wave and wind stress data measured from stable platforms, most which are located in coastal zones. Recent data from the open ocean, and theoretical analysis of flux divergence for coastal offshore flow, suggest the opposite, i.e., that the wave dependent drag coefficient might, at times, be a misinterpretation of flux computations when there is strong flux divergence in the surface layer. Our analysis suggests that if one correctly treats the surface layer as a layer of weak to moderate flux divergence, drag coefficient measurements will become nearly constant with fetch and will only insignificantly depend on wave state. This presentation will review the data and theory, as it applies to coastal zones, and recommendations on how to go forward will be presented.

COUPLED RADIATIVE AND THERMAL TRANSFER REGIMES OVER SHALLOW-WATER BENTHIC ENVIRONMENTS

Enrico C. PARINGIT, Kazuo NADAOKA (Department of Civil Engineering, Graduate School of science and Engineering, Tokyo Institute of Technology)

Knowledge on the regimes and dynamics of thermal and light climate is essential for proper understanding of biological responses from shallow-water benthic flora and fauna. A method to compute combined heat conduction and radiative transfer in a transparent water medium is proposed. The heat equation is solved by an implicit finite-difference scheme and the radiation is simulated using a ray-tracing method for different types of benthic structures such as seagrasses, corals, macroalgae and sand. Stability and convergence for the coupling of both methods is shown together with its performance relative to field measurements of temperature and irradiance. The model is extended to predict light requirements and heat tolerance, potential distributions and densities of benthic habitats in turbid, light-limited environments as a function of flow, degree of nutrient enrichment, sediment abundance and effect of inland outflows. The implications of modeling for monitoring and remote sensing temperature and irradiance retrievals, particularly of coral reef areas are discussed.

LAND OCEAN INTERACTIONS IN THE COASTAL ZONE: ON THE ROLE OF COASTAL FLORA IN STABILIZING TERRESTRIAL GAINS

Balchand N. ALUNGAL (IAPSO)

The tropical shoreline of State of Kerala exhibits features of dynamic equilibrium acting under varying forces of land - ocean interactions. Erosion/deposition is common along the coastal plain, particularly during the southwest monsoon season when wind - wave - precipitation is predominant to alter beach stability. However, in recent years, conspicuously, coastal flora is playing a significant role in stabilizing those areas which have been won over from the sea. Social forestry coupled with active beach protection measures ensures the upkeep and stability of many a number of sites along the vulnerable beaches. The integration of new plant species and continued vegetation practices have aided acceleration to beach nourishment programs apart from implementing concrete steps to take advantage of land - ocean interactions. The coastal processes are described in light of changes in ocean dynamics during different seasons and the appropriate approaches on a regional to local scale are elaborated in order to achieve better results. These include use and regulation of beaches and material therein, promotion of eco-friendly coastal flora growth, restricted human interferences, wave damping - cum - regulated beach sediment movements, conducive eco-tourism and all the more, a through perspective of the prevailing coastal climate and its responses to land - ocean interactions. Examples from Azhikkal, Vypeen, Thankkasherry and other locations of Kerala state exemplify the ongoing practices and the resultant achievements.

CHANGE IN CHLOROPHYLL CONCENTRATION AFTER EARTHQUAKES AND ASSOCIATED LAND-OCEAN-ATMOSPHERIC PROCESSES

Ramesh P. SINGH[1], Sagnik DEY[2] ([1]Professor, Department of Civil Engineering, Indian Institute of Technology, Kanpur, [2]Department of Civil Engineering, Indian Institute of Technology, Kanpur)

Earthquake is a complex phenomenon, which induces change in land, ocean and atmospheric parameters. Detailed analysis of multisensor data has been carried out to study the changes in ocean and atmospheric parameters. Significant changes in chlorophyll concentrations in ocean have been found along the Gujarat coast after the earthquake. In the present paper, we present the analysis of IRS P4 OCM (Ocean Color Monitor) data. Prior and after the Andaman earthquake (13.087 N, 93.112 E) of September 14, 2002. IRS P4 OCM data have better ground resolution (236 m along track and 360 m across track) compared to SeaWiFS data. The data are mostly covered by clouds, however the chlorophyll concentrations from the cloud free regions have been deduced which show changes in chlorophyll concentration after the Andaman earthquake of September 14, 2002. The significant changes in chlorophyll-a concentrations in the ocean are also found to be associated with other earthquakes around the globe. The detailed analysis of OCM and SeaWiFS data from the earthquake affected region show that the chlorophyll concentration is associated with the shallow earthquakes (focal depth < 30 km). The associated land-ocean-atmosphere processes will be discussed in view of the changes observed after the earthquake.

JSM03/08P/A13-007   **1620**

TRANSFERTS DE FLUX ET STABILIT - DE LA FACADE MARITIME DU DELTA DU FLEUVE SÉNÉGAL

Alioune KANE (department of geography/ Faculty of Arts and Human Sciences/ University Cheikh Anta Diop)

La bordure maritime du delta du fleuve Sénégal entre dans la catégorie des littoraux où l'équilibre des côtes sableuses est le résultat d'un bilan qui concerne la plage,mais aussi tout le profil actif,du sommet du cordon dunaire aux fonds de 10 à 20 m environ. C'est un système complexe et instable sous l'effet de la conjugaison de phénomènes naturels et de phénomènes anthropiques liés à l'édification du barrage de Diama. Le delta du Sénégal a été classé parmi le type extrême à prédominance très nette des effets de houle,qui a pour résultat une dérive littorale édifiant des cordons littoraux parallèles à la côte. Les contours de la côte du delta du Sénégal sont le résultat d'un état d'équilibre entre l'action du fleuve et des courants de houle. Au niveau et en aval de Saint-Louis,le fleuve n'est séparé de l'océan que par un cordon sableux,la Langue de Barbarie,résultat d'un long processus alternatif d'engraissement et de démaigrissement de la plage par la dérive littorale. L'embouchure du Sénégal,depuis son origine,s'est acheminée régulièrement vers le sud, avec des replis de 4 - 5 km vers le nord. L'évolution du bief estuarien est sous la dépendance des apports sédimentaires transportés par les flots de la crue, et par les actions de remontée des eaux

océaniques dans l'estuaire. Les observations à Gandiole montrent une variation moyenne en volume se traduit par un déficit de l'ordre de 400 m³ par mètre linéaire de rive, soit un approfondissement de 30 cm . Le transport solide du fleuve Sénégal reste relativement faible. C'est un fleuve de faible compétence dans l'estuaire, qui ne joue pas un rôle essentiel dans l'édification de la flèche littorale, mais peut contribuer à l'érosion des cordons. L'embouchure jusqu'à Gandiole demeure largement sous influence marine avec des courants de marée qui semblent s'intensifier, empêchant l'envasement du chenal qu'on note plus au nord. L'évolution sédimentologique montre vers l'embouchure, un lit du fleuve chargé en sables à grains moyens et homogènes. Plus en amont, les formations sont des dépôts fluvio-deltaïques sableux fins silto - argileux, le lit du fleuve se charge en sables fins à très fins et plus hétérogènes. La fraction fine négligeable dans les sédiments de l'embouchure devient importante dès qu'on remonte le bief estuarien. Les sables sont grossiers en fin de crue du fait de la prépondérance des apports marins et de l'érosion des berges. Par contre là où le chenal est limité par des dépôts fluvio - deltaïques et où les actions marines sont réduites, les lutites deviennent très importantes dans les sédiments. L'instabilité de l'embouchure du fleuve demeure très élevée depuis l'avènement des barrages. En vue des aménagements portuaires, les profondeurs relevées sont insuffisantes pour permettre une navigation de gros bateaux pour assurer le désenclavement du Mali. La sédimentation marine dominante constitue un obstacle majeur pour la navigation.

JSM03/08P/A13-008   **1640**

RESERVOIR INTERCEPTION OF GLOBAL SEDIMENT FLUX TO THE COASTAL ZONE

Charles J. VOROSMARTY[1], Michel MEYBECK[3], Balazs M. FEKETE[1], Keshav SHARMA[4], Pamela GREEN[1], James SYVITSKI[5] ([1]Water Systems Analysis Group, University of New Hampshire, [2]Earth Sciences Department, University of New Hampshire, [3]UMR Sisyphe, Universite de Paris IV, [4]Dept of Hydrology and Meteorology, Babar Mahal, [5]INSTAAR, University of Colorado at Boulder)

A framework for estimating global-scale impacts from reservoir construction on riverine sediment transport to the ocean is presented. Study results depict a large, global-scale, and growing impact from anthropogenic impoundment. This study analyzes data on 633 of the world's largest reservoirs (LRs) (≥ 0.5 km3 maximum storage) and uses statistical inference to assess the impact of the remaining >44,000 smaller reservoirs (SRs). Information on the LRs was linked to a digitized river network at 30ÅE(latitude x longitude) resolution. A residence time change (DtR) for otherwise free-flowing river water is determined locally at each reservoir and used with a sediment retention function to predict the proportion of incident sediment flux trapped within each impoundment. More than 40% of global river discharge is intercepted locally by the LRs analyzed and a significant proportion (≈ 70%) of this discharge maintains a sediment trapping efficiency in excess of 50%. Half of all discharge entering LRs shows a local trapping efficiency of 80% or more. Several large basins such as the Colorado and Nile show nearly complete trapping due to large reservoir construction and flow diversion. From the standpoint of sediment retention rates, the most heavily regulated drainage basins reside in Europe. North America, Africa, Australia/Oceania are also strongly affected by LRs. Globally, greater than 50% of basin-scale sediment flux in regulated basins is potentially trapped in artificial impoundments, with a discharge-weighted sediment trapping due to LRs of 30%, and an additional contribution of 23% from SRs. If we consider both regulated and unregulated basins, the interception of global sediment flux by all registered reservoirs (n ≈ 45,000) is conservatively placed at 4 to 5 Gt yr-1 or 25-30% of the total. There is an additional but unknown impact due to still smaller unregistered impoundments (n ≈ 800,000). From a global change perspective, the long-term impact of such hydraulic engineering works on the world's coastal zone appears to be significant but has yet to be fully elucidated.

APPLICATION OF LASER STRAINMETERS IN GEOPHYSICAL STUDIES OF TRANSITIONAL ZONES

Grigoriy I. DOLGIKH (Dep. of Seismoacoustics)

Laser strainmeters have been applied in geophysical studies for a long time. Laser strainmeters of IPIO FED RAN are applied to the study of generation and dynamics of infrasonic waves in the hydrosphere and their transformation at the atmosphere-hydrosphere-lithosphere interface. Using laser strainmeters of the equal-and unequal-arm types in one-coordinate, two-coordi-nate. and spaced variants, the following results were obtained: the loading effect of the diurnal and semidi-urnal ocean tides on the microstrain level of the crust was estimated; some ultralow-frequency oscillations of the Earth can be pro-duced by seiche of adjacent water areas; the energy of internal sea waves is not transformed into the energy of small-scale turbulence, as was previously believed, but is converted into the energy of elastic vibrations of the seafloor (lithosphere); and general regular patterns of the origination of microseisms of first and second kind due to the interaction of standing and trav-eling waves with the seafloor in the shelf zone have been established and their main spectral characteristics have been studied. During the interaction of internal and surface sea waves with the seafloor, the energy is withdrawn into the lithosphere, mostly in the form of Rayleigh waves, and the major semiaxis of the polarization ellipse of the latter contrib-utes most to vertical displacements of the crust. In order to obtain accurate numerical estimates of the energy withdrawn into the lithosphere, not only horizontal components of displacements but also vertical ones should be measured. For this purpose, a laser strainmeter with a vertically oriented measuring arm should be developed and mounted in a hole of a suitable size. The joint use of vertical and two horizontal (oriented N-S and E-W) laser strainmeters is promising for the envi-ronmental monitoring in a wide frequency range with energy estimation of wave processes and study of main parameters of waves and vibrations, as well as the medium of their propagation. In 2000, a laser strainmeter with a vertically ori-ented measuring 3.5-m arm was created and tested at a distance of 50 m from a horizontal laser strainmeter with a measuring 52.5-m arm at the marine expedition station of IPIO FED RAN (the Shultz Promontory). Both laser strainmeters are located on the Sea of Japan coast 30 m above the sea level. Their optical schemes are based on a modified Michelson interferometer using as a light source a frequency-stabilized He-Ne laser with a long-term stability of . The main parameters of the setup are as follows: a sensitivity , a microdisplacement measurement accuracy of 0.3 nm, the working frequency range from (conventionally) 0 to 1000 Hz, and a virtually unlimited dynamic rang. The possibility of joint application of vertically and horizontally oriented laser strainmeters in geophysical studies of transitional zones is analyzed in a case study of recording elastic vibrations and waves from a seismoacoustic frequency-tuned radiator and earthquakes, as well as surface sea waves.

NUMERICAL SIMULATION OF STRONG WIND SITUATIONS NEAR THE MEDITERRANEAN FRENCH COAST: COMPARISON WITH FETCH DATA

Alessandro PEZZOLI[1], Gilles TEDESCHI[2], François RESCH[2] ([1]DITIC - Turin Polytechnic (ITALY), [2]LEPI - University of Toulon and Var (FRANCE))

A detailed analysis of typical strong wind situations near the Mediterranean French coast is presented. Special attention is focused on the NNW wind in the Gulf of Lions that is commonly called Mistral. The analysis is made from both the synoptic and mesoscale point of view, with the aid of numerical simulations based on the RAMS model (Regional Atmospheric Modelling System). The main atmospheric, climatic and meteorological characteristics are discussed. The simulations were carried out using this model from 20 to 22 March 1998 and from 24 to 26 March 1998. Afterwards a comparison was made with meteorological measurements collected during the international FETCH campaign in the Gulf of Lions in March and April 1998. The comparison between simulated wind fields and values measured by coastal meteorological stations and oceanographic buoys at sea help to fully understand the complicated physical processes that characterize strong wind situations in coastal zones. Indeed, the results of the model show that, on the one hand it is possible to observe a representation of the wind direction by the model that can be considered close to the reality, while, on the other hand, the calculated wind speed values are, in most cases, underestimated compared with the measured values. It is noted, however, that this is a discrepancy commonly observed in the study and analysis of strong winds coming from the land in an unstable atmosphere and complex orography. In such cases, models are able to simulate the phenomena but often underestimate the wind speed. It is for this reason that it becomes essential, during the final now-casting phase, to compare the measured values with the calculated results. This consideration helps to understand how important it is to have reliable measurements distributed over the entire field using remote measuring methodologies for capturing the meteorological parameters. Furthermore, the comparison between the wind fields at sea obtained by the RAMS model and the wind direction and intensity values measured by the ASIS buoy confirms the effective variability of the Mistral. The study also shows how, under unstable atmospheric conditions, the wind rapidly changes direction and intensity from the coast towards the open sea. Consequently, the wave fetch cannot be considered as constant in space when the wind is coming from the land. This latter consideration is particularly important since the parametric equations that give the significant wave height and the wave period are based on the hypothesis of a constant fetch and completely ignore the atmospheric stratification of the boundary layer. It is therefore possible to conclude that it could be interesting to analyse, in a future research, the possibility of introducing correction factors into these equations. These equations could be based on the thermal characteristic parameters of the boundary layer deduced from in-situ measurements or, possibly more promising, from data obtained from simulations using atmospheric models with limited scale.

PROFILE MEASUREMENT OF THREE-DIMENSIONAL WIND SPEED OVER A COASTAL ZONE OF SHIMOJI ISLAND, JAPAN

Tetsuya HIYAMA, Hiroki TANAKA, Atsushi HIGUCHI, Taro SHINODA, Kenji NAKAMURA (Hydrospheric Atmospheric Research Center, Nagoya University)

For better understanding the development of lower atmospheric boundary layer (ABL) over the ocean, a profile measurement of three-dimensional wind speed has been carried out on Shimoji Island, Japan. The observation period was from 21 to 27 August 2002. This observation has been conducted as a part of the Lower Atmosphere and Precipitation Study (LAPS), Core Research for Evolutional Science and Technology (CREST), Japan Science and Technology Corporation (JST). A Doppler Sodar (Acoustic Wind Profiler; XFAS, Scintec, Germany) was used for the measurement. It measures Doppler shift of acoustic waves backscattered due to atmospheric turbulence for a vertical beam and four oblique beams. Using 10 frequencies of acoustic waves, vertical profiles of three-dimensional wind speed and those variances due to turbulent fluctuation were obtained up to the inversion height of the ABL. From the flux measurement deployed on the Cape Nishi-Henna-saki, Miyako Island, the observation period was divided into two short periods according to the dominant wind direction. These were northern wind from 21 to 23 August (P-N period), and southern wind with fluctuation from 24 to 27 (P-S period). Although the Doppler Sodar was located less than 500 m inland from the coast during P-N period, large values of vertical wind speed and its variances were observed from 100 up to 700 m (inversion height) above the ground surface. The maximum values of vertical wind speed and its variances were around 0.5 ms[-1] which observed in the middle of the ABL. A mobile research aircraft observation using a model aircraft (Aerosonde, Australia), equipped with temperature and humidity sensors, revealed occurrences of turbulent plumes over the sea surface. Thus it seemed that the Doppler Sodar has also detected the turbulent plumes developed on the sub-tropical sea surface. Because the sensible and latent heat fluxes over the sea surface were from –2 to 32 Wm[-2] and from 0 to 145 Wm[-2], respectively, it seemed that the turbulent plumes were developed due to a wet convection system. Turbulent plumes occurred over the sub-tropical sea surface have rarely been observed in previous studies. This study suggests importance of shallow convection system within humid ABL over the sub-tropical sea surface.

FLUX OBSERVATION ON THE CAPE NISHI-HENNA-SAKI, SOUTHWESTERN ISLAND, JAPAN

Hiroki TANAKA, Tetsuya HIYAMA, Kenji NAKAMURA (Nagoya University)

In order to understand the lower boundary condition for development of atmospheric boundary layer over the ocean, a flux observation has been carried out on the tip of the Cape Nishi-Henna-saki, Hirara city, Japan, at 24.91N and 125.26E, from 15th to 27th August 2002. The observation has been conducted as part of the Lower Atmosphere and Precipitation Study (LAPS), Core Research for Evolutional Science and Technology (CREST), Japan Science and Technology Corporation (JST). The measured items on a 10-meter mast were the solar radiation, reflective radiation, atmospheric radiation, sensible heat flux, latent hear flux, momentum flux, carbon dioxide flux, sea surface temperature, ground surface temperature, air temperature profile, relative humidity profile, and the wind velocity profile. The seawater temperature also measured at 5 points under the sea surface. The sea surfaces were expanded from north or southwest from the observation mast, while land surfaces covered with bush were distributed southeast, and a rock pinnacle was mounted on the northwest edge of the cape. Observed solar radiation exceeded 1000Wm-2 on clear days, and the averaged value was 298Wm-2. The reflective radiation, which might mainly come from the land surface around the mast, was observed as 20% of the solar radiation. The atmospheric radiation varied from 380-420Wm-2 at nighttime to 450-500Wm-2 in daytime, accompanied with the change in the air temperature. The mean atmospheric radiation was 428Wm-2. The sea surface temperature obtained by an infrared radiometer agreed well with seawater temperature sensors, when it was computed using the emissivity

of 0.97. The seawater temperature varied 28.9-30.9 degree during the first half of the observation period and 29.4-32.7degree during the second when the wind velocity was smaller. The wind velocity suddenly decreased at 21:00 on 22nd August, then the wind direction suddenly changed at 20:00 on 23rd August from north to south. The observation period was divided into three short periods according to the dominant wind direction. The wind direction was southeast during the period P-SE from 15th to 17th, north during the P-N from 18th to 23rd, and mainly south but fluctuated during the P-S from 24th to 27th. The latent heat and carbon dioxide fluxes during the P-SE and part of the P-S showed the effect of the plant´s activities such as transpiration, respiration, and photosynthesis, while the fluxes might be come from the northern sea surface during the P-N. The sensible heat flux during the P-N varied -2-32Wm-2 and the latent heat flux 0-145Wm-2. The average values were 9Wm-2 for the sensible heat flux and 58Wm-2 for the latent heat flux.

THE IMPACT OF LAND-USE CHANGE ON GREENHOUSE GAS EMISSIONS IN TROPICAL ASIA

Haruo TSURUTA[1], Shigehiro ISHIZUKA[2], Yasuhiro NAKAJIMA[3], Seiichiro YONEMURA[3], Shigeto SUDO[3], Kazuyuki INUBUSHI[4], Shingo UEDA[5], Daniel MURDIYARSO[6], Iswandi ANAS[6], Abdul HADI[7], Mochamad ALI[8] ([1]Faculty of Agriculture, Tokyo Universtiy of Agriculture and Technology, [2]Forestry and Forest Product Research Institute, JAPAN, [3]National Institute for Agro-Environmental Sciences, JAPAN, [4]Department of Horticulture, Chiba University, JAPAN, [5]College of Bioresource Sciences, Nihon University, JAPAN, [6]Bogor Agricultural University, INDONESIA, [7]Lambung Mangklat University, INDONESIA, [8]Jambi University, INDONESIA)

Land-use change in the Asia-Pacific region has been rapidly progressing since the 1970s, and part of tropical forests has been converted to agricultural fields, rubber and oil-palm plantations, which is different from that in tropical America and Africa. The impact of land-use change on the greenhouse gas (GHG) emissions, however, was not studied in southeast Asia. An intensive field program on the influence of land-use change in terrestrial ecosystems on GHG emissions and soil dynamics was carried out during 1997-2002, in Sumatra and Kalimantan, Indonesia, where humid tropical forests and peat wetlands are typical terrestrial ecosystems. The following sub-programme were included: (1) Field measurements of GHG emissions (CO2, CH4, N2O) from soils under different land-use and on a regional scale in humid tropical forests in Jambi province, Sumatra, and in peat wetlands in south Kalimantan and east Jambi; (2) Studies on controlling factors of greenhouse gas emissions from soils in humid tropical forests in Jambi; (3) Meteorological and biological influences on carbon dioxide(CO2) flux and carbon budget in the tropical secondary forests in Bukit Soeharto, Samalinda, east Kalimantan, and (4) Development of database for ecosystem changes and of methodology for scaling-up the estimate of GHG emission on a regional scale. The major findings of (1) and (2) are summarized as follows: (1) N2O emission rate from humid tropical forests in Jambi was less than 10 ugN m-2 h-1 much lower than in other tropical regions, and was affected by soil and land-use types. N2O emission was greatly enhanced after the forest was cut and burned, while it decreased to the same level as that before deforestation within two and half years. Nitrification is the major process for N2O production by incubation experiment. The uptake rate of CH4 was about 20 ug m-2 h-1, and CH4 flux frequently was positive, which was strongly affected by termite. It was very low after the forest was cut and burned, and was gradually increased to the same level as that before deforestation. The emission of CO2 from the forest soils was lower than in other tropical regions. (2) In peat wetlands in South Kalimantan, N2O emission rate was in a range of 0.06-0.14 mgN m-2 h-1, higher than in the humid tropical forests in Jambi. CH4 emission rate was less than 3 mg m-2 h-1 much lower than in Amazonia, and rice paddy fields. The land-use change in peat wetlands to agricultural fields also enhanced the GHG emissions.

JSM04/09A/B23-002   0930

ATMOSPHERIC TRACE GAS EMISSIONS FROM LIVESTOCK IN SOUTH, SOUTHEAST, AND EAST ASIA

Kazuyo YAMAJI, Hajime AKIMOTO, Toshimasa OHARA (Frontier Research System for Global Change)

Our group has been developing an original emission database of atmospheric trace compositions to provide input data for models predicting future atmospheric and climate change. We focus on the spatial distribution of trace gas emissions with high resolution of a 0.5 degree x 0.5 degree latitude-longitude. The target area of this study is South, Southeast, East Asia, that is one of the most important sources of various trace gases and is also an area worthy of attention in the light of the atmospheric composition change which may be brought about by the changes of industrial structure, life style, and land use due to economic growth here. In this presentation, we focus on atmospheric trace gas emissions from livestock which is one of important anthropogenic sources of atmospheric compositions, CH_4, NH_3, and N_2O. The increase of human population and the changes of land use due to recent rapid economic growth have expanded livestock breeding and changed its forms, especially in South, Southeast, and East Asia, so it is worthwhile to construct more accurate the emission database incorporating emission factors and activity data with enough regional specifics and detailed geographical information in this area. Hence, this presentation shows the spatial distribution of CH_4, NH_3, and N_2O from livestock in South, Southeast, and East Asia in 2000 with a 0.5 degree x 0.5 degree. The basic methodologies to obtain the emissions were quoted from the IPCC guidelines and the EMPE / CORINAIR guidebooks. These emissions were estimated using livestock populations in each country and in divided regions of some countries (India, China and Japan) and the emission factors with considering regional specificity. Our primary source of the livestock population was the FAO database. In addition, livestock populations at province (state, prefecture etc.) level were available from other countries´ statistical databases. As country specific emission factors for some countries were used, CH_4 emissions from livestock which summed up emissions from their manure management systems and enteric fermentation were about 30 $TgCH_4$ comparatively agreed with emissions calculated from the default IPCC emission factors. NH_3 and N_2O from manure management systems were estimated at about 13.0 $TgNH_3$-N and 0.3 TgN_2O-N using the default emission factors, respectively. These emissions were allocated into a 0.5 degree grid indicating vegetations and land covers that domestic animals seem to

be bred on using grided datasets; area grid database (GPW area estimates on a 2.5′ grid): land cover database (AARS Asia 30-second Land Cover Data Set): 1km mesh dataset in geographical information for Japan. With expanded livestock populations in this area, on the other hand, these emissions have been increasing recently, for example, CH_4 emissions from livestock increased at a rate of 2 % a year during 1965-2000 in average. In particular, recent upward tendency was remarkable in China.

JSM04/09A/B23-003   1000

CARBON ISOTOPE EXCHANGE BETWEEN THE ATMOSPHERE AND BIOSPHERE: IMPACT OF LAND-USE

Marko SCHOLZE (Max-Planck-Institue for Meteorology)

One of the fundamental challenges in carbon cycle studies concern the identification of the different sources and sinks of atmospheric CO_2. Changes in the concentration and stable isotope ratio of atmospheric CO_2 can be used to constrain the global carbon budget and imply location and magnitude of carbon sources and sinks. During the last years the global average rate of CO_2 increase and also the isotopic ratio of carbon dioxide has varied widely and somehow irregularly, and it is believed that the terrestrial biosphere contributes significantly to these signals. A common top-down method to infer the ocean and land contributions to thesevariations is the double-deconvolution of the atmospheric CO_2 and ^{13}C records. This partitioning calculation is sensitive to various quantities, one of them the assumed isotopic disequilibrium between uptake and release of terrestrial carbon. However, the isotopic signature of the terrestrial biosphere is highly variable in space and time due to vegetation composition but also to inter-annual climatic variability. Here, the isotope LPJ framework, which includes isotopic fractionation of^{13}C during assimilation and a full isotopic terrestrial carboncycle, is used to calculate the atmosphere-biosphere exchangeflux of CO_2 and its $\delta^{13}C$ for the years 1901 to 1998. The model thus allows a quantitative analysis of both, the net ecosystem exchange of CO_2 and ^{13}C with the atmosphere as a function of present and pastequilibrium and transient observed forcing factors: changes in atmospheric CO_2 andits isotope ratio, climate and changes in land use over the industrial era (app. last 100 years).In additttion, the impact of C_4 land use (e.g., corn and sugarcane but also tropical C_4 pastures) on the isotopic disequilbrium will be analyzed.

JSM04/09A/B23-004   1030

STABLE CARBON ISOTOPES IN SEDIMENTS OF THE EAST-SIBERIAN SEA

Igor P. SEMILETOV[1], Oleg DUDAREV[2], Kyung-Hoon SHIN[1], Nori TANAKA[1] ([1]International Arctic Research Center/University Alaska Fairbanks, [2]Pacific Oceanological Institute)

The Arctic Ocean accounts for 20% of the world´s continental shelves. The amount of terrestrial organic carbon stored in the wide circum-Arctic shelf and slope areas is certainly of importance for calculation of organic carbon budgets on a global scale [Aagaard et el., 1999; Codispoti et al., 1990; Gobeil et al., 2001; Macdonald et al., 1998]. Greater than 90% of all organic carbon burial occurs in sediment deposition on deltas, continental shelves, and upper continental slopes [Hedges et al., 1999], and the significant portion of organic carbon withdraw occurs over the Siberian shelf [Bauch et al., 2000, Fahl and Stein, 1999].The Arctic coastal zone plays a significant role in the regional budget of carbon transport, accumulation, transformation, and seaward export.   Hydro-chemical anomalies obtained over the shallow Siberian shelves demonstrate   significant role of coastal erosion in the formation of the biogeochemical regime in the Arctic seas (Semiletov, 1999; Dudarev et al., 2001) that could effect a hydro-chemical regime of the surface and halocline waters over the Arctic Basin.Determining the magnitude of particulate and dissolved fluxes of old organic carbon and other terrestrial material from land is critical to constraining a range of issues in the Arctic shelf-basin system, including carbon cycling, the health of the ecosystem, and interpretation of sediment records. Most of the eroded terrestrial organic matter accumulates in coastal zones; however, significant amounts of this material are transported further offshore by different processes, such as sea-ice, ocean currents, and turbidity currents. The role of the coastal zone in transport and fate of terrestrial organic carbon has not been discussed sufficiently. In this report we present a new data about the distribution of the organic carbon (C-13) and nitrogen (N-15) isotope ratios, OC/N, mineraolgy and size distribution of the surface sediment in the most unexplored area of the Arctic Ocean: the East -Siberian Sea.

JSM04/09A/B23-005   1115

BIOSPHERIC CONTROL OF ATMOSPHERIC COMPOSITION IN AMAZONIA

Paulo ARTAXO[1], Meinrat O. ANDREAE[2], Alex B. GUENTHER[3], Daniel ROSENFELD[4], Luciana V. GATTI[5], Jose V. MARTINS[1] ([1]Instituto de Fisica, Universidade de Sao Paulo, Rua do Matao, Travessa R, 187, Sao Paulo, SP, CEP 05508-900, Brazil, [2]Biogeochemistry Department, Max Planck Institute for Chemistry, P.O. Box 3060, D-55020 Mainz, Germany., [3]Atmospheric Chemistry Division, National Center for Atmospheric Research, PO Box 3000, Boulder CO USA 80307-3000, United States., [4]Institute of Earth Sciences, The Hebrew University of Jerusalem, Jerusalem 91904, Israel., [5]Laboratorio de Quimica Atmosferica, IPEN, Av. Lineu Pretes, 2242; Cidade Universitaria, Sao Paulo, CEP 05508-900, Brazil.)

There is growing evidence that the Amazonian forest have some mechanisms that controls the composition of the atmosphere above it, in terms of trace gases and aerosols. The majority of the cloud condensation nuclei population (CCN) under natural conditions is biogenic in origin. The CCN population consists of small particles from gas-to-particle conversion of some biogenic VOCs, and in the large particle fraction there is a significant number of primary biogenic aerosol particles that are efficient as CCN. Under pristine conditions, PM10 aerosol concentrations are in the range of 10-15 ug/m³, of which 70-80% consists of organic matter. Natural sulfate and nitrate concentrations are very low compared to other sites influenced by anthropogenic emissions. Due to the high precipitation rate, the basin-wide influence of marine aerosols is small. Concentrations of soil dust particles are also low, because the forest litter and low wind speeds under the forest canopy makes soil resuspension difficult for most of the forested area of Amazonia. The cloud field is of shallow clouds, mostly with warm precipitation, making a quite efficient precipitation mechanism. The emission of VOCs from the vegetation varies significantly both seasonally and geographically, and the control mechanisms are not fully understood. Ozone concentrations in undisturbed forest are low (peaks at 10-14 ppb), and CO background concentrations are on the range of 50-100 ppb. The forest CO2 flux have strong seasonal dependence, from the dry to the wet season, and also varies from site to site, but in general consists of a small sink of CO2. The radiative forcing of aerosol particles in the dry season is very strong, peaking at up to 300 watts/m². The complex Biospheric control of the atmospheric composition possibly has some important climate feedbacks.

JSM04/09A/B23-006   1145

A COMPARISON OF MODIS AEROSOL OPTICAL THICKNESS TO HANDHELD SUN PHOTOMETER AND AERONET SUN PHOTOMETER MEASUREMENTS DURING THE DRY SEASON IN WESTERN AMAZON BASIN, BRAZIL, 2002

Wei Min HAO[1], R.E. BABBITT[1], B.L. NORDGREN[1], E.N. LINCOLN[1], S.P.BAKER[1], R.A. SUSOTT[1], M. YAMASOE[2], P. ARTAXO[3], B.N. HOLBEN[4] ([1]USDA Forest Service Fire Sciences Laboratory, Missoula MT, [2]Instituto de Astronomia, Geofisica e Ciencias Atmosfericas, Universidade de Sao Paulo, SP, Brazil, [3]Instituto de Fisica, Universidade de Sao Paulo, SP, Brazil, [4]NASA/Goddard Space Flight Center, Laboratory for Terrestrial Physics, Greenbelt, MD)

The MODIS instrument on the NASA Terra and Aqua satellites provides global measurements of aerosol optical thickness (AOT). Our previous work during the fire season in Zambia, 2000 has shown that the MODIS AOT was lower by 40%-50% compared to ground-based measurements of Forest Service handheld sunphotometers and AERONET sun photometers. Part of the algorithm used to derive the MODIS aerosol optical thickness was based on the results of field experiments during the SCAR-B Campaign in Brazil, 1995. Therefore, it is essential that we compare the MODIS AOT with the AOT values from ground-based measurements in Brazil. Thirty-five handheld sun photometers were deployed in the Western Amazon Basin, Brazil from early September to late October 2002, coinciding with the LBA-SMOCC Campaign. The sites were distributed over a wide variety of land cover types. Eight of the 35 handheld sun photometers were co-located with AERONET sun photometers in the study area. We also retrieved more than 260 MODIS AOT images from the Terra satellite and 180 AOT images from the Aqua satellite over the study area. We will present the results of the comparison in aerosol optical thickness at spectral bands of about 660, 550 and 470 nm measured by the MODIS instruments, handheld sun photometers, and AERONET sun photometers. We will discuss the effects of land cover properties, look angles, and the homogeneity of atmosphere on the derivation of aerosol optical thickness from the MODIS instruments.

JSM04/09A/B23-007   1215

A DETAILED MICROCLIMATE MODEL TO PREDICT BVOC EMISSION FLUXES ABOVE THE CANOPY

Sabine A. WALLENS[1], Jean-Francois J. MULLER[1], Alex B. GUENTHER[2] ([1]BIRA-IASB (Belgian Institute for Space Aeronomy), [2]NCAR-ACD)

Natural emissions of volatile compounds are an important component of the Earth system responsible for determining the composition of the atmosphere. The biogenic volatile organic compounds (BVOC) are produced by vegetation and emitted into the atmosphere.In addition, the emissions of BVOC depend on the leaf level microclimate, in particular on leaf temperature and Photosynthetically Active Radiation (PAR) (Guenther et al., 1993, 1995). For these reasons, the need for accurate estimates of BVOC emissions as input to global chemistry and transport model led us to 1) the development of a detailed canopy environment model and 2) the validation of the BVOC emission algorithms used in Guenther et al., 1995.Among the large Earth ecosystems, tropical rainforests are estimated to be a major source of BVOC, mainly isoprene and monoterpenes. Here, we present comparisons between the emission fluxes estimated using a detailed canopy model and measurements obtained in a typical forest, Tapajos in Amazonia.

CARBON AND NITROGEN WET DEPOSITION IN AMAZON BASIN: CONSEQUENCES OF LAND-USE CHANGES

Luciene Lorandi LARA[1], Paulo ARTAXO[2], Theotonio PAULIQUEVIS[2] ([1]Lab of Isotopic Ecology, University of São Paulo, [2]Instituto de Fisica, Universidade de São Paulo Brazil)

In tropical regions convective clouds produce abundant rainfalls which are the main sink of water-soluble gases and aerosols emitted into the atmosphere through wet deposition processes. Wet deposition plays an essential role in controlling the biogeochemical cycles of carbon and nitrogen and as a source of nutrients to ecosystems. In the LBA experiment (Large Scale Biosphere Atmosphere Experiment in Amazonia), rainwater chemistry composition has been studied in three different sites; Rondonia, Balbina and Santarem, with different degrees of anthropogenic activities. Rondonia site is located in the western part of Amazonia, and is a heavily disturbed site with significant land use changes, Balbina is located in Central Amazonia, about 150 Km North of Manaus and represents a pristine area and Santarem is the closest site to the sea. During one year samples of rain water were sampled and analyzed for ion chromatography (inorganic and organic ion), DOC (dissolved organic carbon) and DIC (dissolved inorganic carbon).For the three sampling sites H+ was the most abundant ion. However, the sequence of the other most abundant ions was not the same for the sites, indicating that there are differences in the composition of the rainwater in these sites. In fact, due to the anthropogenic activities, N deposition was significantly higher in Rondonia while DOC deposition was significantly lower in this site. By the other hand, in Balbina the VWM concentration of organic anions (acetate, formate, oxalate) was significantly higher than the other sites, which is probably associated with biogenic emissions. Principal component analysis results showed that there are different sources of rain acidity in each site, which are associated with land cover. The main source of compounds in the rainwater composition are also different in these three sites. Biomass burning appears to be the main source in Rondonia, biogenic emissions in Balbina and in Santarem a mixing of sea-salt and biogenic emissions. If the deforestation process continues at the present rate, in a few years, significant regional biogeochemical cycles changes can be expected and, also alterations in the regional climate with possible global impacts.

VARIABILITY IN GLOBAL AND DIFFUSE PAR AT A TROPICAL SOUTHEAST ASIAN SITE AND ITS SIGNIFICANCE FOR TERRESTRIAL PHOTOSYNTHESIS

Dennis G. DYE[1], Yoshifumi YASUOKA[2], Akkaneewut CHABANGBORN[3], Boossarasiri THANA[3] ([1]Ecosystem Change Research Program, Frontier Research System for Global Change, Japan, [2]Ecosystem Change Research Program, FRSGC, and IIS, Univ. of Tokyo, Japan, [3]Dept. of Geology, Chulalongkorn Univ., Thailand)

Recent research indicates that the radiation-use efficiency and CO_2 assimilation rate of an unstressed vegetation canopy tends to increase as the diffuse fraction of incident (global) photosynthetically active radiation (PAR, 400-700 nm) increases. Because measurement data on diffuse PAR are rare, much of this research has relied upon model estimates of diffuse PAR. Such estimates typically ignore the 3-dimensional cloud effects on the surface irradiance, and thus may include biases or uncertainties that hinder a more exact

determination of radiation-canopy-photosynthesis relations. As part of a broad effort aimed at an improved ability to monitor PAR by satellite remote sensing and to model the role of PAR dynamics in the terrestrial carbon cycle, we have initiated a project to measure diffuse and global PAR at multiple sites representing diverse ecosystems and climate regimes. In this paper, we examine variability in global, diffuse, and direct PAR at a seasonally moist tropical site in north-central Thailand (Sri Samrong, 17.1 deg. N, 99.9 deg. E), and discuss its significance for modeling of vegetation canopy light absorption, primary production and ecosystem-atmosphere carbon exchange.

METHANE EMISSION FROM RICE FIELDS IN MAINLAND CHINA: AMOUNT, SEASONAL AND SPATIAL DISTRIBUTION

Xiaoyuan Yan YAN[1], Zucong CAI[2], Toshimasa OHARA[1], Hajime AKIMOTO[1] ([1]Frontier Research System for Global Change, [2]Institute of Soil Science, Chinese Academy of Sciences)

China is the largest rice producer in the world. Methane (CH_4) emission from its rice fields has been widely measured since the late 1980s. In this study, we collected results of most of the field studies available so far, which constitutes 207 season-treatment measurements conducted on 23 sites. Analysis of these data shows that input of organic materials such as green manure, animal waste, and crop straw increases CH_4 emission by a factor of 2; average CH_4 flux from intermittently irrigated rice fields is 53% of that from continuously flooded rice field; and average CH_4 emission flux from late rice fields is 1.6 and 2.3 times those from early and single rice fields. There is regional difference in emission factors, with a decreasing trend from south to north. We assume half of the rice fields in China received organic input and two-thirds of the irrigated rice fields were intermittently flooded by taking into account of expert judgments and the frequencies of these managements in field studies. Based on these assumptions and the region-specific emission factors and statistical data on rice area of 1995, we estimated CH_4 emission from rice fields during rice-growing season (from transplanting to harvest) in Mainland China to be 7.67 Tg yr[-1], with a range of 5.82 to 9.57 Tg CH_4 yr[-1] due to the uncertainties in the assumption on rice area receiving organic input and under intermittent irrigation. This estimate is significantly lower than many earlier ones. A generalized seasonal flux pattern was developed separately for early, late and single rice. Monthly distribution of the annual emission was estimated from rice calendar and these flux patterns, showed that highest emission occurs in August. Geographically, the emission mainly occurs in the middle and lower reaches of Yangtse River, around 30°N.

ANNUAL VARIATION AND LONG-TERM OF GREENHOUSE GASES CONCENTRATION AND IT'S CAUSES IN THE BACKGROUND AREA OF THE KOREAN PENINSULA

Jae-Cheon CHOI[1], Hyo-Sang CHUNG[2], Sung-Nam OH[2], So-Young BANG[1], sang-Soon PARK[1] ([1]Korea Global Atmosphere Watch Observatory of KMA, [2]Meteorological Research Institute, KMA)

The greenhouse gas is one of the major parameters of climate change which makes a role of positive radiative forcing, and Korea Meteorological Research Institute(METRI) has started systematic monitoring on the greenhouse gases recently, in Korea Global Atmospheric Watch Observatory (KGAWO) in Anmyeon-do, which is a regional station measuring the background concentration in East-Asian region. In this study, the fluctuation tendency of greenhouse gases is analyzed by using 3-year measurement(January 1999~December 2001) of KGAWO. The measured CO_2 concentration data is validated by the method of World Data Center for Greenhouse Gases(WDCGG), and compared with the flask sampling data operated by NOAA/CMDL, to assess the level of greenhouse gases in Korea. The variation of the concentration by wind direction and other meteorological parameters is also investigated from the measured data. By using statistical method, the relationships among each greenhouse gas and trace gases are analysed to explain the effect on the background concentration. The results of this study is expected to be an essential information for the prediction of climate change in Korean peninsula, and to establish a tool for prediction of climate change by learning the advanced application technology of climate data in participating the round robin. The measurement of greenhouse gases which is used in this study will be operated systematically based on the standard of WMO, so that it will be used as a basic information to work out a counter measure for the united nations framework convention on climate change.

INFLUENCES OF THE WARMING ON PLANT PHENOLOGY IN EAST ASIA

Futoshi MATSUMOTO, Yoshitaka FUKUOKA (Risshou University)

Recent changes of plant phenology such as budding, flowering and change in color and falling of leaves are related to global warming. For example flowering dates of cherry blossoms (*Prunus yedoensis*) have been getting earlier annually in Japan. Because many weather stations which observe the plant phenology are located in urban area. So it is considered that these phenomena are caused by climatic changes such as urban warming including global warming. In this study the authors examined the effects of urban warming on flowering dates of *Prunus yedoensis* in Kumagaya City, Saitama Prefecture, Japan. This study consists of observing both the distribution of flowering dates of *Prunus yedoensis* and the spatial urban climate at the same time in spring in urban area. The objects of this study are firstly to evaluate how urban climate influences the flowering dates of *Prunus yedoensis* , and secondly to search whether the flowering dates of *Prunus yedoensis* are possible indicators that show climatic changes such as urban warming including global warming. The results of this study are follows: 1. Flowering dates of *Prunus yedoensis* in the center are 2 days earlier than those in the suburbs in urban area. 2. Heat island phenomena, which are known as high temprature occurances in central part of a city, are observed. Therefore it is concluded that heat island influences the flowering dates of *Prunus yedoensis* . Heat island or the distribution of urban temperatures at observation time is calibrated to the mean monthly temperatures in March, which has a close relation to the flowering dates of *Prunus yedoensis* . As a result, the mean difference between mean monthly temperatures in urban area(at the earliest flowering dates points) and that in suburban area(at the latest flowering dates points) is evaluated as 0.64 degrees. So it is estimated that the influences of urban warming on the spatial quickening of the flowering dates of *Prunus yedoensis* are at a rate of 1 day per about 0.3 degrees. 3. On the other hand, the influences of warming on the year —to —year quickening of flowering dates of *Prunus yedoensis* at Kumagaya Meteorological Observatory are also at a rate of 1 day per about 0.3 degrees. And it is possible to evaluate the effects of urban warming by substituting the spatial variation in Kumagaya City for the year —to —year variation of flowering dates of *Prunus yedoensis* at Kumagaya Meteorological Observatory. 4. It is clarified that the flowering dates of *Prunus yedoensis* are possible indicators that show climatic changes and urban warming.

VARIABILITY OF AEROSOL PARAMETERS IN NORTHERN INDIA

Sagnik DEY[1], Ramesh P. SINGH[1], Brent HOLBERN[2] ([1]Department of Civil Engineering, Indian Institute of Technology, Kanpur, India, [2]NASA Goddard Space Flight Center, Greenbelt, Maryland 20771, USA)

ABSTRACT Due to the urbanization and industrialization in the Ganga basin the pollution level is increasing, which has been mapped by ADEOS Polder 1 data. The air pollution in this region has also been detected by satellite data. The observations are supported by the measurements by CIMEL SUNPHOTOMETER, deployed in Kanpur in collaboration with NASA AERONET on January 2001. In the present paper, the seasonal variations of the spectral aerosol optical depth (AOD), size distribution of the aerosols, the radiative forcing of the aerosols which affect the climatic condition of the region and single scattering albedo (SSA) have been studied using CIMEL SUNPHOTOMETER. The aerosol over the Kanpur shows strong seasonal influence. Seasonal variability of the AOD shows highest values (> 0.7) during the month of August. Another peak in the AOD values has been observed during the month of November, but only at the wavelengths less than 500 nm. The size distributions of the aerosols indicate considerable amount of anthropogenic input over the last few years. The air monitoring data measured by Central Pollution Control Board supports the increasing air pollution. The SSA, a climatically unique parameter retrieved by AERONET and its significance in the climate of the north India has also been studied. The spectral and temporal variability of the aerosol parameters over northern India will be discussed in view of the meteorological parameters and the increasing human activities as a part of the monitoring the air pollution in the northern India.

WEATHER DROUGHT INDEX AND FIRE IN BERBAK PARK, SUMATRA

Asril Asril ASRIL[1], Daniel MURDIYARSO[2], Bambang Hero SAHARJO[2] ([1]Agency for the Assessment and Application of Technology, [2]Post Graduate Program, Bogor Agricultural University)

The fires in Sumatra and Kalimantan in 1997 have caused extensive environmental damage including transboundary haze that blanketed the region and the neighbouring countries. Around 10.5 million hectares land and forest have burnt (Saharjo, 1999) with total cost (caused by fire and haze) of more than US$ 9 billion (ADB, 2001). Climate and weather, together but in different way, affect forest fire (Chandler, *et al.*, 1983). This study is conducted at Berbak National Park, Sumatra and aimed at evaluating fire opportunity based on weather dryness index, fuel characteristics and burning practices conducted by the local people. Weather dryness index (named Keetch-Byram Dryness Index, KBDI) is determined by Keetch-Byram method that employs daily maximum air temperature and 24-hour rainfall as inputs (Keetch and Byram, 1968). Biomass measurements to estimate fuel load follow Hairiah, *et al.* (1999). Fire intensity to identify the intensity of a fire was calculated using Byram's equation (Chandler, *et al.*, 1983). Fuel load was observed at two areas, representing the protected area inside the Berbak National Park (including the area that burnt in 1997 fire) and the buffer zone of the park. The results show that the peaks of drought occur between May and October. The drought intensity varies throughout the years and extreme drought when the KBDI was higher than 1,950 occurred in 1991, 1993, 1994 and 1997. The longest and most extreme drought occurred in 1997 from August 1st through November 9th. The fire in Berbak Park began at least early September (Dennis, 1999), after extreme drought occurred for a month. The similar drought pattern occurred in 1994 but there was no fire in Berbak Park. Surface fuel load at protected zone was 647.4 ton/ha and at buffer zone was 139.4 ton/ha. Dead-fuel moisture at protected zone (40 %) was relatively higher than at buffer zone (17 %). Fuels at both study area were able to burn (flammable) since their moisture content lower than the moisture of extinction, the maximum moisture content that a fuel can have and still support flaming combustion (Chandler, *et al.*, 1983). Fuels at protected zone were more burnable since they had silica content (4.75 %) lower than at buffer area (6.63 %). Based on these fuel characteristics, the protected zone was at higher danger to catch fire. Fire intensity at several burning practices varied between 90 kW/m at small fire flame and 1,994 kW/m at big fire flame. Fire from several burning practices may escape and ignite unexpected fires. It is seemed that the combine of extreme drought and burning practice have caused the fire in Berbak Park.

THE CLIMATIC SIGNIFICANCE OF δ13C IN TREE-RING ON TIBET AND THE IMPLICATIONS FOR CLIMATIC RECONSTRUCTIONS

Xiaohong LIU[1], Dahe QIN[1], Xuemei SHAO[2], Tuo CHEN[1], Jiawen REN[1] ([1]Cold and Arid regions environment and engineering research institute, Chinese academy of sciences, [2]Institute of Geographic Sciences and Nature Resources Research, CAS)

Based on cross-dating tree-ring age, stable carbon isotope ratios in tree rings were measure on the α-cellulose of Linzhi region on Tibetan plateau. The global-descending of delta-13C in CO_2 which induced by the increasing concentration of atmosphere carbon dioxide, were recorded in delta-13C series of fir and spruce. There are different response to concentration change of CO_2 between two species. Through the standardization of delta-13C series (Δ13C), there were common climatic information in two delta-13C series.Using meteorological data from Nyingchi observatory, the responds of standardization series of delta-13C to climatic factors were analyzed. The results suggest that the Δ13C time series is in good correlation with precipitation and relative humidity of 9-11 months in local instrumental data, and with strong "lag effect". Compared with other results in China and other countries, the Δ13C series with good relationship to the climatic factors of 9-11 month (November) are different with the climatic information in delta-13C of trees in arid region and Semi-arid region. This difference may be a results of distinct climate on Tibetan plateau.

STABLE CARBON ISOTOPE EXCHANGE BETWEEN THE TERRESTRIAL BIOSPHERE AND ATMOSPHERE SIMULATED BY AN ECOSYSTEM MODEL

Akihiko ITO (Ecosystem Change Research Program, Frontier Research System for Global Change)

There remain substantial uncertainties in stable carbon isotope (12C and 13C) dynamics of terrestrial ecosystems, leading to an uncertainty in our quantification of the global carbon cycle. The uncertainties include the followings. (1) How strong is the discrimination effect of photosynthetic CO2 assimilation on stable carbon isotope ratio (i.e. d13C)? (2) How much carbon is assimilated by C4 plants, which have disparate isotopic discrimination effect from C3 plants? (3) How much of CO2 released from plant and soil is re-cycled within canopy, leading to apparently larger isotopic discrimination effect? (4) How large isotopic disequilibrium does take place, due to human emission of CO2 with lower d13C to the atmosphere? In this study, we address these uncertainties with a process-based model of terrestrial carbon cycle (Sim-CYCLE), in which terrestrial carbon dynamics from photosynthesis to decomposition is simulated in an ecophysiological manner. Sim-CYCLE considers the isotopic discrimination effect at three levels: (I) leaf-level gas exchange and enzymatic CO2 assimilation, (II) canopy-level recycling of CO2 respired from plants and microbes, and (III) continental-level distribution of C3 and C4 plants in grassland ecosystems. Based on the NCEP/NCAR reanalysis climate data and observed concentration and d13C of the atmospheric CO2, carbon budget of the terrestrial biosphere was estimated for the period from 1953 to 1999. Sim-CYCLE estimated that the average annual gross photosynthesis is 121 Pg C, and average isotopic discrimination (compared with d13C of atmospheric CO2) is -18.2 per mil. The recycling of CO2 within canopy resulted in a larger discrimination effect by on average 2.1 per mil; this effect was especially larger in closed forests with higher leaf area index. Because of the predominance of C4 plants, tropical savannas and temperate grasslands have smaller isotopic discrimination than forest ecosystems. Interannual variability in the magnitude of discrimination effect seems small, compared with latitudinal and seasonal variability. During the 47-year experimental period, average d13C value of the biospheric carbon storage decreased by 0.3 per mil, while d13C of atmospheric CO2 dropped by 0.7 per mil. The long residence time of biospheric carbon, especially in woody stem and soil humus, is responsible for the isotopic disequilibrium. These results are verified by comparing with observations at different site, with respect to seasonal phase and amplitude of atmospheric CO2 concentration and isotopic composition. Based on the simulation result, finally, I will discuss how to improve our understanding of the global carbon cycle by means of stable isotopes and model experiments.

THERMAL HISTORY RECONSTRUCTION AND THERMAL MATURATION OF HYDROCARBON-BEARING FORMATION IN EAST CHINA SEA BASIN

Shengbiao HU[1], Shuchun YANG[1], Dongsheng CAI[2], Xiaojie FENG[2] ([1]Institute of Geology & Geophysics, Chinese Academy of Sciences, [2]Research Center, China National Offshore Oil Corporation)

Based upon the available vitrinite reflectance and fission track data as well aspresent-day temperature logs from borehole in the East China Sea Basin, thermalhistory are reconstructed and applied to the maturation of source rocks. The pre-Tertiary formation, distributed in the western Taibei Depression reached their maximum paleotemperature at the Paleocene, with a average paleo-heat flowvalue of 81 mW/m², and the Tertiary formation in the eastern Xihu Depression experienced their maximum temperature at the end of the Oligocene, with a mean of paleo-heat flow of 83 mW/m², corresponding the end of rifting as indicated by the subsidence history. Incorporated with the thickness of the removed section on the unconformity, the hydrocarbon generation period and maturation for both the pre-Tertiary and Tertiary formations have been evaluated.

INFLUENCE OF WATER SOLUBLE SALTS ON THE ICE NUCLEATING ABILITY OF AGI-AGCL-CUI SYSTEM

Sivanesan SUBRAMANIAN, Balasubramaniam NALLATHAMBI, Ramamurthy VEERAPPAN (Chemical Engineering)

Salt content is an inescapable factor which will have bearing upon the heterogeneous freezing nucleation of cloud droplets in the atmosphere. Moreover, the generator effluent that contains appreciable amount of soluble salts largely affects the ice nucleating properties of the seeding materials. More relevant to natural or induced precipitation process in clouds are possibly the studies made with specific nucleants along with soluble salts. From the survey of literature,it has been found that the heterogeneous freezing nucleation can be appreciably influenced by the soluble salts and the effects were found to be specific to each nucleant tested. In the earlier studies the author has reported that the 50:25:25 mole percent composition of AgI, AgCl and CuI has the lowest misfit with ice and hence the highest nucleation temperature. In order to evaluate the solute effects on this specific AgI-AgCl-CuI ice nucleant, the present study has been undertaken. This will help to draw a conclusion of the influence of soluble salts on the ice nucleability of AgI-Agcl-CuI. Salts such as NaCl, MgCl2 and NaSO4 were chosen. Since they include a number of components of sea salt, which is one of the main sources of hygroscopic aerosols.In addition, the halides of NH4 and Li, the sulphates of K, Na, NH4 and Mg were also considered. In the present study, the various salt solutions at different concentrations with the nucleant have shown an appreciable influence on nucleation temperature. Also, the activity is found to decrease with the increase in concentration of the salts, due to the production of water disruption and breaking of bonds by the salts. Among the soluble salts examined, the sulphates have better performance with nucleant at 0.01 M concentration. As a matter of fact, (NH4)2SO4 at 0.01M concentration has significantly improved the nucleation activity of the nucleant and the nucleation temperature is as high as-0.60 0C.The possible reason for the enhanced nucleation activity has been discussed.

JSM04/09P/D-005   Poster   1400-042

A NUMERICAL STUDY OF GLOBAL CO2 INTERACTIONS USING SIM-CYCLES BIOSPHERE MODEL

Takao IGUCHI[1], Hideji KIDA[2] ([1]Disaster Prevention Research Institute, Kyoto University, [2]2. Department of Geophysics, Graduate School of Science, Kyoto University)

To investigate the role of terrestrial ecosystems to play in the global budget of atmospheric CO2, numerical simulations were performed using a global transport model and a biosphere model (Sim-CYCLE). The transport model developed by Iguchi and Kida calculates three-dimensional CO2 distribution. The Sim-CYCLE model of Ito and Oikawa (1998) predicts the amount change of carbons in plant and soil. Both models are driven by given wind, temperature, pressure, humidity, solar radiation, and so on. In this study, ECMWF/TOGA and NCEP/NCAR re-analysis data sets were employed. The first stage of CO2 increasing

experiment was run with Sim-CYCLE only. CO2 increase since the industrial revolution was decided by the data of ice core collected at Antarctica and CO2 monitoring at Mauna Loa, Hawaii. As input climate data, NCEP/NCAR reanalysis data set for 50 years (1951-2000) was repeatedly used for the 250 years experiment. Our result showed that the carbon reservoir of terrestrial ecosystems increased as atmospheric CO2 concentration did. 10 years average of increase of carbon reservoir in 1990s was 1.57GtC/y. Inter-annual variation of flux was approximately 1.0GtC/y in maximum amplitude. Next, atmospheric CO2 distribution of 1990 was simulated together with the transport model and Sim-CYCLE. The two models are combined through CO2 concentrations; the change of carbon reservoir of terrestrial ecosystems calculated by Sim-CYCLE was treated as CO2 flux in the lowest layer of transport model, and the CO2 concentrations calculated by the transport model were input to Sim-CYCLE. Time step is 20 minutes for the transport model and 1 day for Sim-CYCLE. There is no diurnal variance of CO2 flux from vegetation. As CO2 flux from fossil fuel combustion, ocean, and land use change, NASA/GISS CO2 flux data was used. The result at beginning day of the 1990 in the former CO2 increasing examination was given as the initial condition of the simulation. The present result was compared with the observation and also the result of our past simulation using the transport model including CO2 flux data from vegetation. For observed CO2 distribution, WMO/WDCGG observation data set was employed and the CO2 concentrations at the grid points were interpolated from the observed data. Our past simulation without the Sim-CYCLE model showed some unsatisfied discrepancies of seasonal change of zonal mean of CO2 concentrations, but the present simulation with the ecosystem model greatly improved such past shortcoming. In concluding, the need of a CO2 ecosystem is stressed in this study and the estimated carbon absorption by terrestrial ecosystems in 1990 was 1.24GtC.

JSM04/09P/D-006   Poster   1400-043

TRACE ELEMENTS IN ANDEAN BACKGROUND AEROSOL FROM A NEVADO ILLIMANI ICE CORE, BOLIVIA, FROM 1919 TO 1999

Alexandre L. CORREIA[1], Robert J. DELMAS[2], Remi FREYDIER[3], Jefferson C. SIMOES[4], Jean-Denis TAUPIN[5], Bernard DUPRE[3], Paulo ARTAXO[6] ([1]Institute of Physics, University of Sao Paulo, Rua do Matao, Tr R, 187, 05508-900 Sao Paulo, Brazil; LGGE, CNRS and Universite Joseph Fourier, [2]LGGE, CNRS and Universite Joseph Fourier, [3]UMR5563, LMTG, CNRS and Universite Paul Sabatier, [4]Institute of Geosciences, University of Rio Grande do Sul, [5]LGGE and IRD, [6]Institute of Physics, University of Sao Paulo)

Atmospheric aerosols play an important role in climate, with physico-chemical characteristics highly variable in temporal and spatial scales. In South America only a limited number of studies have documented these characteristics over the Andes Cordillera. This work addresses this issue, by studying the trace elemental composition of aerosol deposited in an ice core along 20th century over Eastern Andes, which receive a strong impact from easterly air masses coming from Amazon Basin. In 1999 a 137 m ice core was drilled from Eastern Bolivian Andes (Cordillera Real) at the summit of Nevado Illimani (16°37´ S, 67°46´W, 6350 m asl). The upper 50 m of this ice core were dated by multi-proxy analysis. This 50-m ice core section corresponds to a record of environmental variations of about 80 years from 1919 to 1999. It was sub-sampled under laminar flow in a clean bench in 744 aliquots. These aliquots were analyzed by several techniques, among which Inductively Coupled Plasma Mass Spectrometry (ICP-MS) for the concentration of 45 chemical species from Li to U. The high number of samples produced translates into high temporal resolution along the record, allowing classification of samples as belonging to dry or wet seasons. Average Li concentration along 20th century is 0.035 and 0.90 ng g^{-1} for wet and dry seasons, respectively. Main Li sources in the region are ubiquitous salt lakes, like Salar de Uyuni for instance. Regional crustal dust load in the aerosol deposits is overwhelming during dry season, obfuscating the contribution of other possible sources like plumes of biomass burning from Amazon Basin. As a result of that, dry season aerosol has low crustal enrichment factors and typically high elemental concentration values, while wet season samples are more enriched and show lower elemental concentration values. Heavy metals typically associated with anthropic origins show high average crustal enrichment factors, indicating a contribution of these sources to the aerosol deposits at Illimani. During wet season, average Cu crustal enrichment is above 10³, while As, Sb, Zn, Cd, Mo, Co, Ni and Cr are between 10² and 5 x 10². P and K have average wet season enrichment factors above 10. Zn, together with P and K are important elements participating of biogeochemical cycles in Amazon Basin, and their crustal enrichment factors during wet season suggest they may originate from multiple sources. Allying the large number of samples analyzed from Illimani ice core with a simple tool like the assessment of crustal enrichment factors, it was possible to derive an effective chemical characterization of the deposited background Andean soil dust aerosol, based on the 45 elemental concentrations measured, during 20th century.

JSM04/09P/D-007   Poster   1400-044

THE IMPACT OF BIOMASS BURNING SOOT OVER TAIWAN

Hsiao-Wen LIN, Jen-Ping CHEN (Department of Atmospheric Science, National Taiwan University)

Biomass burning, the burning of vegetation, occurs in developing countries quite frequently. It is one of the sources of greenhouse gases, and also of aerosols. What made it different from other anthropogenic sources is that biomass burning is highly 'episodic' it varies with locations and seasons. Among all the emitted aerosols, soot entered the center stage recently. First, this is because soot not only cools the surface but also heats the atmosphere by absorbing solar radiation. Its warming effect could be compared in the magnitude with greenhouse gases like CO2, CFC, or methane. Furthermore, local air quality is severely influenced by soot. There are several major sources of biomass burning emissions in East Asia. Southeastern Asia is a previously well-known hot spot. But our data showed that Mainland China is also a large source that cannot be ignored. Most intensive emissions occur in springtime, but events in pre-spring wintertime are reported. Since the geographical location of Taiwan is somewhat between two of the heavy emission sources of biomass burning mentioned above, long-range transport of soot from biomass burning over Taiwan is of great concern. However, biomass burning can not be avoided in Taiwan either. To know the impact of soot over Taiwan, we must know the ratio of soot from long-range transport and local emission.. To access this, we adopted FLEXPART 3-D Lagrangian trajectory tracer model developed by Andreae Stohl(1996) to see the transport route of biomass burning over East Asia. Then we use the soot emission data in Taiwan Air Quality Module (TAQM) to look at the details of soot transformation during transportation, and to estimate the ratio between long-range transported and locally generated soot. The results will be verified with NASA's MODIS L3 Aerosol Index and Fire product.

CHEMICAL AND PHYSICAL PROPERTIES OF ASIAN DUST IN KOREA PENINSULAR

Ki-Jun PARK[1], Jae-Cheon CHOI[1], So-Young BANG[1], Sung-Nam OH[2], Byoung-Cheol CHOI[1], Kyoung-Sook CHO[1] ([1]Korea Global Atmosphere Watch Observatory of KMA, [2]Meteorological Research Institute, KMA)

Atmospheric particles are emitted from natural sources such as sea spray, volcanic

emissions and yellow sand(or Asian dusts) and from anthropogenic processes such as fossil fuel combustion and industrial emissions. In this study, airborne particle matter(0.3~25μm) and particulate smaller than 10m were collected in Anmyeon-do Korea Atmosphere Watch Observatory (KGAWO). Through the chemical and statistical analysis of particulate composition, an attempt was made to elucidate the chemical characteristics and contributing sources of atmospheric aerosols in Anmyeon-do KGAWO during spring when Asian dust event occurred. The aerosol samples were collected by Optical Particle Counter(OPC), PM$_{10}$ High Volume Air Sampler(HVAS) and β-ray PM10 sampler. The sampling of PM$_{10}$ has been basically carried out three times a week. The measurement items were mass concentration and chemical composition by PM$_{10}$ sampler and particle number concentration by OPC. The aerosol number concentration was also analyzed with the 8 channels(0.30μm-25μm) measurement. In general, the variation of total particle number concentration was well agreed with that of mass concentration by β-ray PM$_{10}$ sampler. The major ion components in PM$_{10}$ were SO$_4^{2-}$ and Ca^{2+} with the concentration of severe yellow sand was 8.459μg/m³ and 10.891μg/m³, respectively.

VARIABILITY OF TRACE GAS CONCENTRATIONS DURING THE LBA/SMOCC 2002 BIOMASS BURNING EXPERIMENT IN THE AMAZON BASIN

Luciana Vanni GATTI[1], Amelia YAMAZAKI[1], Carlos A. Bauer AQUINO[2], Lizia MURBACH[2], Paulo ARTAXO[3], Duli CHAND[4], Meinrat ANDREAE[4] ([1]Atmospheric Chemistry Laboratory, Travessa R, 400, CEP 05508-900, Sao Paulo, Brazil - lvgatti@net.ipen.br, [2]Univ. Luterana do Brasil - Ji-Paran(ULBRA), [3]Instituto de Fisica, Universidade de Sao Paulo, Brazil, [4]Biogeochemistry Department, Max Planck Institute for Chemistry, Mainz, Germany)

The LBA/SMOCC 2002 experiment (Smoke Aerosols, Clouds, Rainfall and Climate) was aimed at understanding the connection between the composition and abundance of biomass burning aerosol, and its climatic effects, in particular on cloud structure and physics. This experiment was performed in Rondônia, a region in Amazonia that is severely perturbed by biomass burning emissions, with a ground based sampling station located in Ji-Parana (10º46.42?S, 62º20.22?W). The experiment was run during September to November 2002. The concentrations of O3, CO and NOx were measured simultaneously with aerosol mass, light scattering and absorption. Several meteorological parameters such as solar radiation, PAR, temperature, humidity, wind speed and direction were also monitored.In the dry season, it was observed three different atmospheric regimes: the peak of burning season (1), the transition were the biomass burning happens at lower scale (2) and the initial part of the wet season (3). During the regime 1, the trace gases concentrations were up to 5 times higher than in the step 3, emphasizing the critical importance of biomass burning in determining atmospheric concentrations in Amazonia. During nighttime, the average for the three regimes for CO concentration were 1,100 ppb, 400 ppb during the step 2 and less than 200 ppb during the step 3. During daytime similar values were around 600, 300 and 150 ppb respectively. The average ozone concentration during the regimes 1 and 2 were the same during daytime, at around 50 ppb, and during nighttime O3 values were around 13 ppb. The average for the wet season regime was 22 ppb for daytime and 10 ppb for nighttime O3. The atmospheric oxidant capacity is so high that the NO concentrations were less than 50 ppt during 95% of the sampling time. A very high correlation for the dry season between CO, NOx, and black carbon and aerosol mass was observed, but a rather different variability patterns for NOx was observed, probably due to chemical transformations during regional transport.Research project financed by CNPq.

OZONE PROFILES AND AEROSOL MEASUREMENTS OVER THE WESTERN AMAZON DURING THE DRY SEASON

Ana Maria CORDOVA[1], L.V. GATTI[2], P. ARTAXO[2], K.M. LONGO[4], A. SILVA DIAS[3], M.O. ANDREAE[5], G. NISHIOKA[2] ([1]Departament of Enviromental Chemistry - IPEN, [2]Instituto de Fisica, Universidade de São Paulo, Brazil, [3]Instituto de Astronomia, Geofisica e Ciências Atmosféricas, Universidade de São Paulo, Brazil, [4]Centro de Previsão de Tempo e Estudos Climáticos, Brazil, [5]Biogeochemistry Department, Max Planck Institute for Chemistry, Mainz, Germany)

Land use changes in Amazonia cause large changes in atmospheric composition, especially because of the biomass burning emissions during the dry season. Trace gases and aerosol concentrations were measured at ground sites as well as in large scale using an instrumented aircraft, as part of the Smoke Aerosols, Clouds, Rainfall and Climate (SMOCC) experiment in the dry season 2002. Horizontal and vertical distributions of carbon monoxide (CO), ozone (O3), carbon dioxide (CO2) and aerosol were measured over the Western Amazon. Thirty one flights were performed from 25 September to 19 October 2002 of which twenty-four vertical profiles were performed from 400 to 4500 m in Rondonia and Acre States, Brazil. CO, CO2 and aerosol concentrations present a good correlation, with general concentrations decreasing with altitude. On the contrary, ozone concentrations present a distinct behavior from the other gases, were in the majority of the cases the O3 concentrations increases with altitude. The vertical profiles over Rebio Jaru Tower (10 º 05,15´S 61 º 56,04´W) show concentrations next to surface (500-1500m) of 350-1500 ppb for CO, 4000-6000 particles/cm ³ for aerosol number and 395 ppm for CO2. Peaks of CO, CO2 and aerosol concentrations were observed between 3000 and 4000 m, but the concentrations were lower than near the ground. Ozone presented concentrations of 70 ppb at 3000m, in general, but with strong biomass burning impacts O3 can present a similar behavior to other gases, with concentrations of 150 ppb near the surface. The higher O3 concentrations at larger altitudes suggest the influence of long range transport for this gas. Horizontal flights at 990 m from Ji Paran to Rolim de Moura towns show ozone concentrations of 60 ppb. CO and CO2 concentrations were 350 ppb and 374 ppm respectively. Aerosol concentrations were on the order of 3,000 particles/cm ³. Large trace gas and aerosols gradients were observed from regions heavily impacted by biomass burning, to relatively pristine regions, indicating the large atmospheric impact of land use change in Amazonia, with possible regional climatic impacts.

ASSESMENT OF DAILY EVAPOTRANSPIRATION USING REMOTE SENSING DATA

Gouldaria Karimovna NOURBAEVA, So KAZAMA, Masaki SAWAMOTO (Department of Civil Engineering, School of Engineering, Tohoku University)

Estimation of daily evapotranspiration is one of the key points in hydrological problems. For practical use the daily value of evapotranspiration (ET) is meaningful. Operational technique to derive daily ET estimates from instantaneous value is based on assumption that diurnal curve of solar radiation can be approximated by sine function. The instantaneous estimation of ET is obtained from the modified Priestly-Taylor equation, which relies primarily on remotely sensed inputs. To derive the ET estimates the coefficient α of Priestly-Taylor equation is ranged using two step linear interpolation based on the correlation between surface temperature and Normalized Difference Vegetation Index (NDVI) value. The parameterization of ET comes from two assumptions, based on physical relationship between land surface parameters. First step was to classify the image pixels by NDVI

values, which were associated with land uses. Within each NDVI class the upper and lower boundaries of parameter α were determined by ranging proportionally to NDVI values, assuming that high ET value can be found on the pixel with maximum NDVI and vice versa. The global minima of parameter α equals to zero and the global maxima can be found on the pixel with the maximum NDVI for whole catchment. At the second step within each NDVI class, the parameter α was corresponded to each pixel using the value of land surface temperature (LST). The classification based on idea that the highest ET value can be obtained from the pixel corresponding to the lowest temperature within NDVI class and the highest temperature pixel gives the lowest NDVI values. Consequently, the ET values for each of the pixels can be determined using the spatial context of remotely sensed parameters LST and NDVI. To assess the land surface temperature value and NDVI within a cathment, the remote sensed data from 1km NOAA-14 AVHRR sensor is utilized. Proposed scheme allows obtaining the time series of daily evapotranspiration map over the Natori River basin in 1992. Results of modeling have reasonable agreement with estimates from general water balance equation and Thornthwaite equation. Taking into account that the data from NOAA-14 AVHRR sensor are available once a day, proposed scheme can be useful for operational assessment of water resources redistribution over a large area at temporal and spatial scale.

MEASUREMENTS OF ISOPRENE FLUXES BY A GRADIENT TECHNIQUE IN DIFFERENT REGIONS IN THE AMAZON FOREST

Carla R. TROSTDORF[1], Luciana V. GATTI[1], Amelia YAMAZAKI[1], Carlos A.B. AQUINO[2], Williams C. MARTINS[3], Lizia L. MURBACH[3] ([1]Department of Environmental Chemistry - IPEN, [2]ULBRA, [3]Universidade Federal do Para)

Volatile organic compounds (VOCs) emissions from vegetation have been estimated to be several times higher than anthropogenic emissions. On a global scale, the largest biogenic VOC emissions occur in the tropics with isoprene being the dominant compound emitted, and tropical rainforests are estimated to be the major source of VOCs into the atmosphere, due to combination of high temperatures and large biomass densities. Measurements of vertical fluxes of isoprene above a west and east Amazon forest by the gradient technique are reported in this paper. The sampling was performed as part of the Large-scale Biosphere atmosphere experiment in Amazonia (LBA) from December, 2001 through October, 2002 at four sites in Amazonian. The first two sites near Santarém, Para State, Brazil in the National Forest of Tapajós, one at a primary forest and another at a forest were selective logging is taking place. The measurements were made at 65 and 55 m heights simultaneity in an LBA Tower. The other two sites are located in the Rondônia state, at a primary forest (Biological Reserve of Jaru) and also at a pasture site (grass vegetation). The forest site with the gradient measurements taking place at 65 and 55 m above the ground and in the pasture site the gradient measurements are taking place at 8 and 5 m above the ground. The mean daytime isoprene fluxes were 1.5 mg m$_2$h$_1$ and 0.9 mg m$_2$h$_1$ at the primary forest and selectively logged sites, respectively, and the peak fluxes were 3.0 mg m$_2$h$_1$ and 1.0 mg m$_2$h$_1$ in the Para State. In the Rondônia state, the mean daytime isoprene fluxes were 1.2 mg m$_2$h$_1$ and 0.2 mg m$_2$h$_1$ at the primary forest and pasture site, respectively, and the peak fluxes were 3.2 mg m$_2$h$_1$ and 0.4 mg m $_2$h$_1$, respectively. The expected seasonality of VOC fluxes and emissions are being captured. The results are being used to evaluate emission models.

GLOBAL CHANGE AND CHANGING CHEMISTRY OF THE ATMOSPHERE: A STUDY WITH REFERENCE TO IMPACT OF HUMAN ACTIVITIES ON AIR POLLUTION IN MAJOR METROPOLITAN CITIES OF INDIA: IDENTIFICATION OF MAJOR DIMENSIONS

Shanmuganandan SAMARAJALINGAM (Madurai Kamaraj University)

The changing chemistry of the atmosphere has already caused environmental and economic damage to the resource industries (forests, fisheries, agriculture, ecotourism, hydroelectric generation) in tropical countries including India. Some of the atmospheric changes are local but continental- and global scale processes are also at work The purpose of the present study is to analyze the extent of anthropogenic activities has caused a change in the atmospheric chemistry of major selected metropolitan cities (Delhi, Mumbai (Bombay) and Chennai (Madras). The study probes into the man made activities responsible for an increase in the concentration of major pollutants (carbon monoxide, nitrous oxide, carbon dioxide etc.,) in the selected major metropolitan cities in India and also attempted to identify the major dimensions with reference to selected variables drawn from urbanization, industrialization, socioeconomic and sociocultural activities as initiated by human activities. The study was based on the secondary data collected from published sources and the data were analyzed with the help of multivariate statistical analysis factor analysis to identify the major dimensions. The study has also made an attempt to conduct a perception study of the city dwellers on the impacts of pollution and also possible causes for changing local atmospheric conditions and chemistry. The study identified the major dimensions such Volume of Traffic and atmospheric pollution, Atmospheric pollution and Industrialization, Changing atmospheric chemistry and historic land use changes, Urban growth and Impact of anthropogenic activities and Increasing air pollutants etc determined local atmospheric conditions of the selected major metropolitan activities. Although the human activities and their extent may differ from region to region, the concentration of air pollutants in various composition ultimately determined the atmospheric chemistry within the Earth system.

WEST SIBERIA REGION AND LARGE URBAN AREA IN NORTHERN EUROPE (ST.-PETERSBURG) AS ATMOSPHERIC METHANE SOURCES

Svetlana V. JAGOVKINA[1], Igor L. KAROL[1], Alexander I. RESHETNIKOV[2], Nina N. PARAMONOVA[2], Victor E. LAGUN[3] ([1]Main Geophysical Observatory, [2]Research Center for Atmospheric Remote Sensing, [3]Arctic and Antarctic Research Institute)

Methane plays an important role in atmospheric warming being one of the strongest greenhouse gases. Also methane is among of the main sinks for hydroxyl therefore it influences the life times of active atmospheric species and it is one of the ozone precursors forming the background ozone levels. The atmospheric methane content increases since the middle of XIX century due to anthropogenic impact mainly. Due to the long life time of methane this atmospheric compound is spread almost evenly over the globe, nevertheless there are enclosing strong and permanent methane sources regions with higher methane concentrations, such as West Siberia and some industrial areas. Present investigation is devoted to the assessment and inventory of methane sources from such regions as West Siberia with intensive methane fluxes from gas deposits and wetlands and large urban area (Saint–Petersburg) located in the Northern part of Europe. The estimations of methane emission scenarios, proposed in this study, is based on combination of specially organized measurement campaigns with 3D transport modeling of methane distribution which allowed to correct the estimate of methane flux intensity in these regions. The comparison of two regions is presented and main paths of air masses are traced. Statistical analysis of multiyear surface methane measurements near Saint-Petersburg is presented. Seasonal

and interannual variations of methane concentration are discussed. Natural and anthropogenic methane fluxes are calculated for studied areas for numerical input estimation into regional and global budget of greenhouse gases.

ATMOSPHERIC TRACE GAS AND AEROSOLS MEASUREMENTS DURING WINTERS OF 1999 TO 2002 IN THE URBAN AREA OF SAO PAULO, BRAZIL

Angelica PRETTO[1], Luciana Vanni GATTI[1], Luiz Augusto DE PAULA REINO[1], Jose Roberto ROGERO[1], Amelia YAMAZAKI[1], Paulo ARTAXO[2] ([1]Department of Environmental Chemistry - IPEN, [2]Instituto de Fisica, Universidade de Sao Paulo, Brazil)

The Sao Paulo city area is located in the south eastern part of Sao Paulo state (23o32?S and 46o38?W). The urban area comprises 8000 km2 ranging in elevation from 650 to 1200 m. The population is about 18 millions people and 5.5 millions vehicles. Nowadays the main pollutants are NO2, NO, CO, PM and Ozone. The vehicular air pollution represents 95% of the total air pollution emission with the remaining 5% mainly generated by industries.A study integrating measurements of ozone (O3), nitrogen oxide (NO), nitrogen dioxide (NO2), carbon monoxide (CO) and sulphur dioxide (SO2) with aerosol mass concentration, organic and elemental carbon concentration and black carbon concentration particle measurements was performed in Sao Paulo at the winters of 1999 to 2002. Meteorological variables such solar radiation, temperature, relative humidity, wind speed and direction were also measured. The objective is to study the associations between trace gas and aerosol particle concentrations with meteorological conditions.The variation of NO2, NO, CO, SO2 and aerosols for favorable dispersion days and unfavorable dispersion days show that the common concentrations of gases related to direct emissions depends of behavior of traffic and of meteorological conditions, such as wind speed and direction for dispersion, boundary layer height, temperature, relative humidity and other factors. The cloudy day has the highest wind speed and the trace gases and aerosols for this days is the smallest concentration because this day good dispersion conditions. The daily variability of O3, NO2, NO, CO, SO2 and aerosols with meteorological conditions are discussed and the interrelationship between the trace gas concentrations can be easily observed in the plots. The SO2 concentrations were very low, because of the reduced emissions in the urban area of Sao Paulo. (Research project financed by FAPESP and CNPq)

SOLAS ACTIVITIES IN CHINA

Guangyu SHI[1], Hui WANG[2], Xiu-Lin WANG[3], Hui-Wang GAO[3], Xin LI[1] ([1]The Institute of Atmospheric Physics, Chinese Academy of Sciences,China, [2]Division of Marine Science, National Science Foundation of China, Beijing, China, [3]Ocean University of China, Qingdao, China)

During the past two years, Chinese scientist from the oceanic and atmospheric sciences made great efforts to participate in the International Surface Ocean and Lower Atmosphere Study (SOLAS). A Chinese Working Group for SOLAS (CWG-SOLAS) has been established in September, 2001. And a preliminary China – SOLAS Program was reported in the SOLAS Amsterdam Meeting which was held in June, 2002, by Dr. SHI as a national contact person. China SOLAS is intent to focus on biogeochemical interactions between upper ocean and low atmosphere in the regime of China Seas, and is attempting to answer how these biogeochemical interactions will affect the global and regional environmental variability. It reflects overall the initiative for the international SOLAS programs while China SOLAS will be focusing on processes that are critically important in order for tackling China Seas' regional environment issues that have broader global impact. An example is given to Asian dust: its transport, input and its impact on the surface ocean productivity. It emphasized the China Seas in the context of regional and global environmental/climate change since the China Seas are located at a significantly sensitive region in the Earth Climate System modulated by Tibet Plateau and Equatorial Pacific Warm Pool and by significant land-sea interactions driven by large Chinese river systems such as Changjiang, Huanghe and Zhujiang.Considering both of the international SOLAS science plan and actual condition in China Seas, the presentation reflects the six FOCI from the international SOLAS science plan as follows: (1) Exchange processes at the air-sea interface; (2) Air-sea CO2 flux in China Seas; (3) The impacts of sulfur emission from China Seas on the processes of clouds and radiation; (4) Contribution of Atmospheric Nitrogen Deposition to Nutrients in the China Seas; (5) The impacts of Asian dust on marine primary productivity in China Seas; and (6) Radiation transmission in the atmosphere-ocean system and primary productivity in the coastal waters of China. Each focus is divided in several activities.Recently Chinese National Committee for IGBP (CNC-IGBP) has approved formally to establish a Working Group for SOLAS and the National Science Foundation of China (NSFC) has decided to set up a Key Project for supporting the SOLAS Activities in China.This paper will introduce the China – SOLAS Program, the structure of the CWG-SOLAS and the activities related to the SOLAS in China in some details.

CHARACTERISTICS, TREND AND CHEMICAL COMPOSITION OF ATMOSPHERIC PRECEPITATION AT SHAHROOD, NORTHEAST IRAN

Gholam Abbas KAZEMI, Hossein MEHDIZADEH (Department of Geology, University of Shahrood)

The trend, characteristics and chemical composition of atmospheric precipitation at Shahrood, a medium size city in the northeast Iran, are largely affected by the role of Alborz Mountain Ranges acting as the barrier for the rain bearing clouds originating from the Caspian Sea. While the long term average annual precipitation of the city in the form of snow and rain is 153 mm, a major drought has severely hit the region over the past 9 years causing extensive pressure on existing water resources. Statistical analysis indicate that the present drought is similar to early 1970´s drought and is thus expected to last for another 3-4 years. Large temporal variations (daily, monthly and annual) are of the characteristics features of the precipitation in the region. Year 1972, for example, had a rainfall of 286 mm while the total rainfall in year 1961 was only 65 mm, i.e. less than a forth. Similarly, the maximum recorded monthly precipitation is 103 mm, 25 folds higher than 40% of the months which have a rainfall of less than 5 mm. Daily precipitation show the highest variations. In 1996, for instance, 42 mm of rain fell in one day which accounted for 23% of the whole year rain. Chemical analysis of precipitation samples show that while the pH of the precipitation is about 7, its total dissolved solids (TDS) is higher than the world average and reaches 400 mg/l in some events. The dominant cation is calcium with an average concentration of 11.5 mg/l and the average concentration of nitrate and sulfate is 2.4 and 7 mg/l, respectively. There is a good correlation between the depth of precipitation, the number of precedent dry days and the TDS of precipitation at any event. The enrichment factor (the ratio of Ion/Cl- sample to the Ion/Cl- seawater) for most ions indicates that the precipitation salts are of continental origin. The high TDS of the precipitation is believed to be due to low average rainfall, mountainous landscape, wind and weather pattern, anthropogenic impacts and less likely analytical errors.

THE CRYOSPHERE, SNOW, ICE SHEET MASS BALANCE AND ICE CORES

JSM10/07A/B23-001   **0900**

THE WORLD CLIMATE RESEARCH PROGRAMME (WCRP) CLIMATE AND CRYOSPHERE PROJECT (CLIC): A GLOBAL INITIATIVE

Barry E. GOODISON[1], Ian ALLISON[2], Roger G. BARRY[3], Chad DICK[4], Vladimir RYABININ[5] ([1]Climate Research Branch, Meteorological Service of Canada, Environment Canada, Downsview, Ontario, Canada M3H 5T4, [2]Australian Antarctic Division and Antarctic CRC, Private Bag 80, Hobart, Tasmania, 7001, Australia, [3]National Snow and Ice Data Center, U. Colorado, Boulder, CO, 80309-0449, U.S.A, [4]International ACSYS/CliC Project Office, Norwegian Polar Institute, NO-9296, Tromso Norway, [5]Joint Planning Staff for WCRP, WMO Secretariat, Geneva 2, CH-1211, Switzerland)

The objectives of the World Climate Programme (WCRP) are to understand the physical climate system, develop a predictive capability and understand the extent of human influence on climate. Through its projects – CLIVAR, GEWEX, SPARC and ACSYS/CliC – WCRP provides a coordinating mechanism for research on the climate system. ACSYS (the Arctic Climate System Study), whose scientific goal is to ascertain the role of the Arctic in global climate, will sunset at the end of 2003. The new core WCRP project "Climate and Cryosphere" (CliC), established by WCRP in March 2000, is global in scope. CliC aims to improve understanding of the cryosphere (snow cover, sea-, lake- and river- ice, glaciers and ice caps, ice sheets and shelves, and frozen ground including permafrost) and its interactions with the global climate system, and to enhance the ability to use parts of the cryosphere for detection of climate change. The principal goal of CliC is to: ·Assess and quantify the impacts of climatic variability and change on components of the cryosphere and their consequences for the climate system, and determine the stability of the global cryosphere.In order to achieve this goal, CliC has the supporting objectives to: ·Enhance the observation and monitoring of the cryosphere ·Improve understanding of the physical processes through which the cryosphere interacts within the climate system ·Improve the representation of cryospheric processes in models. CliC seeks to develop activities and facilitate international co-ordination of research aimed at increasing the understanding of four main scientific themes involving: interactions between the atmosphere and snow and ice on the land surface; interactions between glaciers and ice sheets and sea level; interactions between sea ice, oceans, and the atmosphere; and, cryosphere-climate interactions on a global scale. The scientific strategy is similar in each of the areas of interaction: a combination of measurement, observation, monitoring and analysis, field process studies and modelling over a range of time and space scales. A CliC modelling strategy must address improved model parameterization of the direct interactions between all components of the cryosphere, the atmosphere, and the ocean at scales from regional to global, and with a hierarchy of models. It is essential to provide improved in-situ and remote sensing data sets needed for validation of models and parameterization schemes and the development of cryospheric indicators of climate change. This paper will provide an overview of the planned approach of CliC to address cryosphere and its role in the climate system. It will introduce some of the scientific issues considered to be important, summarize planned activities and discuss the critical importance of co-ordination with national and international initiatives and scientific bodies. Open discussion and feedback on the project is welcomed.

HISTORICAL TRENDS IN LAKE ICE COVER IN CANADA

Claude R. DUGUAY (Geophysical Institute, University of Alaska Fairbanks)

Long series of lake ice observations can serve as a proxy climate record, and the monitoring of freeze-up and break-up trends provide a convenient integrated and seasonally specific index of climatic perturbations. The most recent study on historical freeze-up and break-up records of ice on lakes (Magnuson et al., Science, 2000) indicates that later freezing and earlier break-up dates are observable around the Northern Hemisphere from 1846 to 1995. However, some lake sites may deviate from this general trend depending on the hydroclimatic region in which they are located. In a country as large as Canada, lakes are likely to respond differently from east to west and north to south. Given this and the fact that global climate models predict that high latitude regions will be the most strongly affected by climate warming, a study was undertaken to test for temporal trends in freeze-up and break-up dates across Canada. A set of 91 lakes, with time series of 20 years or longer, was analyzed using the Mann-Kendall test for monotonic trend. Trends towards earlier break-up dates are observed for most lakes during the period of study (1940s to 1990s). Freeze-up dates, on the other hand, show few significant trends as well as a low temporal coherence when compared to break-up dates. These results suggest that freeze-up dates are influenced by local factors more than break-up dates.

RELATIONSHIPS BETWEEN SPATIAL PATTERNS OF SNOW WATER EQUIVALENT AND SYNOPTIC SCALE TROPOSPHERIC CIRCULATION FOR CENTRAL NORTH AMERICA 1978 - 2001

Chris P. DERKSEN[1], Chris P. DERKSEN[1], Ellsworth F. LEDREW[2], Anne E. WALKER[1], Barry E. GOODISON[1] ([1]Climate Research Branch, Meteorological Service of Canada, [2]Department of Geography, University of Waterloo, Canada)

Characterizing regional snow cover patterns and identifying the atmospheric triggers totheir accumulation and ablation is significant given the important role that snow coverplays in global energy and water cycles. Satellite passive microwave data are a useful source of snow cover information for synoptic scale studies of this nature because of all-weather imaging capabilities, rapid scene revisit, and the ability to derive quantitativeestimates of snow water equivalent (SWE). When Special Sensor Microwave/Imager(SSM/I; in operation 1987 to present) and Scanning Multichannel Microwave Radiometer(SMMR; 1978 - 1987) data are combined, the time series of 20 years of dual polarized, multichannel,spaceborne passive microwave brightness temperatures extends from 1978 to the present. In this study, 23 winter seasons (December, January, February 1978/79 to 2000/01) of five day averaged

(pentad) passive-microwave derived SWE data are derived for a ground-validated western North American study area using a land cover sensitive algorithm suite developed at the Meteorological Service of Canada. When no brightness temperature adjustments are employed, SWE estimates derived during SMMR winter seasons are systematically and significantly lower than retrievals during SSM/I seasons. The SMMR brightness temperatures were subsequently adjusted to an SSM/I F-8 baseline using regression relationships from the August 1987 SMMR and SSM/I overlap period. The resulting adjusted SWE dataset produces a time series of acceptable cross-platform homogeneity when assessed with in situ SWE measurements and remotely sensed snow extent data. Rotated principal components analysis (RPCA) was used to identify the dominant spatial patterns for a cross-platform (SMMR and SSM/I) pentad-to-pentad change-in-SWE (ΔSWE) dataset. Eight dominant patterns are identified within the time series: the positive and negative phases of the first four rotated ΔSWE components. A composite analysis of 500 mb geopotential height fields produced from National Center for Environmental Prediction (NCEP) data illustrate that regional SWE increases occur when there is a deep 500 mb Arctic low over eastern North America, which displaces a ridge westward over the eastern Pacific resulting in strong north-south advection of cold Arctic air through the continental interior. Alternatively, regional patterns of decreasing SWE are associated with an eastward migration of the 500 mb ridge, allowing advection of warm air into central North America from the south-west. Difference-of-means tests illustrate that significant differences in tropospheric circulation between increasing and decreasing SWE events are expressed in a tripole pattern with centers of action over Alaska, the continental interior, and the Eastern Canadian Arctic. Geopotential height data alone are insufficient to explain tropospheric links with specific ΔSWE component patterns; however, model produced isentropic potential vorticity (IPV) fields show potential for identifying linkages between regions of synoptic development and the dominant patterns of ΔSWE.

JSM10/07A/B23-004   1020
INFLUENCE OF SNOW PROCESSES ON SURFACE EXCHANGE OF MASS AND ENERGY

Michael LEHNING, Perry BARTELT, Thomas EXNER, Charles FIERZ, Ingo Meirold MAUTNER, Norbert RADERSCHALL, Sergey SOKRATOV (Swiss Federal Institute for Snow and Avalanche Research SLF)

There are many influences of snow on the surface exchanges of mass, energy and momentum. The most important ones are: a) Change of surface albedo through snow on the ground; b) Change of surface roughness through snow on the ground; c) Change of surface roughness through drifting snow; d) Change of latent heat transfer (sublimation) through drifting snow; e) Insulation of soil layers and vegetation through snow on the ground. When analyzing the processes in more detail, it becomes clear that all exchange processes are highly interdependent and cannot be separated from the processes that take place within the snow cover. For example, metamorphic changes of surface snow such as the formation of a wind slab or a melt-freeze crust will prevent subsequent erosion of the snow. Or erosion of snow will create surface ripples and sastrugis with the effect of changing surface momentum and heat fluxes. Another example is the dependence of the surface latent heat flux on ventilation and vapor flux in the upper snow layers. Thus, the correct representation of snow processes is a crucial part in assessing the snow atmosphere interaction This presentation gives an overview of the relevant processes at the snow atmosphere interface. It shows how these processes are represented in the detailed snow cover model SNOWPACK. Focus is on the interaction between latent heat and thus moisture fluxes, surface roughness, vapor transport within the snow and snow ventilation effects as well as radiation transfer in snow. The energy balance over and in the snow cover is discussed using field data from summit at Greenland, from the Weissfluhjoch experimental site at Davos Switzerland and laboratory data from the cold wind tunnel in Davos Switzerland. It is shown that the correct representation of the snow processes is necessary to close the energy balance. At the same time, snow development itself depends crucially on these processes. Applications of such a detailed model are discussed, which include avalanche warning, ice core interpretation and ecological research.

JSM10/07A/B23-005   1100
SURFACE PROCESSES AND ICE SHEET MASS BALANCE

Elizabeth M. MORRIS (Scott Polar Research Institute, University of Cambridge)

This talk will review the surface processes involved in snow ablation, accumulation rates over glaciers and ice sheets. It will also review relevant processes in the surface boundary layer. The role these different processes play in the large scale dynamical response of ice sheets to climate change will be discussed using both models and observations. Detailed observations of snow stratigraphy from cores will be presented using a new sensor that detects annual variations in snow density. The review will also include recent remotely sensed data of ice sheets and ice shelves and will discuss their implication for terms in the overall mass balance of ice sheets.

JSM10/07A/B23-006   1140
CHARACTERISTICS OF PRESENT CLIMATIC CHANGE RECORDED BY MALAN ICE CORE CENTRAL QINGHAI-TIBETAN PLATEAU

You-Qing WANG, Tandong YAO, Ninglian WANG, Jianchen PU, Keqin DUAN, Weizhen SUN (Key Laboratory of Ice Core and Cold Regions Environment, CAREERI, CAS)

The climatic change during 1920~1998a was reconstructed based on annual delt 18-O from a 102.07 m ice core recovered from the Malan Ice Cap in Kekexili region in central Tibet in May 1999. Malan ice core shows that the warming trend of present climate in central Qinghai-Tibetan Plateau is similar to the warming of the Northern Hemisphere and records around the Qinghai-Tibetan Plateau. The warmest period recorded by Malan ice core is during the earlier 1980s, oppositely, the climate during the 1990s was colder. The record suggests that the global warming is evident global, and short term cooling fluctuation might be happening in some regions.

JSM10/07A/B23-007   1200
SEASONAL DIFFERENCES OF FRESH SNOW CHEMISTRY FROM MT. EVEREST: IMPLICATIONS FOR ICE CORE DATING

Shichang KANG[1], Paul A. MAYEWSKI[1], Dahe QIN[2], Junying SUN[2], Sharon A. SNEED[1] ([1]Institute for Quaternary and Climate Studies, University of Maine, Orono, ME 04469, USA, [2]Key Laboratory of Ice Core and Cold Regions Environment, Cold and Arid Regions Environment and Engineering Research Institute, CAS, Lanzhou 730000, P. R. China)

Essential to the reconstruction of ice core records is dating accuracy. One ice core dating method is to measure the seasonal variation of chemical species and use these to count annual layers. This requires investigating the modern timing of precipitation chemistry in the region from which the ice core has been extracted. Presently, chemical data of fresh snow are available only for two climbing seasons on the northern slope of Mt. Everest: spring (April to May) and late summer (August to September). Here we present chemistry data from fresh snow sampled during the late 1998 summer from Mt. Everest and compare our data with earlier results from Jenkins and others (1987) to investigate seasonal differences of snow chemistry and their significance for ice core dating on Mt. Everest. The glaciochemisty from snowpit are also presented to verify our results. The mean value of ion balance ΔC (sum of anions − sum of cations) for the summer fresh snow samples is 1.08 μeq/L, indicating that there is an excess of anions. Average relative ion composition (%) shows that Cl^- and Ca^{2+} are the dominate species. The crustal species Ca^{2+} and Mg^{2+} correlate with SO_4^{2-} and NO_3^- indicating potentially associated sources for these species (e.g. local crustal aerosols). NH_4^+ doesn't correlate with the others suggesting it has unique sources in summer (e.g. biogenic sources). From our data set, there is no significant effect of elevation on snow composition. Compared with earlier results from Jenkins and others (1987), the ion concentrations of fresh snow in 1998 summer are much lower than those in 1986 spring. The most dramatic difference of chemical composition between the two seasons is crustal Ca^{2+} concentration in which the spring value is about 22-fold higher than summer value. Differences of SO_4^{2-} and Na^+ concentrations between seasons are also striking. Due to the absence of NH_4^+, K^+ and Mg^{2+} measurements in 1986 snow (Jenkins and others, 1987) we cannot compare these species. The marked seasonal differences for crustal species (e.g. Ca^{2+} and SO_4^{2-}) are much more distinct than others (e.g. NO_3^-). Thus, these crustal species may present the most definitive indicators for ice core dating in the Mt. Everest region. To examine the possibility of ice core dating through variations of crustal species, the chemical compositions of the snow pit from 1998 summer on Mt. Everest is investigated. Generally, the chemical differences between summer and spring snow from the snow pit agree with those from fresh snow. Notably, the spring Ca^{2+} peak in the snow pit is more dramatic than for other species and is consistent with fresh snow results. This study verifies the assumption that the maximum of Ca^{2+} concentration in spring snow is a significant horizon for dating ice cores on the northern slope of Mt. Everest. High spring concentrations of other species (e.g. Na^+ and Mg^{2+}) may also provide additional references layers for ice core dating.

MARINE CRYOSPHERE: SEA ICE AND ICE SHELVES

JSM10/07P/B23-001   1400
CLIMATE INTERACTIONS IN THE MARINE CRYOSPHERE

Ian ALLISON (Antarctic CRC and Australian Antarctic Division)

Sea ice forms a boundary between the atmosphere and the ocean over about 10% of the surface area of the global ocean, considerably influences atmosphere-ocean interaction, and thus plays a key role in the global heat balance and the global thermohaline circulation. A retreat of sea ice may therefore have global consequences and contribute, through various feedback processes, to enhanced climate change. To facilitate credible prediction of the state of the polar pack ice, both theoretical and observational knowledge of the processes of interaction among the ice, the ocean, and the atmosphere must continue to be improved. This paper reviews what we know about the mean state and natural variability of sea ice characteristics in both polar regions (although with an emphasis on the Antarctic) and the physical processes that determine these. A special focus is made on ice formation and water mass modification in Antarctic coastal polynyas, regions of intense heat loss from the ocean to the atmosphere, and significant as ˝ice factories˝ for the total sea-ice zone. In some cases processes in polynyas play a role in control of the vertical overturning that regulates the thermohaline circulation. Evidence of trends in sea ice volume and distribution in both hemispheres is discussed as is the possible impacts of projected global warming.

JSM10/07P/B23-002   1440
AIR-ICE INTERACTIONS DURING THE SHEBA DEPLOYMENT IN A 2-DIMENTIONAL COUPLED MODEL

Xiangdong ZHANG[1], Bin CHENG[2], Timo VIHMA[2], John E. WALSH[3] ([1]Frontier Research System for Global Change, International Arctic Research Center, University of Alaska Fairbanks, [2]Finnish Institute of Marine Research, P. O. Box 33, FIN-00931, Helsinki, Finland, [3]International Arctic Research Center, University of Alaska Fairbanks, Fairbanks, AK99775, USA)

It has been demonstrated that synoptic activities, such as cyclones, has increased during recent decades in the Arctic Ocean (Serreze et al. 2001). The effects of cyclones on the sea-ice export through Fram Strait (Brummer et al., 2000) and on the local ocean hydrography in the Beaufort Sea (Yang et al. 2001) were detected. However, such effects on the sea-ice pack and their feedback have not been documented well. From a large-scale point of view, cyclones may also leave a lasting imprint on sea-ice states and, in turn, affect climate variability. One important feature of a cyclonic system is its accompanying advection of warm air, which originates from low latitudes. The SHEBA deployment was carried out for an entire year from October 1997 to October 1998 and captured an outstanding warm air advection event in the middle of May 1998, when a well-developed cyclonic system moved slowly northward from the Bering Sea and the Gulf of Alaska. The Beaufort Sea was covered by the advection of warm air mass from east to west during a period from 10th through 12th May. We employed a 2-dimentional coupled atmospheric boundary layer (ABL) and sea-ice thermodynamics model (Cheng and Vihma, 2003) to investigate the air-ice interactions during this period. The model domain was configured in the dominant direction of the prevailing winds and extended 420km downwind from the SHEBA Camp with a horizontal resolution of 5 km. The ABL had 50 levels from surface up to 3 km, while the snow and the sea-ice had 10 vertical layers, respectively, in the model. The ABL inflow boundary condition was updated every hour based on the SHEBA rawinsounding data. The ABL and the sea-ice models were spun up to a quasi-equilibrium in which the modeled surface temperature was close to the AVHRR retrieval skin temperature. During the three-day simulation, the model apparently captured the warm air advection well. The modeled spatial distribution of surface temperatures were close to the AVHRR derived values. An increase of temperature occured in the snow and upper sea-ice layer, in response to the penetration of solar radiation and invasion of warm air mass into the model domain. The former factor predominates, while the latter amplifies the effects of the former. Heat accumulates in the snow layer, a response in part to the increasing solar radiation during this transition season. Due to the increases of air moisture carried by the advection, condensation occurs. The diurnal amplitude of the low-level air temperature and the snow/ice temperature is damped in the simulation. Parallel simulation in an uncoupled model provided insight into the feedback produced by the coupling.

SURFACE ENERGY BUDGETS AND CLOUD FORCING ON THE ARCTIC ICE CAP: ONE YEAR OF DATA FROM THE SHEBA EXPERIMENT

Chris W. FAIRALL[1], Janet INTRIERI[1], Taneil UTTAL[1], Ola PERSON[2] ([1]NOAA Environmental Technology Laboratory, [2]University of Colorado Cooperative Institute for Research in Environmental Sciences)

From November 1997 to October 1998 the Surface Heat Budget of the Arctic (SHEBA) engaged in a variety of atmospheric, ice, and oceanic measurements on the Arctic icecap as part of ice station SHEBA. The ice station was launched at 143 W and 75 N and ended at 166 W and 80 N. The measurements included eddy-correlation measurements of sensible and latent heat flux, upward and downward solar and IR fluxes, and snow/ice temperatures. Profiles of cloud information were obtained with an 8-mm-wavelength Doppler cloud radar and a 0.523 micron wavelength depolarization and backscatter lidar (dabul). This is the first set of eddy-correlation heat flux, radiative fluxes, and comprehensive cloud data obtained over an entire annual cycle on the ice cap. In this paper we will present simple statistics on the annual cycle of the components of the surface heat budget and cloud properties (fraction, thickness, ice vs water, etc). We will also provide a detailed analysis of the annual cycle of cloud forcing of the surface heat budget of the icecap. Comparisons with several climate models will be presented.

JSM10/07P/B23-004   1520

MOMENTUM CONSERVING ICE-OCEAN COUPLING FOR INERTIAL AND TIDAL SEA ICE VARIABILITY

William HIBLER III[1], Petra HEIL[2], Harper SIMMONS[1], Jennifer K. HUTCHINGS[1] ([1]University of Alaska Fairbanks, [2]University of Tasmania)

Most ice ocean circulation models utilize separate ice and ocean modelswith the stress transfer between the ice and ocean treated by the stressbetween the ocean and ice. While such a stress transferral is quite usefulfor the study of boundary layer dynamics, in a full three dimension oceancirculation model this procedure distorts the overall stress transfer intothe coupled ice ocean model. It can be shown, for example, to introduceartificial discontinuities into the ice margin ocean dynamics even if thewind stress over ice and water are identical. Such a coupling differssubstantially from the coupling utilized by Hibler and Bryan (1987) forthree dimensional ocean circulation models whereby the stress transfer intothe upper layer of the ocean is taken to be the wind stress less the iceinteraction. This latter coupling is however, difficult to implement in amanner that preserves high frequency variability in the ocean if separateice and ocean models are employed. Recently, Heil and Hibler (2002) haveemployed an ice model utilizing an embedding procedure whereby the ice isembedded in the oceanic boundary layer following a procedure proposed by McPhee( ) and modified the ice drift equation so one equation is solvedfor the ice momentum balance, ice interaction and boundary layer motion. Utilizing this procedure they obtained greatly improved high frequencyinertial variability in the predicted ice drift as well as low frequencypredicted drift of ice motion compared to the classic passive dragformulation. Interestingly, the high frequency variability in the icemotion, which for both drift and deformation was found to be coherent withdetailed hourly buoy drift and deformation results, was found to begenerated by a non linear cascade of energy induced by ice mechanics forcedby low frequency wind forcing. Insignificant linear correlation betweenwind forcing and the essential linear boundary layer formulation was found. In this paper we extend the coupling procedure to a full multilevel zco-ordinate ocean model and investigate the response of this coupled modelfor the Arctic Basin with fixed baroclinic forcing, but 6 hourly varyingwind forcing. A free surface ocean model is utilized so the effect of tidalforcing is also examined by non coupled tidal results from a barotropictidal model (Kowalik and Proshutinsky. Using this framework this modelis integrated over a multi year period for the Arctic basin with a variablethickness sea ice model and compared to models using more conventional´stress´ coupling. The comparisons include detailed comparisons to buoymotion and deformation but also include and analysis of the increased tidalresponse and its effects on the ice mass budget as well as the modificationsto the ice mass balance in the central Arctic due to inertial and tidaleffects in the full three dimension ice ocean model.

JSM10/07P/B23-005   1600

MODELLING OF THE THICKNESS DISTRIBUTION OF THE ARCTIC SEA ICE

Jari Juhani HAAPALA[1] ([1]Department of Physical Sciences, University of Helsinki, [2]Finnish Institute of Marine Research, Helsinki, Finland)

In the framework of the Finnish global change research program (FIGARE) a new advanced sea ice model applicable for climate research has been developed. The model resolves sea ice thickness distribution for arbitrary numbers of undeformed and deformed sea ice thickness categories. The sea ice model has been implemented in the ocean circulation model, MPI-OM-1, developed in the Max-Planck Institute of Meteorology. The MPI-OM-1 model is global, however it employs curvi-linear coordinates which allows to model coastal regions and adjacent seas of the Arctic Ocean with a high horizontal resolution, which are known to be vital regions for a sea-ice production.Ten-years simulations have been made with the global model and the evolution of the sea ice thickness distribution in the Arctic has been analysed. The temporal behaviour and horizontal extension of the deformation regions was largely dependent on the synoptic scale wind field. Deformed ice production regions were concentrated in coastal regions, particular important regions were found to be the Lincoln Sea, the Beaufort Sea and the Northern regions of the Spitsbergen, Franz Josef Land and the Severnaya Zemlya.

JSM10/07P/B23-006   1620

THE RELATIONSHIP BETWEEN ANTARCTIC COASTAL TEMPERATURES AND SEA ICE EXTENT

Steven Richard COLWELL, John TURNER (British Antarctic Survey)

Passive microwave satellite imagery has shown that the total extent of Antarctic sea ice has increased by about one percent per decade since the late 1970s. However, there is a high degree of spatial variability in the trend in the sea ice around the continent, with there having been a marked decrease of ten percent per decade in sea ice over the Bellingshausen Sea since the satellite record began. In this region there is a high correlation between the winter season extent of the sea ice and the temperatures at the coastal stations on the western side of the Antarctic Peninsula. Since the late 1970s winter temperatures have risen as the sea ice has decreased. The warming is much less in the other seasons. The Peninsula is unique in the Antarctic in that it is the only significant northward extension of the continent that projects into the circumpolar trough the belt of low pressure that rings the continent over 60-70 S. Low pressure systems become slow-moving over the Bellingshausen Sea and the western side of the Peninsula is under a prevailing north to north-westerly flow. This area is the only region of the Antarctic where the prevailing wind is orthogonal to the ice edge, giving

a close linkage between surface pressure over the Bellingshausen Sea and the meridional extent of the sea ice. For the rest of the Antarctic, the relationship between coastal temperatures and sea ice extent is less clear. Earlier studies, covering a 15 year period up to 1987, suggested a correlation between temperature and sea ice trends, but this was much less than on the western side of the Peninsula. In this talk we will present a new analysis of temperature and sea ice trends for the Antarctic. The temperature data have been taken from the READER project (http://www.antarctica.ac.uk/met/READER/), where monthly mean temperatures were re-derived from the 6 hourly synoptic reports. Sea ice data were from the Ocean Modelling Branch of NOAA/NESDIS.

JSM10/07P/B23-007   1640

EFFECTS OF SURFACE FRESHWATER FLUX INDUCED BY SOUTHERN HEMISPHERE SEA ICE TRANSPORT ON THE GLOBAL THERMOHALINE CIRCULATION

Yoshiki KOMURO, Hiroyasu HASUMI (Center for Climate System Research, University of Tokyo)

Effects of surface freshwater flux induced by sea ice formation and melting on the thermohaline circulation are investigated by numerical experiments.A sea ice-ocean coupled general circulation model is used.The model domain is global, and the model is forced by monthly climatology derived from the NCEP reanalysis data.Restoring to the observed sea surface salinity is not employed in order to precisely evaluate the sea ice effects.We perform three cases, that is, a control case, a case in which sea ice motion is turned off, and a case in which salt and freshwater flux between sea ice and the ocean is turned off.All the cases are integrated for 3100 years. In the control case, mass transport associated with thermohaline overturning circulation is realistically represented, and the amount of northward sea ice transport in the southern hemisphere is reasonable compared with observations.Deep water formation around Antarctica occurs under compact sea ice cover.Precipitation exceeds evaporation in this region, but positive annual-mean sea ice production and resultant salt input into the sea surface are responsible to salinify the underlying water and maintain the deep water formation. When sea ice motion is turned off, annual-mean sea ice production is almost zero everywhere, and the deep water formation as in the control case is no longer maintained.Instead, it is driven primarily by thermal destabilization of water columns.Consequently, the deep ocean around Antarctica is warmer and less saline compared with that for the control case, and the Atlantic bottom circulation is weakened by 16 %.We analyze salt transport in the deep ocean in both the cases, and show that northward salt transport from the Southern Ocean in the bottom layer also decreases in the case without sea ice motion.The amount of the decrease is greater by one order of magnitude than that of the surface salt input associated with sea ice in the control case. In the case where the freshwater flux at the ice-ocean interface is turned off, results are similar to the case without sea ice transport, although surface heat and momentum fluxes significantly differ between them.This suggests that the influence of sea ice on surface freshwater/salt flux is more important than on surface heat and momentum fluxes in affecting the global thermohaline circulation.

JSM10/07P/B23-008   1700

ICE SHELVES SHAPING THE SOUTHERN OCEAN ENVIRONMENT

Hartmut H. HELLMER (Alfred Wegener Institute for Polar and Marine Research)

The importance of ice shelves and the processes at their base for the Southern Ocean and beyond was recognized late during Antarctic exploration. Modification of dense shelf waters due to melting and freezing at glacial bases can be directly linked to the formation of bottom waters at the continental shelf break and the ventilation of the world ocean abyss. To study the impact of ice shelf/ocean interaction on the southern environment the results of two numerical realizations were compared using the regional coupled ice-ocean model BRIOS2.2 with and without most of Antarctica´s ice shelf cavities. The dominant effect of closing the cavities is the missing freshwater outflow destabilizing a weakly stratified shelf water column. As a result, deep convection enhances, increasing shelf water salinities and thinning the sea ice cover on and beyond the continental shelf, and the northward transport of dense bottom water intensifies. This study therefore indicates the effects of decreasing sub-ice freshwater fluxes on the Southern Ocean not only due to present ice shelf decay but also past ice shelf advances which closed or reduced the cavity size beneath.

JSM10/07P/B23-009   1720

THE AMISOR PROJECT: AMERY ICE SHELF DYNAMICS AND ICE-OCEAN INTERACTION

Ian ALLISON[1], Helen FRICKER[2], Mike CRAVEN[1], Neal YOUNG[1] ([1]Antarctic CRC and Australian Antarctic Division, [2]Institute of Geophysics & Planetary Physics, Scripps Institution of Oceanography, University of California, San Diego, USA)

The Amery Ice Shelf (70oS, 70oE) is the third largest embayed shelf in Antarctica, and the largest entirely within East Antarctica. This ice shelf has been studied by the Australian Antarctic program for more than 50 years, although only in the past decade has the importance of ice-ocean interaction beneath the shelf become fully apparent. This has led to the establishment of a project of ' Amery Ice Shelf Ocean Research (AMISOR) This multidisciplinary project has overall aims of quantifying the interaction between the ocean and the Amery Ice Shelf (AIS); and determining the implications of this interaction for the discharge of grounded ice and to water mass modification. The project includes components of hot-water drilling through the AIS to make measurements in the underlying cavity; glaciological measurements of the ice shelf velocity, strain and thickness; oceanographic measurements in Prydz Bay; investigation of sub ice shelf sediments and sediment dynamics; remote sensing; and numerical modelling of ice shelf-ocean interaction and ice shelf dynamics. This paper provides an overview of the AMISOR project and the preliminary results from it.

CLIMATE VARIABILITY AND CLIMATE CHANGE

JSM10/08A/B23-001   0830

HIGH-LATITUDE CLIMATIC RESPONSE TO ENHANCED GREENHOUSE FORCING

John E. WALSH (University of Illinois, Urbana, IL USA)

A challenging feature of recent global climate model simulations is that the response to external forcing is greater in polar regions than elsewhere, while at the same time the simulated climates show the largest across-model variance in the polar regions. The well-known polar amplification of greenhouse warming is actually stronger in the Arctic than in the Antarctic in most models because of the land-sea configuration and the role of sea ice.

Feedbacks involving water vapor and the atmospheric circulation also play roles in the polar response to greenhouse forcing. The amplification's strong seasonality in most models is potentially useful for the detection and attribution of future climate changes. A comparison of the current generation of global climate model simulations shows that ocean-ice-atmosphere coupling leads to widely varying greenhouse scenarios in the Antarctic and in the subpolar North Atlantic, where changes in oceanic convection represent a "wild card" in the climatic response. Oceanic mixing reduces, and sometimes eliminates, the warming locally in some models, while in others a freshening of the upper ocean serves to cap the convection, with broader consequences for much of the ocean thermohaline circulation. The rate of retreat of sea ice is generally proportional to the rate of warming in the models, although the rate of retreat is also related to the amount of sea ice in the control simulation. Physical processes related to the distribution of sea ice in the model scenarios include changes in the atmospheric circulation and cloudiness, in addition to radiatively driven warming and changes in the upper ocean hydrography of the polar seas. Nearly all models project an acceleration of the hydrologic cycle in the polar regions, where enhanced precipitation and evapotranspiration accompany the higher temperatures and the reduced coverage of sea ice and snow cover. The hydrologic consequences include an earlier and stronger springtime discharge pulse, a longer (and warmer) melt period that hastens the degradation of permafrost, and a negative mass balance of small glaciers. The glacier wastage, in turn, contributes to a freshening of coastal waters. The response of the larger ice sheets is further complicated by increases in snowfall. A potentially noteworthy caveat concerning projected rates of change is that many global climate models show less sensitivity to variations of external forcing than is indicated by paleoclimatic evidence from the actual climate system.

JSM10/08A/B23-002   0910

RESPONSE OF THE PAN ARCTIC AND NORTH ATLANTIC OCEAN CLIMATE TO THE ARCTIC OSCILLATION

Jia WANG[1], Bingyi WU[2], Moto IKEDA[3], John E. WALSH[4] ([1]IARC-FRSGC, University of Alaska Fairbanks, [2]Institute of Marine Science, University of Alaska Fairbanks, USA, [3]Graduate School of Environmental Science, Hokkaido University, Japan, [4]IARC, University of Alaska Fairbanks, USA)

Using a coupled ice-ocean model developed by Wang et al. (2002), we investigatethe responses of the Arctic Ocean climate (or ice-ocean system) to the Arctic Oscillation(AO). Seven high AO index winters and six low AO index winters were simulated by thecoupled ice-ocean model under forcing provided by the NCEP/NCAR reanalysis.Statistical analyses and tests were applied to the composite differences between the highand low AO indices. For the high AO index phase that predominated during the 1990s,the results showed a reduction of sea ice in the Arctic Basin accompanied by an increaseof sea ice in the Labrador Sea. This pattern resembles the North Atlantic Oscillationseesaw pattern (Roger and van Loon 1979; Wang et al. 1994). During the high AO phase,the Arctic surface salinity increases and the surface temperature decreases, implying thatmore new ice was produced. The enhanced ice production is a consequence of greater iceexport from the Arctic Ocean in response to anomalous cyclonic wind stress. From thesubsurface layer to the Atlantic water layer, there is also a seesaw pattern in oceantemperature between the Barents and the Labrador Seas. During the high AO phase, themodel reproduces the anomalous temperature intrusion of the Atlantic Water. While boththe anomalous surface wind stress and the thermodynamical forcing contribute to sea iceand ocean variability, statistical analyses (EOF, regression, etc.) and significance tests (T-test and F-test) show that the wind stress accounts for a greater portion of these changesduring the high AO phase than the thermodynamical forcing.

JSM10/08A/B23-003   0930

NORTHERN HEMISPHERE SEA ICE VARIABILITY AND ITS LINKAGE TO THE NAO AND ENSO

Jinro UKITA[1], Meiji HONDA[2], Hisashi NAKAMURA[3], Yoshihiro TACHIBANA[4], Hiroshi KOIDE[5], Donald J. CAVALIERI[6], Claire L. PARKINSON[6] ([1]GEST, UMBC/NASA-GSFC, [2]Frontier Research System for Global Change, [3]University of Tokyo, [4]Tokai University, [5]Meteorological Research Institute, [6]NASA Goddard Space Flight Center)

Evidence is presented that Northern Hemisphere (NH) wintertime sea-ice variability on interannual time scales has a distinct modal structure characterized by a set of two orthogonal modes. One mode is spatially dominant and composed of synchronous seesaws in the North Atlantic and the North Pacific. This mode is closely linked to the North Atlantic Oscillation (NAO) with an extended domain of influence over the North Pacific. The other mode is the residual of the first mode with respect to the NH total SIE and closely related to the influence of the El Niño-Southern Oscillation (ENSO) phenomenon. This set of modes explains a significant part of the temporal and spatial variations in NH wintertime sea-ice and provides a clue as to how sea-ice extent responds to the NAO and ENSO on the hemispheric scale.

JSM10/08A/B23-004   0950

NORTHERN HEMISPHERE CLIMATIC COVARIABILITY BETWEEN CRYO-, HYDRO-ANDATMOSPHERE ON SEASONAL TO SUB-DECADAL TIME SCALE

Kazuyuki SAITO[1], Judah COHEN[2] ([1]Hydrological Cycle Research Program, Frontier Research System for Global Change, [2]Atmospheric and Environmental Research, Inc.)

By use of visible-derived satellite observations and NCEP/NCARreanalysis data for 1971-2000, correlation analysis of monthly timeseries has recently shown that the continental-scale snow cover extent(SCE) in the warm (May - August) as well as fall (October - November)season has significant association with the dominant mode of atmosphericvariability (annular mode or AO/North Atlantic Oscillations or NAO) inthe wintertime Northern Hemisphere, and suggested that the former mayplay an important role in keeping persistency of the latter. Greaterthan normal SCE in either season is associated with the negative phaseof the winter AO/NAO. On the longer time scale, according tocross-spectral analysis of the monthly normalized and low-passed timeseries, the two climatic variables have common preferred time scales,quasi-bienniel and sub-decadal, and their coherency at low frequency(sub-decadal) is statistically significant with the snow cover leadingthe atmosphere by several months. These results suggest potential rolesof continental-scale snow cover on a range of time scales. Linkage between the fall SCE variability (mostly in easternEurasia) and the winter AO/NAO has been considered as dynamical throughtroposphere-stratosphere coupling and/or middle atmosphere wave-meanflow interaction. It is more adequate to infer, however, that the warmseason snow cover is a reflector, rather than an activator or amodifier, of the mechanism at work, for the geographical extent of itsfluctuation is limited mostly in the high latitude coastal areas. Inorder to search for the factors bridging variabilities between the warmseason SCE and the atmosphere, we look at fluctuations in thehydrological variables (river discharge for Obi and Yenisei for1971-1999, and Lena for 1971-1994; ´Global Runoff Data Centre´ (GRDC)),permafrost conditions (soil temperature for most stations until 1995;´Russian Historical Soil Temperature Data´ by National Snow and Ice DataCenter), and the sea ice

concentration (sic) for 1971-2000 (´HadISST 1.1dataset´). On the seasonal time scales larger discharge in Lena for August -September, which implies larger snow melt, is associated with positivephase of the AO/NAO for the next winter. In the Arctic Ocean April toJune sic in the region of [140-80W, 80-90N] also show significantcorrelation. On longer time scale significant coherency is foundbetween the Lena river discharge show and the AO/NAO around six-yearperiod with no lead or lag, while the SIC of the above region showsignificant covariability in the lower frequency (almost decadal).Connection of these signals with the SCE and atmospheric fluctuation and possible mechanisms are discussed.

JSM10/08A/B23-005   1010

THE POTENTIAL ROLE OF SNOW COVER IN FORCING SEASONAL-TO-INTERANNUAL VARIABILITY OF THE MAJOR NORTHERN HEMISPHERE MODE

Judah L. COHEN[1], Kazuyuki SAITO[2] ([1]AER, Inc., [2]Frontier Research System for Global Change)

Decadal trends have been noted in the leading mode of boreal winter variability. Given that this mode is thought to be an internal mode of the atmosphere it remains unclear as to what is responsible for seasonal to interannual oscillations of this mode. We demonstrate that continental-scale snow cover varies at the same multi-year time periods as the atmosphere but leads the atmosphere by several months through their mutual oscillations. Therefore we propose snow cover as a potential contributor to the seasonal-to-interannual variability of the leading boreal winter mode of the atmosphere.

JSM10/08A/B23-006   1050

CLOUD EFFECTS ON THE DECAYING TREND IN THE ARCTIC ICE COVER

Motoyoshi IKEDA[1], Jia WANG[2], Alexander MAKSHTAS[2] ([1]Graduate School of Environmental Earth Science, Hokkaido University, [2]International Arctic Research Center, University of Alaska)

The sea ice cover in the Arctic Ocean has declined in the last 40 years,while its decadal variability has increased. One might imagine that the ice reduction is an indication of global warming as a consequence of positive feedback between a sea ice reduction and an albedo decrease. In this study, however, the trend is clearly influenced by the radiation balance over all seasons. A cloudiness increase in the fall, winter and spring has been detected with North Pole (drifting) Station data and contributes to a reduction in the absolute amount of net long wave radiation at the sea surface. In the summer, the reduced cloud cover has led to an increase in shortwave radiation, permitting more net outgoing radiation, and yielding a small increase in the total incoming radiation. All of these trends promote ice reduction. The effects of clouds and radiation are comparable with the albedo reduction associated with more open water, which absorbs more solar radiation in the summer. Analyses of the decadal variabilities reveal qualitatively the same effects as those of the radiation on the ice cover. Although some of doubled CO2 experiments seem to reproduce the current global warming, the further analysis is recommended to verify these models by identifying the mechanisms of the ice reduction.

JSM10/08A/B23-007   1110

IMPACTS OF CLIMATE CHANGE IN THE ARCTIC

Gunter E. WELLER (University of Alaska Fairbanks)

Regional assessments of climate change and its impacts are a high priority in the international programs on global change research. In the Arctic, climate models indicate an amplification of the global greenhouse warming, but the observed high-latitude climate trends over the last few decades are much more regional and patchy than predicted by the models. While considerable uncertainties remain in the long-term prediction of change there is some agreement between model results and observed trends by season on shorter time scales. The warming observed over the landmasses of the Arctic over the last few decades is matched by corresponding observed decreases in snow cover and glacier mass balances, by thawing of the permafrost, and by reductions in sea ice extent and thickness. The available evidence strongly suggests that the observed changes are in part due to anthropogenic global warming. While uncertainties exist about the future, climate change in the Arctic during the past few decades can be shown to have had major impacts already on the arctic environment. If these trends continue, as they are expected to do, the natural resource-dependent economies of many regions in the Arctic, as well as the polar ecosystems with their distinct fauna and flora, will be affected. Socio-economic consequences to populations, industry, and lifestyles will be inevitable. Not all of these changes are necessarily negative as will be discussed in this paper.

JSM10/08A/B23-008   1130

CLIMATE CHANGE IN THE POLAR REGIONS MODELLED BY THE CSIRO MK3 COUPLED MODEL

Siobhan OFARRELL, Hal GORDON (CSIRO Atmospheric Research, PMB 1, Aspendale, Victoria, 3195, AUSTRALIA)

Two transient climate change experiments have been performed with the CSIRO Mk3 climate model. The model has been forced with the observed changes in radiative forcing for the 20th Century and the A2 scenario for changes in greenhouse gases and sulphate aerosols for the 21st Century. The talk will focus on changes in the climatein the polar regions, the changes to sea ice and changes in both the atmospheric and ocean components. The talk will compare these results with the previous results from the CSIRO Mk2 model. A particular focus will be on understanding changes in the Southern Ocean thermohaline circulation. Progress on plans to incorporate additional cryospheric components into the coupled model will be discussed.

JSM10/08A/B23-009   1150

THE IMPACT OF THE VARIABILITY IN SEA ICE ON THE CLIMATE OF THE ANTARCTIC PENINSULA IN A GLOBAL CLIMATE MODEL

Tom LACHLAN-COPE (British Antarctic Survey)

The variability of the surface temperature on the western side of the Antarctic Peninsula is the highest in southern hemisphere. Also surface air temperature observations in the same area have shown a warming during the last 50 years. This study investigates the role of sea ice in the variability of the climate and as a possible cause of the observed warming. The atmosphere only version of the Hadley centre global climate model (HadAM3) is forced with a range of observed sea ice fields for the last 25 years and also with possible scenarios for future sea ice extents. It is found that model surface warming over the last 25 years agrees well with the surface observations of temperature. We have also looked at climate produced in the coupled atmosphere/ocean version of the Hadley centre global climate model (HadCM3) that include the observed anthropogenic forcing for the last 100 years. These

IA

runs do not reproduce a realistic sea ice for the Antarctic Peninsula region; the sea concentrations in the Bellinghausen Sea in the model are much lower than those observed. However by looking at areas around Antarctica where the sea ice decreases over the last 50 years we can investigate the cause of these decreases and speculate on the role of ice-ocean-atmosphere feedback in these areas.

JSM10/08A/B23-010   **1210**

MODELING THE ENSO MODULATION OF ANTARCTIC CLIMATE IN THE LATE 1990S WITH POLAR MM5

David H. BROMWICH, Andrew J. MONAGHAN, Zhichang GUO (Byrd Polar Research Center, Ohio State University)

The Polar MM5 is employed to examine the strong El Niño-Southern Oscillation (ENSO) modulation of Antarctic climate for July 1996-June 1999. This provides a more comprehensive assessment than can be achieved with observational datasets by using a regional atmospheric model adapted for high-latitude applications (Polar MM5). The most pronounced ENSO response is observed over the Ross Ice Shelf-Marie Byrd Land and over the Weddell Sea-Ronne/Filchner Ice Shelf. In addition to having the largest climate variability associated with ENSO, these two regions exhibit anomalies of opposite sign throughout the study period, which supports and extends similar findings by other investigators. The dipole structure is observed in surface temperature, meridional winds, cloud fraction and precipitation. The ENSO-related variability is primarily controlled by the large-scale circulation anomalies surrounding the continent, which are consistent throughout the troposphere. When comparing the El Niño / La Niña phases of this late 1990s ENSO cycle, the circulation anomalies are nearly mirror images over the entire Antarctic, indicating their significant modulation by ENSO. Large temperature anomalies, especially in autumn, are prominent over the major ice shelves. This is most likely due to their relatively low elevation with respect to the continental interior making them more sensitive to shifts in synoptic forcing offshore of Antarctica, especially during months with considerable open water. The Polar MM5 simulations are in broad agreement with observational data, and the simulated precipitation closely follows the European Centre for Medium-Range Weather Forecasts Tropical Ocean - Global Atmosphere precipitation trends over the study period. The collective findings of this work suggest the Polar MM5 is capturing ENSO-related atmospheric variability with good skill and may be a useful tool for future climate studies.

GLACIERS AND PERMAFROST

JSM10/08P/B23-001   **1400**

RESPONSE OF MOUNTAIN GLACIERS AND PERMAFROST TO CLIMATE CHANGE

Andreas KAEAEB (Department of Geography, University of Zurich)

Snow, glaciers and permafrost in cold mountain areas are especially sensitive to changes in atmospheric conditions, because of their proximity to melting conditions. In addition, mass wasting is most intense in high mountain areas with steep slopes. As a consequence, environmental variations most strongly affect high mountain regions. Changes in ice occurrences and corresponding impacts on physical high-mountain systems could, in fact, be among the most directly visible signals of global warming and seriously affect human activities. Glacier mass-balance depicts a direct climate signal. Recent world-wide mass-balance series, as collected by the World Glacier Monitoring Service (WGMS), underline a continuous trend of accelerated loss of mountain glacier mass in most regions of the world. Such trend can be best illustrated from glacier area changes. Within the Glacier Measurements from Space project (GLIMS) glaciers are globally monitored using satellite remote sensing. For the Swiss Alps, for instance, a loss of more than 10% per decade since 1985 was observed compared to a loss of less than 5% per decade since the little Ice Age. Especially small glaciers turned out to be affected. For regions such as the Himalayas many mountain glaciers are not any more capable to dynamically adjust for the accelerated warming by retreat, but rather react by down-wasting and decoupling of glacier parts. Compared to glaciers, the influence of climate change on permafrost in high mountains is much less visible, more complex, and, thus, less known. On the other hand, mountain permafrost covers significantly larger areas than glaciers do. Primarily, changes in climate conditions affect the permafrost ground thermal regime. Borehole monitoring in high mountain regions shows indeed a trend of ground warming. Also, changes in the stability of frozen slopes become more and more evident. An upward shift of the permafrost belt in high mountains is, therefore, expected to take place presently and in the near future. The ongoing changes in the cryospheric systems have (already today) severe impacts on the environment. Water runoff is affected with consequences for drinking water supply and hydropower generation. Well visible landscape changes such as glacier retreat have a considerable effect on the awareness of the environmental consequences of climate change, and they influence tourism industry. Here, we especially focus on glacier- and permafrost-related hazards, and their potential development under atmospheric warming. Accelerated glacier retreat is responsible for the evolution of gigantic glacier lakes, which outburst floods endanger entire valleys. An increasing number of rock/ice avalanches and debris flows is expected from the lower boundary of the permafrost zone. Related devastating consequences are illustrated by recent disasters such as the 20 September 2002 rock/ice avalanche in the Caucasus that killed over 120 people.

EVALUATION OF SNOW COVER AND PERMAFROST FEATURES IN NORHTERN EURASIA FOR SOME CLIMATE CHANGE SCENARIOS

Andrey B. SHMAKIN (Laboratory of Climatology, Institute of Geography)

Several series of experiments has been carried out using SVAT model involved in PILPS and alike projects, and a simplified (or intermediate complexity) model of heat/water exchange. Input meteorological variables were specified for some possible scenarios of future climate change in Northern Eurasia. SVAT model allowed us to evaluate changes in snow cover features and permafrost thawing depth under climate change conditions at several locations tested for the study. The simplified model made it possible to study main features of continental-scale snow distribution. Qualitative estimates of snow period length and snow water equivalent variations under changing climate are made. Typical interannual variations of snow characteristics under climate change scenarios are evaluated too. With limited warming, the snow parameters don´t change considerably, except for the territories with unstable snow cover. Under considerable warming scenario, seasonal snow cover in Eurasia shrinks substantially, especially in the western regions. Average depth of permafrost seasonal thawing for tested sites is examined. Under limited warming, the depth of thawing doesn´t change significantly to take this into account. As the climate warming becomes stronger, thin permafrost layers disappear completely in several decades - first centuries

---

time scale, while the depth of seasonal thawing increases significantly much faster. The study was supported by the Russian Foundation for Basic Research (grant 01-05-64707).

SEASONAL CHANGES IN RUNOFF CHARACTERISTICS AT A SMALL WATERSHED IN THE SOUTHERN MOUNTAINOUS REGION, EASTERN SIBERIA

Yusuke YAMAZAKI[1], Jumpei KUBOTA[2], Kazuyoshi SUZUKI[3], Tetsuo OHATA[4], Valery S. VUGLINSKY[5] ([1]Graduate School of Agriculture, Kyoto University, [2]Research Institute for Humanity and Nature, [3]Frontier Observational Research System for Global Change, [4]Institute of Low Temperature Science, Hokkaido University, [5]State Hydrological Institute)

Water and energy cycle in Siberia is characterized by permafrost. Climate changes by the global warming in high latitude. Siberia is expected to be grater than for many other places on earth. The objective of this study is to clarify the effects of seasonal changes in active layer thickness on runoff characteristics using the hydrological and meteorological data obtained by the observations carried out by State Hydrological Institute, Russia (SHI).The Mogot experimental watershed is located in the southern mountainous region in eastern Siberia. The watershed area is 30.8km2. The elevation ranges from 550m to 1130m. The average annual precipitation and discharge from 1976 to 1985 were 572mm and 303mm, respectively. The average annual air temperature was -7.7 degrees centigrade in the same time. Larch is dominant at the lower part of slopes and birch and red pain are dominant in other areas. Hydrological and meteorological observations were carried out from 1976 to 1985 by SHI. Active layer thickness increased with temperature. Although temperature began to decrease at the middle of July, active layer thickness still kept increasing till the end of September, exceeding 150cm. The increasing rate was small at the beginning. It became large till the middle of July, then it became small again. In order to analyze effects of active layer thickness on runoff characteristics,we focused on seasonal changes in direct runoff ratio and recession gradient with time. Usually, there are few breaks in a recession period of storm hydrograph. We defined an amount of direct runoff as a volume of the upper part above a straight line between the rising point and the first break point. Also we analyzed the second recession gradient between first brake point and the second one, also the third recession gradient. There was weak tendency that direct runoff ratio was high in spring and decreased with time. Both gradients of second and third components were the highest in spring and decreased at the same rate with time. The observation results suggest that frozen soil plays the same role as impermeable layer and the water holding capacity in the active layer, which thickness changes with time, controls runoff characteristics, such as direct runoff ratio and recession gradient. Seasonal change in active layer thickness is one of the key factors that controls runoff characteristics in permafrost regions.

JSM10/08P/B23-004   **1520**

ON THE USE OF A DISTRIBUTED ENERGY BALANCE MODEL TO SIMULATE THE MELTING OF A TROPICAL GLACIER

Jean E. SICART[1], Regine HOCK[2], Pierre RIBSTEIN[3] ([1]Department of Geography and Earth Sciences, University of Wales, Aberystwyth, UK, [2]Department of Physical Geography and Quaternary Geology, Sweden, [3]IRD, Maison des Sciences de l'Eau, Montpellier, France)

This study deals with the melt discharge of an Andean tropical glacier: the Zongo glacier, Bolivia (16°S). The year is marked by a dry season in austral winter (may-August) and a wet season in summer (December-March). One important peculiarity of tropical glaciers is that both accumulation and ablation are maximum in wet season. Melting is derived from energy fluxes measured on the glacier by meteorological stations. The fluctuations of net radiation, the main source of energy, are controlled by cloud cover and surface albedo. This latter depends on sporadic snowfalls covering a permanent melting surface. The tropical glaciers are characterized by a marked seasonality of net long-wave radiation: almost zero in wet season, in dry season it represents an important sink of energy during the day. The turbulent fluxes are small in wet season; in dry season the energy lost by latent heat (sublimation) exceeds the gain by sensible heat. The simulation of melt discharge with the distributed energy balance model of Hock [1998] allows for a better understanding of the melting processes. The discharge remains high in wet season because of the alternation of ice melting by solar radiation during cloudless periods with snow melting by thermal radiation during cloudy periods which cause precipitation. The reduction of melting in dry season is mainly due to long-wave radiative losses during the day and cooling of the glacier during the night, but also to the energy lost by sublimation.The study of the energy exchanges at the surface of the glacier allows the inter-annual variability of the glacier mass balance to be related to climate. We show that 'El Nino' events are associated with a marked mass balance deficit because of a delay in the set-up of the wet season, in turn causing a peak of melting around the austral summer solstice.

MODELLING THE DEGREE OF CONTINENTALITY OF GLACIER REGIMES AS A TOOL FOR CLIMATE HISTORY RECONSTRUCTION

Georg KASER (Institut fuer Geographie, Universitaet Innsbruck)

Various climatic proxy data for the Younger Dryas in the European Alps and the circumalpine region show that subarctic climatic conditions prevailed in central Europe during this period, which lasted from ca. 12,700 - 11,500 cal BP. The reconstruction and interpretation of Younger Dryas glaciers and derived equilibrium line altitudes (ELAs), combined with biological and geological proxy data, show not only lower temperatures compared to present day climate but also remarkable changes in the degree of continentality and its spatial gradients. Different combinations of processes related to the advection of atmospheric moisture allow to explain the reconstructed distribution of Younger Dryas ELAs. The obtained general picture clearly indicates a pronounced westerly to northwesterly atmospheric circulation patterns under generally cooler conditions responsible for the observed spatial ELA variability. This example shows how observed and/or reconstructed glacier fluctuations in any climatic scale can be useful indicators for changing atmospheric circulation patterns. A glacier mass balance model which provides the implementation of humidity related variables as a measure for continentality is presented. The model is based on the analytical reconstruction of vertical mass balance gradients, which are highly sensitive to continentality related climatic variables. A sensitivity analysis quantifies how glacier behaviour can be different due to different air humidity and moisture conditions under given thermal conditions. Under different humidity conditions a given change in temperature leads to varying responses of glacier behaviour. This concept of climate reconstruction from carefully documented glacier history shows the importance of changes in climatic variables other than air temperature. The model-based interpretation of observed ELA patterns may serve as a check for the validity of the results from Atmospheric General Circulation Models.

JSM10/08P/B23-006   1620

RETREAT OF SUNTAR-KHAYATA GLACIERS AS A CONSEQUENCE OF THE REGIONAL CLIMATE CHANGE

Maria D. ANANICHEVA[1], Jean Luc MERCIER[2] ([1]Institute of geography RAS, [2]Faculty of geography, Louis Pasteur University, Strasbourg, France)

Comparison of data obtained in the end of 1950-s and 2001 about the Suntar-Khayata glaciers (North-East of Asia, Okhotsk Sea basin) positions and their regime shoes that they have undergone appreciable changes. The fixed changes require a substantiation of the reasons for the dynamics specified, and first of all within external factors. Internal properties of the given glaciers (low energy of glaciation, low temperatures of the ice thickness, etc.) do not encourage fast changes in their position and regime due to high inertia. Since temperature regime of Suntar-Khayata region in the 20th century is suggested to be the most essential factor of glacier size changes, in the paper the long-term records of temperature and precipitation for 13 meteo-stations within 62-72 N and 121-152 E, have been analyzed. The analysis of trends was carried out by non parametric test of Kendall-Mann-Snayers with preliminary transformation of the series due to their extraordinary amplitude. We revealed two phases of temperature fluctuations from 1940-s: cooling and subsequent warming taking place up to now. For these phases the annual, winter and summer trends were calculated, spatial schemes of their distributions were obtained. In the mountains during cooling temperature drop is reached at the account of autumn and spring that makes period with negative temperatures longer; however during warming phase the growth is mostly in summer that enhances ablation. Trends of total precipitation until 1992 were slightly negative for the majority of met stations, solid precipitation, calculated by special technique, have been growing insignificantly since 1970-s. The comparison of schematic distributions of seasonal trends and directions of these values increasing in particular, specifies different "sources of intensification" for the winter and summer trend. The former grows from northeast to southwest, under the influence of warming, coming from the central part of Asia, the latter enhances from NW to SE, under the influence of warming of the Okhotsk sea south part. We can also hypothesis that the impact of "continental" winter trend and "marine" of summer trend sources exhibit themselves in the factor analysis performed on a matrix of the 12*473 monthly values from 1953 to 1992. The two first factors described respectively 61.45 % and 23.89 % of the whole variance encompasses more than 85.3 % of the relation between the annual temperature within the extended region under consideration. The two first factors are described by the same three variables, the warming duration, the maximum thermal amplitude and the standard deviation of temperature. Using temperature trend rates and received earlier empirical relationship ablation and mean summer temperature for the region we obtained fluctuation of ablation at the ELA of representative for the Suntar-Khayata Glacier 31. Ablation turned to increase since 1958 (start of warming in the region) totally at 500 mm with gradient of 250 mm per 1 degree C. Under the same trend in 10 years it will reach 120 cm at the ELA area. Similar tendency is anticipated for the other glaciers of the Northern Massif of Suntar-Khayata Ridge.

JSM10/08P/B23-007   1640

THE STUDY OF GLACIER FLUCTUATIONS USING REMOTE SENSING IN PURUOGANGRIMOUNTAINS OF TIBET

Anxin LU, Tandong YAO, Shiyin LIU, Liangfu DING (Cold and Arid Regions Environmental and Engineering Research Institute)

In this paper, supported by GIS, the aerial photos, satellite images, topographical maps and the digital elevation model (DEM) were applied to analyze glacier variations during the Little Ice Age (LIA) maximum, 1974 and 2000. Puruogangri Mountains, with more than 420 km2 area of glacier in Tibet of China, was selected as the test area. The aerial photographs of 1974 and The Landsat TM data in 2000 were used for interpretation on the computer screen and the glacier database (1:100000) were set up combined with DEM. Then towards the main problems of glacier variation, the special statistical analysis and dynamic comparisons were carried out using the database. The main results from this work:: (1) The results of interpretation from aerial of 1974 and from TM data for 2000; (2) The dynamic monitoring results of LGM, LIA, 1974 and 2000 show that the area of glacier were decreased. The conclusions are: 1. By the combination of using aerial photographs and Landsat TM remote sensing data and rich un-remote sensed data, the trend of climate variation during the Little Ice Age (LIA) maximum, 1974 and 2000. 2. For the past years, the area of glacier was decreased remarkable in the Puruogangri Mountains, which meets with the air temperature increasing.

JSM10/08P/B23-008   1700

GLACIER CHANGE AND ITS FORCING CAUSE IN THE SOURCE REGIONS OF THE YANGTZE AND YELLOW RIVERS ON THE TIBETAN PLATEAU

Yongjian DING, Yang JIANPING, Chen RENSHENG, Liu SHIYIN, Lu ANXIN (Cold and Arid Regions Environmental and Engineering Research Istitute, Chinese Academy of Sciences)

Glacier is an important component of eco-environment in the source regions of the Yangtze and Yellow Rivers. The effects of glacier change on eco-environment attract researcher´s attentions for a long time in the source regions. GIS provides an efficient tool to analyze the status and change of glaciers. In the paper, the Geladandong area in the source region of the Yangtze River and A'nyêmaqên Mountains in the source region of the Yellow River are selected as the test areas. Based on RS data in the two periods-one in 1969a and the other in 2000a in Geladandong area of the source region of the Yangtze River, one in 1966a and the other in 2000a in A'nyêmaqên Mountains of the source region of the Yellow River, glacier variation during the Little Ice Age(LIA) maximum, in 1969(1966) and 2000 are analyzed by means of aerial photos, satellite image, topographical map and the derived digital elevation model(DEM). Glacier changes in the whole source regions of the Yangtze and Yellow Rivers are inferred from study of the above two test areas. The results indicate that the glacier area had decreased about 1.7% from 1969 to 2000 in Geladandong area of the source region of the Yangtze River, while about 17% from 1966 to 2000 in A'nyêmaqên Mountains of the source region of the Yellow River, and that the largest retreat rate of glacier terminus is 41.5m per year in Geladandong area, while 57.4m per year in A'nyêmaqên Mountains. Compared with glaciers in the source region of the Yellow River, withdrawal rate of glaciers is smaller and glaciers seem almost steady in the source region of the Yangtze River. Glaciers advance markedly from 1969 to 1995 in the source region of the Yangtze River and from 1966 to 1981 in the source region of the Yellow River. At this period the majority of glaciers is in advance or stable. The changing time from advance into retreat in glacier in the source region of the Yangtze River is later about 10 than that in the source region of the Yellow River. Glaciers retreat to a great extent since the 1980s. Significant increasing air temperature in summer and decreasing precipitation are the basic cause of glacier retreat. Glacier retreat results in 7 million cubic meter losses in glacier water resources every year in the source regions of the Yangtze and Yellow Rivers, respectively. **Key words:** the source region of the Yangtze River; the source region of the Yellow River; glacier change; forcing cause

SEASONAL VARIATION OF SURFACE FLUXES OBSERVED OVER TUNDRA IN EASTERN SIBERIA

Yuji KODAMA[1], Norifumi SATO[1], Hironori YABUKI[2], Yoshiyuki ISHII[1], Mutsumi NOMURA[3], Tetsuo OHATA[2] ([1]Institute of Low Temperature Science, Hokkaido University, [2]2Frontier Observation Research System for Global Change, [3]Field Science Center for Northern Biosphere, Hokkaido University)

Tundra area has a unique water cycle due to the existence of frozen ground, drifting snow and tundra vegetation. In order to better understand the water cycle over tundra, micro-meteorological and hydrological observations have been carried out near Tiksi, Eastern Siberia. A 10m meteorological mast was erected and air temperature, humidity, wind speed and direction were measured at the different height from the ground. Concurrently carried out was the observations of 4 radiation components, soil temperatures and moistures, barometric pressure and precipitation. The heat budget equation at the tundra surface was solved approximating the surface temperature by iteration. In the equation, sensible and latent heat fluxes were expressed by a bulk method and the soil heat flux by the gradient method. The bulk coefficient was a function of the bulk Richardson number and the evaporation efficiency and the thermal conductivity of the surface soil was a function of surface soil moisture. The result was obtained for 1998 and 1999, and well compared with result of Bowen ratio method, but not with the eddy correlation method. The seasonal change of heat balance components was also dependent on the atmospheric conditions. In this watershed, where locates 7 km from the Laptev Sea of the Arctic Ocean, the southwesterly wind was warm and dry, gave the sensible heat flux towards the ground surface and the northeasterly wind was cold and damp, gave the large sensible heat flux to the atmosphere from the tundra surface. The energy fluxes as well as the water fluxes were strongly dependent on the wind direction.

THE SURFACE MASS BALANCE OF MD364, ANTARCTICA ESTIMATED FROM THE ICE CORE ANALYESE

Makoto IGARASHI, Hideaki MOTOYAMA, Teruo FURUKAWA, Yoko TOYAMA, Fumihiko NISHIWO, Kazuhide SATOW, Takawo KAMEDA (National Institute of Polar Research)

Japanese Antarctic Research Expedition (JARE) has collected shallow ice cores in East Queen Maud Land during the last two decades. The object of retrieving the ice cores is to obtain records of climate, atmospheric chemistry and surface mass balance through the ice core analyses. The ice core study is a part of the ITASE (International Trans-Antarctic Scientific Expedition) program, which is an international effort to obtain paleoclimatic records and clarify past environmental changes during the last few hundreds years in the Antarctic. We have been analyzing a shallow ice core drilled at MD364 (74°00´29˝S, 42°59´48˝E, 3353 m a.s.l.). The drilling site is located on the way from Syowa station to Dome Fuji. To determine the annual accumulation late, we employed snow stake data from 1992 to 2000, tritium content, solid ECM and concentration of chemical constituents. The average annual surface mass balance at MD364 is 16 mm a-1 in water equivalent (w. e.) during the last 9 years from continuous accumulation data, 24 mm a-1 in w. e. between 1966 and 1993 by tritium content and 20 mm a-1 in w. e. by solid ECM and concentration of chemical constituents which detected the eruption of Mt. Tambora (AD 1815). These results, which are obtained from three methods, suggest that the annual surface mass balance at MD364 was not stable for last 200 years. The age of Tambora eruption corresponds with the 11.2 m depth and it is only top part of the ice core. We will continue to analysis of the more deep part (until 80 m depth) and estimate the annual accumulation rate of the whole core.

ONE-DIMENSIONAL NONSTATIONARY MODEL OF SEA ICE

Boris Viacheslavovoch IVANOV, Oleg Mihailovich ANDREEV (Arctic&Antarctic Research Institute, 38-Bering str., 199397, Saint-Petersburg, Russia)

ONE-DIMENSIONAL NONSTATIONARY MODEL OF SEA ICE.B.V. Ivanov (1), O.M. Andreev (1).(1) State Research Center of the Russian Federation - Arctic and Antarctic Research Instituteb_ivanov@aari.nw.ru/Fax: (812) 3522685, (812) 3522688 The heat exchange provided by radiation of the atmosphere and the underlying sea ice is an important component of the Arctic climate system. In the Earth´s polar regions the change of the radiation characteristics of the atmosphere and the underlying surface makes influence on the climatic conditions more than in any other place of the globe. It occurs primarily due to significant seasonal albedo changes of the aforementioned surfaces. The development of large-scale motions in atmosphere also depends on the energy exchange intensity including the radiation exchange with theunderlying surface. The short-wave solar radiation, unlike the incoming long-wave radiation, is not fully absorbed by the surface penetrating to the lowerlying snow and ice layers. The penetration determines the change in thermal physical, radiation and physical-mechanical properties of these media. Data of the radiation-thermal physical properties of snow are necessary to improve parameterization of the snow-ice cover melting processes in modern thermodynamic models of sea ice. Based on the numerous experimental data obtained in the Arctic areas, a mathematical model of the sea ice cover was developed at AARI. The model allows us to calculate the temperature profile in the snow and ice cover given the actual variability of the ambient meteorological parametersand the radiation-thermal physical characteristics of the snow and sea ice. Additionally, the vertical turbulent heat and moisture fluxes are calculatedby this model using integral aerodynamic formulas with heat and moisture exchange coefficients depending on atmospheric stratification in the surfaceair layer. The long-wave radiation balance is calculated by the method specifically developed for the Arctic conditions. The short-wave radiation balanceis determined by actual incoming global radiation data and moderate estimations of snow and ice albedo. One of the main peculiarities of our model is a correct account of solar radiation, which penetrates into the snow or sea ice active layer. Relationship between the transmission and extinction coefficients and thermophysical features of snow and ice and parameters of model numerical chart (grid vertical interval) has been proposed. The obtained results make it possible to define more correctly the amount of short-wave solar radiation penetrating to snow and ice cover and also simulate more adequately the processes of sea ice cover melting from the physical aspect. The described snow cover model is an integral

part of a one-dimensional thermodynamic model of the snow-ice cover developed at AARI. Our model, based on good agreement of experimental and calculateddata, can be used both for estimation of the state and variation of drifting ice in Central part of Arctic Basin and for land fast ice of near of shore areas.

JSM10/09P/D-004	Poster	1400-058

IMPACT OF SEA ICE DYNAMICS ON THE SEA ICE DISTRIBUTION

Tomoo OGURA, Ayako ABE-OUCHI, Hiroyasu HASUMI (Center for Climate System Research, The University of Tokyo)

Sea ice has a substantial influence on the atmosphere and the oceanin a global scale as an interactive component of the climate system.Among many factors controlling the sea ice distribution, we focus on the sea ice dynamics (advection) and assess their effect on the present-day sea ice climatology. Previous studies using numerical models have shown that summer sea ice area in the Southern Ocean decreases due to the sea ice dynamics.In winter, on the other hand, sea ice dynamics cause little differencein the simulated sea ice distribution. However, one of the reasons for this less sensitivity in winter may be that dynamic response of the ocean, such as convection, has not been incorporated in the sea ice models used in the experiments. In the present study, therefore, we employ a coupled ocean-atmosphere GCM (OAGCM) to verify whether sea ice dynamics can affect sea ice distribution by controlling the ocean convection process.The model used in the experiments is the low resolution version of the OAGCM being developed at CCSR. It consists of the CCSR/NIES AGCM5.6 at T21 resolution (11 vertical levels), the CCSR OGCM (COCO2.1) with 2.8 x 2.8 resolution (20 vertical levels), and a dynamic-thermodynamic sea ice model.Two kinds of numerical experiments are conducted to evaluate the impact of sea ice dynamics:1. `CONTROL´, in which a dynamic-thermodynamic sea ice model is used,and2. `NO-DRIFT´, in which a thermodynamic sea ice model (without dynamics) is used.Significant difference between the two numerical experiments appears in the time evolution of winter sea ice area in the Southern Ocean.Sea ice area fluctuates in a decadal scale in the NO-DRIFT run, whileit is kept more stable in the CONTROL run, suggesting that sea ice dynamics suppress one mode of decadal variation in the Southern Ocean.The fluctuation of sea ice area in the NO-DRIFT run mainly occurs around the Weddell Sea, accompanied by variation in the ocean convectionintensity. Smaller ice extent corresponds to more intense ocean convection. More detailed comparison between the CONTROL and the NO-DRIFT revealsthat two factors contribute to the greater stability of sea ice distribution in the CONTROL run:(a) sea ice dynamics increase the static stability of the ocean byenhancing freshwater release near the ice edge, and(b) sea ice dynamics increase the static stability by decreasing thesea ice concentration and thickness, which enhances the deep watercooling in winter (especially near the Antarctic continent).In the Northern Hemisphere, on the other hand, sea ice dynamics made little impact on the sea ice extent, although significant effect on sea ice thickness was found. The reason for this different behavior of sea ice distribution between the Arctic and the Antarctic will be discussed at the symposium.

JSM10/09P/D-005	Poster	1400-059

LONG-TERM AND INTER-ANNUAL VARIABILITY OF ICE CONDITION IN THE OKHOTSK - BERING-CHUKCHI SEAS

Larisa S. MUKTEPAVEL[1], Roger COLONY[2], Vladimir PLOTNIKOV[3] ([1]Pacific Research Fisheries Center (TINRO), [2]International Arctic Research Center/UAF, [3]Pacific Oceanological Institute)

The intermidate time- scales of sea ice allows it to be a good indicator of large scale variability of ocean/ice/atmosphere system. The annual cycle of sea ice extent in each of the three seas is shown with statistics for both intra-annual variability and inter-annual variability. Coverance studies indicate that ice extent in the Okhotsk and Bering seas are out of phase-reduced ice extent in the Okhotsk is usually associated with increased ice in the Bering while ice extent in the Bering is positively correlated with ice extent in the Chukchi Sea. A trend analyses (1960-2000) reveal that all seas and all months have decreasing ice cover. However, only mid-winter ice for the Sea of Okhotsk passed the 95% confidence test. Ice pack has considerable time lag that results in its being optimal indicator of large scale variability of ocean/ice cover/atmosphere system. The nature of large-scale variability of ice pack in some areas of water of the Northern hemisphere is similar, and is determined by evolutionary processes of climatic system. Being located at the turn of the Arctic and Pacific basins, Chukchi/Bering Seas system to some extent conducts the processes going on in those basins. The mechanism of halocline formation in Arctic basin confirms it. Halocline is formed by means of the transfer of salted waters of the northern part of the Bering sea through the Bering Strait. Those salted waters are formed during the winter period as the result of the process of ice formation.

JSM10/09P/D-006	Poster	1400-060

SENSITIVITY OF A COUPLED ICE SHELF - OCEAN SYSTEM TO CHANGES IN CLIMATIC BOUNDARY CONDITIONS

Henner SANDHAEGER[1], Klaus GROSFELD[2], Manfred A. LANGE[3], Hartmut H. HELLMER[1] ([1]Alfred Wegener Institute for Polar and Marine Research, Bremerhaven, Germany, [2]Department of Geoscience Modeling, University of Bremen, Germany, [3]Institute of Geophysics, University of Muenster, Germany)

The largest interface between the Antarctic Ice Sheet and the Southern Ocean corresponds to the bases of floating ice shelves which constitute about one half of Antarctica´s coast line. Heat and mass (melting and freezing) fluxes across this interface directly affect ice shelf geometry, dynamics, mass balance, and steady state configuration. Since changes in ice shelf geometry influence adjacent regions of grounded ice, ice shelf - ocean interaction seems also to be important in the context of the stability of the West Antarctic Ice Sheet. Furthermore, basal melting and freezing significantly contribute to water mass formation and modification. The export of Ice Shelf Water from huge ice shelf cavities to the open ocean leads to a preconditioning of shelf waters and the formation of deep water at the continental shelf break. In order to quantify the impact of melting and freezing on the combined ice shelf - ocean system, we performed a series of basic model studies with a dynamic ice shelf model coupled to an OGCM. The results obtained for idealised configurations (comparable in size to the Filchner-Ronne Ice Shelf) indicate high sensitivity of system geometry and dynamics especially in regions, where high ablation or accretion rates occur. Model runs with different boundary conditions (surface accumulation rate, ocean temperature) reveal a strong dependence of system evolution on climatic forcing within decadal time scales.

RELATIONSHIPS BETWEEN SEA ICE AND PRESSURE DISTRIBUTION IN SEA ICE DECREASING PERIOD AROUND THE SEA OF OKHOTSK

Takashige KAWAI (Department of Earth Information Mathematical Sciences, Graduate school of Integrated Basic Sciences, Nihon University)

The sea of Okhotsk is one of seasonal sea ice area. Its variability is presumed to be larger than annual sea ice area. Seasonal differences of interactions between sea ice and atmosphere are considered. Interactions of sea ice increasing period are presumed mainly atmosphere to sea ice. In sea ice decreasing period, they are presumed reverse. In this study, focusing sea ice decreasing period, variability of sea ice area and its effect to the atmospheric circulation in and around the Sea of Okhotsk are investigated. Significant correlations are found between sea ice decreasing area in the Sea of Okhotsk and 1000hPa, 850hPa and 500hPa monthly mean geopotential heights in the northern part of the Sea of Okhotsk in June. Thereupon, differences of pressure distribution pattern between large sea ice decreasing (SID) years and small SID years are explored. In large SID years, Mongolian cyclones are extended to eastward at 1000hPa. North part of the Sea of Okhotsk is included a cyclonic anomaly area. Troughs are found in the Sea of Okhotsk to west Bering Sea at 850hPa. These results suggest in large SID years, cooling water mass from sea ice melting is stronger cooling of lower atmosphere than normal years. Reversly, small SID years, the North Pacific anticyclones are extended to northwestward at 1000hPa. North part of the Sea of Okhotsk is included an anticyclonic anomaly area. Ridges are found in the Sea of Okhotsk to west Bering Sea at 850hPa. In monthly mean weather charts, this anticyclonic anomaly is shown a part of the North Pacific anticyclone. But from individual weather chart, the Okhotsk anticyclone as separated from the North Pacific anticyclone is found. A development of the Okhotsk anticyclone in June is presumed to be related sea ice phenomena. However, small SID years and large anticyclonic anomaly years in the sea of Okhotsk is not corresponded all cases. Former researchers found some characters of Okhotsk anticyclone. Sea ice phenomena are presumed to affect in limited cases of Okhotsk anticyclones.

ANNUAL VARIATION OF ACTIVE LAYER IN ALASKA

Takeshi SATO[1], Kenji YOSHIKAWA[2], Atsushi SATO[3] ([1]Snow and Ice Research Group, National Research Inst. for Earth Science and Disaster Prevention, [2]Water and Environment Research Center, University of Alaska Fairbanks, [3]Snow and Ice Research Group, National Research Institute for Earth Science and Disaster Prevention)

The temperature rise due to the recent global warming is remarkable in Alaska, Canada and Eurasia. This leads to the melting of permafrost in the polar region, which will enhance the emission of greenhouse effect gas such as methane. In this paper, the annual variation of the active layer, a part of permafrost which melts in summer, is investigated focusing on its relationship to the air temperature and snow cover which vary year by year. Meteorological and snow cover observations have been conducted at Caribou Poker Creek (CPC), located in the suburb of Fairbanks, since Aug, 1997. Meteorological elements, snow depth, soil temperature etc. have been measured continuously. By comparing the temporal variations of snow depth and soil temperature profile, it was found that the cooling of soil in winter is small in the year with much snow due to the thermal insulation effect of snow cover and the heating of soil in the subsequent summer is large, which suggests that the active layer develops. And the converse is clear in the year with little snow. The database of the active layer thickness in the Arctic region after 1990 is opened on the web of the CALM project. Analysis of the data of active layer thickness in Alaska showed the difference in its annual variations between the 3 sites around Fairbanks and the 3 sites around Barrow. The relationship between the active layer thickness and the mean air temperatures, in summer (Jun-Aug) and in winter (preceding Dec-Jan) were analyzed. The correlation between the active layer thickness and summer air temperature is positive around Barrow, and there is no such correlation around Fairbanks. There is a site around Fairbanks which has positive correlation between the active layer thickness and winter air temperature. Next, the correlation between the active layer thickness and the maximum snow depth from the preceding Nov to Jan was examined. There is a good correspondence around Fairbanks, that is, the active layer thickness tends to increase as the snow depth increases up to about 60cm, which agrees with the observations at CPC. And beyond 60cm, the active layer thickness does not depend on snow depth or slightly decreases with the increase in snow depth, which may be ascribed to the additional effects of snow cover such as the increase of melt water and/or the delay in the snowmelt season. On the other hand, snow depth dependence is not clear around Barrow. Since the snow cover is thin around Barrow, the active layer thickness is controlled mainly by the temperature in summer. However, snow depth greatly influences the active layer thickness around Fairbanks where snow cover is thick.

JSM10/09P/D-009	Poster	1400-063

SPATIAL DISTRIBUTION OF ABLATION ON KORYTO GLACIER, KAMCHATKA, RUSSIA

Keiko KONYA, Takane MATSUMOTO, Renji NARUSE (Institute of Low Temperature Science, Hokkaido Uninersity)

To estimate a glacier's discharge and mass balance, it is necessary to investigate the spatial distribution of the glacier's ablation rate. However it is difficult to observe the hourly ablation rate continuously over the whole glacial area. Using ablation models with published meteorological data, it is easily accomplished to investigate inaccessible glaciers. Empirical models have been used for a long time, but they cannot be used for many glaciers because they are not sufficiently accurate. On the other hand, physically based models require a lot of observation data for the calculations. In this study, we constructed a model for a maritime glacier with fewer parameters than previous models and used it to estimate the ablation rate of Koryto Glacier on the Kamchatka Peninsula. For this glacier, we measured the daily melt rate using snow stakes and recorded hourly meteorological data on the glacier. As a result of our heat balance calculations for the accumulation area, we obtained the mean contribution rates to ablation for 50 days in mid-summer 2000 as follows: net radiation 33%, sensible heat flux 44%, and latent heat flux 23%. In the model, continuous meteorological and established geographical data are used as parameters to estimate the distributed ablation rate on snow and ice surfaces. The difference in ablation rate along the crossing line is caused by the distribution of global radiation, which is affected by the surrounding ridges and slope of the glacier surface. To estimate hourly surface melt rates, we solved the equations for each snow and ice surface using multi-regression from the calculated hourly heat balance and our meteorological data. Calculations were done using GIS (Geographical Information System, ArcView version 3.2) with 50-m spatial resolutions. We obtained an asymmetric pattern for the hourly ablation rate over the glacier, which flows from east to west.

JSM10/09P/D-010 Poster 1400-064

PRECIPITATION CHANGE IN CENTRAL HIMALAYAS OVER THE PAST 300-YEAR

Ke Qin DUAN (China)

The melt water from glaciers in Himalayas form the headwaters of such important rivers as the Indus and the Ganges. Precipitation in Himalayas is responsible for the glacier development and hydrology circulation in Himalayas region. In the global warming condition, what precipitation and glaciers in Himalayas change will influence directly on the water lever of the important rivers. However, there exists only limited knowledge concerning precipitation variations in Himalayas in secular time scale due to its high altitude, which limits our ability to predict variability of glacier. This data gap can be addressed with high-fidelity paleoclimate records from ice core in Himalayas. As snow deposits and metamorphoses into ice, ice sheets continuously record the chemical and physical nature of the Earth's atmosphere. The water amount of an annual ice layer in the glacier accumulation area is almost equal to that of the snow deposited on the glacier surface in one year. This means we can reconstruct the precipitation history in Himalayas by recovering the annual ice layer of a glacier. Here, we present a 300 years precipitation record reconstructed from Dasuopu glacier in central Himalayas, Tibet, which allows us to examine the long-term precipitation variability in Himalayas under the condition of the Global warming. The result shows that the central Himalayas has suffered a dry period in early 1800-1820, thereafter a wet condition between 1820-1930, and again a dry period since 1930 to present. Moreover, there exists a strong negative correlation between the precipitation in central Himalayas and the northern global temperature. According to IPCC reports, a global temperature will increase of 0.1-0.2°C/10a. If this is the case, the glaciers on Himalayas, including our studying site, have been continual retreating, decreasing precipitation and accumulation and negative mass balance. Just as science online report, if the Himalayan glaciers continue to dissolve at their current pace over the next 25 years, the Ganges will swell and then, with the most vulnerable portions of the glaciers gone, get perilously low in summer.

ANTARCTIC ICE-SHEET MASS BALANCE FROM SATELLITE ALTIMETRY 1992 TO 2001

H. Jay ZWALLY[1], Anita C. BRENNER[2], Helen CORNEJO[2], Mario GIOVINETTO[2], Jack L. SABA[2], Donghui YI[2] ([1]NASA Goddard SFC, [2]Raytheon ITSS)

A major uncertainty in understanding the causes of the current rate of sea level rise is the potential contributions from mass imbalances of the Greenland and Antarctic ice sheets. Estimates of the current mass balance of the Antarctic ice sheet are derived from surface-elevation changes obtained from 9 years of ERS-1&2 radar altimeter data. Elevation time-series are created from altimeter crossovers among 90-day data periods on a 50 km grid to 81.5 S. The time series are fit with a multivariate linear/sinusoidal function to give the average rate of elevation change (dH/dt). On the major Ronne-Filchner, Ross, and Amery ice shelves, the dH/dt are small or near zero. In contrast, the ice shelves of the Antarctic Peninsula and along the West Antarctic coast appear to be thinning significantly, with a 23 +- 3 cm per year surface elevation decrease on the Larsen ice shelf and a 65 +- 4 cm per year decrease on the Dotson ice shelf. On the grounded ice, significant elevation decreases are obtained over most of the drainage basins of the Pine Island and Thwaites glaciers in West Antarctica and inland of Law Dome in East Antarctica. Significant elevation increases are observed within about 200 km of the coast around much of the rest of the ice sheet. Farther inland, the changes are a mixed pattern of increases and decreases with increases of a few centimeters per year at the highest elevations of the East Antarctic plateau. The derived elevation changes are combined with estimates of the bedrock uplift from several models to provide maps of ice thickness change. The ice thickness changes enable estimates of the ice mass balances for the major drainage basins, the overall mass balance, and the current contribution of the ice sheet to global sea level change.

JSM11/10A/B18-002 0920

GREENLAND CLIMATE CHARACTERISTICS IN HADCM3

Jeff RIDLEY[1], Philippe HUYBRECHTS[2], Jonathan GREGORY[1], Jason LOWE[1] ([1]Met Office, [2]Free University of Bruxelles)

The HadCM3 AOGCM has been coupled to a 3D dynamic model of the Greenland ice sheet, which includes a visco-elastic solid Earth model. Once every year the AOGCM provides the ice sheet model with precipitation and temperature anomalies which it uses in order to calculate ablation, ice dynamics and basal rebound. A new orography and fresh water fluxes are passed back to the OAGCM to be utilised over the subsequent year. The water from the melting of calved Icebergs is applied evenly to the sea region adjacent to Greenland whilst runoff enters the ocean through ´river´ outlets. A multiple century experiment starting from the present day ice sheet with an atmospheric CO2 concentration of four times pre-industrial levels is being undertaken to determine the rate of ice ablation and the impact of ice sheet changes on simulated sea level, and oceanic and atmospheric circulation. The effect of orographic changes in the ice sheet on its own mass balance is also of interest. The results from the first 180 years of the simulation indicate that the modelled surface air temperature over Greenland in the 4xCO2 climate is around 8 degrees warmer than in the pre-industrial control, compared with a global mean difference of 5 degrees. Precipitation is increased by 33% in the 4xCO2 experiment but the rate of ablation rises by 640%, causing a direct sea-level rise of 5mm per year. To understand the mechanisms of change we will examine the spatial patterns of temperature and precipitation anomalies for the model control and 4xCO2 experiments and compare them with data from anomalously warm years determined from in situ (ice core) data.

JSM11/10A/B18-003 0940

COMBINING TIME VARIABLE GRAVITY AND OTHER GEODETIC MEASUREMENTS TO UNDERSTAND THE POLAR ICE SHEETS

Isabella VELICOGNA, John WAHR (CIRES and Dept of Physics,Univ. of Colorado)

Predictions of the future evolution of the Antarctic and Greenland ice sheets require knowledge of the present state of ice sheet mass imbalance. Ice flows to achieve equilibrium, redistributing the mass and changing surface elevations. In principle, these changes are observable using geodetic observations of various types: GPS measurements of crustal motion, measurements of changes in the Earth´s gravity field from space and from the Earth´s surface, and radar and laser altimeter measurements of changes in ice sheet elevations. Each of these data types is sensitive to the mass imbalance and post glacial rebound in a different way, and each is subject to ambiguities in interpretation. It is not trivial to separate effects of present-day mass imbalance from the effects of the Earth´s continuing viscous response to mass imbalance in the past. This talk will describe the characteristics of present-day mass imbalance and viscous rebound signals that are likely to be present in geodetic observations with particular focus on Antarctica. We will examine how different observation types can be combined to better understand the evolution of the ice sheets, and we will discuss the strengths and limitations of combining different data sets.

JSM11/10A/B18-004 1000

RECENT THICKENING OF GLACIAR PERITO MORENO, SOUTHERN PATAGONIA

Renji NARUSE[1], Pedro SKVARCA[2] ([1]Institute of Low Temperature Science, Hokkaido University, [2]Instituto Antartico Argentino, Cerrito 1248, Buenos Aires 1010, Argentina)

Most of 70 outlet glaciers from two Patagonia Icefields (total area: 17,200 km[2]) calve into lakes on the east side and into fjords on the west side. Analyses of various kinds of data since 1945 revealed that the most calving glaciers have significantly been retreating: e.g. 5 km during the last 20 years at Glaciar Upsala. Thickenning rates of ice were also measured as -3.5 m/a (1983-98) at Glaciar Soler, -3.7 m/a (1985-93) at Glaciar Tyndall, and -11 m/a (1990-93) at Glaciar Upsala: all indicated large thinning. Based on these ground and satellite data, Aniya (1999) roughly estimated the contribution of the shrinkage of Patagonian glaciers to the global sea-level change as about 2 mm in 51 years, which corresponds to about 3.6% of the sea-level rise since 1945. Among major glaciers in Patagonia, the behavior of an eastward outlet Glaciar Perito Moreno is rather unusual because of its near-steady terminus position during the last half century. The glacier, 30 km long and 258 km[2] in area, flows northeastward from the ice divide on the Southern Patagonia Icefield. The ablation area forms a valley-type glacier about 4 km wide, and calves into the southwestern arm of Lago Argentino. The glacier front reaches currently the opposite bank with an ice tunnel which drains water in the lake. Small-scale but frequent oscillations of the terminus are known at the glacier during the 20th century, and ruptures of ice-dams were recorded about ten times. However, it is regarded that the glacier has been almost stable since 1970. As to ice flow velocity, seasonal fluctuations were not recognized significantly, but daily variations were markedly. Surface elevations of the ablation area of Glaciar Perito Moreno were measured five times in 1990, 1993, 1996, 1999 and 2002, with the conventional survey method using an electronic distance meter. As the results, average thickening rates of seven points in the mid-reaches were obtained as +0.2 m/a in 1990-93, -0.2 m/a in 1993-96, +0.5 m/a in 1996-99, and +1.5 m/a in 1999-2002. Thus, while the glacier has been almost in the equilibrium profile in the early half of the 1990s, it has recently been thickening with accelerating rates. Judging from other features of the glacier behaviors, this thickening trend is not likely to relate to a surge, but may be attributed to the dynamic causes of the glacier.

JSM11/10A/B18-005 1020

RANDOM FLUCTUACTIONS OF THE ICE SHEETS BOUNDARY CONDITIONS AND THEIR RELATION WITH SEA LEVEL

Frederique REMY, Benoit LEGRESY (Legos-OMP)

Ice sheet mass balance changes are mostly controlled by atmospheric, dynamics and sea level changes. However, due to the large inertia of the ice sheet dynamics and to the non-linear effects of some changes in the boundary conditions, the short-scale fluctuations of the ice sheets environment or boundary may induce a large-scale signal on ice sheet mass balance and then on sea level. We will focus the presentation on the effect of random change in accumulation rate and in the outlet glaciers conditions. First, the large relaxation time of an ice sheet induces a low-frequency response to random fluctuations of snow accumulation. However, the time scale of the response is big compared to the average human lifetime and the effect of these random fluctuations on sea level change may be important even if they are not linked to climatic change. Short-term changes in the volume of ice sheets as analyzed by radar altimetry may not be related to long-term climatic change. We express the relaxation time of an ice sheet with respect to the ice thickness, surface slope and ice velocity. These parameters are deduced from the precise topography derived from the geodetic cycle of the ERS1 radar altimeter. Then we apply a stochastic process to model the accumulation rate random fluctuations. The variance of the induced effect on ice elevation is found to be around 3 m over a 30-yr scale and with a maximum of 10 m in Wilkes Land and in the western part of the West Antarctic ice sheet. Near the coast, this effect can mask a climatic signal and thus be critical for altimetric mass balance surveys. The estimated changes in Antarctica´s elevation between Seasat (1978) and ERS (1993) epochs could be explained at least partially by such processes. In terms of sea level change over the 30-yr scale, the standard deviation of the induced effect is 8 ± 2.8 cm. Finally, we show that the probability of a present day, induced sea level rise of between 0.5 and 1 mm/yr over a 30-yr time scale is estimated at 10% ± 10%, with coastal areas accounting for half of this signal.   Second, the boundary conditions of the outlet glaciers are controlled by ice dynamics and sea level. Any changes affect the grounding line position or on the ice thickness near the coast that in turn affect the flow ice volume in the upslope direction. The propagation is very long so that the actual state does not correspond to actual boundary conditions. The effect of the past fluctuation in outlet glaciers conditions will be investigated in term of ice sheet mass balance change and of sea level change.

JSM11/10A/B18-006 1040

SYOWA STATION, ANTARCTICA, FOR GLOBAL GEODYNAMICS NETWORK STATION (A REVIEW REVISITED)

Kazuo SHIBUYA, Koichiro DOI, Shigeru AOKI (Center for Antarctic Environment Monitoring, National Institute of Polar Research)

Shibuya (1993) made a review of the solid-earth geophysics programme by the Japanese Antarctic Research Expedition (JARE) at Syowa Station, Antarctica, and summarized the status of each component at the year of 1993. VLBI was in the planning stage yet, AG team just arrived for the first measurement, SG observation also just started. GPS was yet in a campaign mode. After 10 years, with continuing support from the geodetic society, Syowa

IA

Station has now become one of the key stations for global geodynamics in the southern hemisphere, and the JARE program will maintain all components including VLBI, GPS (IGS and regional), DORIS, SG and AG, sea level variation by BPG, together with monitoring by broadband seismometer, magnetic variographs, etc. Syowa 11-m antenna also acquired many SAR scenes of JERS-1 and ERS-1/-2 tandem orbits, covering approximately 3/4 of the East Antarctic ice sheet. In this symposium many results in relation to Syowa observations are presented. We will make brief review of current status of each component and present near-future plans. Detection of time variable gravity fields by GRACE is a challenging topic in relation to the mass balance of the Shirase Glacier region and the ground truth surveys which are tied to the Syowa reference marks will also be introduced.

LOW-FREQUENCY OCEAN VARIABILITY AND THE GLOBAL MEAN SEA LEVEL RISE PROBLEM

Rui M. PONTE[1], Detlef STAMMER[2], Carl WUNSCH[3] ([1]Atmospheric and Environmental Research, Inc., [2]Scripps Institution of Oceanography, [3]Massachusetts Institute of Technology)

Sea level records contain much variability at seasonal to decadal scales, which can make the determination of long term trends difficult and erroneous. The correct estimation of the seasonal to decadal signals over the global oceans is thus very important for understanding mean sea level rise, both regionally and globally. Here we use in situ tide gauge and hydrographic data, satellite altimeter measurements, and multidecadal numerical model simulations to quantify the low-frequency signals in sea level, and how they relate to variability in the ocean circulation and atmospheric forcing, as a function of region and time scale. Particular attention is given to analyzing misfits between data and model simulations, determining the impact of the seasonal to decadal variability on the long term trend estimates, and providing ways to improve those estimates.

JSM11/10P/B18-002   1420

DETECTING THE FINGER-PRINT OF FORCING FACTORS CONTRIBUTING TO DECADAL AND SECULAR SEA LEVEL VARIATIONS

Hans-Peter PLAG (Geodetic Institute, Norwegian Mapping Authority, Kartverksveien 21. N-3511 Honefoss, Norway)

The main forcing factors contributing to coastal relative sea level variations at decadal to century time scales are (1) steric changes, i.e. changes in the volume of the sea water, (2) mass exchange with the continental cryosphere and hydrosphere, (3) post-glacial rebound, (4) local vertical movement of the crust, and (5) variations in the atmospheric circulation. Utilising the large and global database of local monthly mean sea level values available at the Permanent Service for Mean Sea Level, an search is carried out for the ˝finger-prints˝ of the different forcing factors in the sea level. A complex regression model is used to weight the ˝finger-prints˝ of the different factors. The forcing factors are represented by model predictions (General Circulation Models for steric effects, geophysical model for post-glacial rebound), theoretical finger-print functions (for mass exchange with the cryosphere, where the static sea-level equation is used to compute the finger-print functions for the sea-level signal due to linear trends in the Antarctic and Greenland ice sheets), and observational data (atmospheric circulation). For each forcing factor, a parameterised contribution is included in the regression. In an inversion, these parameters are determined for large sets of models and/or assumptions. Particular emphasis is on the correlation between the different forcing factors, which is found to be as high as 0.4 in some cases. As a particular result, the secular changes for the Antarctic and Greenland Ice sheets will be discussed.

JSM11/10P/B18-003   1440

SECULAR SEA LEVEL RISE IN THE RUSSIAN SECTOR OF THE ARCTIC OCEAN

Richard W. PELTIER[1], Andrey PROSHUTINSKY[2] ([1]Department of Physics, University of Toronto, [2]Woods-Hole Oceanographic Institution)

Tide gauge observations of secular sea level change continue to provide the only means whereby one may estimate the global rate of sea level rise that has been characteristic of the most recent 50-100 years of Earth history. Until recently, the only such estimates that have been available were based upon the analysis of data from sites contributing to the Permanent Service for Mean Level and which were included in the archive prior to 2003. One characteristic of this data is that it included very little information from either high northern or southern latitudes. Very recently, however, the data base has been expanded by the addition of measurements from a large number of sites in the Russian sector of the Arctic Ocean. A total of approximately 60 such time series, each of 50 years or greater duration, are now included in the archive. Given the duration of each of these records they are expected to enable one to average out the influence of interannual variability upon estimates of the secular rates of change. The availability of such Arctic records is especially important as the thermal expansivity of ocean water near the poles is substantially less than that which is characteristic of lower latitudes. For a given increase in surface temperature the contribution of the thermal expansion of the oceans to the rise of sea level is therefor expected to be significantly less at high latitude than at mid-or equatorial latitudes. We have analysed the secular rates of sea level rise recorded on this dense set of Russian gauges by employing a detailed model of the process of global glacial isostatic adjustment to filter the influence of the last deglaciation event of the current ice age from the data. When we average over the filtered results we obtain an estimate for the rate at which the influence of modern climate change may be causing sea level to rise in the Arctic Ocean of approximately 2.3 mm per year. This rate is very close to that inferred on the basis of analysis of data from the East Coast of the US, for which region a value of approximately 2 mm per year was determined. It is also close to but somewhat greater than the most recent estimate of approximately 1.85 mm per year for he globally averaged rate of sea level rise. These numbers all significantly exceed the IPCC best estimate of the global rate of relative sea level rise. Possible reasons for this discrepancy will be discussed.

JSM11/10P/B18-004   1500

WHAT IS THE MAIN CAUSE OF SEA LEVEL CHANGE AROUND JAPAN DURING 1969-1998

Sin-Iti IWASAKI, Tomonori MATSUURA, Wataru SASAKI, Isao WATABE (National Research Institute for Earth Science and Disaster Prevention)

A trend of the oceanic origin sea level change was deduced from the tide gauge records for the last 30 years around Honshu Is. of Japan. The Height Difference Data (results of the ground leveling from 1969 to 1998 made by Geographical Survey Institute of Japan) was used to extract the effect of the crustal movements from the tide gauge records. It was assumed that the Japan Datum of Leveling had been stable. The trend of the oceanic origin sea level change can be divided into two parts by the 137°E longitude line. Average rate of the oceanic origin sea level change for the West Japan was +2.4 mm/year, while it was -3.1 mm/year for the East Japan. The relation between the trend of the oceanic origin sea level and the sea surface temperature was also investigated. We found that the trend of the oceanic origin sea level had good correlation to the trend of the sea surface temperature. Separately from our work, Cabanes et al. (2001) stated that the sea level rise observed by the satellite and tide gauges was well explained by the thermal expansion of the seawater. Our results agree well with their conclusions. Reference Cecile Cabanes, Anny Cazenave and Christian Le Provost, Sea Level Rise During Past 40 Years Determined from Satellite and in Situ Observations, Science, 294, 840-842, 2001

JSM11/10P/B18-005   1600

LONG TERM VARIABILITIES OF TIDES AND MEAN SEA LEVEL IN BRAZIL

Joseph HARARI[1], Carlos Augusto De Sampaio FRANÇA[1], Ricardo DE CAMARGO[2], Afranio Rubens DE MESQUITA[1] ([1]Instituto Oceanográfico da Universidade de SãoPaulo, [2]Instituto Astronômico, GeofÅEico e Ciências Atmosféricas da Universidade de São Paulo)

Sea surface level measurements have been regularly performed along the Brazilian BR coast and have provided relevant information about long-term variabilities of BR tides and mean sea level (computed by filtering out the tidal oscillations BR in the observations). Results of analyses are relative to two ports of the Brazilian BR North / Northeastern coast (Belém, 1° 26.2° S 048° 29.6° W, with observations f BR from 1948 to 1987, and Recife, 8° 3.3° S 034° 51.9° W, 1946 - 1987) and two BR of the Southeastern region (Santos, 23° 57° S 048° 19° W, 1944 - 1989, and BR Cananéia, 25° 01° S 047° 55° W, 1954 - 1990). There is special interest on BR monthly, seasonal and annual mean levels, which indicate seasonal BR hydrodynamical variations and long term trends. The following rates were BR computed: mean sea level variations of 3.500 (Belém), 5.432 (Recife), BR 1.132 (Santos) and 4.046 cm/decade (Cananéia); M2 amplitude trends are, BR respectively, -1.100, 0.070, -0.162 and 0.470 cm/decade; M2 phase rates are BR 0.600, 2.200, 0.191 and ?0.370 degrees/decade; S2 amplitudes vary with BR -0.290, 0.090, 0.130, 0.531 cm/decade; and S2 phases present trends of BR 1.000, 2.600, 0.425 and 0.160 degrees/decade. These trends must be carefully BR interpreted since they are superimposed to several long period oscillations BR and the ports are subject to many human activities, such as periodic BR dredges in the Port of Santos. Efforts have been made in order to insert BR recent observations in the study and correlate the results to other BR long-term analyses, especially atmospheric temperatures at the surface and BR precipitation rates. These correlations will indicate the importance of the BG greenhouse effect and its possible consequences melting of polar caps, BR increase of mean sea level in tropical and sub-tropical areas, and BR modifications in the tidal propagation regimes.

JSM11/10P/B18-006   1620

SEA LEVEL CHANGE IN INDONESIAN ARCHIPELAGO DERIVED FROM A DECADE TIDE GAUGE DATA

Parluhutan MANURUNG, Bambang S. PRATOMOSUNU, Rudolf W. MATINDAS, Cecep SUBARYA, Joko ANANTO (National Coordinating Agency for Survey and Mapping (BAKOSURTANAL), Jl. Raya Jakarta-Bogor Km 46 Cibinong, INDONESIA)

Data derived from tide gauge stations operated by the National Coordinating Agency for Survey and Mapping (BAKOSURTANAL) since 1986 was used to determine mean sea level series. The stations were selected with criteria namely, (i) continuously observing from more than ten years, (ii) connected to well established benchmarks, (iii) the locations could represent water level condition of the main and several small islands of Indonesian archipelago. The trend of mean sea level series derived from both monthly and annual data suggest that there is an indication of sea level change in the Indonesian archipelago. The initial result shows that the trend is larger than that of Intergovernmental Panel and Climate Change. This suggests that efforts should be made for precise monitoring of the tide gauge benchmarks, allowing separation of tectonic and local effects from the sea level signal. It is expected that participation of BAKOSURTANAL in the ongoing international program for performing continuous GPS observations at tide gauges would make a significant contribution to the sea level monitoring of Indonesia.

RECENT EXAMPLES FOR THE CONSEQUENCES OF CLIMATE CHANGE ON THE FLOODS

Hamza OZGULER (General Directorate of State Hydraulic Works)

Leading serious damages and harms both on people and land, flooding events are very common in Turkey. Especially in the recent years, a number of devastating flood events have occurred in the various river basins of Turkey. Considering the climatic characteristics of the country whose social and economical structure is changing and developing rapidly, the information on flood events that frequently hits urban areas, infrastructures, industrial facilities, agricultural land and recreational sites is getting more important. Climate change is among the trigger agents of unusual floods. It causes changes in timing, regional patterns and intensity of precipitation events, and in particular, in the number of days with heavy and intense precipitation occurences. Floods are now being experienced in areas where there were no floods in the past. This implies the regional impacts of the global climate change. In this paper, it is intended to give some local examples to be able to indicate for the regional consequences of the climate change.

FORECASTING THE CASPIAN SEA LEVEL

Sadegh YARI, Nahid KHODAYARI (Author)

During two last decades significant fluctuations in Caspian Sea level have resulted and continued to result in ecological and economic damage that estimated at 1500 billion Rials (less than 200milion $) in Iranian coastal areas. It is evident that the availability of reliable calendar forecasts of sea level fluctuations would help reduce such damage, but it would not eliminate them entirely. The principal solution for these fluctuation problems would be management of Caspian Sea level where the level would be fixed at some optimal mark. This management approach would need to use forecast of sea level fluctuation. Long-term fluctuations in the level of Caspian Sea vary over a wide range. As an analysis of information available over several decades shows, the water level of Caspian Sea is formed by: fluctuations in river inflow, evaporation from and precipitation into reservoir, and outflow into the Kara-Bogaz-Gol Bay and climatological changes like greenhouse effect and men's effect. In order to decrease the economic and ecological losses caused by Caspian Sea level fluctuations, it is necessary to use sea level forecasting and undertake measures that decrease sea level variation. Adequate information about interanual changes in sea level is available only for the last 150 years. When regular measurements of the level where carried out, using several measuring devices. The amplitude of sea level fluctuations for the period of instrumental observations (1830 to present) was 3.8m, with the highest recording in 1882 at –26.2m and the lowest in 1977 at –29.0m. In 1995, the mean annual level was –26.51m. Conditionally, tree time periods, having sharply distinct sea level regimes can be distinguished:1. Up to the beginning of the 1930s2. From 1931 to 1977, and3. From 1978 to present. The first of these periods had a stable level, a mean annual level of about –26.2m ands maximum amplitude of fluctuations that did not exceed 1.5m. In the second period, the level declined annually and, by 1941, the mean annual reduction in level was 16cm. The total decline in Caspian Sea level for the second period was 2.8m. In the third period, a continuous rise in level over 18 years averaged about 14cm per year. The total rise in sea level in this period was 2.5m. The studies executed have shown that the forecast based on the dynamic-stochastical model of the Caspian Sea level fluctuations has come true. In Iranian coast of Caspian Sea, there are some observatory stations (in Anzali, Astara, Noushahr, Babolsar, Amirabad, Bandar-Torkman) that report sea level fluctuations daily. The oldest station is in Anzali, since 1927. Now there is a projects that its goal is forecasting Caspian Sea level and so reducing the damages caused by Caspian Sea level fluctuations.

GLOBAL ATMOSPHERE WATCH AND CLIMATE CHANGE MONITORING IN KOREA

Sung-Nam OH (Meteorological Research Institute, Korea Meteorology Administration)

The earth´s climate has increased 0.7C for the past 100 years. However by the increase in greenhouse gases, the increase of temperature in the troposhere appears more strongly in the high latitude region, and so in the Korean peninsula, the atmospheric temperature has almost risen 1°C since 1880. This phenomenon is interpreted to be a result of global warming. However, this is related to the economical and industrial development of the countries in North East Asia, centered on the Korean area and is also related the entrainment of aerosol due to the desertrification of China regions. Since the year of 1996 when the Korean Global Watch Observatory(KGAWO) was established, the techniques in measuring and collecting data have continuously been developed in this country, and so some of the techniques in measuring greenhouse gases are ranked to be the level of the world standard. In particular, the monitoring of climate change in the Korean peninsula includes the measurement technique that observes the background atmospheric constituents such as greenhouse gases, aerosols, and radiation together with the various other factors affecting climate change, the modeling technique for estimating the budget and transfer process of the atmospheric radiation, and the radiative forcing technique due to greenhouse gases and aerosols in the regional climate change. The objectives and study include as : (1) Measurement of background concentration of greenhouse gases atmospheric and the trend analysis on their variation. (2) Establishment of monitoring system for the effect of Asian particles by continental desertrification and climate environments. (3) Measurement of atmospheric radiation and development of its data analysis technique. The results of our study are as follow : (1) The concentration of CO2, analyzed by using the flask-sampling method during the period 1990-2000 at Kosan in Cheju, maintains larger seasonal fluctuations as an amplitude of about 16 to 17 ppm every year.(2) The background concentrations of atmospheric CFC-11 and CFC-12 have been monitored to assess their effect on stratospheric ozone depletion and global warming during the period of 5 yrs from September 1995 to March 1999 atKosan, Korea. (3) The size-separated number concentrations of aerosols ranging from 0.3 to 25 μm were observed by using the Optical Particle Counter (OPC) in Seoul and Anmyyon Island in the west coast of Korea during Asian dust period in spring 1998. (4) The aerosol optical properties of the background atmosphere in the Korean peninsular were measured at both of Jeju Kosan super-site and Anmyondo GAW station during the intensive observation period (IOP) of ACE-Asia campaign.

GLOBAL AND REGIONAL SEA LEVEL CHANGES FROM ALTIMETRY - RELATION WITH SEA SURFACE TEMPERATURE AND CLIMATE INDICES

Ole B. ANDERSEN[1], Per KNUDSEN[1], Brian BECKLEY[2] ([1]National survey and Cadastre - KMS, [2]Raytheon ITSS, Goddard Space Flight Center)

TOPEX/POSEIDON (T/P) and JASON-1 sea level observations and Reynolds AVHRR sea surface temperature observations for the last decade have been used to study regional changes and regional correlations between long-term changes in sea level and sea surface temperature taking into account sea level changes due to ice mass fluctuations. The effect of the recent recalculated sea state bias correction for the T/P Alt B observations has been taken into account, as well as the effect of the bias between T/P and JASON-1 observations. Consistent increases in both sea level and sea surface temperatures are found in most parts of the Atlantic Ocean over this period. In the Indian Ocean and particularly the Pacific Ocean, the trends in both sea level and temperature are dominated by the large changes associated with the El NinÅESouthern Oscillation (ENSO), and the Pacific Decadal oscillation (PDO). Spatial correlation between sea level changes and pressure indices like NAO, SOI, PDO and ENSO are carried out to investigate these in more detail. Sea level changes over the most recent decade detected by T/P sea level observations are correlated with changes in the Reynolds AVHRR sea surface temperature observations with a global averaged correlation of more than 0.65. On regional scales this number becomes higher. Specifically, in the tropical part of the Pacific and Atlantic Ocean where the correlation computed over 10 and 20° latitude bands increases to more than 0.9.

CHANGES IN THE ANTARCTIC AND GREENLAND ICE SHEETS MASS AND THE INSTABILITY OF THE EARTH ROTATION OVER THE LAST 110 YEARS

Nikolai S. SIDORENKOV (Hydrometceter of Russian Federation)

The redistribution of water masses on the Earth entails changes in the components of the Earth´s inertia tensor and causes the motion of poles and changes of the Earth´s rotation speed. N.S.Sidorenkov (1982) has deduced equations which connect the fluctuations of the World Ocean water mass ζ_O or the ice mass of Antarctica ζ_A, Greenland ζ_G and ˝the rest part of land˝ ζ_C with the parameters of the Earth´s rotation (coordinates of the North Pole v_1, v_2 and velocity of rotation v_3). Presently, parameters v_1, v_2 and v_3 of the Earth´s rotation are measured with a very high accuracy and can be used for the calculation of water exchange (values ζ_O, ζ_A, ζ_G and ζ_C). According to this idea, we have calculated the unknown increments of the specific amount of water in the World Ocean ζ_O and the accumulation of ice in Antarctica ζ_A, Greenland ζ_G and ˝the rest part of land˝ ζ_C for 1891-2000 with a one-year step. The computed (theoretical) series ζ_O, ζ_A, ζ_G are compared with the empirical values ζ_O, ζ_A, ζ_G. A close correlation between theoretical and empirical series ζ_A for Antarctica and ζ_G for Greenland is revealed.

INVESTIGATION OF VERTICAL LAND MOVEMENT AND CURRENT EUSTASY BY MEAN SEA LEVEL TWO-FRAGMENT SERIES

George S. METREVELI (IAG)

BR The global climate warming, wich started in the 1880`s, has provoked the BR current eustasy- a level permanent rise in the oceans and seas because BR of water thermal expansion and a shift in the continental water budget BR toward the World ocean.BR Therefore every MSL series contents two trends. The first trend is result BR of Vertical land movement (VLM), wich represents high-inertial, long-term BR process (geological or epeirogenic trend, C mm/year). The second trend BR is result of the global climatic warming (eustasy trend, ΔH mm/year). BR So long as the eustasy started about 15-45 years late than modern climate cycle,BR some of MSL series, contents SL data of eustasy period and before it. BR Consequently, such series may be divided into two fragments. MSL series,BR wich are consist two fragments has a form:BR H1,H2,…Hk,Hk+1,...Hn ={Hi}iexcl;=1,K ,{Hi} iexcl;=K+1,n I=1,2,…,k,...,n.BR Trend of the first fragment {Hi} iexcl;=1,K, V1 represents geological trend - BR with the opposite sign: BR V1= -C .BR Trend of the second fragment {Hi} iexcl;=K+1,n, V2 is algebraic sum of both trends: BR V2= ΔH + C. BR For calculation of numerical meanings of ΔH and C may be use regression BR analysis methods (such as method of the least squares). Finally, MSL climatic BR trend can be calculated as:BR ΔH = V2 - C.BR It´s really, that the numerical meanings of ΔH and C are rates of MSL BR climatic rise and VLM. Clearly, that sucsessful fulfillment of such operations BR represent some difficulties. The initial operation for its is selection BR of MSL long series into two fragments, statistical duration of wich is enough BR for determination ΔH and C to within 0,1 mm/year. The following steps BR are separation of fragments and implementation some mathematical operation BR for their preparation for computation. The finally operations are oceanography BR generalization of local magnitude of the eustasy (ΔHi) and determinationBR of regional and global climatic influences on SL.BR By this method eustatic level rise was started in 1896-1900 at Aberdeen II,BR in 1906-1908 at Brest and later at the Cascais and in the Mediterranean and BR Black sea basin in 1914-1926. The average rates of level rise at BR the Aberdeen II, Brest, Cascais, Sevastopol, Batumi and Sidney Fort Denis BR amounted to 2,9; 2,6; 2,0; 2,0, 2,6 and 1,5 mm/year. The average rates BR of the VLM at that towns are accordingly: 1,7; -0,3; 0,8; 0,2; 0,4 and BR 0,7 mm/year. BR These investigation was made by information till 1990´s.BR One of the merits of methods is using statistically enough duration fragments, BR on wich have effect all SL accuracy determined factors; BR The methods accuracy is increased as far as of fragment`s lengthening;BR The method´s accuracy was estimated by results of the Repeated Geodesy Survey BR RGS), wich was realized in 1902 and 1952 along railway on the Caucasus coasts.

GLOBAL MEAN SEA LEVEL RISE DURING THE 1990S AND THE PREVIOUS DECADES

Anny CAZENAVE[1], R.Steven NEREM[2], Alix LOMBARD[1] ([1]LEGOS-GRGS/CNES, [2]CCAR, University of Colorado, Boulder, CO, USA)

For now 10 years, global mean sea level variations are routinely measured by the Topex/Poseidon altimeter satellite. Sea level rise measured by Topex/Poseidon during the 1990s amounts to 3 mm/yr. Based on in situ ocean temperature data, we show that thermal expansion is the dominant contribution to the observed rate of rise. We quantify thermal expansion and water mass exchange with continental reservoirs not only during the Topex/Poseidon lifetime but also for the previous few decades. Regional analyses as well as EOF decomposition of the thermal component over the last five decades allow us to give some insight into the spatio-temporal behavior of thermal expansion. We show that the steric sea level has experienced two periods of accelerated rate of rise, in the early 1970s and early 1990s. We also show that the Atlantic ocean is the main contributor to this behavior.Recently published estimates of continental glaciers melting, ice sheets melting and land water mass change suggest that the latter sources have contributed to about 1 mm/yr eustatic (i.e., non steric) sea level rise during the 1990s. This observation raises the following question: since Topex-derived sea level rise is well explained by thermal expansion, this additional 1 mm/yr water mass contribution has to be counterbalanced by a similar contribution of opposite sign. Possible sources of sea level drop are water vapor stored in the atmosphere, ocean waters salinity increase and water mass stored in continental reservoirs as a result of human activities. Among these, the anthropogenic contribution is the most likely cause of sea level drop, albeit still very poorly known.

BASAL SLIDING OF ICE SHEET OBTAINED FROM BALANCE VELOCITY AND SURFACE TOPOGRAPHY IN THE EAST DRONNING MAUD LAND, EAST ANTARCTICA

Shuhei TAKAHASHI[1], Okitsugu WATANABE[2] ([1]Department of Civil Engineering, Kitami Institute of Technology, [2]National Institute of Polar Research)

The Japanese Antarctic Research Expeditions (JAREs) have made glaciological studies on ice sheet dynamics and surface mass balance in the East Dronning Maud Land, mainly around Shirase Glacier drainage basin, during 30 years or more. The ice flow velocity was observed along a route transversal to the Shirase Glacier flow by the optical survey method in 1969 to 1974, along two routes of a longitudinal route to Shirase Glacier and a transversal route from Mizuho Station to the Sor Rondane mountains by the satellite doppler positioning system of NNSS (Navy Navigation Satellite System) in 1982 to 1987, and along a route from coastal region to Dome Fuji Station by GPS (Global Positioning System) in 1992 to 1995. In

IA

these observations the thinning of ice sheet was observed in the middle part of Shirase drainage basin, which was suggested to be caused from basal slip of ice sheet. On the same observation period, surface mass balance was extensively obtained in the East Queen Maud Land mainly by snow stake method. From the surface mass balance and ice sheet thickness, balance velocities were obtained on the assumption of steady flow, which were well correlated with observed surface velocities. Assuming no-basal slip flow, the balance velocity has some relation with surface gradient that derives from flow law. In inland region the obtained balance velocity were well correlated with surface gradient in this relation, but in coastal region and in the middle part of Shirase drainage basin the balance velocity was larger than the one predicted from this relation, which means the basal slip occurred at the bottom of ice sheet. Along ice streamlines the existence of basal slip was examined and a distribution of basal slip was obtained. Relating to this basal slip, the instability of ice sheet flow and the difference of observed and estimated mass balance of Shirase glacier are discussed.

SEA LEVEL CHANGE IN THE LAST DECADE-WHAT DO WE UNDERSTAND

Jens SCHROETER, Joanna STANEVA, Manfred WENZEL (Alfred-Wegener-Institut for Polar and Marine Research)

Global and regional sea level change is studied by assimilatingsatellite altimetry, sea surface temperature and hydrographicdata into an ocean general circulation model.The free sea surface of the model changes due to steric expansion,mass exchange through the surface and local redistribution by internaldynamic processes. These processes are analyzed separately inorder to interprete the measurements correctly and understandthe underlying reasons, which are prerequisite for predictingsea level change. The global mean sea level of the model is most sensitive to theglobal ocean mass budget, i.e. inflow by rivers, melting ice,precipitation and evaporation. This budget is poorly knownin comparison to the evolution of the volume of the ocean as determined from altimetry.It seems more reasonable to use the assimilation results toimprove the estimates of freshwater fluxes than to usemeasured fluxes to determine the oceans mass change.

MODELLING GLOBAL CYCLE OF CARBON DIOXIDE IN SYSTEM OF "ATMOSPHERE-OCEAN" AND GLOBAL WARMING EFFECT

Alexander GLUSHKOV[1], Valery KHOKHLOV[1], Elena PONOMARENKO[2] ([1]Innovative Geosciences Researchs Centre, [2]2. Department of environment monitoring , Odessa Environmental University)

A studying the global warming phenomenon, global cycle of the carbon dioxide etc attract a great interest. The purpose of this paper is carrying out the detailed model of the CO2 global turnover in system of 'atmosphere-ocean' Practically all carried out models are functioning in the average annual regime and accounting for the carbon distribution in biosphere in most general form (c.f. Nefedov-Narko,1995; Glushkov et al, 1999). We construct a modified model for cycle of the carbon dioxide, which allows to reproduce a season dynamics of carbon turnover in ocean with account of zone ocean structure (up quasi-homogeneous layer, thermocline and deepest layer). It is taken into account dependence of the CO2 transfer through the bounder between atmosphere and ocean upon temperature of water and air, wind velocity, buffer mechanism of the CO2 dissolution. It is obtained a temporal and space distribution for concentration of non-organic carbon in ocean, partial press of dissolute CO2 and value of exchange on the border between atmosphere and ocean. It is estimated a role of the wind intermixing of the up ocean layer. The increasing of this effect leads to increasing the plankton mass and further particles, which are transferred by wind, contribute to more quick immersion of microscopic shells and organic material. It is fulfilled investigation of sensibility of the master differential equations system solutions from the model parameters. The master differential equations system, describing a dynamics of the CO2 cycle, is numerically integrated by the four order Runge-Cutt method under given initial values of valuables till output of solution on periodic regime. At first it is indicated on possible realization of the chaos scenario in system. On our data, the difference of the average annual values for the non-organic carbon concentration in the up quasi-homogeneous layer between equator and extreme southern zone is 0.15 mol/m³, between the equator and extreme northern zone is 0.12 mol/m³. the maximum amplitude of season oscillations (40°-50°n.l.) is 0.07 mol/ M³.

OVERVIEW OF THORPEX: A GLOBAL ATMOSPHERIC RESEARCH PROGRAM

Melvyn Allen SHAPIRO[1], Alan J. THORPE[2] ([1]Noaa Office of Weather and Air Quality, [2]University of Reading)

Despite steady increases in forecast skill over the past three decades, there continue to be significant limitations in our ability to predict high-impactweather and to fully utilise forecast information for the benefit of society. High-impact weather is defined by its effect on society and the economyand is often associated with: cyclones of arctic, extratropical and tropical origin; flooding precipitation events; zones of very high surfacewind-speeds; dust-storms; heat stress and droughts. Overcoming current limitations in forecasting such weather events and the associated hazards isone of the great scientific and societal challenges of the 21st century. High-impact weather forecasts are strongly influenced by the evolvingglobal-to-regional context within which the subsequent local hazardous weather develops. Emerging advances in atmospheric science andtechnology provide the means to respond to this challenge. These developments include: (i) advances in knowledge of atmospheric predictability,including the dependence of forecast skill on inter-annual, and intra-seasonal climate variability; (ii) new satellite, aircraft, and earth-basedobserving technologies, including advanced methods for assimilating their observations into operational numerical weather prediction systems; (iii)improved forecast models aided by exponential increases in computational technology; (iv) innovative approaches to maximize the societal andeconomic benefits of weather forecasts. The expertise to develop and exploit these advances resides across many nations. Accelerating improvementsin forecast skill therefore requires an

organised international effort of the scope of THORPEX. THORPEX is a ten-year international programmedesigned to accelerate improvements in short-range (up to 3 days), medium-range (3 to 7 days) and extended-range (week two) weather predictions,and advanced forecast products. The programme builds upon ongoing advances within the basic-research and operational-forecasting communities.

CANADIAN WEATHER RESEARCH PROGRAM: TRANSFER FROM RESEARCH TO OPERATIONS

James David ABRAHAM (Meteorological Service of Canada)

In response to a decline in available resources and a measurable deteriorationin performance, the Meteorological Service of Canada (MSC) recently initiated the Canadian Weather Research Program (CWRP). The CWRP is currently the highestpriority activity within the Environment Canada´s meteorological research program. Furthermore, the CWRP is developing significant collaborations with the United States Weather Research Program (USWRP) and the World Weather Research Program (WWRP). Within this strategy of collaboration, government anduniversity scientists are partnering on a variety of weather research initiatives.Universities are using these collaborations to obtain funds through opportunities like the CFCAS (Canadian Foundation for Climate and Atmospheric Science) and the CFI (Canadian Foundation for Innovation).The general objective of CWRP is to improve our forecast ability at all scales,and in particular the forecast of extreme weather. Given the important impactof precipitation, and in particular snow and freezing rain, precipitation is being emphasized within CWRP. Furthermore, CWRP will emphasize the transfer of science to operational forecast offices, and improve the links between prediction of extreme weather and reduced socio-economic impacts. The CWRP initiative led to the MSC becoming partners with the U.S. National Weather Service (NWS) and the University Corporation in Atmospheric Research (UCAR) in the COMET program (Cooperative Program for Operational Meteorology Education and Training) to facilitate the research infrastructure being used for professional development of meteorologists. Government scientists are working in collaboration with universities on a numberof important research programs within CWRP. Some of these include: understanding the behavior of hurricanes affecting Eastern Canada; improved prediction of precipitation in the short-term (nowcasting) using our new Doppler Radar Network; better forecasts of precipitation amounts using numerical weather prediction models and assimilation of data; better forecasts of heavy snow near the Great Lakes; improved detection and prediction of hazardous aircraft icing; understanding the formation of severe thunderstorms and heavy rain induced by lake breezes; development of new ways to observe weather over the data sparse Pacific Ocean.In the spirit of collaboration within CWRP, the MSC along with McGill and LavalUniversities have partnered to obtain Canadian Foundation for Innovation supportfor the installation of a world class remote sensing observatory and highdensity observing network in the Montreal area. Furthermore, the research and development and operational weather forecast communities in the Montreal area are forming a special consortium (Extreme-Weather Academic Research Network: E-WARN) to effectively transfer science to applications using the research infrastructure in Montreal. This presentation will provide the rationale for developing the CWRP, along with a number of examples of progress and achievements, as well as future plans.

ON STEADY-STATE PROPERTIES AND STATISTICAL DISTRIBUTION OF TORNADO-LIKE VORTICES IN THE ATMOSPHERE

Michael V. KURGANSKY[1] ([1]Department of Atmospheric and Ocean Physics, Faculty of Physical and Mathematical Sciences, University of Concepcion, Chile, [2]A.M. Obukhov Institute of Atmospheric Physics, Russian Academy of Sciences, Moscow, Russia)

Both thermodynamical and fluid dynamical arguments are given to construct a simple version of the similarity theory for the mature, quasi-steady stage of a helical moist-convective vortex. On this basis, a steady equilibrium negative-exponential distribution of tornado-like vortices with respect to their size is introduced, which corresponds to a two-dimensional Maxwell distribution on maximum wind intensity. This reference distribution is critically compared to some statistical data on tornadoes distribution with respect to the Fujita scale wind speed, over territory of USA and Russia. A question of estimating the probability of a tornado occurrence at a given location is shortly addressed, using the above reference statistical distribution. Finally, some peculiarities in inter-decadal variations of the tornadoes statistics, possibly related to overall climate changes, are discussed briefly.

SIMULATION EXPERIMENT OF TORNADO ASSOCIATED WITH SUPERCELL USING THECLOUD RESOLVING STORM SIMULATOR

Kazuhisa TSUBOKI[1], Atsushi SAKAKIBARA[2] ([1]Hydrospheric Atmospheric Research Center, Nagoya University, [2]Research Organization for Information Science and Technology)

We have developed a cloud-resolving numerical model which was named theCloud Resolving Storm Simulator (CReSS). In this paper, characteristicsof CReSS will be introduced and results of simulation experiment oftornado which occurred within a supercell will be presented. CReSS is formulated based on the non-hydrostatic and compressibleequation system with terrain-following coordinates. Prognostic variablesare three-dimensional velocity components, perturbations of pressure andpotential temperature, subgrid-scale turbulent kinetic energy (TKE), andcloud physical variables. A finite difference method is used for thespatial discretization and the mode-splitting technique is adapted fortime integration. Cloud physics is formulated by a bulk method of coldrain with variables of mixing ratios and number densities of watersubstance. The turbulence is parameterized by the 1.5 order closer withTKE. Parallel processing is performed by the Massage Passing Interface (MPI). Three severe tornadoes occurred in the Tokai District, the central part ofJapan, on 24 September 1999. Observation showedthat their width was several hundred meters and their rotation wascyclonic. The Doppler radar of Nagoya University observed the parentmesoscale convective systems (MCSs) of the tornadoes and found characteristics of supercell in the MCSs: a hook-shaped echo and a bounded weak-echo region. Vorticity of themeso-cyclones within the MCSs estimated from the Doppler velocity was anorder of 0.01/s. The simulation was aiming at resolving the vortex of the tornado withinthe supercell. The computation domain was about 45 km in horizontal with agrid size of 75 m and 12.5 km in vertical with the smallest gird size of 25 m. The basic field was give by a sounding at 00 UTC, 24 September 1999. After about one hour from the initial time, aquasi-stationary supercell was simulated. An intense updraft occurredalong the surface flanking line. At the central part of the updraft, atornadic vortex was formed after 90 minutes from the initial time. Thesimulated tornado was successively developed and maintained at thecentral part of the strong updraft. The diameter of the vortex was about 500 m and the maximum of vorticitywas about 0.5 /s. These characteristics correspond to the observedtornado. The central pressure perturbation of -12 hPa was in the cyclostrophicbalance with the rotating flow of the tornado. In this simulation experiment, both the supercell and the tornado weresimulated in the common uniform grids. The tornado was produced purelyby the dynamic process

formulated in CReSS. Detailed analyses of thesimulated data showed the mechanism of the tornado genesis within thesupercell.

RECENT STUDIES ON THE DYNAMICS OF LINE SQUALLS IN WEST AFRICA USING SATELLITE DATA

Simon Oyediran OJO (Department of Geography,University of Lagos)

With recently available satellite data in Nigeria, there arises a big challenge to use the data to critically examine the characteristics and patterns of line squalls and their consequences on climate and environmental dynamics in West Africa. This paper therefore uses some of the available satellite data to examine the variability characteristics and consequences of line squalls as a weather event in the study region during the 1996-98 rainy seasons with particular reference to (a) the beginning of the rainy season (b) the middle of the rainy season (c) the little dry season and (d) the end of the rainy season. The paper first examines the significance of line squalls as an element and factor of climate in the region relative to other factors (including the intertropical discontinuity (ITD) and the ocean factor, winds, topography and land and sea contrasts, which are especially significant for local scale weather systems. The paper also examines the variability characteristics of the weather event with particular reference to wind speeds, frequency of occurrence and impacts on aspects of rainfall, which in the region may be equated to climate The results of the study show that in general (a) the source regions of most of the line squalls include the highland areas around (i) Congo (Brazzaville) at the beginning of the rainy season (ii) Central African Republic in the middle of the rainy season and (iii) the Ethiopian Highlands at the end of the rainy season (b) wind speeds accompanying line squalls are generally stronger in the south than in the north by about 30-50 per cent (c) while wind speeds in the south vary from between 25-40 knots, those of the north vary from between about 35-50 knots sometimes reaching extremes of more than 60 knots ((d) the frequency of occurrence are generally more at the beginning and end of the rainy season than in the middle of the rains (e) the frequencies of occurrence are more in the northern areas than in the south (f) the relative contributions to rainfall at the beginning and end of the rainy season are more than at the middle of the rainy season and (g) the relative contributions to rainfall in the north are more than the contributions in the south. More detailed illustrations of the variations and variability of the characteristics of the climatic event are discussed using monthly and daily values for some representative stations in the region. The paper finally discusses the problems of predictability of the climatic event in the study region especially with respect to problems of data availability on the weather event and discusses the need to improve data acquisition especially through the continued acquiring of satellite data in the region.

JSM14/07A/A05-006   1130

CONVECTIVE ACTIVITY AND LOCAL CIRCULATION OBSERVED AT SERPONG, WEST JAWA, INDONESIA

Ryuzo ARAKI[1], Manabu D. YAMANAKA[1], Fumie MURATA[1], Hiroyuki HASHIGUCHI[2], Tien SRIBIMAWATI[3], Mahally KUDSY[3], Findy RENGGONO[3] ([1]Graduate School of Science and Technology, Kobe University, [2]Radio Science Center for Space and Atmosphere, Kyoto University, [3]Agency for the Assessument and Application of Technology (BPPT), Indonesia)

Wind variations with daytime rainfalls in November 1994 at Serpong near Jakarta, Indonesia (6.4 S, 106.7 E) were investigated by utilizing a UHF-band wind profiler, Geostationary Meteorological Satellite and a tipping-bucket type rain gauge data . Serpong is situated at the south of Java Sea coastline which roughly extends to east - west direciton. Distance from the coastline to Serpong is about 40 km. There are no mountains between the coastline and Serpong. Serpong is located in a plain area. Sea-land breeze circulation is dominant in meridional wind in the dry season at Serpong. Sea-breeze (northerly) and return flow (southerly) were observed at a height range of 0.5 - 1.2 km and 1.2 - 2.0 km, respectively, during 12 - 19 LST (LST = UTC + 7). Land-breeze (southerly) and return flow (northerly) were observed at 0.5 - 1.0 km and 1.6 - 2.0 km, respectively, during 06 - 11 LST. November 1994 corresponded to the end of dry season. The peak time of sea-breeze (13 - 15 LST) corresponded to the time of strong precipitations, which 5 minutes mean rain intensity was more than 50 mm/hr, at Serpong. The number of days in which strong precipitation occurred (Strong precipitation days) were 5 days in this period. Sea-breeze (northerly) velocities from 0.3 to 1.0 km height on the strong precipitation days were stronger than those on the non-precipitation days. In November 1994, diurnal variation of the convective activity became strong in the mountainous range in the south of Serpong. However, strong precipitations at Serpong were not due to clouds developed in the mountainous range. They occurred when Serpong was covered with clouds developed in the plain area. It was thought that convective activity with daytime strong precipitations at Serpong interacted with sea breeze in this period.

A COMPREHENSIVE STUDY ON TROPICAL MESOSCALE CONVECTIVE SYSTEMS USING VHF AND UHF RADARS OVER A TROPICAL STATION

Kishore Kumar KARANAM, Atma Ram JAIN (National MST radar Facility, India)

A large number of recent observational studies of mesoscale systems have been signifying a renewed interest in tropical mesoscale convective systems (TMCS) and their impact on general atmospheric circulation and hence the global climate. There is a need to thoroughly understand each and every physical process associated with these systems, so that one can exactly parameterize them for improved numerical weather models. Thus, a need of global climatology of the convective systems has been driving many research groups across the globe to carry out various experiments to explore such systems. In this regard, several campaigns have been carried out to study the convective systems over Gadanki (13.50N, 79.20E), a tropical station in India, using VHF and UHF radars. Structure and Dynamics of the convective systems are among the central objectives of these campaigns. The height-time sections of several convective systems are studied to explore their reflectivity, turbulence and vertical velocity structure. The observed systems are classified into single, multi and super cell systems and height- time sections of the same are presented. It has been observed that most of the convective systems at this latitude are multi cell systems. It has been noted that the vertical velocity cores play a significant role in providing heavy rainfall observed at the surface. Simultaneous VHF and UHF radar data are used to classify the observed precipitating systems as convective, transition and stratiform regions. Composite height profiles of vertical velocities in these regions were obtained and the same were compared with the profiles obtained at other geographical locations. These composite profiles of vertical velocity in the convective region have shown their peak in the mid troposphere indicating that the maximum latent heat being released at those height regions. These profiles are very important for numerical simulations of the convective systems, which vary significantly from one geographical location to the other.

JSM14/07A/A05-008   1200

NUMERICAL SIMULATION OF KANGNUNG HEAVY RAINFALL EVENT OCCURRED BY 'LUSA' DURING AUG. 30-31, 2002 WITH CRESS

Jai ho OH, Jeong-Hui KIM, Tae-Hun KIM, Kazuhisa TUSBOKI (Department of Env. & Atmos. Sci., Pukyong National University)

In summer season, because topography is very complex in Korea and moistures are supplied from south-western ocean, heavy rainfall case around a northern area of Jiri mountain are often occurred (Kim and Chun 2000). During 30-31 August 2002, when typhoon ´Rusa´ passed Korea, a heavy rainfall about 890 mm within one day occurred around Kangnung area. This heavy rainfall might be related to the fact that huge amount of moisture was supplied to the mountainous regional by typhoon ´Rusa´. In this study, we try to reproduce this heavy rainfall event occurred at Kangnung during Aug. 30-31, 2002 with cloud resolving model ´CReSS´. To simulate the 15th typhoon ´RUSA´ case fot the period of Aug. 30 to 31, 2002, we provided the initial and boundary data from the JMA(Japan Meteorological agency) RSM(regional spectral model) output. As results the typhoon´s eye-wall and cloud and rain bands were clearly reproduced with CReSS model simulates the location of typhoon´s eye-wall and cloud and rain band clearly. As 'Rusa' moved northward to Korean pwninsula, heavy rainfall started at Jeju island and Jiri mountain area, and then at the east coastal mountainous region including Kangnung by strong easterly associated with 'Lusa'.

JSM14/07A/A05-009   1215

SIMULATION OF A RECENT TROPICAL CYCLONE IN BAY OF BENGAL USING MM5 MODEL AND A COMPARITIVE STUDY OF DIFFERENT CUMULUS AND PBL SCHEMES

Venu G. NAIR[1], Sijikumar S[1], Mohankumar K[2] ([1]Research Fellow, [2]Professor)

Tropical cyclones are frequent in Bay of Bengal during the Pre-monsoon (Apr-May), Southwest monsoon (Jun-Sep) and Northeast monsoon (Oct-Nov) periods. The climatological study of the Occurrence of the storms indicates that an average of five nos. of cyclones develops in a year in Bay of Bengal. A detailed study of the cyclogenesis and the movements of these tropical revolving storms is one of the major challenges in front of the Meteorologists. With the advent of the latest Meso-Scale models like MM5, the scientists could have made a remarkable attempt to predict the track of the system. In the present study an attempt has been made to simulate the cyclone which formed in the Southeast Bay of Bengal on 10-11-2002 and moved north-northeast direction and finally made a land fall on 14-11-2002. The model simulated the cyclone well with varying accuracy of different combinations of the parameterization schemes. Present study simulated the cyclone with eight different combinations of cumulus and PBL schemes. The study has been carried out for the two cases. In the first case PBL scheme is fixed with MRF and the four cumulus schemes (Grell, Anthes-Kuo, Kain-Fritsch and Betts-Miller) have been used. The second case is tested with Blackadar in the PBL with same four Cumulus schemes. The best physics options which produces this tropical cyclone are Grell-Blackadar, Kane-Fritsch-MRF and Kane - Fritsch- Blackadar. Grell-Blackadar combination well produces the central pressure of the system and matches with the direction of the system as observed. It even catches the formation of the system and the others are lacking in it.

ENVIRONMENTAL CONTROL OF TROPICAL CYCLONE INTENSITY

Kerry EMANUEL (Program in Atmospheres, Oceans and Climate, MIT)

The influence on tropical cyclone intensity of various environmental factors is explored using a simple coupled ocean-atmosphere model. It is first demonstrated that this model is capable of accurately replicating the intensity evolution of storms which move over oceans whose upper thermal structure is not far from monthly mean climatology and which are relatively unaffected by environmental wind shear. A parameterization of the effects of environmental wind shear is then developed and shown to work well in several cases for which the magnitude of the shear is relatively well known. When used for real-time forecasting guidance, the model is shown to perform better than other existing numerical models while being competitive with statistical methods. In the context of a limited number of case studies, the model is then used to explore the sensitivity of storm intensity to its initialization and to a number of environmental factors, including potential intensity, storm track, wind shear, upper ocean thermal structure, bathymetry and land surface characteristics. All of these factors are shown to influence storm intensity, with their relative contributions varying greatly in space and time. It is argued that in most cases, the greatest source of uncertainty in forecasts of storm intensity is uncertainty in forecast values of the environmental wind shear.

JSM14/07P/A05-002   1435

SIMULATION EXPERIMENT OF TYPHOON SPIRAL BANDS BY THE CLOUD RESOLVING STORM SIMULATOR

Mitsuharu NOMURA[1], Kazuhisa TSUBOKI[1], Atsushi SAKAKIBARA[2], Taro SHINODA[1] ([1]Hydrospheric Atmospheric Research Center, Nagoya University, [2]Research Organization for Information Science and)

Spiral bands are mesoscale characteristics of a developing typhoon.Observational study showed that spiral bands cause strong rainfall.It is still unknown what dynamic and microphysical processes work to produce the strong rainfall within spiral bands, because it is difficult to perform an in-situ observation of a typhoon in its mature stage.Previous numerical studies have been reported the typhoon-scale distribution and structure of spiral cloud bands.Detailed three-dimensional mesoscale structure and physical processes of the typhoon spiral band, however, are little known. In order to simulate detailed structure of a spiral band within a typhoon and to reveal its dynamic and microphysical processes, we used the Cloud Resolving Storm Simulator (CReSS)(Tsuboki and Sakakibara, 2002) in this study.CReSS is a three-dimensional cloud resolving numerical model which is formulated in the non-hydrostatic and compressible equation system with the cold rain parameterization of the microphysics. In order to understand the mesoscale structures and physical processes of the spiral band, a numerical experiment was conducted with a fine mesh.Horizontal and minimum vertical resolutions are 1km and 100m, respectively.In the present study, Typhoon 0216 in mature stage was simulated.The result showed that the mesoscale structures of spiral bands, an eyewall and the eye were successfully simulated.We focus on the three-dimensional structure of the spiral band and its developing and maintenance processes.The maximum mixing ratio of precipitation particles was present on the outer side of the maximum of cloud mixing ratio in the radial direction and on the lee side in the tangential direction.It is shown that the structure and intensity of the spiral band were related to

distributions of cloud and precipitation particles of spiral bands.For understanding developing and maintenance of the spiral band, cloud microphysical processes were examined.This showed that cold rain processes are important to intensify the rainfall.In particular, generation and growing of graupel are the most effective processes to produce the intense spiral band.

JSM14/07P/A05-003   1450

DETECTION AND TRACKING OF TYPHOON 0115 CENTER FROM DUAL DOPPLER RADAR MEASUREMENTS

Masayuki MAKI[1], Koyuru IWANAMI[1], Ryohei MISUMI[1], Sang-Goon PARK[1], Mihoko STO[1], Takeshi MAESAKA[2], Masaki KATSUMATA[3], Daisuke HASHIMOTO[4] ([1]National Research Institute for Earth Science and Disaster Prevention, [2]Hokkaido University, [3]Japan Marine Science and Technology Center, [4]Tsukuba University)

To improve nowcasting of heavy rainfalls and strong winds, experimental observations with two X-band radars were carried out in 2001 in the Kanto plain, Japan. This paper demonstrates usefulness and possibilities of real time monitoring of severe storms by dual Doppler radar measurements. Two research radars MP-X and X-DOP of NIED were set up in Tsuchiura (N36°04´09.7˝, E140°14´39.1˝) and Kitakawabe (N36°12´28.4˝, E139°39´54.0˝), respectively. Reflectivity data and Doppler velocity data dealiased by the dual pulse repetition frequency technique were sent to the National Research Institute for Earth Science and Disaster Prevention (NIED) via 128kbps telephone lines. Doppler velocity data from two radar sites were analyzed on real time and retrieved wind fields were opened to public on a web site. The example shown in this paper is the Typhoon 0115 which landfall near Kamakura City September 11, 2001. Dual Doppler radar measurements started at 1017LST, 11 Sep. when the center of T-0115 approached the dual Doppler radar analysis area. Two research radars were able to track the typhoon center in the dual Doppler analysis area until 1306LST when the wind speed exceeded the critical value for MP-X radar operation. Detailed wind field near the typhoon center is retrieved every 90 seconds during about three hours from the volume scan data with three tilt angles. A simple algorithm to find and track the typhoon center using wind filed is developed and applied to the retrieved wind field. The obtained trajectory of typhoon center shows trochoidal movement. The speed of the typhoon center is variable ranging from 3.5 ms[-1] to 10 ms[-1]. A sudden decrease in moving speed is observed at the turning point of the trochoidal motion. Analysis of kinematic properties around the typhoon center show clear change in deformation: stretching begins to decrease and shearing begins to increase at the turning point of trocoidal motion.

JSM14/07P/A05-004   1505

LABORATORY AND NUMERICAL MODELING OF TYPHOON-LIKE VORTEX

Gennadiy BOGATYRYOV[1], Gennadiy BOGATYRYOV[1], Ilya KOLESNICHENKO[2], Galina LEVINA[2], Mikhail POVARNITSYN[4], Andrey SUKHANOVSKY[2] ([1]Perm State University, Perm, [2]Institute for Continuous Media Mechanics, Ural Branch of the Russian Academy, Perm, [3]Space Research Institute, Russian Academy of Sciences, Moscow,, [4]Institute for Thermophysics of Extreme States,)

Results of laboratory and numerical experiments carried out to confirm a fundamental theoretical hypothesis on hydrodynamic alpha-effect are presented. This phenomenon is based on special generating properties of small-scale helical turbulence favoring the large-scale structure formation in turbulent media. Conditions for excitation of the large-scale helical vortex under thermal turbulent convection in rotating fluid and ways for controlling this vortical instability are investigated. Laboratory experiments to generate a typhoonic vortex, which rotates in a rotating frame, were carried out in a fluid layer with a large aspect ratio of horizontal to vertical dimension and local heating from below in the central zone. Such a scheme of experiment is assigned to simulate a mechanism of typhoonic vortex generation based on the interaction between an intensive updraft formed in the central zone by small heat carriers rising from a temperature boundary layer near the heater, large-scale advective flow and the Coriolis force. Two different experimental apparatuses were used: with a cylindrical and square in a plane cuvette filled with a fluid. Various liquids were tested so that the corresponding Prandtl numbers could differ in two times and greater. To study the influence of spatial temperature distribution in the heated area on initiation of the vortex, different heaters were used. It has been found that there exists a threshold for the vortex excitation that strongly depends on how uniform is a temperature distribution along the heater. Neutral curves in terms of rotation - intensity of convection have been obtained for different liquids and heaters of divers constructions. They showed no dependence for vortex generation on the Prandtl number and favorable influence of slow rotation for all the experiments. An increase in the angular velocity of apparatus leads to a decrease in the angular velocity of vortex rotation, and finally, to the vortex break. Numerical modeling by DNS has been performed for flows generated in the laboratory apparatus with square cuvette and showed a good agreement between DNS results and experimental observations. A way proposed to influence the rotating vortex is connected with introducing of an external small-scale helicity into the fluid layer. To this purpose small propellers were used in the square cuvette. This allowed us to suppress the initiation of the vortex as well as to change the rotation intensity of developed vortex. This work is supported by the RFBR, Grants No. 01-05-64232, MAC 02-05-06209, 02-05-06210.

CHARACTERISTICS OF CLOUD CLUSTERS AROUND THE MEIYU/BAIU FRONT

Hiroshi UYEDA, Kohei SAKAMOTO (Hydrospheric Atmospheric Research Center, Nagoya University)

To understand the formation and maintenance mechanism of Mesoscale Convective Systems (MCSs) around the Meiyu/Baiu front, characteristics of Cloud Clusters (CCs) which appeared around the front over China continent and East China Sea during June and July of five years (1998-2002) were investigated by using infrared TBB data of Geostationary Meteorological Satellite (GMS). Diurnal variation of convective activity is predominant over land during warm season in East Asia. The magnitude of the diurnal variation is known to be different over different geography like a plain, mountains, ocean, etc. However few researchers have investigated the relationship between the appearance characteristics of CC and the geography. In this study, analysis areas containing the eastern part of China and East China Sea, where CC appears frequently along the Meiyu/Baiu front, were classified into four domains: Yangtze River basin, Southeast Mountains, northern part of East China Sea, southern part of East China Sea. Characteristics of CC were investigated for each of the four domains and surrounding areas. An algorithm to detect and identify CC objectively was developed and 2044 CCs were tracked. Following characteristics of CC around the Meiyu/Baiu front in the four domains were clarified. Over land, diurnal appearance of CC having an afternoon peak was predominant in Yangtze River basin in July, and Southeast Mountains in both June and July. However, it was not predominant in Yangtze River basin in June. CCs in Southeast Mountains had shorter lifetime and smaller maximum area than those in Yangtze River basin on average. Over East China Sea, a lot of CCs appeared around 6 o'clock (local time) in the northern part in both June and July. They had longer lifetime and larger maximum area than those over land. Though CCs in the southern part were smaller and lived shorter, some of them appeared simultaneously nearby each other and developed to a huge cluster. Diurnal variation of surface temperature calculated from objective analysis data provided by Japan Meteorological Agency was consistent with the diurnal appearance of CC in each domain. These findings would contribute for the improvement of forecasting CCs and associated heavy rainfalls. By tracking CCs objectively, a generation area of CCs, which develop to meso-alpha low and produce heavy rainfalls, was recognized around the downstream of Yangtze river and the west pat of East China Sea. The relation between characteristics of CC in the Meiyu/Baiu front and structure of rainfall systems is discussed in comparison with Doppler radar analyses on a few intensive field experiments.

JSM14/07P/A05-006   Invited   1655

RADAR OBSERVATIONS OF MESOSCALE CONVECTIVE SYSTEMS IN THE TAIWAN MEIYU SEASON

Jong-Dao Ben JOU (Professor, Department of Atmospheric Sciences, National Taiwan University)

Individual thunderstorms developed into organized thunderstorm lines orcomplex mesoscale convective storms are commonly observed in the Taiwan Meiyuseason. The spatial scale of these storms is about hundred kilometers in longaxis and the time scale spans from a few hours to about a day. Significant precipitation and rapid change of wind causes severe damages to the society frequently. Meiyu period in Taiwan, i.e., May and June, is a season of transition. In this season, the cold air mass from Siberia is weakening and the warm air mass from Tropics is strengthening. The boundary of these two air masses forms a stationary front in the subtropical area, extending from south of Japan to Taiwan and southern China. Accompany with the stationary front, a wide cloud band with embedded organized convective systems are commonly observed from satellite images. Strong interaction between Taiwan topography and the frontal system induced many interesting weather phenomena along the coast and over the island. The Weather Bureau of Taiwan has just completed an around-the-island NEXRAD-type Doppler radar network by 2002. This data set provides an unprecedented opportunity for meteorological scientists in Taiwan to study the severe local storms in great depth. In this paper, four kinds of mesoscale convective systems with different organization characteristics observed by the Doppler radar network in Taiwan are summarized. Cases of prefrontal squall lines, frontal rainbands, mountain convections, and tropical convections will be presented and the effort on prediction of these storms will be also described.

JSM14/07P/A05-007   1730

NUMERICAL STUDIES OF THE MESOSCALE PRECIPITATION SYSTEMS OVER TAIWAN

Pay-Liam LIN (National Central UNiversity)

The particular shape of the Central Mountain Range(CMR) over Taiwan is oriented in NNE-SSW direction with the maximum height over 3000m. Over this complicated topography, there are not only the passage ofenvironment flow will be modified by CMR tremendously, but also severe local storm associated with local circulations will be initiated resulted from the differential heating and the terrain blocking ffects . It is also found that the rainfall distribution is concentrated on some special region and location in Taiwan.When northeastern monsoon prevailed , precipitation in the windward side of northeastern Taiwan was very significant. For example, the maximum of long-term monthly mean precipitation at I-Lan occurred in Autumn season. The percentage of monthly precipitation to annual precipitation rangeed from 11% to 17% during Autumn season. The maximum daily rainfall amount during this season can be over 300 mm at some station in northeastern Taiwan. The Mei-Yu is a climatic phenomenon found over southeaster China , Taiwan and Japan. It occurs during the transition period between the northeastly monsoon in the winter and the southwestly monsoon in summer. During this period ,a number of flash floods occurred in the island of Taiwan.   In this study, the PSU/NCAR MM5was used to simulate the mesoscale weather and precipitation systems over Taiwan to investigate the orographic effects on the distribution and the characteristics of precipitation in Taiwan and the surrounding area. A Mei-Yu front passed over Taiwan during 7-8 June 1987. There were two types of precipitation system found during this passage. One of them is the prefrontal local convection, and the other is the frontal precipitation. Modeling studies showed that prefrontal convection is af first triggered on the slop of CMR by the local convergence formed by the environmental flow with the thermal induced circulation.The sensitivity tests also indicate that the land-sea breeze, latent heat release and the surface fluxes have influence effects on the generation on the mesoscale convection systems. As the shallow front penetrated to Taiwan, the local convergence was intensified due to the interaction between Mei-Yu front and the CMR.Deep convetion associated with front passage made heavy rainfall in the inland area of Taiwan. For the northeasterly monsoon precipitation, the heavy rain event occurred on 10-12 December ,1998 will be presented in this studies. It is found that the northeasterly flow was retarded by the CMR and the local convergence was generated in the windward slop. The upstream influence results from the flow blocking and spliting with the supplying moisture and the surface fluxes triggered the local convective. systems

JSM14/07P/A05-008   1745

REGIONAL VARIABILITY OF WARM-SEASON CLOUD/PRECIPITATION EPISODESOVER EAST ASIA BASED ON GMS INFRARED OBSERVATIONS

Chung-Chieh WANG[1], George Tai-Jen CHEN[2], Richard E. CARBONE[3] ([1]Department of Environmental Management, Jin-Wen Institute of Technology, [2]Department of Atmospheric Sciences, National Taiwan University, ROC, [3]MMM, National Centers for Atmospheric Research, USA)

Based on radar data, Carbone et al. (2002) have recently reported that heavy precipitation episodes in distance/time space over the continental United States during the warm season (May-August) exhibit coherent patterns and propagating characteristics. The longevity of these episodes, up to 60 h, suggests an intrinsic predictability with a lead-time significantly longer than the lifetime of individual convective systems, and thus the potential for

improvements in precipitation forecasts at the range of 6-48 h. Using GMS Infrared brightness temperature, Wang and Chen (2002) have also compiled a similar climatology of cloud episodes for East Asia (20-40 N, 95-145 E). Results suggest that statistics for events that exhibit stronger propagating characteristics are comparable to those found in the North America, while regional differences are also evident due to a more complicated atmospheric environment as well as variations in the underlying surface inside the calculation domain. The present study extends the work of Wang and Chen (2002) and examines regional variations in characteristics of warm-season cloud episodes in East Asia. The domain is further divided into western and eastern halves using the 120 E meridian, as well as the northern and southern halves using 30 N. Preliminary results suggest that longer cloud streaks (> 2000 km and 30 h) occur more frequently over the ocean, and also more frequently in the Meiyu season (May-June) than in mid-summer. When the calculation domain is limited to the northern half, passages of synoptic-scale baroclinic waves show stronger influence and nearly all cloud streaks propagate eastward even in mid-summer. Over the southern half of domain, on the other hand, cloud streaks are considerably less organized and less propagating, and diurnal forcing show a relatively strong control. Under the influence of subtropical high, westward propagating events originating at lower latitudes are also common during most part of the warm season, from middle of June through August. Other aspects of statistics and peridicity of of events in the four quadrants are also examined, compared, and discussed.

CHINA HEAVY RAINFALL EXPERIMENT AND STUDY (CHERES)

Yunqi NI (Chinese Academy of Meteorological Sciences)

Heavy rain is one of major disastrous in China. To understand detailed structure of mesoscale heavy rains within Meiyu front and its formation and evolution, experimental observation in the area has been designed reasonably according to intensive observing approaches available for the field observational experiment rather than just based on routine observation networks. The design of observational system for CHeRES is divided into three parts: One is a large-scale background field observation. Another is two mesoscale intensive observation areas (meso-alpha scale) for the middle and lower reaches of the Yangtze River. Still another is three meso-beta intensive observation areas for the same region. The background field, which is presented by routine upper air sounding of meteorological operational system and ground-based air observations within the large-scale region, provides environmental condition for heavy rain system . The intensive observation in middle reaches of Yangtze River constructed by Doppler and digital weather radar located in Yichang, Wuhan, Nanchang and Jinzhou, while the radar system located in Shanghai, Hefei, Fuyang, Nanjing, Huangshang and Hangzhou for lower reaches of Yangtze River area and other remote sensor platforms as well as with the advantage of time-intensive routine meteorological data both for surface and upper-air observation ,are expected to address the 3D structure of the meso-alpha scale convective system within the Meiyu front. Three meso-beta intensive observation areas, one in middle reaches of Yangtze River, another two in lower reaches of Yangtze River, use dual or three Doppler Weather Radar array, wind profiler, and boundary-layer observation for further providing observational fact on study of precision structure and triggering mechanism of heavy rainfall. The experimental periods are respectively from 10th June to 20th July in 2001 and 2002. The studies of this project based on the above field experiments have made distinct progresses, indicating that to advance the ability of heavy rain prediction is possibly. Firstly, a formation mechanism and physical pattern of the persistence heavy Rain systems in Yangtze River Basin was shown properly. Secondly, large amount of work has been done on the retrieving of satellite remote sensing data concerning the heavy rain systems. Thirdly, significant improvements have been made on the retrival of the three dimensional structure of heavy rains with single and multiple Doppler radars . Fourthly, the three dimensional variation analysis system has been set up and a new four-dimensional variation data assimilation system is being developed on the basis of AREM. Fifthly, the meso-scale heavy rainfall numerical model AREM has been developed and experimentally predicted with real time. At same time, the new generation non-static and higher-resolution meso-scale model has been developing now.

JSM14/08A/A05-002   0910

A CASE STUDY ON THE EVOLUTION OF A MESO-?-LOW IN ASSOCIATION WITH THE MEIYU FRONTAL ACTIVITY OVER CHINA AROUND 28 JUNE 1999

Kuranoshin KATO[1], Yafei WANG[2] ([1]Faculty of Education, Okayama University, [2]Chinese Academy of Meteorological Sciences)

Meso-α-scale lows sometimes appear on the Meiyu/Baiu front and play important roles in the multi-scale interaction processes between the large-scale and the meso-β- and γ-scale convective systems. However, the processes on initiation of a meso-α-scale low and its interaction with the rainfall systems show great variety dependently upon the features of the basic fields around the Meiyu/Baiu front. The previous studies pointed out the important role of the so-called SW vortex initiated around the eastern foot of the Tibetan Plateau. On the other hand, our group presented that a meso-α-low is sometimes initiated after activation of the Meiyu frontal activity. In such cases, the heat-low over the arid region in China played an important role in the temporal activation of the Meiyu front, togetherwith the moisture transport by the subtropical high. Meso-α-low initiated over China also affects the frontal-scale water cycle around the Japan Islands, as illustrated in a case around 29 June 1999 by our group. In the last case, meso-α-scale low was initiated in Central China (the lower reach of the Changjiang River Basin). Thus the present study will examine the evolution process of the meso-α-low over China around 28 June 1999, based on the operational observational data together with the GAME/HUBEX data. The Meiyu cloud zone was once weakened after the eastward passage of a meso-α-low in Central China around 00 UTC 26 June. The GMS IR data shows that the area with low TBB on the Meiyu front enhanced and expanded from 12 UTC 26 to 06 UTC 27 June (around 30N/115-120E) (referred to as Convection Developing Stage). After that, meso-α-low in the lower layer was generated there around 18 UTC 27 June (Low Formation Stage). Then the meso-α-low began to move eastward toward the western part if the Japan Islands with its center pressure decreasing (from 18 UTC 26 to 12 UTC 26) (Low Propagation Stage). Interestingly, the trough was not extended to the upper layer (e.g., 500 hPa level) from the surface-level low until the Low Propagation Stage. In this case, activation of the Meiyu front in the Convection Developing Stage seems to be associated with approach of a low-level cyclonic circulation from the southeastern edge of the Tibetan Plateau (maybe, the so-call SW vortex). However, the vortex itself did not propagated to the Central China directly and it might contribute to the generation of a new meso-α-low by activating the Meiyu frontal rainfall in its eastern area.

JSM14/08A/A05-003   0925

A NUMERICAL EXPERIMENT OF A MESOSCALE DISTURBANCE ALONG THE MEI-YU FRONT OBSERVED DURING GAME/HUBEX 98

Kozo NAKAMURA[1], Yasushi FUJIYOSHI[1], Kazui SAITO[2], Masanori YOSHIZAKI[3] ([1]Frontier Research Syatem for Global Change, Yokohama, Japan, [2]Numerical Prediction Division, Japan Meteorological Agency, Tokyo, Japan, [3]Meteorological Research Institute, Tsukuba, Japan)

One of the research subjects of the Hydrological Cycle Research Program (HCRP) of FRSGC is to understand and to model the mesoscale organization processes of the cloud and precipitation system. In order to improve our understanding of the processes, we performed a numerical experiment of the system observed near Fuyuang radar site (115.83 E, 32.93 N) on July 2nd, 1998.   The model used in this study is Non Hydrostatic Model (NHM) developed by the Meteorological Research Institute. We used two datasets, i.e., the GAME-Reanalysis and ECMWF data to make initial and boundary conditions, and we investigate the organizing process by comparing the two results. The land surface temperature is predicted by the heat balance equation with wetness parameter denoted by w, (w=0.1 for land, and w=1.0 for sea in the control runs). We used the data at 06UTC (14 BST, Beijing Standard Time) July 1 for the initial condition. In both data, a subtropical high was analyzed to the south of Japan, strong southerly wind in the southern part of China, which went to the large shear zone at the Mei-yu front. The difference between the two data sets, such as the intensity of the vorticity, does not seem so large, except the surface air temperature in the southern part of China, which is much warmer in the GAME Reanalysis data than in the ECMWF data. It can produce active convection that might enhance the moisture transport to the front area. In both runs, the model successfully reproduced the development of the large-scale horizontal shear, convergence, and the precipitation along the Mei-yu front. However, the disturbance of the GAME-Reanalysis run was too strong and moved too fast to the northeastward, and after its movement there is no intense convection. On the other hand, in the ECMWF run, there occurred many convection systems along the front region and properly reproduced the persistent heavy rainfall area. We preformed several experiments (w=0.1, w=1.0) to investigate the effect of the surface conditions. It is shown that although the effect of the wetness parameter on the boundary layer structure is large, its effect on the convective activity appears to be small. When the surface wetness is large, the moisture becomes large in the boundary layer, while the surface temperature becomes lower because of the evaporation. Because the effects of these two processes on the convective activity are opposite with each other, the convection does not becomes so active. The reason why the effect of the wetness parameter is small may be because the runs are started at 06UTC, when the surface temperature becomes highest.

JSM14/08A/A05-004   0940

THE STRUCTURE AND EVOLUTION OF A RAINBAND INDUCING HEAVY RAINFALL IN THE DOWNSTREAM OF YANGTZE RIVER

Biao GENG, Hiroyuki YAMADA, Krishna REDDY, Hiroshi UYEDA (Frontier Observational Research System for Global Change)

This paper investigates the structure and evolution of a rainband observed in the downstream of Yangtze River during the Meiyu season in 2001. The rainband, which developed over a Meiyu front in the early morning of June 24, brought more than 110 mm rainfall in a narrow region within only two hours. The rainband was stationary and oriented from southwest to northeast. The length of the rainband was more than 200 km, while the width of the rainband was only about 50 km. A low-level southerly jet was observed in the south side of the rainband. Meanwhile, a medium-scale low-pressure system existed under the rainband. The southerly flow was lifted over the rainband, with the stronger ascent area corresponding to the stronger radar echo area. It is interesting to find that the whole rainband and related rainfall intensified with about 40-min periodicity. The development of the rainband was associated with the periodical development of updrafts within the rainband and surface pressure and wind under the rainband. Meanwhile, downdrafts within the rainband were weak and no distinct gust evolved under the rainband. The in-phase covariance between the surface pressure, wind and rainfall under the rainband suggests that the evolution of the rainband was associated with a kind of mesoscale gravity wave. The interaction between gravity wave, low-level jet and Meiyu front would be important for the development of the strong rainband and the heavy rainfall.

SYNOPTIC-SCALE DYNAMICS OF 18-DAY LONG CONSECUTIVE MESOSCALE CONVECTIVE SYSTEMS DURING THE HEAVY RAIN PERIOD OF 1998

Dong-Kyou LEE, Jeong-Gyun PARK, Jo-Han LEE (Atmospheric Sciences Program, School of Earth and Environmental Science, Seoul National University)

The 18-day long lasting heavy rainfall events occurred over the Korean Peninsula from 31 July to 17 August in 1998. These consecutive heavy rainfall events were a climatologically exceptional heavy rain period with record-breaking cases over South Korea from 1980 to 1999. The 18-day mean synoptic fields well revealed synoptic environments of the successive occurrence of mesoscale convective systems responsible for heavy rain. The continental polar lows north of Korea and the westward extended, strong western Pacific high south of Japan maintained an elongated monsoon front which were supported by baroclinic forcings for about 20 days. The strong southwesterly flows that were sustained by the increased pressure gradient between the continental low and the western Pacific high played an important role in accumulated sufficient moisture over Korea, establishing a wide-spread baroclinically unstable region over the Korean Peninsula. The synoptic-scale upward motions over Korea was concentrated on the mid- and lower-level attributing to diabatic heating and shearing deformation forcings. Primary pattern of vertical motion was produced by the diabatic heating and shearing deformation forcings. Synoptic-scale vertical motion was relatively weak and confined in the lower troposphere because the shearing and stretching deformation forcing contributedmainly to horizontal ageostrophic motion in the upper levels. The vertical structure of the apparent heat source and moisture sink indicated that rainfall over central China was frontal precipitation with upper tropospheric stratiform cloud, while that over Korea and Japan had deep convective characteristics. For the 18-day period, the heavy rainfall occurred with periods of 1 day and 2~3 days and with meridional variation in the South Korean Peninsula. The variation of the heavy rainfall events was highly related with the variation of the upper level wind, lower level temperature and moisture, and middle level geopotential height. The synoptic variables were interacted with each other by secondary circulations and diabatic processes, producing the periodic feature of heavy rainfall occurrence.

SEVERE EAST-ASIAN MONSOON STORM SYSTEMS AND CLOUD PRECIPITATION PARTICLES

Tsutomu TAKAHASHI (Core Education Center, Obirin University)

Monsoons often produce torrential rainfall. During the past 15 years, 208 videosondes have been launched into monsoon clouds from 13 different locations in east Asia. The camera in the sonde captures particle images and transmits them to a ground station and associated Doppler radars record the systems through which the videosondes flew. The storm systems differ in different areas. When intense, low-level southerlies blew over Shanghai, rainbands developed within a meso-rain system. A cloud cell within a meso-rain system moving over southern Kyushu during Baiu suddenly ceased its forward motion. As small cells from the front and side merged into it, the stationary cell grew larger and produced heavy rainfall. A vortex, having formed over the see off Vietnam, entered a monsoon through our Chiangrai. A meso-rain system developed, composed of a thick upper layer and low-level stratocumulus and produced heavy rain for about three hours. At Songkhala, a typhoon and a northeasterly monsoon formed low-level convergence from which multi-cellular clouds formed, one after the other, producing heavy rain. At Ubon, thunderstorms, formed over the mountains, merged, producing an extremely large, anticyclonic echo. Outflow from this area produced a new rainband in the northeast. Over Melville Island, near Darwin, a cloud cluster developing along an east-west line within a sea-breeze convergence, suddenly changed direction, forming a north-south squall line, producing torrential rain and frequent lightning. Heavy rain over Ponape was produced from a rainband. Data from videosondes revealed three regions in which precipitation processes differed: Cool rain over interior China; mixed rain over the maritime continent; and a frozen drop mechanism over the western Pacific. Although the distribution of precipitation particles differed greatly in different storm systems, one common feature during torrential rain was the explosive growth of graupel, hail, and frozen drops in a narrow area just above the freezing level. The physical processes of rain accumulation through such explosive particle growth has been examined using a three dimensional cloud model containing detailed microphysics.

REVIEWS OF FIELD OBSEVATIONS ON MESOSCALE CONVECTIVE SYSTEMS OVER EAST CHINA SEA AND KYUSHU IN THE BAIU SEASON AND OVER THE JAPAN SEA IN WINTER

Masanori YOSHIZAKI, Teruyuki KATO, Chiashi MUROI, Hisaki EITO, Shugo HAYASHI (Meteorological Research Institute, Japan Meteorological Agency)

Several field observations on mesoscale convective systems (MCSs) and associated disturbances were conducted over East China Sea and Kyushu in the Baiu season and over the Japan Sea in winter. Some observed cases were studied by using the non-hydrostatic numerical model with fine horizontal resolutions. Various types of MCSs were observed: propagating rainbands, orographic stationary lines, meso-beta-scale vortices, longitudinal modes, transverse modes, and so on. Analytical works were done with data of upper-air sounding, Doppler radars, boundary-layer radars, GPS instruments and aircrafts. We review these MCSs and associated disturbances briefly.

JSM14/08A/A05-008   1115

STRUCTURE OF A COLD FRONT INDUCING A HEAVY RAINFALL DURING X-BAIU-99

Teruyuki KATO (Meteorological Research Institute)

The band-shaped heavy rainfall observed in northern Kyushu on 29 June 1999during the special observation of X-BAIU-99 was brought by the passage of a cold front that had been rapidly enhanced for a few hours. Radar observations show that when the cold front passed over northern Kyushu, convective cells in the front moved eastward at a speed of 15 m/s and northward at a speed of 20 m/s. The cells organized several meso-beta-scale convective systems (MbCSs). Each MbCS moved eastward at a speed of 10 m/s and northward at a speed of 5 m/s. Its speed was slow and the direction of its movement has a southward component in comparison with those of the cells. New convective cells repeatedly generated at the upstream edge of each MbCS. This buck-building formation maintained the present precipitation system. The present heavy rainfall was successfully reproduced by a nonhydrostatic model with a horizontal grid of 2 km. The structure with three horizontal scales of the cold front, MbCSs and convective cells was also simulated well. Developing height of simulated cells can divide into two levels. Most simulated cells developed to middle level of a height of 5-7 km in the western part of the simulated rainband, while developed heights of simulated cells in the eastern part of it have two peaks at the middle level and the tropopause (about 14 km). These peaks are not resulted from the release of latent heat of solidification because almost the same result can be gotten even in a sensitive experiment without the ice-phase processes. Since drier and colder air flowed from the west into the middle level of the eastern part of the simulated rainband, the convective instability was enhanced there. The convective cells reaching the middle level could develop to the tropopause.

JSM14/08A/A05-009   1130

STRUCTURE AND FORMATION PROCESS OF AN OROGRAPHIC LINE-SHAPED SYSTEM DURING BAIU SEASON IN WESTERN KYUSHU, JAPAN

Ayako NAKAMURA[1], Hiroshi UYEDA[1], Osamu MORITA[2], Yasufumi KITAZAKI[3], Hideki BEPPU[3] ([1]Hydrospheric Atmospheric Research Center, Nagoya University, [2]Graduate School of Sciences, Kyushu University, [3]Fukuoka District Meteorological Observatory, Japan Meteorological Agency)

During Baiu season, orographic line-shaped rainfall systems often appear in the west of Kyushu Island. They extend northeastward from an isolated island or a peninsula. One of them is the Goto line: the line-shaped rainfall system extending from the Goto Islands locating to the west-northernmost coast of Kyushu Island. The line forms along the northwestern coast of Kyushu Island.This system has about 150 km length, although its appearance is not much.The northeastern end of the line brings heavy rainfall over Fukuoka, which is a major city about 130 km far from the Goto Islands. For an accurate prediction of the heavy rainfall, case studies on formation mechanisms of the Goto line are necessary. As few researchers have studied the Goto line, the purpose of my study is to clarify the structure and formation process of the Goto line with the maximum length of 200 km on 19 June 2001. According to surface weather charts, the Goto Islands are located in the warm sector on the southern side of the Baiu front before the formation of this system. Upper-air sounding data in Fukuoka shows that the lower atmosphere has much moisture and nearly convectively stable stratification.There is a strong wind shear in the lower layer, with southerly winds around the surface and southeasterly on the low-middle level. The JMA Fukuoka operational radar data at 2.0 km height indicates thatrainfall region extends northeastward from the northeastern side of the Goto Islandsand forms a line-shaped rainfall system about 150 km in length with many convective cells.The axis of this line-shaped system rotates

counterclockwise graduallywith the shift of middle-level wind direction. In terms of a generation of individual cell that makes up the line,there are not only convective cells generating near the northeast side of the Goto Islandsbut also convective cells generating on the coast and mountain peaksof northern Kyushu in the downstream of the Goto Islands. On the former, it was found that the upslope forcingdue to isolated obstacles triggered convection from high Froude number (Fr=3.2).They are advected by middle-level winds.Some convective cells can re-develop or generateon the coast and mountain peaks of northern Kyushu.In this way, the Goto line keeps having about 150 km lengthand brings heavy rainfall at its northeastern end. We will discuss factors for the appearance of such orographic line-shaped rainfall systems.

JSM14/08A/A05-010   1145

CASE STUDY OF A DISSIPATING CLOUD CLUSTER: A TRMM-AIRCRAFT SIMULTANEOUS OBSERVATION

Sento NAKAI[1], Kenji NAKAMURA[2], Haruya MINDA[2], Hiromu SEKO[3] ([1]Snow and Ice Research Group, NIED, JAPAN, [2]Hydrospheric Atmospheric Research Center (HyARC), Nagoya University, JAPAN, [3]Forecast Research Department, Meteorological Research Institute, JAPAN)

A simultaneous observation of a dissipating cloud cluster (CC) was made over the East China Sea by Tropical Rainfall Measuring Mission (TRMM) and a dropsonde-equipped aircraft. Hourly GMS equivalent blackbody temperature (TBB) showed that the CC was in the dissipating stage. SSM/I precipitable water (PW) data showed that the CC developed in the area where $PW > 60mm$. The structure of the CC was analyzed using TRMM, dropsonde and rawinsonde data. The precipitation within the CC cloud area was mostly stratiform, and corresponded to dense anvil of the CC. The CC had multi-layer structure and thin anvil extended out of apparent CC cloud area. Shallow convection was developed below the thin anvil. The shallow convection generated the outflow from its upper part, resulting in a wet southerly flow directed toward the stratiform precipitation area. A minimum of potential temperature and a maximum of relative humidity were seen below thin cirrus of the CC. They were accompanied by increase of the wind speed. A positive potential temperature anomaly in the upper troposphere induced the negative pressure anomaly at the lower levels. The negative pressure anomaly could contribute to the acceleration of the southerly wind generated by the shallow convection in the lower troposphere. Meanwhile, southeasterly dry wind blew into the stratiform precipitation area of the CC. The dry inflow was cooled by evaporation within the precipitation of the CC, then mixed with the southerly flow, resulting in the formation of the negative potential temperature anomaly. Evaporation cooling occurred in the stratiform precipitation region, however, the negative temperature anomaly did not reach to the surface. The development of the shallow convection was not by convergence between ambient air and a cold pool, and can be attributed to the very humid environment of the lower troposphere favorable to the development of a convection.

JSM14/08A/A05-011   1200

A HIGH-RESOLUTION WIDE-RANGE NUMERICAL SIMULATION OF CLOUD BANDS ASSOCIATED WITH THE JAPAN SEA POLAR-AIR MASS CONVERGENCE ZONE (JPCZ) IN WINTER USING A NON-HYDROSTATIC MODEL ON THE EARTH SIMULATOR

Hisaki EITO[1], Chiashi MUROI[1], Syugo HAYASHI[1], Jun-ichi ISHIDA[2], Kouhei ARANAMI[2], Teruyuki KATO[1], Masanori YOSHIZAKI[1], Takayo MATSUO[1] ([1]Meteorological Research Institute, Japan Meteorological Agency, [2]Numerical Prediction Division, Japan Meteorological Agency)

A high-resolution wide-range simulation of cloud bands associated with the Japan Sea Polar-air mass convergence zone (JPCZ) in winter is performed using a non-hydrostatic model (NHM) with a 1-km horizontal resolution and a 1000 x 1000 km calculation domain (1km-NHM) on the Earth Simulator (ES). During winter monsoon season, broad cloud bands extending southeastward from the base of the Korean Peninsula sometimes bring heavy snowfalls to the Japan-Sea-side coastal regions of the Japan Islands. These cloud bands form over the JPCZ to which two cold airflows with different property converge. In this study, typical broad cloud bands that developed over the Sea of Japan on 14 January 2001 are examined. The NHM developed by Japan Meteorological Agency (JMA) is used in this study. The fully compressible equations with the conformal mapping are employed as the basic equations of NHM. Primary physical processes such as cloud physics, atmospheric radiation and mixing in the planetary boundary layer are also included in NHM. The NHM has been transferred to the ES, which is the fastest supercomputer in the world. The optimization of NHM to the ES is underway. In the present study, the vertical grid with a terrain-following coordinate contains 38 levels with a variable grid interval of 40 m near the surface and 1090 m at the top of the domain. The model top is 20.36 km. The time step interval is 5 seconds. The 1km-NHM is one-way nested within the forecast of the NHM with a 5-km grid (5km-NHM). The initial and boundary conditions for the 5km-NHM are provided from output produced by Regional Spectral Model (RSM). The RSM with a horizontal grid size of about 20km is a hydrostatic model used operationally in JMA. The 1km-NHM successfully reproduced cloud bands associated with the JPCZ, extending southeastward from the base of the Korean Peninsula to the San-in and Hokuriku districts over the Sea of Japan. Several cloud streets were also simulated around cloud bands. The JPCZ formed due to the convergence between warmer west-northwesterly flow from Korea Peninsula and colder north-northwesterly flow from Primorskii. A strong horizontal convergence line and an updraft line were found at the southwestern edge of the JPCZ. Deep convective clouds with a height of about 4 km formed along this line. Ice and snow particles from the convective clouds were transported by the southwesterly flow and organized anvil-like stratiform clouds extending northeastward. These two types of clouds formed the cloud bands over the JPCZ. The simulated features almost agree with those of the observations using by meteorological satellites, meteorological radars and an instrumented aircraft.

JSM14/08A/A05-012   1215

DIABATICALLY FORCED CIRCULATIONS AS TRIGGER FOR THE RELEASE OF STRONG CONVECTION

Manfred KURZ (Institute of Meteorology, University of Karlsruhe)

One prerequisite for the formation of mesoscale convective systems is the existance of moist potentially unstable air masses in the lower tropsphere. For the release of the instability, however, often an ascending motion is necessary in order to destroy stable layers on top of the moist air which would prevent convection, and to bring the air to saturation. In this respect the macroscale ascent ahead of an approaching upper trough or the mesoscale circulation across active fronts may function as trigger for the release of convection. During summer real fronts are often ill defined over the continent. There is, however, a mechanism which may lead to the formation of a very strong temperature contrast near surface within short time. That happens at the edge of larger cloud and precipitation areas during day time due to the different heat fluxes at both sides of the edge: Whereas the temperature below the cloud masses remains constant or is even reduced by the evaporation of falling rain, it rapidly increases due to heating from the ground in the area with no or only few clouds. As consequence of this diabatically forced frontogenesis a solenoidally direct circulation across

the newly established frontal zone is released with ascent of the heated air, desent of the cooler air and an ageostrophic motion from the cold to the warmer air near surface. If the warm air is potentially unstable, the ascent may lead to the releaseof the instability and the formation of convective clouds ahead of the cloud edge and parallel to it. Due to the production of cold air in the downdraft of these clouds the temperature contrast to the warm air is further enhanced which in turn leads to an intensification of the circulation. Altogether the new front may be transformed into a squall-line. As example for such a process a weather situation from July 2001 is presented. On two consecutive days marked surface fronts originated during the forenoon at the edge of cloud and precipitation areas produced by macroscale ascent ahead of short wave troughs over western and central Europe becoming vigorous squall-lines later and causing a lot of damage and even loss of life. It is important to note that the operationally used high-resolution model of Deutscher Wetterdienst provided clear signals for the described development of the surface fronts and also for the transformation into mesoscale convective systems.

THE AUGUST 2002 FLOOD IN CENTRAL EUROPE - LESSONS LEARNED

Gerd TETZLAFF, Manfred MUDELSEE, Michael BOERNGEN (Institut f?E Meteorologie Universität Leipzig)

Large parts of eastern Central Europe were affected by catastrophic floods in August 2002, caused by widely spread large precipitations. The damage was extraordinary high in particular in the catchment area of the river Elbe and its contributaries. The damage in Elbe region amounted to altogether over 5 Billion?. In the discussion following the flood many reasons were suggested to be responsible for the enormous height of the damage ranging from local land use to global climate changes.The return periods of the rains and the floods exhibited a wide interval bewteen about 100 to 200 years for the Elbe Flood and the areal precipitation, while on the slope of the Erzgebirge some of the smaller catchment areas return periods of up to about 1000 years were observed. The maximum measured 24 hour precipitation was 312 mm on the ridge of the Erzgebirge, a hitherto unreached magnitude.These rains were going with a weather situation all to well known to cause heavy rains on the mountain ranges of eastern Central Europe. The actual rain bearing low followed the the so called Vb path, part of an otherwise outdated classification of paths of low pressure systems. This path starts south of the Alpine Mountain range and curves northwards just east of the Alps. In August 2002 it brought warm and humid air to the north in a rather slow moving cyclone. The region of the Elbe catchment is characterised by several horizontally long mountain chains with different orientations, forcing the air to rise. No matter what exact orientation the air flow shows, there is always a mountain ridge there to enhance the upward air flow and the precipitation. In August 2002 it was the Erzgebirge that was located in the air flow and which was doubly effective, first in the southern flow and than with the propagation of the cyclone centre with the northern flow. The main rains were observed on the 12th of August.The main part of the rains, that is more than 100 mm, fell within one day, mainly on the northward slope of the Erzgebirge and its immediate northern surroundings. In some parts the major part of the rains fell within a time period of less than 12 hours. This caused two different of flood types. The small river and streams in or close to the mountain ranges experienced flash flood waves with often devastating effects, enormous damage and short warning periods. The Elbe flood wave had the character of an inundation.The weather forecast showed a rather good quality about 72 hours before the strong downpour started it was clear that unusually high amounts of precipitation were to be expected. The forecasts were substantiated until about 24 hours before the event. However, although the warnings were distributed timely it often proved difficult to transmit this information right through all levels down to the later victims.

JSM14/08P/A05-002	Invited	1435

DYNAMICS OF HEAVY PRECIPITATION EVENTS ON THE SOUTH-SIDE OF THE EUROPEAN ALPS

Huw C. DAVIES, Francois GHEUSI, Alexia MASSACAND, Heini WERNLI (Atmospheric and Climate Science, ETH Zurich)

During autumn there are frequent events of heavy precipitation on the south-side of the European Alps. Diagnoses are undertaken of (a) realized events using ECMWF analysis fields and (b) simulated events using an NWP model. The diagnoses are geared to examining :– (i) the significance and origin of the upper-level precursor flow signature that takes the form of a potential vorticity (PV) streamer, (ii) the sensitivity of an event to the internal structure of the streamer, (iii) the dependence of the near Alpine precipitating flow to the strength and direction of the incident low-level flow field, and (iv) the role of sub-Alpine topographic features in determining the location of geographically-preferred regions of heavy precipitation.

JSM14/08P/A05-003		1510

SPECTRAL CHARACTERISTICS OF THE BORA WIND

Mirko ORLIC, Miroslava PASARIC, Zoran PASARIC (Department of Geophysics, Faculty of Science, University of Zagreb)

Bora is a cold, dry wind that blows above the Adriatic from the northeast quadrant, most often during winter season. Its average speed is usually not high, but - due to the gustiness - the bora speed maxima may surpass 60 m/s. Thus, bora is one of the severest local winds in the world. Previous measurements of the bora speed and direction were performed either with the large sampling intervals (greater than 1 min) over a day or more or with the small sampling intervals (1-16 s) over an hour at most, thus tending to emphasize low- or high-frequency part of the spectrum, respectively. Measurements carried out recently at Senj, east Adriatic station which is notorious for its strong bora outbreaks, with a 1 s sampling interval over two months (December 2001 - January 2002), enabled for the first time broad characteristics of the wind spectrum to be determined. Micro-m-asta TM anemometer was positioned at the coast, 15 m above sea level. During the two-month measurement interval it recorded more than 20 bora episodes, the longest lasting over 82 hours. The maximum wind speeds surpassed 40 m/s, and they were - as expected - related to gusts, the low-pass filtered speeds being smaller than 20 m/s. Spectral analysis revealed (1) an increase of energy from the smallest resolved period (2 s) to about 1 min, (2) further increase of energy between 1 and 10 min with frequently occurring spectral maxima, (3) a spectral gap between about 10 min and 1 h, and (4) renewed increase of energy from 1 h to the largest periods as determined by the length of bora episodes. The last two are well-known characteristics of wind spectra observed worldwide. What makes the bora wind special is the energy continuum extending from 2 s to 1 min and accounting for more than 50% of the total wind variance - an obvious sign of strongly turbulent wind regime, and significant spectral peaks observed at periods from 3 to 8 min during most bora episodes. The position and intensity of

the peaks vary from one bora episode to the other, and even within an episode, but no regularity could be noticed in their occurrence. This seems to agree with the prevailing wisdom, according to which the bora gustiness is related to unstable gravity waves that develop at the upper boundary of the bora layer.

MOIST SINGULAR VECTORS AND DAMAGING EUROPEAN CYCLONES

Brian HOSKINS, Mariane COUTINHO (Department of Meteorology, University of Reading)

Singular vectors (SVs) are the structures that give optimal growth in a specified time. An investigation has been made of the extratropical impact of the inclusion in the ECMWF SV calculations of a linearised version of the full physics parametrization package. It has been found that it is in general the addition of a representation of large-scale condensation that is important. This leads to somewhat smaller-scale structures and larger growth. Both dry and moist SVs occur in regions of large baroclinicity but the location of the moist SVs is also determined by the availability of significant atmospheric water vapour. A number of damaging European cyclone cases has been studied. In each of these the addition of moist processes led to more focus on the area of actual development. The importance of a tongue of very humid air on the warm side of an extended region of high baroclinicity is apparent.

MOIST BAROCLINIC LIFE CYCLES ON A ZERO-PVE JET

Maurizio FANTINI (ISAC - CNR)

A family of mean atmospheric states in which the release of latent heat has its maximum possibleeffect on large scale flows is designed starting from the condition of zero equivalent potentialvorticity. The above hypothesis is discussed and the growth of baroclinic waves on such mean states is studied, comparing the dry with the saturated behaviour, both in linear and nonlinear phases of evolution. Specifically, we show growth rates, equilibration amplitudes, eddy fluxes and their feedback on the mean state, and overall structure of the meteorological fields, and discuss the impact that the release of latent heat has on idealized simulations of baroclinic cyclones, leadingto severe weather events.

JSM14/08P/A05-006		1715

HAILSTORM MODELING USING DOWNSCALING TECHNIQUE

Ernest N'Dri KOFFI, Stephane GOYETTE, Marc WUEST, Marjorie PERROUD (Department of Geosciences, University of Fribourg)

Global warming of about 0.6°C has been observed during the last century with a marked increase of the mean temperature of the lower atmosphere during the last 10 years. If anthropogenic emissions would not be reduced, current global climate models (GCM) predict a global warming of about 2°C between 1990 and 2100. Such warming may increase the frequency and the intensity of extreme climatic events (i.e., windstorms, heavy rain, tornadoes, thunderstorm days, and hail). The increase of severe weather events may have important impacts on societies, such as loss of life and property damage. However, due to the limited resolutions of GCMs that resolve only large and synoptic atmospheric features, they cannot predict how. To compensate for the limited resolutions of the GCMs, regional climate models (RCM) have been developed during the last decade for downscaling GCM simulations at regional scales. Such technique may be used to simulate severe local weather events, such as tornadoes, thunderstorm and hailstorm events. The purpose of this study is to assess the ability of the Canadian regional climate model (CRCM-2) to help predicting hailstorm events. The CRCM-2, which is a limited-area grid-point non-hydrostatic model that uses a three-time-level semi-Lagrangian semi-implicit time marching scheme, has been applied to the simulation of a hailstorm event observed in Switzerland in 1993. Sensitivity experiments of the model's results to the nested domain and to two moist convection schemes are also presented.

JSM14/08P/A05-007		1730

PREDICTABILITY OF HAILSTORM DEVELOPMENT IN VICINITY OF DEEP VALLEY

Mladjen M. CURIC, Dejan JANC, Vladan VUCKOVIC, Dragana VUJOVIC (Institute of Meteorology. University of Belgrade. 11000 Belgrade. YUGOSLAVIA)

The area of central Serbia is mountainous and intersected by numerous valleies. Strong hailstorms formed in such region produce extensive demage to property. Therefore, better knowledge of hailstorm dynamics as well as the predictability of their behavior in vicinity of deep valley are of essential importance. In this paper we analyze two characteristic cases. The first one relates to the hail cloud which moves down into the valley if the mid-tropospheric wind is parallel to the valley axes orientation. Initially, such cloud can be with or without precipitation and its base is lower compared to the top heights of valley sides. Observations clearly show that such cloud moves fastly along the valley due to the cell regeneration in front of the mother cloud. Due to the relationship between surface friction and pressure gradient force, the leading edge of the cold air outflow can lie close the front boundary of the mother cloud, which in turn, lead to the forced warm moist air updraft and cell regeneration. Such formed cell merges by the mother cloud. This process will prolong the cloud life and increase its propagation speed. Some other cloud moving in the same direction outside the valley, under same other environmental conditions, would have quite different behavior. The other case considers the hail cloud which generates and developes outside valley if the mid-tropospheric wind is not parallel to the valley. The such cloud then changes direction of movement and continues its development along the valley. Its development is controlled by cold air outflow and forced warm air updrafts over its leading edge. Further, the cloud regeneration during its motion along the valley is the same as in the first case. The prediction of behavior of such hail clouds in both cases is very difficult. Because of that, we simulate such cloud characteristics by help of the three-dimensional, fully-compressible cloud model (ARPS) with detailed treatment of hail spectrum. We

performed two experiments with initial soundings. In the first case, the mid-tropospheric wind is parallel to the valley axes and in the second case it is with an angle of   in counter clockwise direction relative to the valley axes. Our simulations show that observed characteristics of considered clouds are well reproduced. This gives us the hope that the direction and duration of cloud life in complex terrain conditions could be predicted successfully by using the numerical models.

JSM14/08P/A05-008   1745
ANALYSIS AND SIMULATION OF THE 4TH NOVEMBER 1966 STORMOVER ITALY

Piero LIONELLO[1], Andi NUHU[2], Simona DE ZOLT[2] ([1]Univ. of Lecce, Italy, [2]Univ. of Padua)

The 4th November 1966 storm was a very intense cyclone that developed in the western Mediterranean Sea, produced by the orographic cyclogenesis associated with a large low pressure system passing over Northern Europe.The 4th November cyclone, blocked by a large high pressure system over Eastern Europe, moved slowly across the Gulf of Genoa and Northern Italy, before being absorbed by a new large low pressure that arrived over Northern Europe from the Atlantic Ocean. During the passage of the cyclone across Italy, a huge amount of precipitation fell over the central and northern regions and the Italian coasts where hit by severe winds and waves. In the center of Florence, flooded by the Arno river, the water level reached the first floorof the houses. The storm surge in Venice reached almost two meters, by far thehighest ever recorded level. Damages to the artistic heritage and property were huge. In this study, a regional coupled atmosphere-wave-oceanmodel is used for the simulation of the event, using both NCEP and ECMWF re-analysis, testing coupled and uncoupled model setup, and differentinitial conditions. The simulations reproduce correctly the event and are very close to the observations, also for the atmospheric precipitationand the surge level, showing that the present model and computer capabilities would be able to predict the event.

THE 1998 ICE STORM: PLANETARY AND MESOSCALE ASPECTS

John Richard GYAKUM, Paul J. ROEBBER (Department of Atmospheric and Oceanic Sciences, McGill University)

The Ice Storm of 5-9 January 1998, affecting the northeastern United States and the eastern Canadian provinces, was characterized by freezing rain amounts greater than 100 mm in some areas. Economic damage exceeded five billion dollars. We study the thermodynamic impact of this unprecedented event with the use of a four-dimensional data assimilation spanning an 18-day period ending at 0000 UTC 9 January 1998. The Ice Storm consisted of two primary synoptic-scale cyclonic events. The first event was characterized by trajectories arriving in the precipitation zone that had been warmed and moistened by fluxes over the Gulf Stream Current and the Gulf of Mexico. The second and more significant event was associated with air parcels arriving in the precipitation zone that had been warmed and moistened for a period of several days in the planetary boundary layer of the subtropical Atlantic Ocean. These parcels had equivalent potential temperatures of approximately 330 K at 800 hPa as they traveled into the Ice Storm´s precipitation zone. We also examine mesoscale processes to understand their role in regulating the persistence, phase and intensity of the event. The region of maximum precipitation occurred in a deformation zone between an anomalously-cold surface anticyclone to the north and a surface trough axis extending from the Gulf of Mexico into the Great Lakes. The persistently cold near-surface air in the precipitating region was linked to orographic channeling of winds from the cold anticyclone to the north. Our model-based results show that, in the absence of the orographic channeling, little or no freezing precipitation would have occurred at Burlington, VT (BTV) during the Ice Storm. A frontogenetical focus within the St. Lawrence, Ottawa and Lake Champlain valleys was provided by orographic channeling of the cold air in combination with geostrophic southerlies in the warm air. The frontogenesis was an important contributor to the higher precipitation amounts during the Ice Storm, with model sensitivity estimates indicating that in the absence of the valleys, total freezing rain volumes would have been reduced by 12.1% and 16.5% in the first and second episodes, respectively. A discussion of the expected predictability of such an event is provided.

PROGRESS IN THE PREDICTION OF HAZARDOUS WEATHER IN THE UK

Brian William GOLDING (Met Office)

Recent severe weather episodes in Europe and the UK have coincided with the 50th anniversary of three major weather disasters: the East Coast storm surge, the Lynmouth flash flood, and the last London smog to highlight the importance of accurate warnings in enabling action to be taken to protect life and property. As well as issuing its own weather warnings, the Met Office provides forecasts at a range of lead times to enable partner organisations to generate warnings and initiate protective action. Considerable effort has recently been put into developing closer relationships with these partners, particularly through tailoring the forecasts to the expected impact of the hazard, in addition to its occurrence. Early warnings of major hazards are provided up to about 5 days in advance using information from the ECMWF Ensemble Prediction System (EPS). An automated processing system, PREVIN, has been developed that calibrates EPS output and identifies occasions when probability thresholds are reached for specific hazardous events. A first guess warning message is prepared for the forecaster on duty, which he may modify before issue. Results from the last winter season will be presented which indicate that successful probabilistic warnings are now being issued significantly earlier than without this guidance. Work is at an early stage to extend these capabilities to shorter ranges. Some good results have been achieved with an international experiment to create a Poor Man´s Ensemble, and this is now being built upon with plans for a Europe-wide super-ensemble. Development of a Met Office short range ensemble as a contribution to this, has just started and plans will be presented. Work is also focussed on impacts at this range, with a particular emphasis on health. At very short range the Nimrod nowcast scheme has been extended to the whole of Europe at 5km resolution and upgraded over the UK to include soil moisture and run-off, with river flow under development. A 2km grid version includes the Gandolf thunderstorm lifecycle models and is specifically focussed on improving the predictability of flash floods in the UK. Current work is focussed both on predicting the impact of severe weather, and on the potential of very fine resolution Numerical Weather Prediction to provide improved nowcasts.

SPECTRAL AND WAVELET ANALYSIS OF PRECIPITATION FROM MODELS AND RADAR

Charles A. LIN[1], Slavko VASIC[2], Isztar ZAWADZKI[1], Diane CHAUMONT[2], Lei WEN[2] ([1]Dept. of Atmospheric and Oceanic Sciences, McGill University, [2]Centre de Recherche en Calcul Applique (CERCA))

We perform a scale decomposition of precipitation fields from weather prediction models and compare with radar-retrieved precipitation fields. Two models are examined: GEM (Global Environmental Multiscale) model of the Meteorological Service of Canada, and the ETA model of NCEP (National Centers for Environmental Prediction) in the U.S. Precipitation values from the U.S. radar network are used to evaluate the model precipitation. A 6-day rain event from May 24-30, 2001 over a domain of extent 3,000 km in the continental US is examined. Spectral and wavelet methodologies are used for the scale decomposition of 3-hour precipitation accumulation in wavenumber space. The radar precipitation is aggregated to the model resolution, which is 24 km for both GEM and ETA models. The model results show less power than the radar at high wavenumbers. Cross spectral analyses of GEM/radar, ETA/radar and GEM/ETA are also performed, which reveal model bias and model uncertainty.

STRUCTURES AND ENVIRONMENT OF EXPLOSIVE DEVELOPING EXTRATROPICALCYCLONES IN THE NORTHWESTERN PACIFIC REGION

Akira YOSHIDA, Yoshio ASUMA (Division of Earth and Planetary Sciences, Graduate School of Science, Hokkaido University)

The characteristics for explosive developing extratropical cyclones inthe northwestern Pacific region were analyzed using a globalobjectively analyzed data set (GANAL) provided by the Japan MeteorologicalAgency (JMA). We classified these cyclones into three types by thepositions of formation and by the positions of most deepening. The first type originatedover the eastern Asian Continent and developed over the Sea of Japanor Sea of Okhotsk (OJ type). The second one also originated over the AsianContinent and developed over the northwestern Pacific Ocean (PO-Ltype). The last one originated and developed over the northwestern PacificOcean (PO-O type). Statistical analyses suggest that: OJ typecyclones frequently appeared in late fall and their deepening rateswere the smallest among the three types; PO-L type cyclones had mediumdeepening rates and mostly occurred in early and late winter; and PO-Otype cyclones had the largest deepening rates and mostly occurred inmid-winter. Two kinds of composite analyses were conducted tounderstand their structures and mechanisms of development. The firstcomposite analysis was the geographically fixed compositeanalysis. The results suggest that the atmospheric favorablecondition for each type cyclone is highly connected to the formation ofthe cold air mass over the Asian Continent. These conditions are largelyrelated to the seasonal variation over the area. The other analysis wasa composite for the cyclone structure at maximum deepening. Theanalyses suggest that: the OJ type cyclone had a short waveupper-level trough accompanied with jet streak and a stronger shallowcold front; the PO-L type cyclone, associated with a zonallystretched strong narrow jet stream, had a remarkable front system inthe mid-level and the warm front was clearly defined than the coldfront at the surface; and the PO-O type had a short and wide strong jetstreak, also a distinct front system in the mid-level, and strongprecipitation around the cyclone center. The analyses using the Zwack-Okossi development equation suggest that the crucial mechanism forthe development was vorticity advection for OJ type cyclones,temperature advection for PO-L type, and latent heat release for PO-Otype, respectively. We concluded that the difference of cyclonestructures between the three types affected the distribution of thevorticity, temperature advections, and latent heat release withinthe cyclone systems and caused their characteristic deepening rates.

SIMULATION OF AN EXTREME STORM EVENT: THE DECEMBER 1999 LOTHAR EVENT

Martin BENISTON, Stephane GOYETTE (Department of Geosciences, University of Fribourg)

Winter storms have been seen to be on the increase in recent decades in the North Atlantic ; while many of these affect northern Europe,some track further south and tend to generate very severe loss of life and damage to trees, agriculture, ecosystems, and infrastructure inregions that are not adapted to storminess (and hence are far more sensitive).In Switzerland, two very severe storms with wind velocities exceeding 175 km/hour (i.e., hurricane-force winds in the mid-latitudes)have been recorded in 1990 and 1999. This paper will present the dynamics leading to the mature phase of the Lothar wind storm that affectedFrance and the alpine region on December 25-26, 1999. Use of the Canadian Regional Climate Model successfully tracked the storm as it enteredEurope from the Atlantic sector, and then swept across France into Switzerland, generating a vigorous secondary system that exerted most ofthe damage in Switzerland. An animated sequence of the storm development will be shown, to enhance the details of the storm´s evolution,e.g., precipitation, enhancement of wind velocities, interactions with the surface, etc.

HAZARDOUS WINTER PRECIPITATION: ITS FORMATION AND STORM ENVIRONMENT

Ronald Earl STEWART[1], Kit K. SZETO[2] ([1]Department of Atmospheric and Oceanic Sciences, McGill University, [2]Meteorological Service of Canada)

Precipitation often leads to the the greatest impact of winter storms.Within extra-tropical cyclonic storm systems, this precipitation can occur in various forms including snow, rain, freezing rain and ice pellets as well as combinations of these. The precipitation is typically initiated through ice-phase processes although, before reaching the surface, it often undergoes phase changes as it falls, for example, through inversions having temperatures above 0C. These phase changes affect the surrounding thermodynamic environment and, consequently, its dynamics. The nature of the precipitation reaching the surface is closely coupled with such responses in its interacting and surrounding environment. In this presentation, a review will be given of our knowledge of precipitation formation within extra-tropical cyclonic storms and the interactions with its environment. This will be followed by an examinationof key outstanding scientific issues associated with this topic.

LEE CYCLOGENESIS IN THE WESTERN CANADIAN ARCTIC REGION

Masaya KATO, Yoshio ASUMA (Division of Earth and Planetary Sciences, Graduate School of

Science,Hokkaido University)

Lee cyclogenesis frequently occurs in the mountainous west coastregion of the North American continent. Several cases were observedin the western Canadian Arctic region during the BASE (Beaufort and Arctic Storms Experiment) in 1994. A strong, almost stationary, parent lowwas over the Gulf of Alaska. There was a quasi-stationary Arctic front over the western Canadian Arctic region on the lee side of the mountainous west coast regions. A positive potential vorticity anomaly in the upper level separated over the Gulf of Alaska and moved across the mountains over the Arctic front. Stability decreased and relative vorticity increased in the lower frontal zone due to potential vorticity conservation, and secondary depression occurred in the lee region. To investigate these mechanisms and structures, we analyzed the 16 September 1994 case, focussing on structures of a potential vorticity, a potential temperature, and moisture using a global objectively analyzed data set (GANAL) provided by Japan Meteorological Agency (JMA) and PSU/NCAR MM5 numerical model. Horizontal temperature gradient associated with an Arctic front intensified due to warm air advection from the parent low. As a result, baroclinicity increased in the lee region. A positive potential vorticity anomaly moved over the region and generated cyclonic circulation. The moisture from the Pacific Ocean advected into the region and the secondary cyclone was depressed. We found that the moisture advection was also an important mechanism for lee cyclogenesis.

HIGH-RESOLUTION MODELING OF A POLAR LOW OVER THE LABRADOR SEA

Rebekah E. MARTIN, G.W.K. MOORE (Department of Physics, University of Toronto)

Polar lows are short-lived, intense mesoscale storm systems that develop over oceans in polar regions. The interaction of the very cold atmosphere with the relatively warm ocean below is what provides these storm systems with their intense energies. As a result of their small spatial and temporal scales, and their development in regions where observational coverage is minimal, models and observations can easily miss the genesis and lifetime of a polar low. A polar low that was imaged by the RADARSAT-1 satellite on December 29, 1997 is simulated with the Penn State?NCAR fifth-generation Mesoscale Model (MM5). Model results of the near surface wind fields are compared to the SAR imagery from the satellite and are found to possess strikingly similar features. Specifically, the low wind speed eye of the storm and high wind speed fronts are apparent in both the SAR image and the model output. The high-resolution output of the model provides a particularly detailed view of the structure and dynamics of this polar low.

JSM14/09A/A05-009   1205
IN-SITU MEASUREMENTS AND THE SYNOPTIC CONDITION OF A POLAR LOW OVER THE NORWEGIAN SEA DURING THE AAMP98 CAMPAIGN

Yoshio ASUMA[1], Masataka SHIOBARA[2], Makoto WADA[2], G.W.K. MOORE[3] ([1]Division of Earth and Planetary Sciences, Graduate School of Science, Hokkaido University, [2]National Institute of Polar Research, [3]Department of Physics, University of Toronto)

Airborne measurements were made within a polar low over the Norwegian Sea on March 9, 1998, during the AAMP98 (Arctic Airborne Measurement Program in 1998). In this presentation, we will report the synoptic scale and meso-scale structures of the polar low using the PSU-NCAR mm5 meso-scale model. A comma-shaped meso-alpha scale low appeared in the NOAA satellite images and the cloud head of the low turned around and became less organized. A well defined polar low formed at the end of the cloud head with a distinct secluded core (˝eye˝) and convective cloud lines. The meso-scale model results show a cold-core vortex over the Scandinavian Peninsula and the meso-alpha scale low was formed over the wedge of relatively warm SST extended toward the west coast of the Svalbard Islands. Although the polar low needs further investigation in the model, an upper level short wave which was deepened by the warm air advection of a strong synoptic scale low over the Iceland approached over the area and a polar low was formed in the actual case.

STRUCTURE OF RAINDROP SIZE DISTRIBUTIONS FROM POLARIMETRIC RADAR VARIABLES IN A TROPICAL SQUALL LINE

S.-G. PARK[1], K. IWANAMI[1], M. MAKI[1], R. MISUMI[1], T.D. KEENAN[2], H. MORIWAKI[1] ([1]National Research Institute for Earth Science and Disaster Prevention, [2]Bureau of Meteorology Research Centre, Melbourne, Australia)

Spatial structure of raindrop size distributions (DSDs) within a tropical squall line is analyzed based on estimates by an improved DSD estimation method using polarimetric radar variables. The improved method is similar to the algorithm of Seliga and Bringi (1976) and Zhang et al. (2001). The key of the improved method is to estimate modified gamma DSD parameters through minimizing a cost function that consists of differences between three polarimetric variables (radar reflectivity ZHH, differential reflectivity ZDR, and specific differential phase KDP) observed by radar and theoretical reference data calculated by T-matrix scattering simulations. In addition, the cost function is constrained by three relationships among the gamma DSD parameters, i.e., N0-μ, N0-Λ, and μ-Λ, with different weights. According to experiments using simulated radar data based on ground-based disdrometer data, it was found that the improved method can estimate Λ, D0, Log(N0), and μ with fractional standard errors of 13.4%, 11.5%, 4.0%, and 47.9%, respectively, when the N0-μ and N0-Λ relationships are considered as weak constraints with weight of 0.01, while the μ-Λ relationship is considered as a weaker constraint with weight of 0.001. The improved DSD estimation method was applied to a tropical squall line of oceanic type observed in Darwin at 0920 UTC 15 January 1999 by C-band polarimetric radar (C-POL) of Bureau of Meteorology Research Centre (BMRC), Australia. The squall line exhibited a deep convective cell in leading area and stratiform region embedding bright bands in trailing area. In particular, the bright bands were collocated with the generating cells aloft that characterized by large positive KDP indicating the presence of ice crystals with their major axes oriented horizontally, such as dendritic crystals. According to the analyses of the

estimated DSDs, the convective region was characterized by large-drop spectra (median volume diameter D0=2.2 mm) due to strong convective motions. In the stratiform region, DSDs below bright band collocated with the generating cell aloft were characterized by relatively large-drop spectra (D0=1.7 mm), while the stratiform DSDs without bright band are characterized by relatively small-drop spectra containing numerous small drops (D0=1.4 mm). This result in stratiform region suggests that ice crystals in generating cell aloft play an important role controlling production of large raindrops by the seeder-feeder mechanism. On the vertical variations of DSDs, the stratiform DSDs were close to the exponential DSD and were characterized by little variations, while the convective DSDs exhibited large variations.

EXTRATROPICAL TRANSITION OF TROPICAL CYCLONES: CANADIAN FORECAST CHALLENGE AND RESEARCH EFFORTS

James David ABRAHAM, Walter STRAPP, Chris FOGARTY (Meteorological Service of Canada)

Extratropical transition (ET) has been raised as a forecast challenge by meteorologists from all ocean basins affected by tropical cyclones. ET is associated with the poleward movement of a tropical cyclone (TC) into the middle latitudes, and is normally associated with the weakening or decaying stage of the TC as it enters a highly sheared baroclinic environment, moving over a cooler sea surface or over land. However, this transition from tropical to extratropical can result in an increase in the storm intensity and the associated hazardous weather elements. The objective of this presentation is to examine this threat.Typical problems for weather forecasters in all regions that experience ET include accurately predicting their track, intensity, and impacts. The most challenging issues are associated with the potential large amounts of precipitation, continued high wind speeds, and the generation of large ocean surface waves and swell. Furthermore, the forward speed of these storms often accelerates from a typical 5 m/s in the tropics to in excess of 25 m/s in the midlatitudes. This requires that warnings are issued with adequate lead-time for mariners or others to take action in order to prevent loss of life or economic damage.Given the ET forecast challenges in Canada, the Meteorological Research Branch and the Canadian Hurricane Centre of the Meteorological Service of Canada (MSC)agreed to consider modest ET field studies. One aspect of this program wouldbe the use of National Research Council's (NRC) Convair 580 to conduct meteorological and microphysical investigations of ETs passing offshore Atlantic Canada. As it turns out, there had never been an aircraft field investigation of ET behaviour before this initiative. During the period 17-20 October 2000, Hurricane Michael provided this opportunity, and a flight was conducted on the afternoon of the 19th. A follow-up flight was conducted nearly one year later on 15 October 2001 into Tropical Storm Karen. In this presentation, we describe an overview of the ET forecast challenge in the Western Atlanrtic Basin. As well, we provide a brief overview of the details of research flights into two distinct tropical cyclones undergoing extratropical transition near Nova Scotia. This preliminary data set showssubstantial asymmetries in moisture and winds associated with these ET systems. Their capacity to maintain large moisture contents while interacting with midlatitude baroclinicity poses a threat of intense rainfall while their rapid translational speeds can create very high winds east of their tracks, endangering the lives of mariners. Furthermore, very strong winds and wind shears in the low-levels reveal the potential danger these storms pose in particular to aviation and marine interests.Further analyses of this data, including comparisons with model simulations and inclusion of additional oceanographic data are planned. These results are also being used to justify a collaborative atmospheric-oceanographic ET field experiment being considered for the 2003 and 2004 hurricane seasons.

A DIAGNOSTIC CASE STUDY OF EXTRATROPICAL TRANSITION OVER EAST ASIA

Chih-Shin LIU[1], George Tai-Jen CHEN[1] ([1]Department of Atmospheric Sciences, National Taiwan University, [2]Weather Forecast Center, Central Weather Bureau)

As tropical cyclones recurve poleward and move into midlatitudes, they often interact with baroclinic systems and transform into extratropical cyclones. During and after extratropical transition (ET), these cyclones can at times develop rapidly, produce extremely heavy precipitation and strong winds, and cause damage of properties and loss of lives. Unfortunately, such processes are often not well predicted by operational models, and still challenge weather forecasters. Recently, the ET process has attracted considerable attention in various regions of the world. But over East Asia, the topic is rarely studied. The present study diagnoses the ET process of Typhoon Winnie (1997) over mainland China. Results suggest that the ET of Typhoon Winnie is different from many prior ET processes, which are similar to Petterssen Type-B scenario. After making landfall over mainland China on 18 August 1997, Winnie weakened rapidly, recurved, and transformed into an extratropical cyclone possessing both cold and warm fronts in the lower troposphere. The cyclone subsequently interacted with midlatitude system and reintensified with a maximum deepening rate of 10 hPa in 12 hours. The mechanism responsible for the cold frontogenesis associated with the transforming cyclone at low levels was evaporative cooling, which strengthened the cold tongue at the western section of the cyclone. Such a frontogenic process is very different from that of a midlatitude cold front associated with an ordinary extratropical cyclone. Preliminary results of diagnosis through the use of piesewise PV inversion indicate that PV anomalies associated with the cyclone in the lower to middle levels induced evident warm-air and cold-air advections at mid-levels when the cyclone migrated into a mid-level baroclinic zone. Through hydrostatic relationship, the dipole structure of temperature advections caused an amplification of the initially weak upper level waves, which, with a proper phase and strong vertical coupling, caused the cyclone to develop rapidly. Through an analysis on the dynamic tropopause (defined by the 2.5 PVU surface where 1 PVU = 10^{-6} K m^2 kg^{-1} s^{-1}), it was found that the PV anomalies associated with the cyclone contributed to an unusual summer tropopause folding, which in turn contributed directly to the surface cyclogenesis as the cyclone was most intense after ET. As a result, the interaction between the cyclone and the baroclinic systems led to the development of upper level waves, which in turn contributed to surface cyclogenesis first by vertical coupling and then by superposition processes. Thus, it is suggested that the cyclones' re-intensification was a manifestation of the self-amplification process.

REGIONAL NUMERICAL SIMULATIONS AND VALIDATION OF A RAINFALL EXTREME EVENT USING TWO DIFERENT CUMULUS PARAMETRIZATION

Giovanni DOLIF NETO, Tercio AMBRIZZI (Department of Atmospheric Sciences, University of Sao Paulo)

This work presents numerical simulations of a rainfall extreme event that occurred in October 1st, 2001 in the State of São Paulo, Brazil. The amount of precipitation during this event was around 103 mm in 24 hours, being one of the biggest of the year. The Emergency State Agency registered 15 flooding points and 2 deaths. The rainfall was associated with a squall line propagating parallel to a cold front. The PSU/NCAR MM5 regional model was run with two schemes of cumulus parametrization: Anthes-Kuo and Grell. There were three nested

grids, with 90, 30 and 10 Km of resolution. Based on the literature (Dudhia et al., 2001), the Grell scheme was fixed for the nests 2 and 3 and, for the mother domain the Grell and Anthes-Kuo eschemes were used. The validation was qualitative and it was done by analyzing the three grids. Accumulated precipitation fields every 3 hours were compared with satellite images and with 3 Km CAPPI. The qualitative comparison showed that the Anthes-Kuo scheme used in mother domain had the precipitation spatial field much closer to the observed than the Grell scheme. This result was also found for the nests 2 and 3 because of the ˝two-way interaction˝ for the three nests. Therefore the Anthes-Kuo escheme seems better than Grell for a 90 km grid resolution. On the other hand, both schemes underestimated the precipitation over the great Grande São Paulo region.

BAIU HUNTER 2003 IN KYUSHU BY AEROSONDE

Tetsuo NAKAZAWA (Meteorological Research Institute)

Special Observation on heavy rainfall system along the Baiu Front over Kyushu by using Aerosonde, Baiu Hunter 2003, is now performed in this June/July 2003. The main objective of the observation is to improve and verify Non-Hydrostatic Model by assimilating the detailed observation data of the Baiu Front over the west of Kyushu and heavy rainfall systems associated with the Front. Under the Global Warming Mission of Japanese Model of "Project on Harmonious Coexistence of Human, Nature and Earth" funded by the Ministry of Education, Culture, Sports, Science and Technology, JMA and MRI will take charge of a program named "Development of high accuracy and resolution climate model" This program includes the observation component to verify and improve the high-resolution model. The observation is for the heavy rainfall systems in the Baiu Frontal Zone. The main observational platform for the observation is an unmanned aircraft, Aerosonde. The observation by Aerosonde is different from the previous passive one, but plunge into the disturbed atmospheric phenomena directly and actively to measure temperature, moisture and wind.

SHORT-RANGE RAINFALL FORECAST WITH QUANTITATIVE PRECIPITATION MODEL

Jai Ho OH[1], Ok-Yeon KIM[1], Hanse HANSE YI[1], Tae-Kuk KIM[1], Ryohei MISUMI[2] ([1]Dept. of Env. Atmo. Sci., Pukyong National Univ., Busan, Korea, [2]National Institute for Earth Science and Disaster Prevention, Tsukuba, Ibaraki, Japan)

Recently, many people have suffered from the unusual severe weather phenomena such as heavy rains and very wild typhoons. However, it is not easy task to provide reasonable information on these severe weather events. Accordingly it has been eager to find a suitable methodology to provide an early warning against these severe weather events. Quantitative precipitation forecasts and probabilistic quantitative precipitation forecasts (QPFs and PQPFs, respectively) might be one of the most promising methodologies for reasonable warning on the flesh floods. QPFs and PQPFs must be on time because severe weather phenomena have a tendency to be developed very quickly and locally. By these reasons, they may not allow to be announced in a reasonable advanced time. Accordingly it is desired to develop a methodology to provide detail information locally and quickly. A fine-mesh non-hydrostatic mesoscale model can be hired, however, it requires a significant computational resources as well as integration time so that it may not meet the time restriction to be forecasted in operational sense. An alternative way to provide necessary information on fine-mesh rainfall is utilizing a diagnostic rainfall model to avoid heavy computational requirement fine-mesh full-dynamic non-hydrostatic mesoscale model.In this study we examine the capability of diagnostic rainfall model in terms of how well represented the observed several rainfall events and which is the most optimistic resolution of the mesoscale model in which diagnostic rainfall model is nested. Also, we examine the integration time to provide reasonable fine-mesh rainfall information. The diagnostic rainfall model used in this study is the named QPM(Quantitative Precipitation Model), which calculates the rainfall by considering the effect of small-scale topography which is not treated in the mesoscale model. As a result, QPM has a capability to provide fine-mesh rainfall information in terms of time and accuracy compared to full dynamical fine-mesh mesoscale model.

STRUCTURE OF CUMULONIMBUS CLOUDS DEVELOPED OVER THE SLOPE OF MOUNTAIN IN SUMMER

Tetsuya SANO[1], Kazuhisa TSUBOKI[1], Ichiro TAMAGAWA[2] ([1]Hydrosheric Atmospheric Research Center, Nagoya University, [2]River Basin Research Center, Gifu University)

In moist atomosphere, the severe precipitation phenomenon often occurrs by a forcing of topography over a mountain region. Especially, insummer, many cumulonimbus clouds in the mountain region develop greatly and cause severe precipitation. In this study, the structureof the cumulonimbus clouds which developed over the south slope of the Ibuki mountains in the afternoon of July 5, 2000, was investigated by Dopplar radar observation. The Ibuki mountains are located in the southwest area of Gifu prefecture in Japan (136.6°E,35.6°N) and have the strike from southwest to northeast. A cold air trough moved over Japan and the atmosphere was convectivity unstable. Many cumulonimbus clouds therefore developed in the mountain regions. The direction of vertical wind shear of the environment was from northwest to southeast whichwas almost parallel to the direction of the south slope of the Ibuki mountains. The cumulonimbus clouds were observed by Dopplar radars forabout 2 hours over the south slope of the Ibuki mountains. It hadabout 20 cellar echos with successive generation and disappearance. Itwas aimed to the behavior of the cellar echos. First cellar echo,named Primary cell, weakening with tilting to downshear sidemoved down the slope. Thereafter some new cellar echos, named Secondarycells, occurred and developed with tilting to downshear side or standing upright on the upstream side of Primary cell,around the occurence point of Primary cell. There were 6 systems in theconvective echo and they occurred with lining in parallel to the strike of the Ibukimountains. The systems of cellar echos, especiarily the development of Secondary cells, contributed to the development of the cumulonimbus clouds. When Secondary cells were developing, the warm wind from the mountain side to theconvective echo was observed for about 1 hour at an AMeDAS point, Tarumi, in the Ibuki mountains. It is considered that the existence of the warm air over the top side of the mountains has influenced to the development of Secondary cells.

A MESOSCALE SIMULATION STUDY OF A HEAVY RAIN EVENT OVER SOUTHERN TAIWAN IN MEIYU SEASON

Lisa T.C. CHANG, George T.J. CHEN (Department of Atmospheric Sciences, National Taiwan University)

There are about 4-5 frontal systems affecting Taiwan during Meiyu season each year. The

Meiyu front is usually accompanied by a nearly continuous cloud band, which produces stratiform and/or convective precipitation. During the period of 28-30 May 2001, a series of mesoscale convective systems (MCSs) developed in a weakly synoptic-scale control environment near Taiwan along a retrograde moving Meiyu front. The development and northeastward propagation of the MCSs produced heavy rainfall over southern Taiwan, with a maximum 24-h accumulation rainfall of 300 mm. This study presents the results of a numerical simulation of this heavy rain event using the atmospheric part of the Coupled Ocean/Atmospheric Mesoscale Prediction Systems (COAMPS) developed by Naval Research Laboratory (Hodur 1997). Part of the difficulty in simulating MCSs is the lack of mesoscale details in the initial state. The mesoscale features may play a more important role in initiating a deep convection especially when the synoptic-scale forcing is weak. In this case, the initial convection developed over the ocean where observational data were sparse. One of the practical approaches to include mesoscale features in the model initial condition is to blend satellite scatterometer QuikSCAT surface wind measurements into the COAMPS analysis procedure where the NOGAPS 1°x1° global analysis data were used as the first guess. The COAMPS control run was conducted with full physics and with the improved initial condition. The ability of the model to reproduce the structure and evolution of these MCSs will be evaluated. Some of the preliminary results from the sensitivity tests, as an effort to investigate effects of different mechanisms in initiating and maintaining of the convective precipitation, will be discussed as well. References Hodur, R.M., 1997: The Naval Research Laboratory's Coupled Ocean/Atmosphere Mesoscale Prediction System (COAMPS). Mon. Wea. Rev., 125, 1414-1430.

BAIU-FRONTAL MESOSCALE CONVECTIVE SYSTEMS IN THE LEEWARD SIDE OF SMALL ISLANDS (KOSHIKIJIMA LINES) OBSERVED WITH A BOUNDARY LAYER RADAR AND RAWINSONDES

Yasuko UMEMOTO[1], Michihiro TESHIBA[2], Yoshiaki SHIBAGAKI[3], Hiroyuki HASHIGUCHI[2], Yoshinobu TANAKA[4], Manabu D. YAMANAKA[5] ([1]Graduate School of Science and Technology, Kobe University, [2]Radio Science Center for Space and Atmosphere, Kyoto University, Japan, [3]Osaka Electro-Communication University, Japan, [4]Meteorological Research Institute, Japan Meteorological Agency, [5]Frontier Observational Research System for Global Change, Japan)

In order to understand the structures and mechanisms of mesoscale convective systems (MCSs) associated with the Baiu front, a special observational campaigns called X-BAIU have been conducted in East China sea and Kyushu Island, located in the western part of Japan, from 1999 to 2002.We installed a boundary layer radar (BLR) at the western side of Kyushu Island to observe the inner structures of MCSs seen frequently in the observational area.In this study, we notice line-shaped MCSs generated by some mountains of Koshiki Island, called ``Koshikijima line´´, and reveal vertical profiles of wind and stability by using the BLR and GPS-sonde soundings.While the Koshikijima line is observed, Kyushu Island is located in the warm sector of a cyclone, and covered by southwesterly winds and a moist convectively unstable atomosphere associated with the cyclone. The direction of the line extends to the leeward of the mountains (Koshiki Islands), and the line lasts for about half a day with the development and weakening.From the results observed by the BLR, we find that the vertical shear of horizontal wind, especially of the component normal to the line, is about 3 m/s/km or larger without depending upon whether the Koshikijima line exists or not.We have observed Koshikijima lines also in 1999, of which the development is much larger than that in 2002.Differences between the cases in 1999 and in 2002 are found in relative humidity and horizontal wind speed.In 2002, relative humidity and horizontal wind speed in the lower troposphere below about 3km altitude are about 80 percent and 20 m/s, respectively, which are both smaller than those in 1999.We consider that the lower humidity and the smaller horizontal wind speed contribute to the shorter lifetime and the suppressed development in 2002.

OBSERVATIONAL STUDY OF THE OROGRAPHIC EFFECT ON THE PROPAGATION OF CONVECTIVE SYSTEMS IN NARA-OSAKA AREA

Ken-ichiro ARAI[1], Masayuki KAWASHIMA[1], Yasushi FUJIYOSHI[1], Masahito ISHIHARA[2] ([1]Institute of Low Temperature Science, Hokkaido University, [2]Japan Meteorological Agency, Tokyo, JAPAN)

The evolution of convective systems that developed in Nara-Osaka area, central region of Japan, is described using data fromdual-Doppler radar system and surface meteorological instruments.At first, convective cells developed in the Nara Basin, which locateson the lee side of the Mountain Range of Ikoma. Then they wereorganized into a stationary rainband. Convective radar echoes began tomove to the Osaka Plain when cold air generated by thunderstormsflowed into the windward side through the col of the mountains.It is suggested that cold outflows from the decaying convective systemover the Nara Basin triggered the new convective cells over the OsakaPlain by forced-lifting mechanism. The analysis suggests the important and interesting role of theMountain Range of Ikoma. First, it may contribute to the developmentand formation of stationary rainband in the lee side of the mountain.Second, it seems to block the outflow of evaporatively-induced coldair into the Osaka Plain until the cold air becomes deep enough.However, once the deep cold air flow out of the Nara Basin, it wouldbe accelerated on the slope of Ikoma and then triggered strongconvections and heavy rainfall at the front. The cold air also causesthe hazardous strong gust for aviation.

STRUCTURE OF MESOSCALE CONVECTIVE SYSTEMS OBSERVED WITH UHF RADAR /INTEGRATED SOUNDING SYSTEM DURING THE SOUTH CHINA SEA MONSOON EXPERIMENT (SCSMEX) AND THE GREEN ISLAND MESOSCALE EXPERIMENT(GIMEX)

Pay-Liam LIN, Hsin-Hon LIN (National Central University)

The NCU(National Central University) ISS(Integrated Sounding System) was deployed in Dongsha island during May 5 to June 25, 1998 for the SCSMEX and deployed in the southeastern coast of Taiwan(Cheng-Kung station) during May 5 to June 30,2001 for the GIMEX. The primary goal of these deployments were to measure the mesoscale structure of convective weather system associated with the onset, maintenance and variability of the monsoon over the South China Sea area and the southeastern coast area of Taiwan. A wide variety of convective systems were observed during SCSMEX and GIMEX. The ISS observations provide a detail kinematic and thermodynamic structure change of the monsoon flow and the local circulations. The UHF profiler radar that operates at 915 MHz in ISS are useful for precipitation structure measurement because of its sensitivity to hydrometers. The identification and classification of the falling paticles associated with precipitation is very helpful for the understanding of the stratiform and the convective characteristics, and the cloud physics and dynamics of the convective systems. The three moents of the Doppler Spectrum provide us with information about the hydrometers in the mesoscale convective systems. Correlations between vertical radial velocity and range corrected signal power of 915 MHz radarwind profiler can be used to determine weather or

not precipitation is presentand what type of precipitation it is. Several major convective events occurred in SCSMEX and GIMEX will be discussed and compared in this investigation.

JSM14/09P/D-012 Poster 1400-076

HEAVY RAINFALL PRODUCED BY A LONG-LIVED LINE-SHAPED PRECIPITATING CONVECTIVE-CLOUD SYSTEM

Sachie KANADA[1], Kazuhisa TSUBOKI[2], Haruya MINDA[2] ([1]Advanced Earth Science & Technology Organization (AESTO), [2]Institute for Hydrospheric-Atmospheric Sciences, Nagoya University)

Heavy rainfall is very often caused in subtropical humid-climate region by a meso-scale precipitating convective cloud system, which are subject to orographic effect. In 1997 dual-Doppler radars of Nagoya University were installed in the Nagasaki Peninsula and Amakusa in the Kyushu District, respectively, in order to study the relationship between an orographically modified convective-cloud system and heavy rainfall. During the observation period, line-shaped precipitating systems were often seen in the observation area. Especially line-shaped precipitating systems around the base of the Nagasaki peninsula lasted longer period than other ones and brought a huge rainfall amount at the same place. The main purpose of this study is to reveal the structure and maintenance processes of the long-lived line-shaped system that produce heavy rainfall. On July 11 in 1997 an extremely heavy rainfall was concentrated around the base of the Nagasaki Peninsula in the Kyushu District. The horizontal distribution of total rainfall amount from 0900 LST on July 11 to 0300 LST on July 12 showed highly concentrated rainfall amount of 176 mm as maximum value. It is noted that total rainfall amounts larger than 10 mm were observed only in the limited area around the base of the peninsula. Radar-data analysis revealed that this highly concentrated rainfall was produced by a long-lived line-shaped convective cloud system that was maintained for about 18 hours almost in the same place and which extended in the direction of low-level ambient winds. The length and width of its radar-echo band were over 60 km and about 10 km, respectively. Interestingly its length extended with period of 2 to 3 hours. The radar-echo band was composed of many convective cells whose radar-echo tops were about 6 km. Most of them formed successively in the upwind side of the band and moved along its direction at a speed of 17 m/s.Totally 72 cellular-echoes were observed in Line-1 and they had a tendency to be intensified, moving in the downwind direction in the area fixed geographically. The intensification of radar-echo was seen in three areas between two mountains, named ´the Bay of Isahaya´. The three-dimensional distributions of airflows were observed by the dual-Doppler radars. The convergence and divergence zone extend widely along the radar-echo band in the northwestern side and the southeastern side, respectively. This feature is evident during the developing stage.The convergence zones distribute all over the half side of the line-system not among each cellular-echo.This feature indicates that this convergence zone comes from not individual convective activity of cellular-echoes but effected by orography. 3-dimentional structure of this line-shaped system including airflow field were analyzed in detail and the characteristic pattern of wind fields affected by orography was revealed. The results of more detailed analysis will be presented together with the results of numerical simulation on airflows and precipitating convective clouds around the Nagasaki Peninsula.

JSM14/09P/D-013 Poster 1400-077

CHARACTERISTICS OF ENVIRONMENT DETERMINING LIFETIME OF CONVECTIVE CELLS WITHIN MESOSCALE CONVECTIVE SYSTEM IN HUMID SUBTROPICAL REGION

Shingo SHIMIZU[1], Hiroshi UYEDA[1], Kazuhisa TSUBOKI[1], Taro SHINODA[1], Yoshimasa TAKAYA[2], Teruyuki KATO[2], Masanori YOSHIZAKI[2], Hiroyuki YAMADA[3], Biao GENG[3] ([1]Hydrospheric Atmospheric Research Center, Nagoya University, [2]Meteorological Research Institute, Japan Meteorological Agency, [3]Frontier Observational Research System for Global Change)

In order to reveal the maintenance mechanism of severe MesoscaleConvective System (MCS), we need to investigate what mechanismdetermines lifetime of convective cells within MCSin a humid subtropical region. Because MCSs in a humid subtropicalregion have convective cells with different lifetime from that in a dry region as the Great Plains in the U.S.The aim of this study is to clarify characteristics of environment determining features of convective cell within MCS in the humid subtropical region such as East Asia. An isolated MCS, observed over the Kanto Plain on 24May 2000, and three line-shaped MCSs, observed during heavy rainfallexperiment in the downstream region of Yangtze River from June to July2001, were selected as examples of MCS developing in the humid subtropical region. These four MCSs were investigated with dual Doppler radar analysis,Meteorological Research Institute Non-Hydrostatic Model (MRI-NHM),and Japan Meteorological Agency Regional objective ANALysis (RANAL). Dual Doppler radar analysis revealed that the four MCSs had following features. The isolated MCS was supercell type with a short-lived convective cell.Three line-shaped MCSs were back-building rainband type with long-livedconvective cells (BBL), back-building rainband type with short-lived convectivecells (BBS), and broken rainband type with short-lived convective cells (BRS). By using MRI-NHM and RANAL, it was revealed thateach four MCSs was formed in environments possessing different buoyancy, vertical wind shear, and vapor distribution.This study compared the differences among environments in which four MCSs were formed. Mid-level humidity mainlydetermined the lifetime of convective cell.In a moist mid-level environment, a convective cell within BBL maintained for 78 minutes. On the contrary, in a dry mid-level environment,convective cells within the supercell, BBS, and BRSmaintained for only 30 minutes. The strength of evaporatively-cooled downdraft corresponded to the lifetime. This paper explained maintenance mechanism of the supercell with short-lived convective cell, and back-building rainband with long-lived convective cell in the humid subtropical region by focusing mid-level humidity. The quantitative, observational or numerical verification of these qualitative understandings obtained in this study would lead us to acquire comprehensive understandingof maintenance mechanism of MCS.

THE APPLICATIONS OF NONLINEAR OPTIMIZATION TO THE PREDICTABILITY OF NUMERICAL WEATHER PREDICTION

Mu MU, Wansuo DUAN, Jiacheng WANG (LASG,Institute of Atmospheric Physics,Chinese Academy of Sciences)

The uncertainties caused by the errors of the initial states andthe parameters in the numerical model are investigated. Threeproblems of predictability in numerical weather prediction are proposed, which are related to the maximumpredictable time, the maximum prediction error, and themaximum admissible errors of the initial values and theparameters in the model respectively. The three problems arethen formulated into nonlinear optimization problems.Effective approaches to deal with these nonlinear optimizationproblems are provided. The results of numerical experiments are also provided.

STATISTICAL ANALYSIS OF DUST STORMS IN THE ARAL SEA REGION

Lyudmila Yur'evna SHARDAKOVA (Central Asian Research Hydrometeorological Institute (SANIGMI))

STATISTICAL ANALYSIS OF DUST STORMS IN THE ARAL SEA REGION.SHARDAKOVA LYUMILA.YU., Usmanova LyumilaV. Central Asian Research Hydrometeorological Institute ,72, K.Makhsumov st., Tashkent, 700052, UzbekistanThe Aral Sea coast is a large center of dust storms springing up over the territory of Central Asia. Last ten years the Aral Sea region is a zone of ecological crisis caused by the recession of the Aral Sea level. To analyze the phenomenon of dust storms in this region the database has been developed (MS ACCESS), informative basis of which were the data from 14 meteorological stations for the period 1990-2002. Data-base contains information about 2000 registered occurrences such as dust storms, dust drifts, dust hazes which were observed over considered territory. Input information: date and time of observations; geo-graphical information about meteorological stations; information about speed, direction of wind and maximal gust at the time of occurrence; characteristics of dust storm intensity and cloudiness. Output in-formation is result of database queries at temporal, spatial and other categories. Statistical analysis of more than 1400 dust storms events was carried out. Next characteristics were obtained: duration of dust storms; daily, annual variations and inter-annual change of dust storms for each meteorological station in this region; geographic distribution of intensity and duration of dust storms events; wind speed spectrum. The characteristics obtained were compared with ones of previous years.

JSM14/09P/D-016 Poster 1400-080

APPLICATION OF A NEW WIND GUST PARAMETERISATION. MULTI-SCALE CASE STUDIES PERFORMEDWITH THE CANADIAN RCM

Stéphane GOYETTE[1], Olivier BRASSEUR[2], Martin BENISTON[1] ([1]Dept of Geosciences, University of Fribourg, Switzerland, [2]Laboratoire d'étude des Transferts en Hydrologie et Environnement, Domaine Universitaire, Grenoble, France.)

The implementation of a physically-based parameterisation used for diagnostic computations of wind gust is described. Based on an innovative off-line method proposed by Brasseur (2001) to compute wind gusts, it is reasonable to implement a similar subgrid-scale parameterisation in a numerical model to simulate them on-line, i.e., during the course of a simulation. The method assumes that gusts occurring at the surface result from the deflection of air parcels flowing higher in the boundary layer. The trigger mechanism for this deflection is attributed to turbulent eddies. This parameterisation is tested against real documented events. Consequently, to illustrate the performances, two severe mid-latitude windstorms are simulated with the Canadian RCM at various resolutions combined with the gust parameterisation using *NCEP-NCAR* reanalysis as driving data. The study is carried out for these two severe wind cases over the complex terrain of Switzerland and over the smoother topography of Belgium. A preliminary analysis indicates that this parameterisation performs as well over flat as over mountainous regions and it responds properly in the strengthening as well as the weakening phases of wind storms. However, the storm-dependent results are also a function of the model configuration during the self-nesting procedure. Consequently, the spatial and temporal distributions of the simulated gusts depend on the accuracy of the simulated flow fields. Furthermore, the gust speeds are highly resolution-dependent: when compared with observations, the simulated gusts are generally more realistic at higher resolution over the complex topography of Switzerland but less sensitive over the relative flat terrain of Belgium. The model response is also dependent upon the resolved topography distribution and height, and on the types of lower boundary conditions which affect the stability of the boundary layer. The latter also modulate the mean anemometer-level winds, which serve as a lower bound of the gust speed. This study also shows that simple scaling coefficients relating gust speeds with resolutions can not be easily determined over these two countries regarding these two storms.

HINDCAST SIMULATIONS OF SEVERE WEATHER EVENTS BY A HIGH-RESOLUTION ATMOSPHERIC GENERAL CIRCULATION MODEL ON THE EARTH SIMULATOR CASE 1: THE AUGUST 2002 STORMS

Wataru OHFUCHI[1], Takeshi ENOMOTO[2] ([1]Earth Simulator Center, Japan Marine Science and Technology Center, [2]Institute for Global Change Research, Frontier Research System for Global Change)

Numerical weather forecasts sometimes fail in predicting severe weather events associated with downstream development. Improvement of their predictabilities is one of the main goals of THORPEX. In association with this project, hindcast simulations of high-impact weather are conducted with a high-resolution global atmospheric model on the Earth Simulator. Hindcast simulations of the August 2002 storms, that caused flood in Europe, with various horizontal resolution and lead times will be presented in CASE 1.

JSM14/09P/D-018 Poster 1400-082

HINDCAST SIMULATIONS OF SEVERE WEATHER EVENTS BY A HIGH-RESOLUTION ATMOSPHERIC GENERAL CIRCULATION MODEL ON THE EARTH SIMULATOR. CASE 2: THE NOVEMBER 2002 STORMS

Takeshi ENOMOTO[1], Wataru OHFUCHI[2] ([1]Institute for Global Change Research, Frontier Research System for Global Change, [2]2. Earth Simulator Center, Japan Marine Science and Technology Center)

As in CASE 1, high-resolution global atmospheric hindcast simulations of a severe weather event are performed on the Earth Simulator with various horizontal resolution and leadtimes. In CASE 2, another example of downstream development in November 2002 is examined. This event seems to be initiated by bursts of convection in the tropics, and the associated downstream development resulted in severe weather events around the globe.

JSM14/09P/D-019 Poster 1400-083

SUMMER SEVERE WEATHER PREDICTABILITY IN SOUTHERN ONTARIO - A DOPPLER RADAR PERSPECTIVE

David Ronald HUDAK, Norman DONALDSON, Sudesh BOODOO, Paul JOE, Robert PATERSON (Meteorological Service of Canada)

A methodology has been developed for creating a summer severe weather climatology from Doppler radar related products. Advanced software (URP) is used to process the King City radar 15 year data archive that extends back to 1988. URP is the operational radar software for the Canadian weather service. Its modular structure that permits the modification of existing modules and the saving of intermediate results for separate analysis makes it well

IA

suited to research applications. Radar parameters of particular interest are areas where Ze > 40 dBZ and extend above 5.5 km, mesocyclone occurrence, vertically integrated liquid, maximum reflectivity in a vertical column, and the bounded weak echo region.These parameters were examined to determine their ability to identify severe weather. Observations of severe weather events from surface reports compiled at the regional weather centre were used to tune the severe weather algorithm thresholds. URP´s Cell Identification, Cell Tracker, and Storm Assessment modules were then applied to the derived radar parameters. The result is a ranking of storm severity and the temporal and spatial distributions of the severe weather events. Conceptual models of severe weather occurrence and evolution are emerging from this analysis that highlight the importance of the Great Lakes in triggering convective instability. Additionally, the year-to-year variation in severe weather occurrence is being examined and related to larger scale weather patterns in an attempt to determine some planetary precursors to severe weather.The identification of radar artifacts and range biases were a major consideration in the analysis. A comparison of results from two adjacent radars (King City and Exeter) for three summers is showing important benefits in making composite displays. Many of the patterns of severe weather over this area are on the 100 km scale - too large for effective single radar coverage. However, two radars allow almost complete coverage of southern Ontario. In addition, the continuity of patterns through the area covered by two radars increases confidence in the validity of results.

JSM14/09P/D-020 Poster 1400-084

USING ISENTROPIC AND PV TECHNIQUES TO ANTICIPATE THE EFFECTS OF A STRONG UPPER COLD FRONT

Chris DOYLE (Environment Canada, Meteorological Service of Canada)

On the afternoon of May 2nd 2002, a strong cold front moving swiftly southward along the British Columbia coast helped foster gale-force northwesterly winds over the waters of the inner south coast of BC and gusty surface winds that exceeded warning criteria over southern Vancouver Island. In addition, several strong and unexpected thunderstorms also occurred with the frontal passage. Traditional forms of NWP guidance were not indicative of the severity of the event. Isentropic NWP guidance is a valuable tool an operational meteorologist can use to forecast these highly dynamic and mesoscale events; especially forecasts of IPV - Isentropic Potential Vorticity. IPV forecasts and trajectory data were examined *post-facto* and found to be very useful in evaluating the dynamics of the frontal feature. In addition, ground level ozone measurements can be used, in part, to assist in the verification of strong fronts with tropospheric folds.

JSM14/09P/D-021 Poster 1400-085

AN AUTOMATED SYNOPTIC CLIMATOLOGICAL PROCEDURE TO PREDICT FREEZING RAIN: APPLICATION FOR OTTAWA, ONTARIO

Chad Shouquan CHENG, Heather AULD, Guilong LI, Joan KLAASSEN, Bryan TUGWOOD (Meteorological Service of Canada-Ontario Region, Environment Canada)

Freezing rain is a major weather hazard, which can compromise human safety, significantly disrupt transportation, and damage and disrupt built infrastructure such as telecommunication towers and transmission wires. In this study, an automated synoptic climatological procedure used principal components analysis, average linkage clustering procedure and discriminant function analysis to classify the weather types which were most likely to be associated with freezing rain events at the city of Ottawa, Ontario. Meteorological data that was used in the analysis included hourly surface observations from the Ottawa International Airport and 6 atmospheric levels of 6-hourly NCEP-NCAR upper-air reanalysis weather variables for the winter months (Nov.-Apr.) of 1958/59-2000/01. The data were divided into two parts: a developmental dataset (1958/59-1990/91) for construction (development) of the model and an independent dataset (1990/91-2000/01) for validation of the model. The procedure was able to successfully identify weather types that are most highly correlated with freezing rain events at Ottawa. Stepwise logistic regression was performed on all days within the freezing rain weather categories to analytically determine the meteorological variables that can be used as forecast predictors for the likelihood of freezing rain occurrence at Ottawa. The results show that the model is best able to identify freezing rain events occurring several hours during a day. For example, in the independent or validation dataset, for likelihood values 0.6, the procedure was able to identify 74% of all freezing rain events occurring 6 hrs or more during a day. Similarly, the procedure was able to identify 91% of all freezing rain events occurring 8 hrs or more during a day. The statistical procedure is being extended to other locations in Ontario, as well as to U.S. cities near the Canada-U.S. boundary. A trends analysis of freezing rain events and their associated weather type frequencies will allow the authors to assess the risks of Ontario communities to severe ice storms. This study has further potential to be adapted to an operational forecast mode to assist in the prediction of major ice storms.

JSM14/09P/D-022 Poster 1400-086

SYNOPTIC TYPING AND ITS APPLICATION TO ANALYSIS OF FREEZING RAIN EVENTS IN ONTARIO, CANADA AND THE NORTHEASTERN UNITED STATES

Chad Shouquan CHENG, Joan KLAASSEN, Heather AULD, Guilong LI, Qian LI (Meteorological Service of Canada-Ontario Region, Environment Canada)

Freezing rain is a major weather hazard which affects many parts of Canada and the United States; however, in Canada, it is especially common in a corridor from Ontario to Newfoundland; and in the U.S., it frequently occurs in the Northeastern U.S. and the Appalachian region. In this study, principal components analysis and average linkage clustering procedure were used to automatically classify distinctive synoptic categories based on the differentiations and similarities of weather types characteristics. Meteorological data that was used in the analysis included hourly surface observations of air temperature, dew point temperature, sea-level air pressure, total cloud cover, wind speed/direction and occurrence of freezing rain as well as 6 atmospheric levels of 6-hourly NCEP-NCAR upper-air reanalysis weather variables of air temperature, dew point temperature, wind speed and direction for the winter months (Nov. - Apr.) of 1958/59-2000/01 for Canadian stations and 1973/74-1999/2000 for the U.S. stations. The study area consists of 14 weather stations in Ontario, 1 station in Montreal, Quebec and 12 stations bordering the Great Lakes. Hourly surface meteorological data were retrieved from Environment Canada's Digital Archive of Canadian Climatological Data for Canadian stations and from the U.S. National Climatic Data Center for the U.S. stations. The statistical procedure was able to successfully identify weather types that were most highly correlated with freezing rain events in the study area. Four weather types were most highly related to freezing rain events in the entire study area, while up to 2 additional weather types were identified at some of the stations. The freezing rain-related weather types that were identified account for 70% to 100% of the freezing rain events over the entire study period for occurrences greater than or equal to 1, 4 and 6 hours during a day. In addition, the relationships among monthly total freezing rain events, monthly total frequencies of freezing rain-related weather types and monthly mean temperature were investigated. In general, monthly total occurrences of freezing rain events

increase/decrease with monthly total frequencies of the freezing rain-related weather types. Trend analyses of the occurrences of freezing rain and the related weather type frequencies were also assessed.

JSM14/09P/D-023 Poster 1400-087

SNOWFALL AROUND NAGAOKA CLASSIFIED BY SNOW-ECHO MODES

Sento NAKAI[1], Koyuru IWANAMI[2], Ryohei MISUMI[2], Sang-Goon PARK[2], Masujiro SHIMIZU[1], Toshiichi KOBAYASHI[1] ([1]Snow and Ice Research Group, NIED, [2]Advanced Technology Research Group, NIED, Tsukuba, JAPAN)

Snow clouds develop over the Japan Sea with sensible and latent heat supply from the sea surface. The snow clouds cause many disastrous phenomena such as avalanche and blizzard after landing on the Japan Islands. We made Doppler-radar observations of the snow clouds and analyzed the relation between the ˝snow-echo mode˝ and the precipitation distribution. Equivalent radar reflectivity factor (Ze) and Radial velocity (Vr) was observed by an X-band Doppler radar (X-POL) settled on the roof of Nagaoka Institute of Snow and Ice Studies located in the central area of Niigata Prefecture (Chuu-Etsu). Ze and Vr obtained on a polar coordinate were interpolated on a Cartesian coordinate whose resolution was 1 km in horizontal direction and 500 m in vertical direction. The analysis period was 10-19 February 2000. The period contained a latter half of a cold-air outbreak and whole of another cold-air outbreak. To classify the snow-echo mode, we made an animation of horizontal sections of Ze and Vr at a height of 1.1 km. The analysis period was divided into 14 cases by examining the animation. Mean Ze was derived for each of the identified cases. Observed snow-echoes were classified into four snow-echo modes, that is, L-, T-, S-, and M-modes. L- and T- modes are well-known longitudinal and transversal snow bands. S-mode was characterized by the precipitation that continued to cover most of the observation area. M-mode means that stationary precipitation was observed around the windward slope of the mountains. L-mode was often seen when the wind direction was west-northwest. T- and M-modes were accompanied by more northerly winds. Mean Ze of L-mode cases showed that the precipitation was strong over the sea as well as over the land. On the contrary, mean Ze of T-mode cases showed that strong precipitation was only over the land. Mean Ze of S-mode cases showed no specific distribution. Mean Ze of M-mode cases showed that the precipitation was mainly over the mountain slope, especially over the slope facing against the prevailing wind. To understand the snowfall processes of snow clouds over the land, it is neccesary to solve the problems such as Z-R relation, low-level wind and orographically forced updraft. Comparison between mean Ze and surface data showed that the mean Ze distribution and surface precipitation distribution was qualitatively consistent in many cases. Similar comparison without snow-echo mode classification showed bad relation between Ze and surface data. It suggests that classifying snow-echo mode is important to know the characteristic precipitation distribution and that each snow-echo mode has its characteristic snowfall processes.

JSM14/09P/D-024 Poster 1400-088

OBSERVATIONAL AND NUMERICAL STUDIES OF A POLAR LOW FORMED OVER THE JAPAN SEA ON 27 JANUARY 2001

Syugo HAYASHI, Masanori YOSHIZAKI, Teruyuki KATO, Hisaki EITO (Meteorological Research Institute, Japan Meteorological Agency)

In January 2001, "Winter MCSs Observations over the Japan Sea 2001" (WMO-01) was conducted (Yoshizaki et al. 2001). On 27 January in WMO-01 IOP, a synoptic-scale low passed on southern side of Japan. At the same time a meso-α-scale low formed over the Japan Sea in the northwestern side of the synoptic-scale-low, and is called a polar low in this study. This polar low was observed by observation ships and an instrumented aircraft (Gulfsteam-2). Murakami et al. (2001) flew this polar low and observed inner structure of organized snow cloud systems. The echo areas were circular /spiral in shape and quasi-stationary, although they were weak in intensity. Characteristic wind fields were detected below the height of 1.5 km. Remarkable cyclonic wind patterns were found at the height of 0.3 km, in which the easterly winds with a speed greater than 10m/s were on the northern side and westerly winds on the southern side. The warm core was found in the central/southern part of the polar low, where equivalent potential temperature at the height of 1.5 km is higher by 2-3 degrees than its surroundings. The purpose of this study is to clarify the structures and the developing processes of the polar low numerically. First, we try to (1) reproduce the polar low using a cloud-resolving non-hydrostatic model, (2) investigate its structures in detail and (3) examine the developing processes with sensitivity experiments. The model used in this study is the Meteorological Research Institute / Numerical Prediction Division unified Nonhydrostatic Model (MRI/NPD-NHM: Saito et al. 2001). It is 5 km horizontal resolution, containing 300 x 300 grids (1500 km square) in horizontal and 38 layers in vertical. The cold rain scheme is used as the cloud microphysics. The MRI/NPD-NHM is nested in the Regional Spectral Model (RSM) of Japan Meteorological Agency (JMA). The RSM is a hydrostatic model with 20 km horizontal resolution, and is used operationally in JMA. The initial and boundary conditions for the MRI/NPD-NHM are produced by the forecasts of the RSM. The structures of the polar low were studied by using MRI/NPD-NHM. The observed features such as the horizontal distributions of the wind and movement of the polar low were well reproduced. The vertical extent of the polar low is about 3 km and its horizontal scale is about 300 km. The center of the polar low and the horizontal wind shear line were occupied by high θe. To investigate the development processes of the polar low, sensitivity experiments were conducted. The condensational heating plays a primary role for developing of the polar lows.

JSM14/09P/D-025 Poster 1400-089

DEVELOPMENT PROCESSES OF COASTAL SNOWBANDS OBSERVED DURING WMO-01

Tetsuya KAWANO[1], Tatsuya TANAKA[2], Masanori YOSHIZAKI[3], Teruyuki KATO[3], Hisaki EITO[3], Yoshinobu TANAKA[3], Ken-ichi KUSUNOKI[3], Koyuru IWANAMI[4] ([1]Department of Earth and Planetary Sciences, Faculty of Sciences, Kyushu University, [2]NEC Soft, Ltd., [3]Meteorological Research Institute, Japan Meteorological Agency, [4]National Research Institute for Earth Science and Disaster Prevention)

The authors investigated the development processes of two convective snowbands which formed on the coastal area of the Joetsu district, the western part of Niigata Prefecture, Japan during WMO-01 (Winter Mesoscale convective systems Observations over the Japan Sea - January 2001). One of the snowbands developed on 17 and the other on 18 January 2001, which corresponded to the period when the winter monsoon cold air outflow from Siberia weakened. The snowbands were observed by two three-dimensional scanning Doppler radars located at Joetsu and Ohmi, respectively. The dual Doppler radar analysis revealed that both snowbands have common features. The bands were about 100km in length and about 10km in width and aligned from the east-northeast to west-southwest. The orientation was approximately parallel to the coastline. The successive development of convective echoes occured in the snowbands. The echoes (the horizontal scale is about 10km and the vertical scale about 4km) moved approximately eastward and the systems

slowly south-southeastward. The low-level convergence region was located along the northern flank of the bands. The convergence layer was about 1km in depth. Furthermore, in order to investigate the formation processes of the snowbands, numerical simulations with the horizontal resolution of 2km were performed using a full compressible, non-hydrostatic numerical model, MRI/NPD-NHM (Meteorological Research Institute / Numerical Prediction Division Unified Nonhydrostatic Model), which is one-way nested within the MRI/NPD-NHM with the horizontal resolution of 5km. The initial and boundary conditions for the 5km-MRI/NPD-NHM are provided from the forecasts of RSM (Regional Spectral Model), which is the operational forecast model of the Japan Meteorological Agency. The simulated snowfall areas corresponded to the observations. The convectively unstable layers with 1.5-2km in depth were found over the Japan Sea north of the systems in both cases. Also, the convergence regions were located in the northern flank of both of the simulated snowbands. The convective cells developed in the convergence region and then the snowbands formed in the region. In the two simulated cases, however, the processes producing the low-level convergence region were different from each other. In the 18 January case, the cold air pool on the coast intensified the low-level convergence. On the other hand, the remarkable cold pool was not found in the area around the snowband in the 17 January case. The convergence region in the case was produced between the winter monsoon flow and the lowest-level offshore flow.

VORTEX CLOUD STREET AND ITS EVOLUTION OVER THE WESTERN OFFSHORE OF HOKKAIDO, JAPAN

Yoshio ASUMA, Atsuo TSUBOTA (Division of Earth and Planetary Sciences, Graduate School of Science, Hokkaido University)

Snow cloud bands are once of the causes for the heavy snow precipitation in Hokkaido and sometimes disturb human activities during winter seasons. The cloud band usually organized in the parallel (L-mode) or perpendicular (T-mode) direction to the prevailing wind. It sometimes observed to be organized as a vortex cloud street. An example was observed by weather radar between 12th and 13th January 1998 over the western offshore of Hokkaido Island. Weather radar and satellite images showed that it appeared at the southwestern offshore of Hokkaido around 18UTC (03JST) 12th January 1998, gradually moved toward the north over the Sea of Japan and finally formed a meso-alpha scale vortex over the northern offshore of Hokkaido around 12UTC (21JST) 13th. The surface wind data showed a strong wind shear between the vortex cloud street. A regional objectively analyzed data set (RANAL) provided by JMA (Japan Meteorological Agency) showed a weak cold air outbreak from the Asian Continent was prevailed over the northern Sea of Japan. A cold air outbreak also occurred from Hokkaido Island and converged in the lower atmosphere at the western offshore of Hokkaido. A vortex cloud street appeared in this convergence zone. The vorticity analysis showed a strong vorticity concentration in this area. The lower level convergence zone gradually moved toward north over the Sea of Japan along the west coat of Hokkaido. An upper level short wave trough, which was associated with cold vortex over the Asian Continent, approached from the continent. The vortex cloud street was finally organized as a meso-alpha scale vortex under the upper level short wave trough. We simulated these conditions with the PSU-NCAR mm5 meso-sacle model.

EXPLOSIVELY DEVELOPED CYCLONES AND WATER TRANSPORTATION OVER THE NORTHWESTERN PACIFIC REGION

Yoshio ASUMA, Akira YOSHIDA, Masaya KATO (Division of Earth and Planetary Sciences, Graduate School of Science, Hokkaido University)

The extratropical cyclone is one of the important driving forces of the heat and water vapor transportation from the lower latitude to the higher latitude. As it brings a large amount of solid precipitation over the area during cold seasons, its activity would affect the growth and decay of the cryosphere. We analyzed explosively developed cyclones over the Northwestern Pacific area during cold seasons between 1994 and 1999 using a global objectively analyzed data set (GANAL) provided by Japan Meteorological Agency (JMA). Explosive cyclones were classified into three types by the places of formation and maximum deepening positions. They are Okhotsk and Japan Sea type cyclones, Pacific Ocean - Land type cyclones, and Pacific Ocean - Ocean type cyclones. These types of cyclones have characteristics for their seasonal appearance frequencies and maximum deepening rates. By the composite analysis, it was found that these characteristics are reflected by the interior structures of the cyclone. Water vapor acts as a driving force for the development of the cyclone through the latent heat release and the water vapor is carried into the cyclone center at its maximum deepening. The cyclone reaches its center sea level pressure minimum after explosive development and achieves large horizontal vapor transportation. Vertically integrated horizontal vapor flux and cyclone tracks were analyzed by month and the following tendencies were found: water vapor transports into the Arctic circle over the Kamchatka Peninsula during the Okhotsk and Japan Sea type cyclones predominant month; it zonally transports toward the Gulf of Alaska during the Pacific Ocean - Land type cyclones predominant month; and it transports into the Arctic circle through the Bering Strait during the Pacific Ocean - Ocean type cyclones predominant month.

A VERIFICATION OF ICEBERG DRIFT OFF CANADA'S EASTERN COAST

Thomas CARRIERES[1], Mohamed SAYED[2], Stuart SAVAGE[3], Greg CROCKER[4] ([1]Canadian Ice Service, [2]Canadian Hydraulics Centre, [3]McGill University, [4]Ballicater Consulting)

Icebergs pose the greatest hazard to marine operations off Canada's east coast. In our ongoing effort to improve ice products and services, the Canadian Ice Service has developed a new iceberg drift and deterioration model. The model drift is compared to more than 50 iceberg drift tracks monitored in 2002 for drilling platforms in the Grand Banks area. The model drift corresponds quite well to observations and errors are generally reduced compared to our older operational model. Iceberg drift direction is better predicted than speed and the latter has a negative bias for larger icebergs. Geographic patterns to the drift error vectors imply that predicted ocean currents are the largest error source. Other significant error sources include underwater shape and the effect of wave radiation stress.

CLIMATE CHANGE AND ITS IMPACT ON MOUNTAINOUS REGION: A STUDY OF SNOW AND ICE IN HIMALAYAN MOUNTAIN ECOSYSTEM AND ITS IMPACT

Shanmuganandan SAMARAJALINGAM (Madurai Kamaraj University)

Global climate change is expected to bring severe impacts in Alpine regions particularly with reference to snow hydrology of mountainous regions of the world. The Alpine regions are particularly vulnerable to the impacts of global climatic change both from an economic and

environmental perspective with climate dependent economies and a vulnerable environment. Usual environmental risk like torrents floods and avalanches are supposed to increase. The Himalayas is amongst one of the youngest folded mountainous formations of the world, and the youngest in India. By comparison the Himalayas date back to only 40-45 million years. They traverse an arc for about 2500 km between the Indus and the Brahmaputra. The average width of this mountain range along the entire longitudinal extension ranges from 100 to 400 km. Being the worlds´ highest mountain chain, the Himalayas is characterized by a complex geologic structure, snowcapped peaks, large valley glaciers, deep river gorges and rich vegetation. A complex interplay of climatic and geological processes, patterns of resource use and economic conditions have led to resource degradation and associated environmental consequences in the Himalayan ecosystem The present study is an attempt to analyse the extent of global change and its impact on snow and ice in the last several decades and also to observe the major ecological concerns and the underlying driving factors (both human and natural processes), socio-economic impacts and the responses. This is followed by an overview of the state of the environment in the region and a detailed analysis of key environmental issues: water resources and their sharing, biodiversity loss, glacier recession, deforestation, land degradation and agriculture systems, natural disasters This is followed by an overview of the state of the environment in the region and a detailed analysis of key environmental issues. The current employment pattern might be disrupted by climate change. In particular local Alpine communities and districts will feel the effects. An attempt is done to quantify the expected losses due to climate change on a local level. As the pace of warming is still unknown the scenarios of warming are provided. Local decision makers should be enabled to judge the economic magnitude of the problem and to develop counter strategies against climate change. The study was based on the secondary data collected extensively from case studies and also from published reports available for Himalayan region on various aspects of snow and ice and also about the Himalayan ecosystem. The study also used the hydro meteorological data to observe the variation in water resources potential due to the impact of climate change in the last several decades. The data on selected variables of climate change and ecosystem were analyzed with the help of factor analysis to identify the major dimensions and spatial pattern of variation is observed. The analysis of findings revealed that there is a need to work out a strategy for sustainable mountain ecosystem in view of the changes introduced by man made changes on mountain ecosystem and also the changes effected by climate change.

MOLECULAR DYNAMICS SIMULATIONS OF ICE SURFACES AND ICE/WATER INTERFACES

Hiroki NADA[1], Yoshinori FURUKAWA[2] ([1]Institute for Environmental Management Technology, National Institute of, [2]Institute of Low Temperature Science, Hokkaido University)

Molecular-scale structures of the surfaces of an ice crystal and the ice/water interfaces are investigated using a molecular dynamics simulation. For the ice surfaces, simulations are carried out for both an ice(0001) and an ice(0001) faces (basal and prismatic faces, respectively) over a temperature range from 170 to 250K. The simulation results clearly indicate that structural transitions occur on both faces as the temperature increases to the melting point, and that the temperatures of the transitions are completely different between in the case of basal and prismatic faces. Especially, we emphasize that the anisotropy in surface melting between the faces obtained by the present simulation study agrees with the experimental results obtained by ellipsometric measurements. The anisotropic surface melting will be discussed on the basis of the interface structures between the quasi-liquid layer and the underlying ice crystal. Moreover, molecular dynamics simulations of ice/water interface at the supercooling state are also performed to elucidate the anisotropic growth kinetics of ice. The simulations are carried out for two kinds of interfacial orientations, namely, an ice(0001)/water and an ice(1010)/water interfaces. It should be emphasized that not only the interface structures but also the growth kinetics are completely different between the interfaces. The simulation results indicate that the growth kinetics are the layer-by-layer process for the ice(0001)/water interface and the collected molecules process for the ice(1010)/water interface. The results will be also discussed in relation to the experimental results of ice growth.

CAPACITANCE OF SOLID AND HOLLOW ICE CRYSTALS

Mihai CHIRUTA, Pao K. WANG (Department of Atmospheric and Oceanic Sciences, University of Wisconsin-Madison)

It is increasingly clear that cirrus clouds have important impact on the global climate process because the ice crystals in them interact strongly with both solar and terrestrial radiations. Using a two-dimensional explicit microphysical cirrus model coupled with radiation, we have demonstrated recently that the heating rate in a cirrus strongly depends on the habit of its constituent ice crystals. The model results indicate that the difference of peak heating and cooling rates between a cirrus of rosette ice crystals and a cirrus of ice spheres can be as much as 600%! Much of this difference is due to the different growth rates of these crystals. To assess the impact of cirrus on climate, therefore, it is important to estimate more precisely the growth rates of ice crystals. Although the growth rates of crystals of simpler shapes, such as columns and plates, are known, many important crystals that are commonly observed in cirrus clouds are not. The latter include spatial crystals such as solid and hollow bullet rosettes and hollow columns. The present paper is to report our recent calculations of the capacitance of these crystals. The electrostatic analogy is currently the main theory used to calculate the ice crystal growth rates and the central quantity in this theory is the capacitance. Due to the complicated shapes and difficulties in experimental techniques, their capacitances are not known. We have recently calculated the capacitances of a number of solid rosette crystals using finite element techniques. This paper will report on our more recent progress in computing the capacitances of hollow columns and hollow rosettes. We will compare the capacitances of solid and hollow crystals and the implications of the different capacitances in the climatic impacts of cirrus clouds.

MASS FLUX AND RECRYSTALLIZATION OF SNOW CRYSTALS AGGREGATES AT THE MICROSTRUCTURAL LEVEL

Sergey A. SOKRATOV, Martin SCHNEEBELI (Swiss Federal Institute for Snow and Avalanche Research)

Most modern practical applications require not only the understanding of the crystal growth phenomena at the single-crystal scale, but also knowledge of the interactions of growing crystals in multi-element systems. Up to now, there is no accepted theory fully describing these processes. Snow is the material corresponding to a multi-element system naturally being at the temperature very close to the melting point. The physical conditions for the formation of different shapes for single ice crystals are well known. However, very few data are available on the corresponding processes in snow as a multi-elements system. Collecting data on how different the shapes and the activity of recrystallization are in snow is of great interest not only to snow physics, but to material science in general. Laboratory experiments and mathematical modeling are done concurrently to understand the mechanism of crystal growth in snow under regulated thermophysical conditions. Experiments are made in a cold laboratory on samples of natural snow. The time-variation of the shape, size and specific surface area, and the corresponding change in the thermophysical properties of the snow samples are observed undisturbed using X-ray computed micro-tomography simultaneously with heat-flux and temperature measurements. The results of this study are presented.

JSM15/07A/B18-004   1000

MONTE CARLO SIMULATION OF SNOWFLAKES

Ken-ichi MARUYAMA[1], Yasushi FUJIYOSHI[2] ([1]National Research Institute for Earth Science and Disaster Prevention, [2]Institute of Low Temperature Science, Hokkaido University, [3]Frontier Research System for Global Change)

A stochastic aggregation model for snowflake was developed, in which the time evolution of the size distribution and the shape of snowflakes are calculated simultaneously and explicitly by combining the Monte Carlo method of Gillespie (1975) with a simple aggregation model. Simulations were performed to study the effect of complexity of shape on the evolution of snowflake size distribution. (1) The size distribution of generated snowflakes is broader than those of the sphere model. The mean radius (R_{max}) and mass of generated snowflakes are also larger than those of the sphere model. (2) The relationships between the maximum diameter and mass of generated aggregates are fitted with the equation $D=aM^b$. The larger the initial variation of size distribution is, the larger the value of b. Besides, the larger constituent particles´ density is, the smaller the value of b. These relationships are consistent with observational results, although the relationships strongly dependent on the parameters of the initial distribution. (3) On average, the density in a snowflake decreases from the center of mass to the edge, because generated aggregates have many branches near the edge. Sensitivity experiments show that small density of constituent particles leads to concentration of mass near the center, and relative variation of the initial size distribution of ice crystals does not cause any significant change in the structure of generated snowflakes.

THE CLASSIFICATION OF ATMOSPHERIC ICE PARTICLES, A CRITICAL REVUE

Roland LIST (UNIVERSITY OF TORONTO)

In 1949 the International Commission of Snow and Ice agreed on the ˝classical˝ schematic display of ice particles normally shown in textbooks. It lists 10 categories, with additional special letters to specify size and other characteristics. Its weakness is that 6 code numbers out of 10 are devoted to pristine ice crystal shapes, while only four remain to deal with the meteorologically important particles. While beautiful to look at, these definitions are rather useless. This is supported by the observation that there are no consistent climatological investigations or any scientific papers which make use of this classification. Thus, a revision is indicated which aims at the real world and not the aesthetics. A product is needed which can be applied and is scientifically useful. While there is no attempt made to come up with a completely new classification, suggestions will be made and a procedure will be described on how to arrive at a better product. At the same time the ˝standard˝ definitions of the different types of ice crystals will be critically reviewed and proposals will be made about possible improvements and replacements.

PATTERN FORMATION OF ICE CRYSTAL GROWN IN SUPERCOOLED WATER AND PERSPECTIVE FOR SPACE EXPERIMENTS

Etsuro YOKOYAMA[1], Yoshinori FURUKAWA[2], Wataru SHIMADA[2] ([1]Computer Center, Gakushuin University, [2]Institute of Low Temperature Science, Hokkaido University)

Development of the interfacial pattern during the growth of a crystal from its melt is a typical example of pattern formation under nonlinear and non-equilibrium conditions. It is well known that the growth form of an ice crystal freely growing in supercooled bulk water changes from a circular disk, to a perturbed disk, and finally to a well-developed dendrite with hexagonal symmetry. It means that the pattern formation of ice crystal displays unusually strong anisotropy in interfacial kinetics. We are now embarking on space experiments involving solidification of ice. We present our experimental results and a new model to understand the unstable ice disk morphologies. First of all, the experimental results for the ice disk growth under the condition of normal gravity are summarized. (1) Two different modes of ice disk growth were observed, depending on the growth kinetics of basal plane. (2) The transition from stable to unstable growth occurs when the disk thickness reaches a critical value, hc. hc was proportional to the reciprocal of supercooling. (3) The asymmetric morphological instability was always observed at the periphery of ice disk. Furthermore, an experiment on ice crystal growth under the microgravity condition of the period of 6 minutes was carried out using a NASDA sounding rocket, TR1A#7. We observed the asymmetric pattern formation in the microgravity condition again. This result means the asymmetric pattern formation at the edge of ice disk is essentially related to the mechanism of morphological instability. These experimental results are explained by a theoretical model recently developed by Yokoyama, Sekerka and Furukawa, (J. Phys. Chem., 2000,B104, 65). In the case of disk growth, the growth of the edge plane is dominantly controlled by the thermal diffusion efficiency of the latent heat but the growth of basal planes is dominated by the interfacial kinetics. We mention that this anisotropic growth characteristic is essential for understanding these growth features of ice disks. On the other hand, we also carried out in-situ observations of thermal diffusion field around a growing ice dendrite under the short-time microgravity condition. The interference fringes obtained by this experiment were analyzed by the newly developed image-processing methods. As a result, clear images of thermal diffusion field were first obtained. In conclusion, we emphasize that the ice disk growth gives a challengeable aspect of space experiment.

OBSERVATIONS OF SNOW AND ICE CRYSTALS USING LOW-TEMPERATURE SCANNING ELECTRON MICROSCOPY

Albert RANGO[1], William WERGIN[2], Richard ARMSTRONG[3], Edward JOSBERGER[4], James FOSTER[5], Eric ERBE[2], Christopher POOLEY[5] ([1]USDA/ARS/Jornada Experimental Range, New Mexico State University, 2995 Knox St., Las Cruces, NM 88003, USA, [2]USDA-ARS-Electron Microscopy Unit, Beltsville Agricultural Research Center, Beltsville, MD 20705, USA, [3]University of Colorado, National Snow and Ice Data Center, Boulder, CO 80309, USA, [4]U.S. Geological Survey, 1201 Pacific Ave., Suite 600, Tacoma, WA 98416, USA, [5]Laboratory for Hydrological Sciences, NASA Goddard Space Flight Center, Greenbelt, MD 20771, USA)

The use of low-temperature scanning electron microscopy (LTSEM) to observe snow and ice crystals has been developed in recent years to provide a viable, alternative method to light microscopy (LM). Since 1994, the methods to collect, preserve, transport, and store snow and ice crystals have been perfected so that samples can be obtained in remote snow and ice regions anywhere in the world and then viewed and photographed with the LTSEM. The LTSEM technique increases the resolution and ease with which samples of snow and ice can be observed, studied, and photographed. The use of conventional LM for observing snow crystals has required cooling of the laboratory and instrumentation to temperatures below freezing. Furthermore, the samples must be analyzed and photographed near the place and time of collection. These disadvantages have been rectified using LTSEM. Additional advantages of LTSEM include the ability to image at high magnifications (up to 150,000x), improved depth of focus and resolution, three-dimensional (stereo) viewing, and the capability to store samples for long periods of time (at least five years). We have compared LM and LTSEM images of the identical crystals (as well as of similar crystals collected under the same environmental conditions in a large field experiment) to document this LTSEM capability. The greater resolution of LTSEM was evident when examining and resolving the small frozen cloud droplets associated with rime and graupel, whereas the greater depth of focus provided clear photographs of these crystals as well as other large crystals such as depth hoar. In addition, LTSEM images specifically illustrate the structural features of the crystal surface that is being imaged, whereas with LM, the surface features are sometimes masked and confused by internal structures and their effect on reflected, refracted, and transmitted light. In comparison to the crystals imaged or described by the Japanese scientists Nakaya and Magono, the LTSEM can also be used to provide higher resolution to characterize the irregular crystals that Nakaya (1954) termed "a lump of frozen droplets". For the 80 different types of snow crystals specified by Magono and Lee (1966), our LTSEM images from field work cover over 70 of their snow crystals plus we have encountered at least 20 types of crystals not included in their classification scheme. Future studies will interface the LTSEMs with energy dispersive x-ray microanalysis systems so that the elemental constituents of contaminants in a snow crystal can be identified. It is hoped that the LTSEM capabilities will be useful in furthering the original studies of Nakaya and Magono.

JSM15/07A/B18-008   1115

ICE PARTICLE HABITS IN STRATIFORM CLOUDS

Alexei KOROLEV[1], George A. ISAAC[2], John HALLETT[3] ([1]Sky Tech Research Inc., [2]Meteorological Service of Canada, [3]Desert Research Institute)

In calculations for climate change predictions, weather forecasting of precipitation, and remote sensing retrievals, idealized crystal shapes such as columns, needles, plates and dendrites are assumed. The existence of such crystals were supported by numerous laboratory studies. The current work presents results of aircraft studies of cloud particle habits in natural clouds. The images of cloud particles were measured by two instruments: PMS Optical Array Probe-2DC (OAP-2DC) at 25 mm resolution, and a newly developed SPEC Cloud Particle Imager (CPI) at 2.3 mm resolution, installed on NRC Convair-580. The processing of OAP-2DC images was conducted with the help of an originally developed algorithm for pattern recognition. Approximately 4.6 106 images of cloud particles having a size larger 125 mm were analyzed from data collected during four field campaigns from 1994 to 1998 in stratiform clouds mainly associated with frontal systems. The cloud particles were classified into four categories: spheres, irregulars, needles and dendrites. The frequency of occurrence of different habits was found for each 5oC temperature interval in the range -45oC $<$T$<$0oC. One important conclusion of this study is that the majority of ice particles in natural clouds have an irregular shape for all temperature intervals. On average, the frequency of occurrence of irregular shaped particles is about 84%. High-resolution CPI images showed that pristine monocrystalline ice particles such as plates and columns occur only in 3% of all cases. Some unusual shapes of ice particles were found in the CPI imagery. Since the data were collected in different climatic zones and covered a significant cloud path length (3.7 104 km), the conclusions from this work should apply to clouds in other regions.

JSM15/07A/B18-009   1130

THE ROLE OF ICE IN TROPICAL LIGHTNING

Tsutomu TAKAHASHI (Core Education Center, Obirin University)

Data from TRMM-LIS show strong differences between tropical lightning activity over the open ocean and over continents. Even in east-Asia, flash rates are two orders of magnitude smaller over the western Pacific than over the maritime continent (Christian et al. 2002). Laboratory wind tunnel experiments and field works in Hokuriku and southern Kyushu indicate that the main charging process in these thunderstorms is the riming electrification mechanism. According to the thunderstorm model given in Takahashi, 1984, the number concentration of ice crystals and graupel required to accumulate sufficient electric charge to initiate lightning must exceed 50/1 and 1.5/1. During the past 15 years, this concept has been examined using data from 208 videosondes launched into Asian monsoon clouds from 13 different areas (Ponape, Manus ls., Brunei, Melville ls., Songkhala, Surat Thanni, Phuket, Ubon, Chaingrai, Pingliang, Shanghai, Tanegashima, and Kagoshima). Data acquired from these videosondes show that the number concentrations of ice crystals and graupel differ greatly between the open ocean and the maritime continent. As lightning activity over the open ocean is two orders of magnitude less than that over the maritime continent, the number concentrations of ice crystal and graupel over the ocean are also lower by the same magnitude. Smaller concentrations of snow over the open ocean lead to different precipitation mechanism: a frozen drop mechanism over the ocean in comparison to a mixed rain process over the maritime continent. Results from a three dimensional microphysics cloud model illustrate the different rain patterns and organizations between the two areas.

JSM15/07A/B18-010   1145
SURFACE INSTABILITY OF ICICLES

Naohisa OGAWA, Yoshinori FURUKAWA (Institute of Low Temperature Science, Hokkaido University)

Quantitatively unexplained stationary waves or ridges often encircle icicles. Such waves form when roughly 0.1-mm-thick layers of water flow down an icicle. These waves typically have a wavelength of about 1 cm, which is independent of external temperature, icicle thickness, and the volumetric rate of water flow. In this paper, we show that these waves cannot be obtained by a na?ve Mullins-Sekerka instability but are caused by a quite different type of surface instability related to thermal diffusion and the hydrodynamic effect of a thin water flow. EFFECT OF ANTIFREEZE GLYCOPROTEIN FOR ICE CRYSTAL GROWTH KINETICS

Yoshinori FURUKAWA[1], Yoshihiro NISHIMURA[1], Etsuro YOKOYAMA[2], Naomi INOHARA[1], Takanori TERASAWA[1] ([1]Institute of Low Temperature Science, Hokkaido University, [2]Computer Center, Gakushuin University)

Freezing of organisms in cold weather can cause death of life. Many organisms have developed a tolerance to both freezing and recrystallization. In particular, it is well known that certain polar and near polar fishes survives by the work of Antifreeze Glycoprotein (AFGP, their molecular weights are ranged in 2000-30000). These proteins suppress the freezing temperature of water. Namely, fish bodies are kept in the supercooling state, but they never freeze. The mechanism of freezing prohibition is considered that AFGP molecules adsorb at the interface between ice and water, and restricts the step migration at the interface. This is the static effect for the ice growth prohibition by AFGP molecules. However, the details of the kinetic mechanism by which these proteins function (so-called dynamic effect) have not been clarified up to now. We have carried out in detail the in-situ observations of the growing interfaces and pattern developments. In this paper, we present the results of one-directional growth experiments of ice from the aqueous solution of AFGP, and discuss the interfacial pattern formation. Based on the experimental results, we determine the interfacial kinetic supercooling of growing interfaces. One-directional growth experiments of ice crystals were carried out by a very thin growth cell, and the interfacial pattern developments were observed in situ using an interferometer. Initial concentration of AFGP was less than 0.1wt%. An interface, which was flat before the beginning of growth, changed to a randomly perturbed one after the beginning of growth, and finally to a periodically jagged pattern that composed of flat prismatic faces. This kind of pattern formation is completely different from that driven by the so-called constitutional supercooling. Interfacial supercooling temperatures, δT, were directly determined from the analysis of zigzag patterns. We clarified that distance between the top and bottom of zigzag patterns relates to the degree of δT. We found that δT increases with increasing growth rate when the growth rate is lower, but this relation is reversed when the growth rate increases. Assuming that δT proportionally depends on the adsorption density of AFGP molecules at the growing interfaces; we will discuss the relationship between the AFGP adsorption and the growth rate. Furthermore, the self-oscillatory growth was also observed during the ice crystal growth in the AFGP solution. The mechanism is discussed based on the nucleation of new interface and the adsorption of AFGP on the ice/water interface.

GROWTH PATTERN DIAGRAM OF SNOW CRYSTALS

Norikazu MAENO[1], Yoshinori FURUKAWA[1], Keiji HIGUCHI[2] ([1]Institute of Low Temperature Science, Hokkaido University, [2]Nagoya City Science Museum)

A growth pattern diagram of snow crystals was first constructed by Nakaya (1954), who tried to show by the diagram that the variety of growth forms of snow crystals can be classified as functions of air temperature and degree of super-saturation of water vapor with respect to ice. Large numbers of laboratory and theoretical results by Nakaya (1954), Shaw and Mason (1955), Kobayashi (1957), Hallett and Mason (1958), and others, were consolidated and summarized by Kobayashi (1961) in a growth pattern diagram of snow crystals. At present, however, it is often noted that the correct form of the diagram is not always introduced in literatures and textbooks in the world, leading to unnecessary misunderstanding and confusions. The present paper aims at making clear the situation and trying to renew the important implication of the diagram by discussing other factors affecting growth patterns of a snow crystal than temperature and super-saturation of water vapor.

MORPHOLOGY OF SNOW CRYSTALS GROWN AT LOW TEMPERATURES IN FREE FALL

Chuji TAKAHASHI (Department of Earth Science, Faculty of Education, Saitama University)

It is well-known that the habit of snow crystals changes with the temperature and the supersaturation since the experiments of artificial snow crystals by Nakaya. However these experiments were carried out for limited conditions of temperatures above about -25°C. Recently snow crystals, which are observed at polar regions(1) or in cirrus clouds(2), has been attracted interest in relation to the study of climatic change. Such snow crystals grow mostly at temperatures below -25°C. The author investigated the growth of snow crystals at low temperatures by using a diffusion cloud chamber(3). He showed that combination of bullet type snow crystals grew at temperatures below -40°C. This study was carried out to investigate the morphology of snow crystals which grow at low temperatures in free fall by using a large cloud chamber of 6.5 m in height. Supercooled cloud was produced in the large cloud chamber and were seeded with kaolinite(clay mineral), silver iodide smoke or frozen water droplets(less than 20μm in diameter). Frozen water droplets were produced by spraying distilled water and allowed the water droplets to fall in the small cooling chamber

attached at the top of the large cloud chamber. They are considered to be nucleated by homogeneous nucleation. Experiments were made also on the condition that no ice nucleus was seeded. In this condition snow crystals grew from natural ice nuclei. Snow crystals were collected at the bottom of the chamber and were classified into six types, single-crystalline plates, single-crystalline columns, assemblages of plates, assemblages of plates and columns, combinations of columns and unusual crystals. The percentages of each crystal types were derived. (1)Single-crystalline columns were observed frequently when supercooled cloud were seeded with silver iodide smoke or no ice nucleus seeded. It is considered that about 30% of snow crystals are single-crystalline column when they grow from natural nuclei. (2)Assemblages of plates or assemblages of plates and columns were observed frequently when kaolinite or frozen water droplets were seeded. The percentages of assemblages of plates decreased and those of assemblages of plates and columns increased with the decrease of temperatures. (3)The percentage of combinations of columns was small when a supercooled cloud was seeded with kaolinite or silver iodide smoke ,or when no ice nucleus was seeded. But it was 16% when frozen droplets were seeded at a temperature -33°C. References (1)Iwai,K. GROWTH PATTERNS OF SNOW CRYSTALS

Etsuro YOKOYAMA[1], Toshiharu IRISAWA[1], Yoshinori FURUKAWA[2] ([1]Computer Center, Gakushuin University, [2]Institute of Low Temperature Science, Hokkaido University)

A spherical single crystal of ice grown from supersaturated vapor in clouds first becomes a hexagonal prism bounded by two basal and six prism faces.At low supersaturation, such a hexagonal prism can grow in a stable manner and retains its form. For higher supersaturations, it changes form by means of preferred growth of edges and corners.A model of formation of two-dimensional patterns during the growth of snow crystals was developed [1].The model takes into account the following elementary processes relevant to the growth:1) A surface kinetic process for incorporating molecules into a crystal lattice, and2) a process for diffusing molecules through air toward the crystal surface. We develop the model and show the effect of aspect ratio on morphological instability during growth of hexagonal prisms. Furthermore, we discuss the conditions for the formation of side branch patterns. Reference [1] E. Yokoyama and T. Kuroda, Phys. Rev.A 41(1990)2038.

PATTERN FORMATION AT INTERFACE BETWEEN ICE AND SALT SOLUTION DURING ONE-DIRECTIONAL GROWTH

Kazushige NAGASHIMA[1], Yoshinori FURUKAWA[2] ([1]Department of Physics, Meiji University, [2]Institute of Low Temperature Science, Hokkaido University)

Development of the interfacial pattern during the one-directional growth of ice crystal from the water containing impurities was observed in-situ using an interferometer. Generally, these kinds of growth experiment are very useful in a discussion of pattern formation and have carried out for many kinds of materials. This methodology was applied to the ice crystal growth from the KCl solution. The solute distribution in front of directionally growing ice crystals was observed in situ as well as the three-dimensional interfacial patterns, using a Mach-Zehnder interferometer. We were able to observe the occurrence of morphological instability at the interface and the development of cellular patterns. We gave a direct evidence for the constitutional supercooling and discussed the wavelength selection of perturbation through the analysis of interference fringes. We also found that the interfacial patterns were developed in three-dimensions, and the instabilities in the direction of cell thickness occurred first and then wavy perturbation appeared in the direction of growth cell width. The relationship between the development of constitutional supercooling and the sequent instabilities was discussed. The three dimensional patterns were also strongly unsymmetrical in the thickness direction. The precise analysis of interference fringes indicated that this asymmetry was originated from the effect of gravity. These experimental results can be applied to the crystal growth of sea ice.

DYNAMIC VISUALIZATION OF SNOW METAMORPHISM USING COMPUTED TOMOGRAPHY

Martin SCHNEEBELI, Sergey A. SOKRATOV (Swiss Federal Institute for Snow and Avalanche Research)

Changes in the shape of snow during metamorphism are observed until now at discrete time-steps, without the possibility to follow the changes of the microstructure within the multi-element crystals. We used x-ray computed tomography at a high spatial resolution (40 μm) and time steps of 8 hours to visualize the changes in crystal morphology. The insulated measurement chamber contains a snow sample of 50 mm diameter and variable height from 20-60 mm. Because a controlled temperature gradient can be produced in the measurement chamber we are able to determine at the same time the effective thermal conductivity. We developed a method to visualize and calculate the changes in the surface, and by that the effective sublimation and re-sublimation at the level of single microstructural units can be measured. Our preliminary results show that the rate of sublimation and re-sublimation is higher than estimated on classical grain size measurement, because the crystals growth seems not to be a steady process, but the grains undergo within a relatively short time span several sublimation-resublimation phases.

JSM15/07P/D-007   Poster   1400-007
GROWTH OF LARGE FROST CRYSTALS IN COLD CHAMBER

Keiji HIGUCHI[1], Hiroji FUSHIMI[1], Yukari NISHIMURA[4], Eri SANDA[4], Sakie SUMIKAWA[2], Sakae SHIMABAYASHI[2], Kenzo KANDA[3] ([1]Nagoya City Science Museum, [2]Explorer Museum Nishibori Eizaburo Memorial, [3]Nakaya Ukichiro Museum of Snow and Ice, [4]School of Environmental Science, Univ of Shiga Prefecture)

Formation of large crystals of frost was found on the wall and ceiling of cold chamber of the Explorer Museum Nishibori Eizaburo Memorial. Size of frost crystals are in order of cm, and largest one was over 10 cm. These frost crystals can be classified into three types; (1) cup, (2) needle, and (3) plate. During the period when air temperature in the cold chamber was warm, the wall of chamber was covered by frost crystals of plate, needle and cup, from the top to the bottom of the wall. During the period when air temperature was cold, the wall was covered only by cup crystals. On the basis of results obtained by observations of types of frost crystals on the wall and measurement of air temperature near the wall, it can be concluded be concluded that air temperature for transition of types from plate to needle was nearly -1°C, and that for transition from needle to cup was nearly -4 to -7°C. Forms of cup

crystal are quite characteristic, and many of them have one side opening inward and continued in hexagonal scroll. Such cup crystals in scroll form were observed in Greenland by Wegener (1935), and in the Antarctic by Knight and De Vries (1985). Detailed observations of scroll form of cup crystals developed in the cold chamber were possible after making plastic replica of them, which will be exhibited at the presentation. In the investigation on artificial snow crystals by Nakaya (1954), it was shown that formation of cup crystal in scroll form occurred at air temperature of -8°C. In the case of the experiments by Kobayashi (1957), scroll development occurred at air temperature of -6°C. These experimental results are in good agreement with air temperature conditions as mentioned above. On the other hand, cup crystal grew at air temperature in the range from -6°C to -10°C, but also -20°C, in the case of experiments by Nakaya. Similarly, sheath or cup crystals grew at air temperature in the range from -7°C to -10°C, and also at air temperature in the range lower than -22°C, in the case of experiments by Kobayashi. Therefore, it would be reasonable to consider that formation of cup crystal in the cold chamber occurred in the warmer temperature range in their experiments,and formation of cup crystals in Greenland and the Antarctic occurred in the cold temperature range.

NORTH POLE ENVIRONMENTAL OBSERVATORTY AND THE SEARCH PROGRAM

James Howe MORISON[1], James OVERLAND[2], Toshi TAKAZAWA[3] ([1]Polar Science Center, Univ of Wash, [2]NOAA Pacific Marine Environmental Laboratory, [3]Japan Marine Science and Technology Center)

The Arctic has undergone a complex of significant, interrelated, atmospheric, oceanic, and terrestrial changes in recent decades. These changes are affecting every part of the Arctic environment and are having repercussions on society. There is evidence that these changes are connected with the positive trend in the strength of the circumpolar vortex as often characterized by the Arctic Oscillation (AO) index. It is unclear what feedback processes on climate or ecosystems may be involved in the recent changes, but modeling and retrospective studies indicate they could be characteristic of global warming. In any event, observations suggest that the impact at high latitudes is substantial. The North Pole Environmental Observatory (NPEO) is an international effort to maintain a distributed observatory centered on the North Pole. It includes annual establishment of an automated drifting station and deep ocean mooring as well as repeated hydrographic surveys. NPEO observations in this critical region have shown that the ocean and ice are to a large extent still in the changed condition characteristic of the 1990s. In many ways NPEO is an example of the measurement philosophy and approach that can be used to implement the Study of Environmental Arctic Change (SEARCH). SEARCH has been conceived as an interdisciplinary, interagency program with international ties and a core aim of understanding the complex of recent changes.

ARCTIC-CHAMP: THE NSF PAN-ARCTIC COMMUNITY-WIDE HYDROLOGICAL ANALYSIS AND MONITORING PROGRAM

Charles J. VOROSMARTY[1], Larry HINZMAN[2] ([1]University of New Hampshire, [2]University of Alaska Fairbanks)

There is extensive and mounting evidence that the contemporary environment of the high north is changing and doing so over a broad, pan-Arctic domain. Water is central to the functioning of the climate, hydrology, heat balance, biology and biogeochemistry of the Arctic and is thus of critical importance to human society. Thus, Arctic environmental change must necessarily encompass changes to the hydrology of the region. Productivity, carbon balance, energy balance - in particular evapotranspiration - and hence runoff are all coupled closely and will be affected by the combined changes in temperature and precipitation. Over decadal time scales the stature and relative abundance of plants may be changing as well, producing new patterns of feedback to the climate system by altering regional-to-global scale energy and carbon balances. Increases in freshwater transport to the Arctic Ocean are now clearly documented and may at some point reduce the formation of North Atlantic Deep Water, resulting in a cooling in the North Atlantic region. These changes have enormous biogeophysical consequences that in turn make them critical to society and sound policy-making. The Arctic CHAMP is a new program supported by the National Science Foundation that seeks a better understanding of arctic hydrology and the natural linkages of hydrology with closely related atmospheric, terrestrial, and oceanic processes and cycles. A review of the status of this program and how it will contribute toward a better articulation of these important issues will be presented.

AN INTEGRATED ASSESSMENT OF CLIMATE CHANGE IN THE BARENTS REGION

Manfred A. LANGE (Institute for Geophysics, University of Muenster)

Global and climate changes will be amplified in the Arctic due to a number of complex feedback processes between marine-, terrestrial- and the climate system. Thus, assessing the impacts of such changes for nature and people in the circumpolar North attains a high priority. Because of the regional manifestation of climate changes and as a result of the inter-linkages between natural and societal systems, integrated regional impact studies (IRISs) have been identified as suitable tools to address this challenge. In the framework of an IRIS, two tasks become central: (i) an assessment of major impacts of climate change to key environmental and economic sectors and their various interlinkages and feedbacks and (ii) the development of an integrated assessment model (IAM). The first issue has been pursued within the Barents Sea Impact Study (BASIS), a former Priority Project of the International Arctic Science Committee which was funded by the European Commission (ENV4-CT97-0637). We considered marine and terrestrial ecosystems as well as the hydrological cycle and fishery, forestry and reindeer herding as important economic sectors.With regard to the Barents Sea, years with enhanced inflow of Atlantic water (so-called 'warm; years result in a reduced sea ice cover, a 30% increase in primary production and an enhanced CO2-uptake by 8% relative to years with a reduced inflow of Atlantic waters ('cold years. Findings related to terrestrial ecosystems indicate a significant diversity of responses patterns of individual species to climate change, similarly differentiated impacts on population dynamics of present

pests and invaders under varying climate conditions and slightly inconsistent climate signals for the last 100 years between the Kola Peninsula and rest of study region. Our results, while indicating a number of important consequences of climate change also demonstrate the importance of non-climatic drivers in the future development of the Barents Sea Region.In order to more thoroughly explore vulnerabilities of the region to climate change, a follow-on project has been funded by the EU and is currently being implemented (BALANCE; Global Change Vulnerabilities in the Barents Region: Linking Arctic Natural Resources, Climate Change and Economies; EVK2-CT2002-00169). A central goal of BALANCE is the development and application of an IAM, which consists of modules describing processes in marine and terrestrial ecosystems and their consequences for key economic sectors. The models are driven by results from a dedicated regional climate model for the Barents Region. The involvement of stakeholders in the project, similarly to BASIS, will be of considerable importance.

VARIATIONS OF ATMOSPHERIC CONSTITUENTS AND THEIR CLIMATIC IMPACT IN THE ARCTIC

Takashi YAMANOUCHI[1], Makoto WADA[1], OTHERS[2] ([1]National Institute of Polar research, [2]Alfred-Wegener Institute for Polar and Marine Research, Nagoya University, Tohoku University, Hokkaido University and NIPR)

The research project *Variations of atmospheric constituents and their climatic impact in the Arctic (1999-2004)* has been conducted to clarify the variation of greenhouse gases, aerosols, and clouds in the Arctic troposphere and stratosphere; to explain the transport and transformation processes, source and sink; to compare with the Antarctic and evaluate the radiative effect and then the climate impact. The following specific research has been carried out during the current year based on support by Norwegian Polar Institute. (1) Long term observations of greenhouse gases: At the Rabben observatory in Ny-Ålesund scientific station, Svalbard, we continued our long term air sampling for greenhouse gases, and continuous measurements of surface ozone and meteorology. Through these observations, and stable isotope analysis, we hoped to clarify the variation in concentrations of greenhouse gases and the causes of variability. We also planed to analyze data accumulated concerning exchange of carbon dioxide between ocean and atmosphere, and to continue relevant operations in collaboration with the oceanographic group (eg. EU project CONVECTION). (2) Aerosol and cloud observations: Measurements of aerosol number concentrations, optical depth, vertical distributions, composition and precursor gases; and observations of precipitable water, cloud liquid water, ice water amount and precipitated snow particles, have been continued at Ny-Ålesund to determine the relationship between aerosols, clouds and precipitation. Doppler radar observation at Bear Island is also coordinated. (3) ASTAR 2000 (Arctic Study of Tropospheric Aerosols and Radiation): In collaboration with the Alfred-Wegener Institute of Polar and Marine Research together with support by other institutions, coordinated airborne and ground-based observations of aerosols (Arctic haze) and radiation were carried out in the Svalbard area through March and April, 2000. A German aircraft Polar 4 (Dornier 228) was used to measure vertical distributions of aerosols and radiation, while remote sensing, sonde observations and sampling were conducted on ground. Trajectory analysis was made using objective analysis data for the same period to estimate the transportation process and the relation to atmospheric circulation in the Arctic. In addition, SAGE-II satellite observations were compared, and the radiative forcing of aerosols over a wide area was evaluated by incorporating into an Arctic regional climate model (HIRHAM). (4) AAMP 98 and 02 (Arctic Airborne Measurment Program): Two similar campaigns of airborne observation using jet plane (Gulfstream-II) were carried out in March 1998 and 2002 with long range stratosphere flights over the Arctic Ocean and local profiling flights in the vicinity of Svalbard. Research objectives were to elucidate spatial distribution, long-range transport and transforation of greenhouse gases and aerosols, related to stratosphere-troposphere exchange and polar vortex; optical properties of aerosols and their radiative forcing; the structure of atmospheric disturbance, especially of polar low, and its microphysical process.

DATA MANAGEMENT SUPPORT FOR NSF ARCTIC FIELD PROJECTS

James A. MOORE, Greg STOSSMEISTER, Scot M. LOEHRER (Joint Office for Science Support, University Corporation for Atmospheric Research)

Access to and integration of multidisciplinary data from field projects in the Arctic Basin recently completed or underway is particularly critical to the timely and accurate understanding of the rapid changes that are now underway in the Arctic. The NSF Arctic System Science (ARCSS) Program is committed to facilitating data archival and provide easy mechanisms for data exchange among researchers interested in the Arctic system. JOSS offers some capabilities that address these two important ARCSS objectives. The University Corporation for Atmopsheric Research (UCAR) Joint Office for Science Support (JOSS) has been involved in the data management support for a number of ARCSS field projects, both domestic and international, including the Surface Heat Budget of the Arctic Ocean (SHEBA), Arctic Transitions in Land, Atmosphere System (ATLAS), International Tundra Experiment (ITEX), Western Arctic Shelf Basin Interactions Project (SBI) and Arctic Regional Climate Modeling Intercomparison Project (ARCMIP). JOSS also participates on committees to further improve the collection, archival and dissemination of all manner of Arctic datasets. JOSS has developed and maintains a state-of-the-art data archive and dissemination system that provides single source access to complete project datasets. Most data are accessible for browsing and orderable on-line with connectivity to distributed archives. If the project includes single or multi-year field phases, JOSS can provide a web-based, on-line field catalog or project web pages to support near real-time documentation of activities and selected data displays. This presentation will discuss data management strategies that have been successfully implemented in ARCSS projects, provide some examples of specific support to projects, including specialized products and datasets, and discuss some of what the future holds for data management support to ARCSS field research.

JSP04/09A/A06-006	1110

ICE-DRIFTING BUOY OBSERVATIONS OVER THE ARCTIC MID OCEAN RIDGE

Takashi KIKUCHI[1], Hirokatsu UNO[1], Kiyoshi HATAKEYAMA[1], James H. MORISON[2] ([1]Japan Marine Science and Techonology Center, [2]Polar Science Center, Applied Physics Laboratory, University of Washington)

We have been conducting temperature, salinity and ocean current observations by ice-drifting buoy, named J-CAD (JAMSTEC Compact Arctic Drifter), in the Arctic Ocean since 2000, in collaboration with North Pole Environmental Observatory (NPEO) Project. J-CAD 4, which was installed on the ice of the Amundsen Basin (88.5N, 76.9E) on April 26 2002, has crossed over the Arctic Mid Ocean Ridge to the Nansen Basin of the Arctic Ocean. J-CAD 4 is equipped with 6 CT/CTD sensors that measure water mass properties at the maximum depth of 250m and an ADCP measuring current data up to 120m. Observational results

show that water mass characteristics in the Amundsen Basin, over the Arctic Mid Ocean Ridge, and in the Nansen Basin are clearly different and the frontal structures exist on the either side of the Arctic Mid Ocean Ridge. Especially, surface salinity of the Arctic Mid Ocean Ridge is higher than that of the two Basins. In other words, there is a weak stratified structure over the Arctic Mid Ocean Ridge. Current data measured by ADCP indicates that there is a steady current with an averaged speed of 1.0-2.0 cm/s flowing toward the Atlantic Ocean along the Arctic Mid Ocean Ridge. This observational data mostly corresponds to the results from J-CAD 1 which was installed in April 2000 and drifted over the Arctic Mid Ocean Ridge. Moreover, the geostrophic velocities calculated from the CTD observation by Oden91 cruise (August to October, 1991) indicate a current with the speed of several cm/sec to the Atlantic Ocean along the Arctic Mid Ocean Ridge. Therefore, it is presumed that over the Arctic Mid Ocean Ridge, there is a weak, average current flowing toward the Atlantic Ocean along the bottom topography.

JSP04/09A/A06-007   1130

SENSITIVITY EXPERIMENTS OF SEA-ICE PROCESSES ON WORLD OCEAN CIRCULATION BY USING A GLOBAL COUPLED OCEAN AND SEA-ICE MODEL

Kenji KOMINE[1], Tatsuo MOTOI[2], Keiko TAKAHASHI[1], Xiangdong ZHANG[3], Nobumasa KOMORI[1], Hirofumi SAKUMA[1], Motoyoshi IKEDA[4], Tetsuya SATO[1] ([1]Earth Simulator Center, [2]Frontier Research System for Global Change, [3]International Arctic Research Center University of Alaska Fairbanks, [4]Graduate School of Environmental Earth Science Hokkaido University)

Recent dramatic change of the cryosphere including sea-ice is considered as a silent precursor of the effect of the global warming to be maximized in the polar region and the development of a reliable sea-ice model is one of the urgent issues for climate variability studies and the global warming assessment. As a branch project of the Earth Simulator initiative, we are collaborating with FRSGC to try to implement the IARC sea-ice model into our OGCM code optimized for the Earth Simulator. The basic design of the IARC sea-ice model is that of Hibler (1979) dynamics and Parkinson and Washington (1979) thermodynamics with some modifications in treating such physical processes as snow and open water as well as in coupling schemes and with a recent contribution on sea-ice and ocean interaction process by Zhang and Zhang (2001). As a first step towards such a goal, we have implemented the IARC model into the OFES (MOM3-based OGCM for the Earth Simulator). In this presentation, we will give a brief description of the current status of our coupled model development and will show some basic physical performances of our model manifested in a test validation of fifty years of time integration. In the validation, it takes five or six years for the sea-ice to reach a quasi-equilibrium state. Sea-ice distribution pattern and the seasonal cycle of thickness and concentration both in the Arctic and Antarctic Oceans turn out to be close to the observational ones. Sea-ice thickness piles up from the Beaufort Sea to the Canadian Archipelago and the northern coast of Greenland. We also performed experiments to explore sensitivity of sea-ice to some physical parameters like ice strength as an example and sensitivity to model resolution. The results show sea-ice motion and thickness changed subject to changes of these physical parameters and model resolution, which finally affect global temperature and salinity through sea-ice/ocean interactions in the polar regions.

JSP04/09A/A06-008   1150

SIMULATING SEASONAL CYCLES OF THE ICE-OCEAN SYSTEM IN THE PAN ARCTIC AND NORTH ATLANTIC OCEAN

Jia WANG, Meibing JIN, Moto IKEDA (IARC-FRSGC, University of Alaska Fairbanks)

A coupled ice-ocean model (CIOM) is configured for the pan Arctic and North Atlantic Ocean (PANAO) with a 27.5km resolution. The model is driven by the monthly atmospheric climatology averaged from the 40-year NCEP reanalysis (1958-1997). The ocean model is the Princeton Ocean Model (POM), while the sea ice model is based on afull thermodyanical and dynamical model with plastic-viscous rheology. A sea ice model with multiple categories of sea ice thickness is utilized. We first focus on seasonal cycles of sea ice and ocean circulation. This model reasonably reproduces seasonal cycles of both the sea ice and the ocean. Climatological sea ice areas derived from historical data are used to validate the ice model performance. The simulated sea ice cover reaches amaximum of 14x10+6 km^2 in winter and a minimum of 6.7x10+6 km^2 in summer, which are close to the 95-year climatology with a maximum of 13.3x10+6 km^2 in winter and aminimum of 7x10+6 km^2 in summer. The simulated general circulation in the Arctic Ocean, the GIN seas, and northern North Atlantic Ocean are qualitatively consistent with historical mapping. We found that the winter low salinity or freshwater content in theCanada Basin tends to converge due to the strong anticyclonic atmospheric circulation that drives the anticyclonic ocean surface current, while summer low salinity or freshwater tends to spread inside the Arctic and exports out of the Arctic, due to the relaxing wind field. We also found that the warm, saline Atlantic Water intrudes farther into the Arctic in winter than summer due to prevailing winter wind stress over the northern North Atlantic that is controlled by the Icelandic Low. Seasonal cycles of temperature and salinity at several selected representative locations reveals regional features that characterize different water mass properties.

CIRCULATION AND VOLUMN, ICE AND FRESHWATER TRANSPORTS OF BAFFIN BAY

C.L. TANG, E. DUNLAP, T. YAO (Bedford Institute of Oceanography)

Baffin Bay is connected to the Arctic Ocean through the Canadian Arctic Archipelago and to the Labrador Sea through Davis Strait. The variability of its mass and freshwater transports is closely related to oceanographic conditions in the Arctic Ocean and Labrador Sea. Freshening of the Arctic Ocean can promote ice growth in Baffin Bay, which may lead to a strong stratification and weak winter convection in the Labrador Sea and a weak thermohaline circulation in the North Atlantic. To investigate the role of Baffin Bay in Arctic-Atlantic interaction, a modelling study in conjunction with data analysis is carried out to quantify the circulation and transports of Baffin Bay. The model used is a coupled ice model and Princeton Ocean Model encompassing the entire Labrador Sea and Baffin Bay with open boundaries along 42° W, 40°N and 55° W. Volume transports are prescribed on the open boundaries and at three northern channels according to data and largescale models. Objectively analyzed high-resolution monthly temperature and salinity fields are used to initialized the model. The model results show that the circulation of Baffin Bay is cyclonic. A branch of the Western Greenland Current flows into the bay through the eastern side of Davis Strait. This northward current spreads over the eastern shelf and converges at the shelf edge at 75°N. In the western part of Baffin Bay, the water flows in the southeast direction parallel to the coast except an excursion into Lancaster Sound. The strongest current occurs over the shelf edge between 70°N and 72°N. The model currents are compared to current meter measurements across Davis Strait and at several sites around the shelf edge taken by C. Ross. There is a general agreement between the model and the data. The current meter data show bottom intensification at the western shelf edge, which is reproduced in the model. The net volume transport through Davis Strait from the model is

2.2 Sv, which compares favourably with the transport calculated from the current meter data, 2.5 Sv. The estimated freshwater and ice transports through Davis Strait based on available data are 3120 km³ yr⁻¹ and 870 km³ yr⁻¹, respectively. Sensitivity of the model transports to boundary conditions and meteorological forcing is discussed.

A COUPLED SEA ICE-OCEAN MODEL OF BAFFIN BAY AND THE NORTH WATER POLYNYA

Todd E. ARBETTER[1], Lawrence A. MYSAK[2], Blandine L'HEVEDER[3] ([1]Cooperative Institute for Research in Environmental Sciences, University of Colorado, [2]Department of Atmospheric and Oceanic Sciences, McGill University, [3]Rennes, France)

The North Water polynya, located in Smith Sound in the northern reaches of Baffin Bay, represents a geophysically interesting area of the Arctic. Despite its high latitude, the polynya is characterized by very thin or absent ice cover throughout winter and spring. Recent field work has greatly increased the amount of information available in the northern Baffin Bay region, but the oceanic processes associated with the polynya are not fully understood. The physical setting of the Baffin Bay region is not well-reproduced in typical general circulation climate models, which have too few grid points to accurately resolve the region. Here, we present a regional coupled ice-ocean model (with granular sea ice rheology) which is specifically developed to model the Baffin Bay region and the North Water polynya. An initial series of sensitivity tests examines the effects of lateral ocean boundary conditions; it is found that the manner in which they are applied has dramatic effects on the solution over the entire model domain, particularly on the simulated stratification of ocean salinity. We believe that active restoring of salinity and potential temperature along the lateral open ocean boundaries provides the most realistic simulation; however, there remain other issues such as surface (atmospheric) forcing which need to be explored.

JSP04/09P/A06-002   1415

ANNUAL VARIATION OF SEA-ICE DRAFT DISTRIBUTION AT THE NORTH POLE ENVIRONMENTAL OBSERVATORY

Richard E. MORITZ, Rebecca WOODGATE, Knut AAGAARD, Jamie MORISON (Polar Science Center, University of Washington)

A time series of sea-ice draft D(t) was estimated from measurements made by an Upward Looking Sonar(ULS) from 10 April, 2001 to 21 April, 2002. Themooring was located at the North Pole Environmental Observatory (NPEO), Latitude 89.56 N, Longitude 66.65 E. Sample statistics and probability density distributions (PDFs) of D(t) have been estimated bygrouping the data in nonoverlapping, two-week intervals with equal weight given to each observation. The sample mean draft varied from 3.7 meters in early April to 2.3 meters in late August, with an overall annual mean of 3.0 meters. The sample mean draft estimated for 15 September, 2001 is 2.3 meters, a value near the middle of the seasonally adjusted estimates derived from submarine sonar profiles near the North Pole in the 1990´s (Rothrock, et al., GRL, 26, 1999, 3469-3472).The modal draft of the sample PDF lags behind the sample mean, with extrema of 2.3 meters in late June, 2001 and 1.6 meters in early January, 2002.The open water fraction (OWF) is defined by integrating the sample PDFs over ice drafts less than .05 meters.OWF exceeded 1 percent from mid-June to early October, and for a brief period in late December. The maximum OWF of 13 percent occurred in mid-July. The evolution of the ice draft PDF on time scales of a few days to one year is discussed with reference to physical processes and to the problem of estimating trends in the climatology of D.

JSP04/09P/A06-003   1430

BASAL HEAT FLUX NEAR THE NORTH POLE DURING THE SUMMER OF 2002

Miles G. MCPHEE[1], Takashi KIKUCHI[2], James H. MORISON[3], Timothy STANTON[4] ([1]McPhee Research Inc., [2]Japan Marine Science and Technology Center, [3]Polar Science Center, University of Washington, [4]U.S. naval Postgraduate School)

Basal heat flux is a major factor in the heat and mass balance of Arctic sea ice. In summer, insolation through open leads, thin ice, and melt ponds is sufficient to heat the mixed layer to well above freezing, despite continual loss of heat at the interface as ice melts. We use data from the North Pole Environmental Buoy Project to estimate basal heat flux during 2002 in a region bounded by 83-86 deg N latitude and 17-34 deg E longitude. Ocean-to-ice heat flux is parameterized as proportional to the product of interface friction velocity (square root of kinematic stress) and the elevation of mixed layer temperature above freezing. Reliable values for the heat and momentum exchange coefficients have been derived from several manned drift stations, most notably the SHEBA drift in 1997-98. Our results are compared with data from two previous manned drift projects: AIDJEX (1975) and SHEBA (1998). We find a surprisingly uniform temporal distribution of mixed layer temperature elevations during summer, despite wide geographic distribution (latitude) in the Arctic, and very different mixed layer salinities. We review the methods used for estimating heat flux, then estimate total basal heat transfer and the amount of solar radiation entering the mixed layer during summer.

JSP04/09P/A06-004   1445

DENSE WATER TRANSPORT ON BOTTOM SLOPE IN HIGH LATITUDE

Jun TAKAHASHI, Jia WANG, Motoyoshi IKEDA (Frontier Research System for Global Change)

Oceanographic observations have revealed importance of dense water formation and its spreading in the Arctic shelf and slope. The dense water is believed as one of the source of cold halocline, and is thought to carried fromcoastal region toward basin through mainly bottom boundary layer. Bottom boundary plays an important role in ocean circulation. Bottom boundary layer carries dense water to one´s neutral depth on formation process of intermediate and deep water. Fine grid interval is needed to simulate bottom boundary layer, but now computational resources are not sufficient to simulate bottom boundary layer exactly, especiallyin global ocean circulation experiment with coarse grid.Several bottom boundary layer models therefore have been developed. But transport by bottom boundary layer is not simulated well as observed, and tends to underestimate the transport. It is important to improve bottom boundary layer model with coarse grid. So we carry out sensitivity experiments with bottom boundary layer model on its parameterization, especially on bottom friction and height of bottom boundary layer.Numerical experiments of descending of dense water with and without bottom boundary layer is done. The primitive equation model with z-coordinate (MOM) is used for rectangular idealized model ocean. The model ocean assumes the shelf region in the Arctic Ocean, with zonal lateral boundary condition

being cyclic.Bottom is inclined meridionally as northern side is deeper.Forcing of surface salt flux is added from southern boundary to y=30 km. The forcing assumes brine rejection in coastal polynya in the Arctic. The flux gradually decreases from y =30 km, and becomes zero at 50 km, and is homogeneous zonally. Only salt flux is used, and surface wind and heat flux are not used. Bottom boundary layer following Gnanadesikan´s model is used. The layer depth is constant.Numerical experiments with coarse grid are carried out to simulate descending of the dense water. The surface salt flux makes surface water denser at southern boundary. The water descends to bottom, and starts to flow along bottom slope. In case of experiments without bottom boundary layer model, dense water flows almost along coast. On the other hand, in case of experiments with bottom boundary layer model, dense water start to descends toward ocean basin, and descending of dense water on inclined bottom isreproduced. Transport of dense water of coarse grid experiment is well simulated even in case of coarse grid experiment.

DEVELOPMENT OF A QUADRILATERAL SPECTRAL/HP ELEMENT OCEAN MODEL

Hideaki KITAUCHI (Frontier Research System for Global Change)

An accurate and fast, vertical two-dimensional non-hydrostatic oceanmodel is being developed by using a quadrilateral spectral/hp element method. In this approach a computational domain is partitioned into quadrilateral elements like a finite element method; within each of these elements every dependent variable is approximated as atruncated polynomial expansion like a spectral method. The Galerk informulation is employed to derive a set of semi-discrete, ordinary differential equations for the expansion coefficients of the dependent variable in each element. Temporal integration is performed by the use of the second-order explicit-implicit stiffly stable scheme; the diffusion term is treated implicitly; the others explicitly. A system of the obtained discrete equations is solved numerically under continuity conditions on the variable between the adjoining elements, appropriate boundary and initial conditions. Theadvantage in the spectral/hp element method is to achieve a high numerical accuracy in a complex geometry. We will present a progress report on the quadrilateral spectral/hp element ocean model.

JSP04/09P/A06-006   1545

EVALUATION OF BE AS A TRACER OF RIVER WATER IN ARCTIC FAST ICE ZONE,CHUKCHI AND BEAUFORT SEAS

Noriyuki TANAKA[1], Hisashi NARITA[2] ([1]IARC, UAF, FORSGC, [2]GRADUATE SCHOOL OF ENV. EARTH SCI. hOKKAIDO UNIV.)

Ba concentration in Arctic seawater has been recommended to use as a chemical tracer to identify river water influences in fresh water burden in Arctic surface water, especially for American river waters with significantly high Bacontents. Since Ba is biologically active elements in the ocean, biogeochemicaleffects on the Ba concentration should be closely examined for its more quantitative use in the Arctic Ocean. In 2000 and 2002, surface water samples have been collected during cruises of R/V "MIRAI" Arctic expeditions in northern Bering Sea shelf, Chukchi and Beaufort Seas in late summer. Stable isotope composition, silicate and Ba concentration of collected seawater were analyzed. Assuming that summer surfacewater consists of three water components; upper halocline water, sea ice meltwater and river water, fractions of those components of each water sample are estimated based on stable isotope composition and salinity. Appling typical silicate and Ba concentrations of McKenzie river and upper halocline water, preformed silicate and Ba concentrations for each sample are estimated. Preformed concentration is defined by the concentration, which is determined only by physical mixing of water masses. By subtracting observed values from the preformed values, we could obtain how much portions of silicate and Ba have been removed from the surface water presumably by biological uptake. The results show 1) up to 100% of silicate removal, 2) about 50% of removal ofBa and 3) The constant removal ratios of Ba/Si about 1.04 to 1.17(95% of confidence level) but slight large pronounced sea ice melt water, which mayimply abiological removal of Ba associated with sea ice. Constancy of the removal ratios give us warrant for further investigation to improve trace ability of Ba as American river water sources.

CHARACTERIZATION OF CHROMOPHORIC DISSOLVED ORGANIC MATTER IN THE BEAUFORT SEA: IMPLICATIONS FOR RIVER WATER INFLUENCE

Celine GUEGUEN, Laodong GUO, Noriyuki TANAKA (IARC/Frontier, University of Alaska Fairbanks)

Arctic climate and environmental changes may have a profound impact not only on the global heat budget and ocean circulation but also on biogeochemical cycles of organic carbon. Dissolved organic matter (DOM) is an important component in global carbon budgets. A fraction of the DOM pool, which absorbs visible and near-ultra-violet radiation, is referred to chromophoric DOM (CDOM). It is proposed that CDOM can be used as a potential tracer in oceanic water mixing, especially in the Arctic Ocean where there is a large share of global river discharge and higher concentration of terrigenous DOM. During September-October 2002, seawater samples were collected from the Beaufort Sea onboard the R/V Mirai and characterized for their optical properties and dissolved organic carbon (DOC) concentrations. The terrestrial CDOM was characterized by a higher emission maximum than its marine counterpart, with a difference as large as 50 nm. Higher concentrations of DOC and abundance of CDOM were related to inputs from the Mackenzie River. In general, the fluorescence intensity was correlated to the DOC concentration, suggesting a possible high resolution DOC measurement using optical properties. In addition, fluorescence intensity decreased with increasing salinity from the Mackenzie River plume to the Beaufort Sea and increased from the west channel to the east channel. Freshwater inflow from the Mackenzie River to the Beaufort Sea was found mostly through the east channel during our sampling season, consistent with results derived from other hydrographic data.

DETECTION OF THE CARBON DIOXIDE FLUX IN THE AIR-SEA ICE-WATER SYSTEM: THE AMERASIAN ARCTIC

Igor P. SEMILETOV, Alexander P. MAKSHTAS, Edgar ANDREAS (CRREL) (International Arctic Research Center/University Alaska Fairbanks)

Atmospheric carbon dioxide levels monitored in Barrow, Alaska, show the largest winter-to-summer variations in the world as well the highest levels of concentration (www.noaa.gov). Measurements along the coast of the Arctic Ocean show that the concentration of carbon dioxide has increased substantially over the past several decades, that tends to coincide with the general shrinking of the sea ice cover in the Arctic Ocean. To our knowledge, over the last decade, most Arctic CO2 research has been focused on terrestrial ecosystems

(Laurila et al., 2001;Oechel et al., 2002, 1998), whereas the Arctic Ocean had been generally ignored in the global CO2 budget (Anderson et al., 1999). During the last five years, only a few expeditions have performed studies of carbonate chemistry in the free-ice Arctic seas. The role of CO2transport across the sea ice in the regional carbon budget has not been evaluated because of the lack of experimental data, except for the pioneering measurements of Gosink et al. (1976) and Kelly and Gosink (1979) in the 1960-70s. They found that numerous tiny brine channels cross the young sea ice allow gases to penetrate through the ice. During the summer, the sea ice and underlying water and numerous leads can be a sink for atmospheric CO2 because of photosynthesis, especially in the coastal zone and over the shelf, whereas in winter the sea ice can became a source (Kelley and Gosink, 1988) for atmospheric CO2. In this report, we present results of the first measurements of CO2 fluxes above and through fast sea ice. We made these measurements in the coastal zone near the Barrow over the Chukchi Sea in June 2002. Our technique was eddy-correlation using a LI-COR 7500 open-path CO2/H2O analyzer and a three-axis sonic anemometer/thermometer installed on a tower 3.8 m high. Additionally, to evaluate the CO2 concentration and to obtain rough estimates of CO2 fluxes through different types of ice cover (melt ponds, dry snow, bare ice), we used a chamber technique and a closed cell LI-COR 820 gas analyzer. We used the static headspace technique for measuring CO2 partial pressure (pCO2) in ice brine and sub-ice water samples taken just beneath the ice and at depths below the sharp shallow halocline just beneath the sea ice bottom. We found that the magnitude of the CO2 flux (generally directed from air to the sea ice) is typically 0.01-0.02 mg m-2 s. This is close to values measured in late June by Oechel et al. (1998) over tundra on the North Slope of Alaska. Our preliminary resultsdemonstrate that the ice-covered Arctic ocean cannot be ignored in the regional carbon budget of the Arctic. Additional research is required, however.

JSP04/09P/A06-009   1700

DISSOLVED AND PARTICULATE ORGANIC MATTER IN THE SOUTHEASTERN BERING SEA SHELF

Laodong GUO[1], Tomoyki TANAKA[1], Deli WANG[1], Noriyuki TANAKA[1], Akihiko MURATA[2] ([1]International Arctic Research Center, University of Alaska Fairbanks, [2]Japan Marine Science and Technology Center, Yokohama, 237-0064, Japan)

The Arctic region has witnessed dramatic environmental and climate changes. How these changes alter the biogeochemical cycling of organic matter in the Arctic region is still poorly understood. Seawater samples were collected along a transect at ~166°W across the continental shelf in the southeastern Bering Sea during September 2001 onboard the R/V Mirai, and measured for dissolved (DOC), colloidal (COC) and particulate organic carbon (POC), dissolved organic nitrogen (DON), and particulate nitrogen (PN), as well as stable isotopic composition (d13C and d15N) of suspended particulate organic matter. The phase partitioning of organic carbon between dissolved (<1 kDa), colloidal (1 kDa-0.7 μm) and particulate (>0.7 μm) phases was examined based on filtration and ultrafiltration. Concentrations of DOC ranged from 61 to 92 μM (averaging 76±9 μM) with a decreasing trend from the south (outer shelf) to the north (inner shelf) along the 166°W, and were negatively correlated with salinity. DON concentrations varied from ~5 to 10 μM, with a more dynamic distribution feature. On average, POC comprised 14±6% of the total organic carbon pool in the water column, and colloidal organic carbon (COC) made up of 36±8% of the TOC, leaving 50±5% of the TOC present in the <1 kDa dissolved phase. Suspended particulate organic matter seems mostly marine in origin, with an average C/N ratio of 7.4±1.1 and a significant correlation between POC and chlorophyll-a concentrations in the water column. Values of stable isotopes in the suspended particles varied from 2.86 to 9.98 per mil (with an average of 6.01±1.92 per mil) for d15N and from -27.17 to -23.41 per mil (averaging -24.57±0.91 per mil) for d13C. Interestingly, particulate d15N values were negatively correlated with NO3 at lower NO3 concentrations (≤5μM) but positively correlated with NO3 when NO3 concentrations were higher (>5 μM), indicating distinct isotopic fractionation mechanisms under different nutrient regimes.

JSP04/09P/A06-010   1715

ICE ALGAE PRODUCTION PROCESSES IN THE COASTAL FAST ICE IN THE WESTERN ARCTIC OCEAN

Kyung-Hoon SHIN[1], Noriyuki TANAKA[1], Tomoyuki TANAKA[1], Terry WHITLEDGE[2] ([1]Frontier Observational Research System for Global Change / International Arctic Research Center, Univ. of Alaska Fairbanks, [2]Institute of Marine Science, University of Alaska Fairbanks)

To investigate ice algae production processes and its related carbon flux, is important and urgent research subject in the Arctic Ocean. Because there is very little understanding regarding to the effect of recent Arctic climate changes on the sea-ice algae production and its contribution to the ecosystem and carbon cycle in the Arctic Ocean. During the last two spring seasons in 2001-2002, time series sea-ice observations and in situ ice algae incubation experiments were conducted off Pt Barrow in the northern Alaska. There are three objectives in this study as follows: 1) to clarify ice algal production processes in the coastal fast ice, 2) to evaluate ice algal contribution to carbon cycle in the Arctic, 3) to provide the data for the Arctic biogeochemical model related to climate change. Chl. a and POC concentrations were extremely high in the bottom layer of sea-ice with the development of brown colouration depending on light availability. The Chl. a concentration in the bottom ice algal layer (bottom 10 cm) was the highest in early May in 2001-2002, showing the large annual variation which might be attributed to the development of ice thickness. The stable isotope ratio (δ13C) of POC indicates that terrestrial organic matter may be the main source of POC in the entire ice core except bottom 10cm, exhibiting comparatively lighter isotopic values. The δ13C ratios of POC were heavier in the bottom 10 cm (reflecting ice algal origin)in June. POC production rate was larger in May rather than in June 2001, indicating faster POC turnover rate in May. In particular, particulate fatty acids turnover rate was remarkably faster, resulting from their large production and consumption rates. Additionally, as an indicator for ecophysiological state of marine diatoms population, C16-PUFA index (a measure of the percentage of C16 fatty acids that are polyunsaturated) suggests ice algae population was in a nutrient-limited condition. Comparing Chl. a concentrations in the bottom 10cm of ice algal between 2001 and 2002, Chl. a concentration on April 3, 2002 was approximately 2 fold higher than on April 5, 2001, and the maximum Chl. a concentration was around 2 fold larger on May 1, 2002 than on May 5, 2001. This observational result reveals that ice algal biomass have a large annual variation between 2001 and 2002. However, the variability of ice algal biomass may be affected by the environmental conditions such as ice thickness, cloudiness and nutrients supply and physical events. Therefore, more thorough investigation should be necessary to understand the ice algal biomass variability.

JSP04/09P/A06-011   1730

ONE-DIMENSIONAL BIOGEOCHEMICAL MODEL FOR THE SOUTHEASTERN BERING SEA

Clara Jodwalis DEAL[1], Meibing JIN[2], Jia WANG[3], Zhenwen WAN[4], Noriyuki TANAKA[1] ([1]Frontier Observational Research System for Global Change/International Arctic Research Center, University

of Alaska Fairbanks, [2]Institute of Marine Sciences, University of Alaska Fairbanks, USA, [3]Frontier Research System for Global Change/International Arctic Research Center, University of Alaska Fairbanks, USA, [4]Marine Biological Laboratories, Woods Hole, Massachusetts, USA)

To improve our understanding of how physical factors (such as retreating sea ice and local climate change) and biogeochemical changes (such as nutrient concentrations) may influence phytoplankton and zooplankton dynamics and thus dimethylsulfide (DMS) dynamics in the Bering Sea, we are developing a physical-ecosystem model (PhEcoM). As a first step in this modeling process, we have developed a one-dimensional physical model coupled with a one-dimensional biogeochemical model that is nitrogen-based (i.e. all biomasses and uptakes are converted into units of nitrogen concentration). This model may provide insights into how environmental changes affect the initiation and maintenance of the coccolithophore bloom in the Bering Shelf. The first recorded bloom of the coccolithophore |Emiliania huxleyi/| in the Bering Sea was coincident with unusual climatic conditions in 1997 and 1998. Two types of phytoplankton (diatoms and flagellates), three nutrients (nitrate + nitrite, ammonium, and silicon), three size-classes of zooplankton, detritus and DMS are included in the model. The model is driven by meteorological data: wind velocity, air temperature, sea surface temperature, specific humidity, cloud cover and light. A unique combination of convective, mechanical and turbulent mixing parameterizations, and high vertical resolution allow more realistic interactions of biological processes in the model. Simulations for the southeastern Bering Sea middle-shelf domain in relatively high and low sea surface temperature years, 2000 and 1999 respectively, have been performed. Sensitivity analysis results will be used to help select parameter values for the upcoming three-dimensional version of the model, which will include sea ice and may have applications elsewhere in the Arctic.

JSP04/09P/A06-012   1745

LATEST ESTIMATION OF PRIMARY PRODUCTIVITY IN THE ARCTIC OCEAN UNDER THE CONSIDERATIONS OF SEA-ICE CONDITIONS AND ITS YEAR TO YEAR CHANGE

Tohru IKEYA, Masayuki Mac TAKAHASHI (Graduate School of Arts & Sciences, The University of Tokyo)

The reported values of primary productivity in the Arctic Ocean thus far indicates that spatial and seasonal change is large due to latitudinal variations of seasonal changes of solar irradiance, distribution of sea ice and stability of water column, in addition to the spatial structure of sea ice itself. However, the estimations of primary productivity in water column and sea ice in the Arctic Ocean have been made for algal habitats independently categorized into coastal and offshore water, and seasonal and multi-year ice (cf. Legendre et al. 1992). The primary production at ice concentration higher than 50% is offset in the satellite radiometer data for the global primary production (Antoine et al. 1996). However, the recent confirmation of statistically significant decreasing trend of annual means of the entire artic sea ice at a rate of 2.7% per decade by satellite observation (Parkinson and Cavalieri 2002) urges establishment of the methodology to estimate primary productivity in the Arctic Ocean in relation to the possible influence of the recent changes of sea ice extent. The estimation of primary productivity not only in the sea ice but in the water column should be made under the dynamic changes of sea ice extent. Thus, in the present study, the examination of geographical structure of the primary production in the Arctic Ocean was based on the latitudinal distributions of multi-year and seasonal ice instead of conventional categories of coastal and offshore water. For the estimation of annual productivity, growing period was assumed to be 120 in seasonal ice regions north of 65°N and 90 in multi-year ice regions most of which locate at higher latitudes north of 70°N. The estimation was made using the values reported by Gosselin et al. (1997) who measured algal production in the water column and sea ice in multi-year and seasonal ice regions along a transact across the central Arctic Ocean. The estimated annual production in the water column plus sea ice in multi-year regions was 5.9 g C m^{-2} y^{-1} and lower than the previous estimation. Nevertheless, the annual total primary production in the Arctic Ocean was estimated to be 0.79 Gt C y^{-1} and nearly three times higher than the previous value. The high value was due to previously unmeasured contribution of dissolved organic carbon release which amounts to around 30% of particulate production and the high productivity in water column in seasonal ice regions (90 g C m^{-2} y^{-1}). The primary productivity within sea ice was 1.3 and 9.1 g C m^{-2} y^{-1} in multi-year ice and seasonal ice regions, respectively, and the total annual production within sea ice was 9% of the total primary production in the Arctic Ocean. The primary productivity in seasonal ice regions was around 1.6 times as high as that in open water regions and suggests that potentially high productivity occurs around these regions.

TRENDS IN PHYTOPLANKTON AND NUTRIENTS OF LAKE BAIKAL DUE TO GLOBAL WARMING

Mikhail N. SHIMARAEV, Sergei V. SEMOVSKI, Valentina N. DOMYSHEVA, Olga I. BELYH (Limnological Institute SB RAS, P.O.Box 4199, Irkutsk, 664033, Russia)

Changes in global climate are reflected in high latitude ecosystems, which are critically sensitive to temperature variations, season duration et al. Ecosystems of northern lakes are good indicators of climate variations due to low anthropogenic impact. Global warming as a result of human activity can threaten the ecosystems of ancient lakes that require conditions to be within narrow ranges. Lake Baikal – the deepest and the most voluminous lake in the World is a natural laboratory for climate change studies because of the long history of its studies (more than 150 years), still stable industrial activity in its basin and peculiar hydrological conditions preventing endemic biota from exchange with surrounding ecosystems. Baikal's ecosystem formation was a long evolutionary development with a stable low temperature regime. Under such specific conditions this ecosystem evolved with 2500 species, 80% of which are endemics, narrowly adapted to the special environmental conditions. Therefore, it is a very important to investigate the possible change in structure of the hydrobionts populations, which would occur from any changes in the Baikal temperature regime. During last decade of 20th century factors of global warming have been reflected in such regional indicators as local air temperature, date of complete freezing and break-up. In the same period significant decreasing of some nutrients in the whole water column was noted using regular filed measurements. For instance, dissolved silicon is assimilated by diatoms mainly during under-ice spring bloom. In condition of relatively stable silicon influx from tributaries, silicon vertical structure is strongly correlated with biological activity and processes of vertical mixing. Inverse box model of silicon dynamics have been used to

estimate intensity of its assimilation by diatoms, rate of vertical turbulent mixing and rate of occasional events of deep penetrative convection, which is able to transport surface waters to the deepest layers of the Lake Baikal. During 90th dissolved silicon concentration in the Baikal water column demonstrates significant decreasing.Picoplankton, green-blue of Sinechocistis and Sinecococcus taxa, is one of the main primary producers of Lake Baikal. Regular observations ofpicoplankton using electronic microscopy show increasing trend in its annual biomass. Numerical bio-optical model of two-component phytoplankton community dynamics in the pelagic ecosystem of the Lake Baikal can serve as a tool to study, in which way climatic factors control productivity of water ecosystem. It is shown that the main factor leading to changes in productivity and therefore to nutrient concentration maybe changes in warm season duration and influence of changes in the temperature is not so significant.

INTERANNUAL VARIATIONS OF CO2, CH4 AND N2O FLUXES IN BOREAL FOREST SOILS SINCE FROSTFIRE BURNING EXPERIMENT, CENTRAL ALASKA

Yongwon KIM, Noriyuki TANAKA (INTERNATIONAL ARCTIC RESEARCH CENTER /UNIVERSITY OF ALASKA FAIRBANKS)

Flux measurements at black spruce stand soils from an area of Long-Term Ecological Research (LTER) interior Alaska during the growing seasons of 1998 to 2002 are used to estimate the fluxes of CO_2, CH_4, and N_2O since 1998. The fluxes of CO_2 and N_2O measured in burned black spruce stand showed the increasing tendency with time after the fire, suggesting that the burned forest soils enhance the microbial activity and the soil temperature. Relationships between the fluxes of CO_2 and N_2O and the soil temperature before and after the fire showed good exponential correlations, indicating that soil temperature was one of the factors determining the fluxes of CO_2 and N_2O in burned black spruce forest soils. However, CH_4 flux did not depend on the temperature throughout the observation period. Q_{10} values between the fluxes of CO_2, CH_4, and N_2O and the temperature at 5 cm below the surface were 2.84±0.22, 1.09±0.02, and 3.32±0.26 for light chamber and 2.79±0.31, 2.28±0.12, and 2.38±0.18 for dark chamber in unburned soils , respectively. Q_{10} values in burned soils since 1998 between the fluxes of CO_2, CH_4, and N_2O and the temperature at 5 cm were 2.75±0.25, 3.27±0.28, and 2.96±0.18 for light chamber and 1.79±0.34, 2.86±0.19, and 3.90±0.19 for dark chamber, respectively. Therefore, the higher soil temperature after the fire may be led to the enhanced diffusion of CO_2 and N_2O by microbial activity between the atmosphere and the forest soils, and to the enhanced fluxe of trace gases in burned black spruce stand soils. Average net respiration rates by aboveground vegetations in soil surface correspond to 56 % and 38 % of total soil respiration rate in unburned and burned black spruce soils, respectively. This demonstrates that net respiration by the vegetations (mainly moss and lichen) was one of the sources of atmospheric CO_2 in boreal forests.

ORIGIN AND CONTENT OF METANE IN SIBERIAN PERMAFROST DEPOSITS

Anatoli BROUCHKOV, Masami FUKUDA (Research Center for North Eurasia and North Pacific Regions of Hokkaido University)

Methane contribution to greenhouse effect and global warming is considerable; permafrost will be melting due to increased temperatures, however, its distribution in permafrost is almost unknown. Frozen alluvial deposits and ice complex were studied for methane and carbon dioxide content from the depths of up to 5 m and more in Eastern Siberia. Methane concentration of pore air is high, up to 60000 ppmv, though ice inclusions do not contain as much methane as frozen soils. Average methane content in permafrost could be estimated minimally as 0.05–10 ml/kg. The anti-proportional relationship between values of concentration of methane and carbon dioxide performed in permafrost indicates possible occurrence of methane oxidizing processin deposits. On the whole, methane and carbon dioxide content in frozen soils rise in accordance to water content increase. Type of landscape determinates methane distribution in upper permafrost. It was found that thermokarst depressions contain less concentration of methane than undisturbed areas; thus, the older the permafrost the more methane it contains. Established relationship between volumetric air content and both values of methane and carbon dioxide concentration in permafrost also suggests thawing-freezing history. Based on published data and the research an estimation of additional emission of methane from permafrost areas was made. It shows that a considerable additional emission of methane could be expected in case of permafrost melting of 0.5 m depth, but probably not as a release of trapped gas, and an additional producing in the active layer. Microorganisms might be also responsible for microbial methane formation in permafrost. Long-term soil incubation experiments in flasks have shown a slow production of methane in different frozen soils at -5°C. Effect of decrease of methane concentration in the pore air during freezing was established. Colonies of microorganisms survived the incubation lasting more then 1 year at –⁰C were found.

MASS, HEAT AND SALT BALANCES IN THE EASTERN BARENTS SEAOBTAINED BY INVERSION OF A HYDROGRAPHIC SECTION

Gleb PANTELEEV[1], Motoyoshi IKEDA[1], Dmitri NECHAEV[2], Max YAREMCHUK[3] ([1]Frontier Research System for Global Change, [2]University of Southern Mississippi, USA, [3]International Pacific Research Center, University of Hawaii, USA)

Standard hydrological section data, collected in the eastern Barents Sea in September of 1997, have been analyzed using the variational data assimilation technique. This method enables us toobtain the temperature, salinity and velocity fields which are balanced within the framework of steady state dynamical constraints under the assumption of large scale geostrophic circulation. Errorbars which are statistically and dynamically consistent with the optimized fields are obtained by explicit inversion of the Hessian matrix. The optimized velocity field is in agreement with independent velocity measurements from surface drifter trajectories in the southwestern part of the Barents Sea. Optimized fields provide the following estimates of integral circulation features: 1. The North Cape current transport is 2.12±0.25 Sv; 2. The Karskie Vorota Strait throughflow is 0.7±0.06 Sv; 3. Heat flux with Atlantic water is 4.7±0.16 10 ^{11} W; 4. Salt import from the Atlantic ocean is 7.41±0.46 10^3 kg/s.

RELATIONSHIP BETWEEN SIBERIAN SPRING SURFACE AIR TEMPERATURE AND SUMMER ATMOSPHERIC CIRCULATION

Shinji MATSUMURA[1], Koji YAMAZAKI[2] ([1]Frontier Research System for Global Change, [2]Graduate School of Environmental Earth Science, Hokkaido University)

Surface air temperature over Siberia of northern Eurasia rapidly rises in the snow-melting season and reaches the maximum temperature in July.The interannual variability of the

IA

temperature rise in the snow-melting season is also large, resulting snow cover condition.On the other hand, there are still sea ice on the Arctic in the snow-melting season, and the contrast of temperature between land and sea also reach the maximum.It is thought that these boundary conditions in summer, in which jet stream is weak, affect the mid-high latitude atmospheric circulation in the position of external forcing.In the point of sight, seasonal simulation has been conducted with the CCSR/NIES atmospheric GCM (AGCM) to investigate the predictability of early summer climate in 1993 which is the typical year.An ensemble experiment consisting of 10 independint integrations from April 21, 22, ..., 30 to the end of August of 1993 was conducted giving observed global monthly SSTs as the lower boundary condition.The initial atmospheric conditions are prepared using the NCEP/NCAR reanalysis data. The initial conditions for snow amount and soil wetness are taken from the model climatology.The ensemble mean reproduces reasonably well the observed patterns of geopotential height anomalies in July.Surface warming over northern Siberia found in the snow-melting season 1993 also appears. These relation can be found by observational data with interannual variability and some year in the CTL run.

PRODUCTION AND FATE OF DIMETHYLSULFONIOPROPIONATE (DMSP) IN ARCTIC FAST ICE

Naoaki UZUKA (International Arctic Research Center, Frontier Observational Research System for Global Change)

Dimethylsulfide (DMS) is the most abundant biogenic sulfur compound emitted from the ocean to the atmosphere. Subsequently, DMS is oxidized in the atmosphere and forms aerosols, which affect the radiative balance of the Earth both directly and indirectly. DMS is formed from its precursor dimethylsulfoniopropionate (DMSP), which is produced by marine phytoplankton. Ice algae are known to accumulate high amounts of intracellular DMSP for the purpose of cryoprotection in addition to osmoregulation. Thereby, substantial amounts of DMSP may be released to the water column resulting in high DMS emissions to the atmosphere during the spring ice-melt season. However, studies of DMSP production by Arctic ice algae are scarce. Observations were conducted six times between March and June, 2002 at a fixed station in the land fast sea-ice zone in Barrow, Alaska. Vertical distributions of DMSP and chlorophyll a concentrations in ice cores were obtained. Concentrations of DMSP showed remarkable temporal variation. High amounts of DMSP, together with high chlorophyll a concentrations were observed at the lowermost part of the ice cores, where ice algae actively developed. Especially high amounts of DMSP (15 μmol/l, 150 times higher than in seawater) and chlorophyll a (0.6 mg/l) were obtained in early-May, 2002 from the bottom 2 cm layer. The highest DMSP concentration in seawater (130 nmol/l) was observed in late-May, when sea ice was melting and DMSP in the sea-ice decreased to 5.5 μmol/l, suggesting mass release of DMSP from detached ice algae to the water column under the sea-ice. This confirms that ice algae in the fast sea ice produce DMSP efficiently and may contribute to the subsequent DMS sea-to-air flux in the Arctic.

SIMULATED ARCTIC FRESH WATER EXPORT VARIABILITY 1900-2000

Cornelia KOEBERLE, Ruediger GERDES, Frank KAUKER, Michael KARCHER (Alfred Wegener Institute for Polar and Marine Research)

The fresh water export from the Arctic exhibits decadal to multi-decadal variability that is made possible by the reservoir of fresh water in the Arctic halocline and sea ice. We will present ocean-sea ice model results from hindcasts forced by NCEP reanalysis data that indicate a decline of the Arctic fresh water reservoir from the mid-1960s until today. This is achieved by an imbalance in the fresh water supply and export through Fram Strait, the Barents Sea opening and the Canadian Archipelago.A long term trend is sumperimposed by several fresh water export events. Hindcast simulations are constrained by the availibility of consistent and comprehensive atmospheric forcing data sets like the 55-years NCEP reanalysis data set. The presence of multidecadal variability in the northern North Atlantic and the Arctic, however, requires longer simulation periods. The most comprehensive single component available for about the last century is that of sea level pressure. From that, wind can be derived and 2m-air temperature can be reconstructed with some confidence. So additional model results will be presented for the years 1900-2000. We will discuss the origin of variability in the fresh water reservoir and the export. The pathways and travel times of the Arctic fresh water into the Arctic and subarctic North Atlantic will be presented. The impact of the fresh water on the horizontal and overturning motion in the North Atlantic will be discussed in comparison to the effects of other forcing components.

JSP04/10A/A06-002   0920

RECENT AND HISTORICAL CHANGE OF SEA ICE EXTENT IN THE ARCTIC

Roger L. COLONY (IARC/Frontier, U of Alaska)

"Northern Hemisphere spring and summer sea-ice extent has decreased by about 10 to 15% since the 1950s", is a quote from the *Summary for Policymakers* in IPCC report (2001), *Climate Change 2001: The Scientific Basis*. There is general consensus on estimates of the recent reduction of ice extent, which are based on a combination of aircraft reconnaissance and satellite remote sensing. However, the statement takes on real meaning when examined in terms of other geophysical variables and/or the historical perspective of ice extent variability. Using the ACSYS Historical Ice Chart Database, recent changes in ice extent can be placed in historical context. In 1596, Willem Barentsz maintained a log of ice conditions during his exploration of the waters around Svalbard. Barentsz also reported a large whale population in the north Greenland and northeast Barents seas; within a few years, highly organized commercial whaling was established with bases on Spitzbergen. These whalers provided additional information on ice edge position during the early 17th century and throughout the 18th century. In the middle of the 19th century, Norway began systematic seal hunting along the ice edge from Iceland to Novaya Zemlya. Ie edge information from many of the whaling and sealing activities were archived by the Norwegian Polar Research Institute. An analysis of the historical record shows general ice edge retreat since the first decade of the 19th century. Recent changes of the April ice extent in the Barents Sea are slightly less then the 200-year trend, while recent changes in the August ice extent appear slightly larger than the long-term trend. Covariance studies suggest that the ice edge position is responds more directly to the mean temperature of the Northern Hemisphere than to the arctic mean. What about the future? Although physically based models are unable to accurately simulate the present ice-edge boundary, there is significant agreement in change. Most models simulate a 40% reduction in sea ice area by the year 2080. This feature of future climate change has gone unreported by the IPCC Summary for Policymakers.

THE BERING STRAIT'S GRIP ON THE WORLD CLIMATE

Agatha M. DE BOER, Doron NOF (Florida State University)

The Holocene interglacial period of the last 10,000 years and the penultimate interglacial approx. 125,000 years ago have been characterized by distinctly stable climates. An analytical-dynamical model, which includes both wind and thermohaline processes, is used here to show that, during interglacial periods, variability in North Atlantic Deep Water (NADW) formation are damped out because of an Arctic freshwater feedback. During glacial periods, the stabilizing feedback is prevented by the closure of the Bering Strait (BS). The open-strait thermohaline circulation recovers exponentially from an internal perturbation with a rapid e-folding time of 32 years. However, a prolonged external forcing anomaly, such as the suggested increase in precipitation due to global warming, may shut down NADW formation entirely.

SENSITIVTY OF THE ARCTIC HIGH TO SEA ICE DYNAMICS IN A PALAEOCLIMATE MODEL

Jennifer K. HUTCHINGS[1], Steve VAVRUS[2], William HIBLER III[1] ([1]IARC, University of Alaska Fairbanks, [2]University of Wisconsin)

We investigate the influence of sea ice dynamics on the atmospheric pressure pattern over the Arctic Ocean. The Genesis palaeoclimate modelis run with and without ice dynamics, and two dynamical models, with and without shear stress are considered. The influence of ice dynamics on the current climate is discussed. It is found that the atmospheric pressure field is improved with the inclusion of ice dynamics. A future climatic warming scenario is run, and the influence of ice dynamics on the evolving atmospheric-ocean coupling is investigated.

UNAAMI - RECENT LARGE BASIN-WIDE CHANGES IN THE ARCTIC

James E. OVERLAND[1], James H. MORISON[2] ([1]NOAA Pacific Marine Environmental Laboratory, [2]Polar Science Center, University of Washington)

Unaami, the Yup´ik word for tomorrow, has been chosen by the Study of Environmental Arctic Change (SEARCH) program to represent the broad interrelated changes occurring in the Arctic. These changes are documented through examination of 86 regionally-distributed time series for 1965-1995 representing seven data types: climate indices, atmosphere, ocean, terrestrial, sea ice, fisheries, and other biological data. These changes are compared with 19th and 20th century temperature records. Although visual inspection of the data collection indicates that Arctic change is complex, two patterns are evident. The pattern based upon the first Principal Component (PC1), representing 23% of the variance, shows an upward trend and has a single regime-like shift near 1989 based on a large number of time series, including projections from a strong stratospheric vortex in spring, the Arctic Oscillation, sea ice declines in several regions, and changes in selected mammal, bird, and fish populations. Most land processes-such as snow cover, greenness, Siberian runoff, and permafrost temperatures-and certain subarctic sea-ice records show a more linear trend over the 30-year interval that also contributes to PC1; these variables are from lower latitudes and often integrate the atmospheric or oceanographic influence over several seasons or years including summer. The pattern based on the second Principal Component (PC2) shows interdecadal variability over the Arctic Ocean Basin north of 70N; this variability is observed in surface wind fields, sea ice, and ocean circulation. Historical surface temperature data support these two patterns with an interdecadal high-latitude/NAO type pattern, and a long-term, pan-Arctic change since the end of the little ice age. That more than half of the data collection projects strongly onto the two patterns, suggests that the Arctic is responding as a coherent system over at least the previous three decades.

JSP04/10P/A06-002   1420

SPACE/TIME CHANGES IN ARCTIC ICE AGE DISTRIBUTION

William J. EMERY, Charles FOWLER, James A. MASLANIK (Univ of Colorado)

With the use of information from satellite instruments, fairly dramatic changes in the Arctic have been observed in recent years in atmospheric patterns, ice extent and ice velocities, which should also result in changes in the distribution of the ages of multi-year ice. Using ice extent determined from passive microwave instruments and advecting the ice using velocities from merged buoy, AVHRR, and passive microwave imagery, it is possible to track the progression of the ice pack as it moves around the Arctic basin until it is lost from melt, either during the summer or as the ice drifts to lower latitudes. Each year, the ice contained within the minimum ice extent is aged one year. This time series of progressively ˝aged˝ sea ice demonstrates a dramatic shift of multi-year ice cover with substantial overall decrease of the oldest ice and a shift of location of this oldest ice to just north of the Canadian Archipelago and directly across the central Arctic to the Siberian Shelf. A separation of the Arctic basin into eastern and western halves shows that the greatest overall loss of the oldest ice is from the eastern Arctic, which is primarily through the Fram Strait. The total reduction in Arctic sea ice coverage is consistent with earlier studies while our unique approach demonstrates the changing nature in the spatial distribution of ice ages through the 24-year time series from 1978 to 2002

SENSITIVITY OF MODELED SEA ICE TO PARAMETERIZATIONS OF HEAT EXCHANGE PROCESSES

Alexander P. MAKSHTAS[1], Sergey V. SHOUTILIN[2] ([1]International Arctic Research Center, University of Alaska Fairbanks, [2]Arctic and Antarctic Research Institute, Russia)

A dynamic—thermodynamic sea ice model with 50-km spatial and 24-hour temporal

resolution and zero-dimensional thermodynamic sea ice models are applied to investigate long-term spatial and temporal variability of the sea ice cover andsurface energy exchange in the Arctic Basin. The models satisfactorily reproducethe averaged main characteristics of the sea ice, the sea ice extent, and the surface heat exchange for different parts of the Arctic Basin. In particular, estimates of the year-to-year difference between mean sea ice thickness in September show reasonable agreement with the essential thinning of sea ice in the Canadian Basin that Rothrock et al. (1999) found. Model shows that the main reason for sea ice thinning is the changes in the atmospheric circulation. It time the evaluation of atmospheric forcing data, namely air surface level temperature and surface wind velocity from NCEP, and cloudiness amount from Gorshkov Atlas show large disagreement with data obtained on the drifting stations "North Pole" The numerical experiments with zero-dimensional sea ice model reveal that some negative feedbacks existing in nature and reproducing in the models artificially reduce the influence of inaccuracy of forcing parameters on the results of modeling. Additionally the dependence of model results to description of heat processesin leads, prescribed geometry and melting rate of ridges, and parameterization of short-wave radiation is investigated.

QUASI-PERIODIC WARMINGS OF THE ATLANTIC LAYER OF THE ARCTIC IN A HINDCAST SIMULATION 1948-2002

Ruediger GERDES, Michael KARCHER, Ursula SCHAUER, Cornelia KOEBERLE (Alfred Wegener Institute for Polar and Marine Research)

The observed 1990s warming of the Atlantic layer in the Arctic has been interpreted in various ways.A major uncertainty is due to possible multidecadal variability of the high latitude climate system. Observations in the West Spitzbergen Current (WSC), the source of the Fram Strait Branch of Atlantic water in the Arctic, show previous warm events. Here, we use a model hindcast for the 1948-2002 period to identify several such warm events in the WSC and their propagation through the Arctic. While decadal time scale warmings are clearly present at many locations in the Eurasian Arctic, an upward temperature trend can be discerned over the period investigated. The relation to large scale atmospheric and oceanic forcing functions will be discussed. The Barents Sea Branch of Atlantic water plays an important role in modifying some of the warm events.

JSP04/10P/A06-005   1520

A NEW VIEW OF PACIFIC WATER CIRCULATION IN THE ARCTIC OCEAN

Michael STEELE[1], James H. MORISON[1], Wendy ERMOLD[1], Ignatius RIGOR[1], Mark ORTMEYER[1], Koji SHIMADA[2] ([1]Applied Physics Laboratory, University of Washington, [2]Japan Marine Science and Technology Center)

What is the fate of summer Pacific water in the Arctic Ocean? Our focus here is on the circulation and variability of the layer containing the slightly warm (usually less than 1 degree above freezing) temperature maximum that resides just below the mixed layer in the western Arctic Ocean. Following recent and much older studies, we separate this layer into 2 salinity ranges which may each contain a temperature maximum. The fresher (shallower) layer is Arctic Coastal Water (ACW), which contains a significant runoff fraction (especially from the Yukon river). The saltier (deeper) layer is Bering Sea Water (BSW), which occupies much of the central Chukchi Sea. A data base of cruise data from the 1990´s is used to trace the extent and variability of these water masses. We also include recent data obtained in 2000 and 2001 as part of the North Pole Environmental Observatory. We find that when the Arctic Oscillation (AO) index is low, the Beaufort Gyre contains both ACW and BSW, and the Transpolar Drift Stream (TDS) has a low Pacific water contribution. On the other hand, when the AO index is high, ACW dominates the Beaufort Gyre, while BSW dominates the TDS. This result is used to explain time series data from the Lincoln, Beaufort, and East Siberian Seas. We also speculate on downstream implications for the flow through Fram Strait and the Canadian Archipelago.

DECADAL VARIABILITY IN THE ARCTIC OCEAN SHOWN BY HYDROCHEMISTRY AND OTHER ENVIRONMENTAL DATA

Motoyoshi IKEDA, Hiroyasu YAMAGUCHI, Takayoshi IKEDA (Graduate School of Environmental Earth Science, Hokkaido University)

Sea ice distribution and atmospheric conditions have shown significantdecadal variabilities: i.e., the ice area reduced (increased) along Russiancoast, responding to the more intense (weaker) Polar Vortex and higher (lower)air temperature. In contrary, it has been difficult to find a correspondingsignal in the ocean interior due to unavailable data. The recent distributionof Russian data set collected from the Arctic Basin has opened up a new sourcefor exploring ocean interior variability. Among various ocean data, silicatecan be used as an indicator of the boundary between the silicate-rich PacificWater and the opposite Atlantic Water, although it is influenced by seasonalbiological productivity and outflow from Siberian rivers. The silicatedistribution shows a clear maximum around 100-m depth in the Canada Basin. Thevertical gradient below 100 m provides information on a vertical motion of theupper boundary of the Atlantic Water. The boundary shifted upward (downward)corresponding to the more intense (weaker) Polar Vortex or positive (negative)Arctic Oscillation, even though the data give significant signals only for twodecades (1965-85). The further study is suggested to compare this new data setand a coupled ice-ocean model with atmospheric forcing so that deeperunderstanding may be achieved on decadal and longer-term variabilities in theArctic Ocean.

DETECTING ARCTIC CLIMATE CHANGE USING KÖPPEN CLIMATE CLASSIFICATION

Muyin WANG[1], James E. OVERLAND[2] ([1]JISAO, University of Washington, [2]PMEL/NOAA)

Ecological impacts of the recent warming trend in the Arctic arealready noted as a decrease in tundra area with replacement by shrubs, and changes in the tree line. The potential impact of vegetation changes to feedbacks on the atmospheric climate system is enormous because of their large land surface areaand the multiyear memory of the vegetation cover. While much of the vegetation information is anecdotical, and satellite NDVI (Normalized Difference Vegetation Index) estimates, which began in 1981, are good source and are rather accurate information. The Köppen climate classification can be used to relate surface types to monthly mean air temperature from the NCEP/NCAR reanalysis and station data, and thus servesas proxy data for earlier period. In Köppen classification,tundra area is defined as the warmest summer monthly meantemperature being less than 10°C. We found a decrease intundra area from the mid 1970s to the present, similar to thetrend of the NDVI data. The decreases are largest in NW Canada,and eastern and coastal Siberia. Köppen proxies show an increasein tundra area from the late 1950s to the 1970s. The calculated tundra area minimum in the 1950s was similar to presentconditions, and occurred about 10

years after the previous 20thcentury temperature maximum.

SEARCHING FOR EVIDENCE OF CLIMATIC CHANGE IN THE LENA RIVER BASIN TOWARD FEEDBACK TO THE LAPTEV SEA HYDROGRAPHY

Svetlana BEREZOVSKAYA[1], Igor DMITRENKO[2] ([1]Russian State Hydrometeorological University, St.Petersburg, Russia, [2]International Arctic Research Center, University of Alaska Fairbanks, Fairbanks, USA)

The Lena river, major source of fresh water into the Laptev Sea, tends to integrate the hydrological and meteorological response of broad territories. Within the frame of this study the river runoffinto the Laptev Sea has been considered not only as a freshwater fluxbut also as an effective indicator of spatially distributed changes. The study is based upon the spatially distributed hydrological, meteorological information for the period 1936-1990(1995) and hydrographical CTD data from 1965 until 2000. The variability of river discharge, air temperature, and precipitation time series has been analysed by application of the statistical methods. The study shows statistically significant increase of air temperature since 1975 and arising of precipitation since mid-sixties. Furthermore, the annual water balance calculation has been provided for the three catchments within the Lena basin to detect the spatial and temporal scale of alteration. The evaluation of a link to climatic factors demonstrates a weak feedback of the water balance components to air temperature increase. Analysis of the runoff variability for the different hydrological seasons (excluding the winter season) indicates that the variance and means have been stable at least till 1990. It has been also shown, that the 30 % increase of the Lena River winter runoff on (since 1970) is merely caused by human activity along the Vilui river. However, even a 30 % increase of winter riverine discharge has a weak influence on marine hydrography. The role summer river runoff plays with the Laptev Sea shelf thermohaline structure has greater order than any other factors. The physical mechanisms that transport riverine waters off the delta region are primarily related to the atmospheric circulation over the Arctic Ocean. The cyclonic (CCR) and anticyclonic (ACCR) atmospheric circulation regimes essentially affect the propagation and redistribution of the Lena river runoff as well as different mechanisms of river and marine water interaction. River discharge itself controls the freshening of the surface water layer under cyclonic circulation: onshore winds prevailing under CCR conditions prevent the northward propagation of the river plume (downwelling); the river plume becomes thicker and stably stratified with limited vertical entrainment, which provides minimum convection through pycnocline. During ACCR periods river runoff via the entrainment of the ambient salty waters favour the salinization of the upper layer: offshore winds persisting under ACCR result in considerable plume northward redistribution and weakening of the vertical density gradient.

INFLUENCE OF DECADAL ARCTIC OSCILLATION ON JAPAN (EAST) SEA AND OKHOTSK SEA

Shoshiro MINOBE (Graduate School of Science Hokkaido University/ Frontier Research System for Global Change)

The subsurface water temperatures in the Japan Sea and the southern part of the Okhotsk Sea are studied by using newly produced gridded temperature anomaly datasets for the late 20th century. These datasets are the first gridded temperature datasets suitable for studies of interannual to decadal variations of those marginal seas. The EOF and CEOF analyses showed that the both marginal seas are strongly influenced by the quasi-decadal component of the Arctic Oscillation via the changes of Siberian Highs. The strong influence of the Arctic Oscillation on the mid-latitude east Asian marginal seas is consistent with the fact that the maximal temperature anomaly associated with the Arctic Oscillation is located far eastern Asia as shown by Thompson and Wallace (1998). The oceanic response of the Japan Sea is more complicated than that of the Okhotsk Sea, involving substantial phase difference between the northeastern and southwestern Japan Sea, with the northeastern temperatures varying in phase with the changes of the Siberian High as well as the Okhotsk Sea. The stronger Siberian high associated with stronger east-Asian winter monsoon corresponds to cold temperatures in the northeastern Japan Sea and the Okhotsk Sea.

JSP04/10P/A06-010   1720

INFLUENCE OF INCREASED ATMOSPHERIC MOISTURE IN THE PROJECTED FUTURE CLIMATE ON THE ARCTIC OCEAN

Xiangdong ZHANG[1], Moto IKEDA[2], John E. WALSH[3] ([1]Frontier Research System for Global Change, International Arctic Research Center, University of Alaska Fairbanks, [2]Graduate School of Environmental Earth Science, Hokkaido University, [3]International Arctic Research Center, University of Alaska Fairbanks)

Changes of the Arctic ocean and sea-ice due to surface air temperature increase and its amplification over the polar cap has been documented and paid much attention. Accompanying the green house gases and surface air temperature increasing, atmospheric moisture and precipitation may rise noticeably in the projected future climate changes over the Arctic region, which has not been well investigated. We employed an Arctic coupled ocean/sea-ice model to examine the changes of Arctic ocean forced by the projected atmospheric moisture increase in future. Our forcing data come from the output of three ensembling experiments of the CCCMA (Canadian Climate Center for Modeling and Analysis) coupled climate model (refer to www.cccma.bc.ec.gc.ca/data/cgcm1/cgcm1.html), in which the atmospheric concentration of green house gases (GHG) corresponds to that observed from 1900 to present and is increasing at a rate 1% per year thereafter until year 2100 and the direct effect of sulphate aerosols (A) is included. In order to solely investigate the effects of increasing atmospheric moisture, all other forcing parameters keep the same as their climatology except 2m air specific humidity and the parameters for latent heat flux calculation. The projected moisture increase is represented by the difference of specific humidity between 2040-60 and 1975-95. The modeling results indicate that evaporation decreases in the Norwegian Sea, the Barents Sea and the marginal area along the Eurasian coast due to the atmospheric moisture increase. Accordingly, the latent heat flux in the Norwegian Sea and the Barents Sea is much decreased, which consequently results in a considerable ocean surface temperature increase, with a maximum occurring in the Barents Sea. The Atlantic layer on the Eurasian side also becomes warmer. A warmer tongue starts from the St. Anna Trough towards the southeastern Nansen Basin and, then, goes towards east along the break of Arctic basin and towards north along the Lomonosov Ridge. Ocean surface and salinity decreases over a large part of the model domain, except a local area near the St. Anna trough, in the Barents Sea, and near the Novosibirskiye Island. Moreover, the Atlantic layer becomes fresher too. Further studies are continuing with the output from the B2 scenario of green house gas increase.

INTENSE WARMING OF ARCTIC GLACIERS SUBJECTED TO SUB-SURFACE MELTING

Oleg V. NAGORNOV, Yurii V. KONOVALOV (Department of Environmental Modeling, Moscow Engineering Physics Institute (State University))

Many Arctic glaciers are subjected to melting due to high air temperatures during summer. It results to the warming of glaciers that is much greater than average increase of regional temperature. Melt water percolates into the snow-firn sequences. Melting intensity during summer months is proportional to the third power of the mean air temperature. Hence, small changes of summer air temperatures induce big changes of the active layer temperatures. The refreezing of melt water results in the sub-surface accumulation of heat. Quantitative estimates of warming in the Eurasian Arctic are obtained by solution of inverse problems for the past temperature retrievals by two new methods. The first one is based on measured temperature profiles and determination of parameters of the oxygen-isotopic paleo-thermometer with accounting for the ˝melting-freezing˝ processes, and this allows for reconstructing both the past surface temperature and power of the sub-surface heat source in the past. The second method retrieves the past temperatures at the low boundary of active layer. It based on the regularization of the ill-posed problem. The borehole temperatures have been measured in the biggest ice caps in Eurasian Arctic: Austfonna (Svalbard), Windy Dome (Franz Jozef Land) and Akademii Nauk (Severnay Zemlya). These ice caps are located in Western, Central and Eastern parts of the Eurasian Arctic. The calculated surface temperatures of the glaciers exhibit weak dependence on the variations of the accumulation rate at the surface and the geothermal flow in the last 200 years. The bottom parts of the of Akademii Nauk Ice Cap and Windy Dome are in a steady state while Austfonna Ice Cap is in non-steady state as a result of the bottom melting. The estimated rate of melting of the Austfonna bottom ice is in the range from 2 to 7 mm/y. The lowest surface temperatures of the Austfonna Ice Cap occurred during the Little Ice Age, started five hundred years ago. Drastic warming recorded in the borehole temperatures started approximately 150 years ago. One hundred and fifty years ago the ice temperatures here were colder by 10-11 C than those that were six hundred years ago. Present ice temperatures are the highest for the last 2000 years. The lowest surface temperatures at the Windy Dome were 300-320 years ago in the middle of the Little Ice Age. They were 13 C colder than the warmest temperatures of approximately 30-40 years ago. The most interesting feature of the recent climate change here is almost 3 C cooling that takes place for the last 30-40 years. With the exception of recent warming the most eastward Academia Nauk Ice Cap had temperature changes similar to the Windy Dome. The Medieval Warming is noticeable only in the Western Arctic. The scale of warming we have calculated for the Arctic glaciers for the last 150 years (about 8 C) turned out to be essentially greater than that averaged over the Arctic region (about 2 C).

JSP04b/10P/D-002 — Poster — 1400-021

A DATA-MODEL COMPARISON STUDY OF ARCTIC SEA-ICE VARIABILITY,1958-1997

Anne ARMSTRONG[1], Bruno TREMBLAY[2], Lawrence A. MYSAK[1] ([1]Department of Atmospheric and Oceanic Sciences, McGill University, [2]Columbia University, Lamont-Doherty Earth Observatory)

The granular rheology sea-ice model of Tremblay and Mysak is validated against 40 years of observed sea ice concentration (SIC) data. Subsequently, the mechanisms responsible for producing SIC anomalies in the model are evaluated by studying the coupled variance (using the Singular Value Decomposition (SVD) method) between the simulated SIC anomalies and the ice speed and air temperature anomalies. To execute this validation, a 49-year (1949-97) simulation (including a 9-year spin-up) of the Arctic and peripheral sea-ice cover using daily varying winds and monthly mean air temperatures is produced. In general, the simulated SIC variations for 1958-97 in the East Siberian, Chukchi and Beaufort seas are in agreement with observations, while large discrepancies occur in the Laptev and Kara seas. Moreover, the sensitivity of the model to southerly wind anomalies in creating summer SIC anomalies compares well with the observed sensitivity; however, the model´s sensitivity to summer air temperature anomalies is weaker than observed. Results from the SVD analysis show that the main source of variability in the peripheral seas is associated with the variation in the strength of the Arctic High; in the East Siberian and Laptev seas, the strengthening and weakening of the Transpolar Drift Stream also plays an important role. The SVD analysis also shows that over the entire Arctic domain, surface air temperature anomalies are negatively correlated with sea-ice anomalies. Finally, the observed downward trend in total sea-ice cover in the last two decades as well as record minima in the East Siberian Sea are reproduced in the simulation.

JSP04b/10P/D-003 — Poster — 1400-022

RECENT VARIABILITY ON THE WATER MASS CHARACTERISTICS IN THE CENTRAL ARCTIC OCEAN

Takashi KIKUCHI[1], Kiyoshi HATAKEYAMA[1], James H. MORISON[2] ([1]Japan Marine Science and Techonology Center, [2]Polar Science Center, Applied Physics Laboratory, University of Washington)

Hydrographic observational data since 1990s is investigated to understand recent variability on the water mass characteristics in the central Arctic Ocean. The data have been obtained by icebreaker cruises, air-borne CTD surveys, submarine cruises, ice-drifting buoy observations, and so on. Especially in the early 2000s, surface salinization and Atlantic Water warming in the Amundsen basin of the Arctic Ocean are clearly found from CTD and buoy observational data from North Pole Environmental Observatory (NPEO) Project. The surface salinization in the Amundsen Basin was observed at the Siberian side in late 1993, extended to the Atlantic side in the mid 90s, and is now still observed in the Amundsen Basin. However, the higher anomalies of the surface salinity are weakening especially over the Lomonosov ridge in the early 2000s. As for the horizontal distribution of the surface salinization, there is no significant salinization of the surface mixed layer on the Makarov Basin side of the Lomonosov ridge since 1990s. The surface salinization in the Amundsen Basin may be related with retreat of the cold halocline layer which have been reported in the previous researches. Atlantic Water warming is also observed in the Siberian side of the Amundsen Basin since early 90´s, and extended toward the Atlantic side. Advection speed of the Atlantic Water warming is slower than that of the surface salinization in the Amundsen Basin and the area of the Atlantic Water warming extends to the Makarov basin side of the Lomonosov ridge. In the early 2000s, the anomaly of the Atlantic Water temperature is still high in the Amundsen Basin and over the Lomonosov Ridge.

JSP04b/10P/D-004 — Poster — 1400-023

SEA ICE VARIABILITY AND FUTURE ARCTIC MARINE OPERATIONS

Lawson W. BRIGHAM[1], Michael S. TIMLIN[2], John E. WALSH[2] ([1]Arctic Research Commission, Arlington, VA, [2]University of Illinois, Urbana, IL)

One of the principal challenges for Arctic sea ice modeling is to provide planners with more reliable and useful projections of changes in access to the Arctic for marine operations. There is already substantial observational evidence that the Arctic sea ice cover is undergoing significant changes, which include larger areas of open water (especially during summer), a diminished presence of multiyear sea ice, and a thinning of sea ice in the central Arctic Ocean. Any continuation of these changes will have important implications for future Arctic marine transport and offshore development systems. As part of the Arctic Climate Impact Assessment, projected changes of Arctic sea ice coverage through the 21st century have been evaluated in the context of potential enhancements of marine access to the Arctic. The evaluation is based on monthly fields of sea ice from simulations by five different global climate models, forced by the conservative B2 scenario of increasing greenhouse gas concentrations. Regionally and seasonally varying bias-corrections based on the models' simulations of present-day ice coverage were applied to the projected sea ice coverage, although these corrections do not remove the differences between the interannual variability of the models and that of observational data for recent decades. The greenhouse warming reduces sea ice coverage in all models, especially during summer. However, there is considerable range among the retreats projected by the different models. The five-model mean decrease of sea ice coverage projected for 2100 is approximately 60% in September (ranging among models from 9% to 100%) and approximately 15% in March (ranging among models from 11% to 18%). One model projects an ice-free Arctic during summer in the 2070-2090 time slice, while three other models lose most of their summer ice by that time. The seasonality of the retreat (largest in summer) is consistent with trends in observed sea ice coverage over the past few decades. The Northern Sea Route offers the potential for a major reduction of transittimes between the Far East and Europe. The region is a good candidate for study because the Russian Arctic coastal waters, except several narrow straits, are open to the Arctic Ocean and therefore reasonably well represented despite the coarse resolutions of all of today's models. By the 2070-2090 time slice, the models project a lengthening of the navigation season in the Laptev and East Siberian Seas by an average (over the five models) of 60-90 days, although the lengthening ranges among models from as few as 10 to as many as 100 days. In most of the model simulations, the retreating ice continues to interact with the northern tip of Severnaya Zemlya, implying a reliance on a transit route through Vilkitski Strait between the Kara and Laptev Seas.

JSP04b/10P/D-005 — Poster — 1400-024

THE RESULTS OF THE COMPLEX ANALYSIS OF SEISMOACTIVITY, TREE-RINGS AND CLIMATIC CHARACTERISTICS FOR THE AREA OF THE WHITE SEA

Taisya Yakovlevna BELENOVICH[1], Svetlana Vladimirovna VIDYAKINA[2] ([1]Laboratory of a deep geological structure and dynamics lithosphere, Institute of the Ecological Problems of the North UD of RAS, [2]Center for ecological research, Pomor State University)

In this work the complex analysis of the results of the researches of the changes of seismoactivity, tree-ring chronologies and climatic characteristics for the area of the White sea is carried out. The statistic analysis of 15 tree-ring chronologies (year indices) on a pine shows, that distinctions in meanings of a standard deviation, received for trees in different types of the forest, between chronologies is not observed, and chronologies have a high variability. The results of calculation of coefficients of linear correlation between chronologies have distinguished two groups of chronologies, general period from 1902 to 1971. Inside the groups the coefficient of linear correlation is from 0,7 up to 0,8. The areas on coefficient of linear correlation are well coordinated with contemporary stretch of seismic zones limiting megablocks (Belenovich et al., 1997). The following stage of the work was carrying out the spectral-temporary analysis of the long-term characteristics, including the meteorological data. Meteorological series of annual and seasonal characteristics on atmospheric pressure, air temperature nearest to tree-ring chronologies of meteorological stations (Kandalaksha, Kem, Onega, Arkhangelsk, Mezen, Solovki, the data of the archives of Hydrometeocenters of Murmansk and Arkhangelsk) and the index of circulation of the atmosphere above the Northern Atlantic (index Jonsa) were processed. The made analysis has distinguished the dominant periods close by 30 years. The cycle close to 30-year´s, is revealed in the work of V.V. Klimenko (1997), where is shown that the 26 years period is characteristic time of rotation of carbon of a long-lived biota. Taking into account physiological peculiarities of growth of trees, the examination of the 30-year´s period excludes from the analysis the smaller periods and is justified for the characteristic of the climate. The results of a low-frequency filtration of the data on average summer pressure and chronologies reveal 30-years period on a examined interval of time, with minimal meanings 1905 - 1907 and 1943 - 1946, showing, that maximum of atmospheric pressure correspond to the minima of ring-widths of trees growing in seismic zones. The results of low-frequency filtrations of air temperatures, the index of North Atlantic Oscillation have shown a positive coordination with the atmospheric factors of ring-widths of trees growing in relatively calm seismoactive areas. Thus, for the period from 1902 to 1971, for the area of the White sea, the factor of circulation of the atmosphere and temperatures dominates for trees located within megablocks (relatively calm in seismoactivity), positively coordinating in time, and the factor of pressure dominates for trees located in seismic zones, (seismoactive areas), negatively coordinating in time.

IMPROVING SATELLITE OCEAN COLOR DATA PROCESSING BY THE USE OF NEURAL NETWORKS : THE NAOC PROGRAM.

Michel R. CREPON[1], Sylvie THIRIA[1], Annick BRICAUD[2], Antoine MANGIN[3], Roland DOERFFER[4], Frank FELL[5], Jesus MORALES[6], Dan CORNFORD[7] ([1]LODYC, BC 100, University P. et M. Curie, [2]LOV, CNRS, 06230, Villefranche/mer, France, [3]ACRI, 06560, Sophia-Antipolis, France, [4]GKSS, D21502 , Geesthaatch, Germany, [5]FUB, D12165, Berlin, Germany, [6]CICEM, 21071, Huelva, Spain, [7]ASTON University, B47ET, Birmingham, England)

Spaceborne ocean color sensors which are now operational or under preparation, have a

large number of spectral band. NAOC, which is an EC supported programme, proposes to use advanced neural methodology which are well suited to deal with this multi-spectral information for retrieving ocean constituents. NAOC is divided into for major tasks : First NAOC intends to perform classification of the satellite signal at the Top of the Atmosphere according to specific criteria (energy, pattern of the spectrum) by using Topological Neural network Algorithm. This allows us to extract information on aerosol and on water type which will be used for atmospheric correction and ocean constituent retrieval. Second NAOC is determining improved algorithms for atmospheric correction which is crucial for obtaining accurate ocean product. As atmospheric correction is sensitive to ocean parameter for case 2 waters, NAOC intends to determine specific Multi-Layer-Perceptron (MLPs) for case 1 and case 2 water atmospheric correction. NAOC will then determine specific Neural Network algorithms for ocean constituent retrieval. At last NAOC is developing an advanced inversion algorithm based on the Spectral matching method of Gordon (1997). This algorithm inverts the radiative transfer equations both in the atmosphere and the ocean by using a combination of variationnal and Neural method. As it takes into account both atmospheric and oceanic parameters, it is well suited to deal with absorbing aerosols.

HIGH RESOLUTION OCEAN SURFACE VECTOR WINDS

W.Timothy LIU, Wenqing TANG (Jet Propulsion Laboratory, MS 300-323)

Spacebased scatterometers, at present, provide ocean surface wind vector at 25 km spatial resolution covering approximately ninety percent of the global ocean under clear and cloudy conditions, night and day. The spatial resolution is not sufficient to study small weather systems, such as tropical cyclones, nor processes in coastal oceans. The spatial resolution of the vector winds can be improved to approximately 12.5 km resolution by using range-compressed backscatter. These high-resolution scatterometer winds can be supplemented by observations of the synthetic aperture radar or assimilated into meso-scale numerical models to cover the last 10 km towards the coastline. Monitoring and predicting weather systems requires wind field at 6-12 hourly frequencies. For oceanographers, the highest frequency requirements are set by the inertial period timescales in mid-latitude and the diurnal timescale near the equator. Such temporal requirements cannot be achieved with a scatterometer flying on a single polar orbiting platform. At present, we have two identical scatterometers flying on QuikSCAT and ADEOS-2, and another scatterometer will be launch on the European operational spacecraft at the end of 2005. The scientific opportunities offered by flying more than one scatterometer in tandem, and producing vector winds at higher spatial and temporal resolutions will be discussed.

AN OPERATIONAL BUOY NETWORK FOR CLIMATE SST

Huai-Min ZHANG, Richard W. REYNOLDS, Thomas M. SMITH (NOAA/NESDIS/National Climatic Data Center)

Over the last decade, international groups have been actively pursuing strategies to accurately monitor global climate change. Part of the planning calls for the design and implementation of a Global Ocean Observing System (GOOS). Our effort under GOOS is to design a system to produce global SST with sufficient accuracy for climate studies. Specifically, we use SST observations from satellite and in situ instruments (including ships and drifting and moored buoys) and statistical tools, such as Optimal Interpolation and Optimal Averaging, to generate SST error for specified spatial and temporal resolutions. We then add simulated buoys, where needed, to reduce the SST error to acceptable levels. These simulated buoys are the buoys needed, henceforth ˝Buoy Need,˝ to reduce the SST error to the required accuracy. Buoys are needed for two purposes: bias correction of satellite data and to supplement SST data in regions without adequate satellite and/or in situ data. Thus, we need to consider bias error as well as sampling and random errors. The Buoy Need is designed to reduce both type of errors. The Buoy Need is first computed as a nowcast, and then by a simulation scheme, including advection of drifting buoys, climatological seasonal adjustments, and current large scale climate events to produce a forecast for the next season. We will show variations of the Buoy Need for seasonal and interannual variations (e.g., El Nino).

JSP06/07A/B21-004   1000

NEW GENERATION SEA SURFACE TEMPERATURE FOR GODAE

Kawamura HIROSHI (Center for Atmospheric and Oceanic Studies, Graduate School of Science, Tohoku University)

Early in 2000, the GODAE project sent "Prospectus for a GODAE SST Project" to world SST researchers to encourage developments of high-resolution satellite-based sea surface temperature (http://www.bom.gov.au/bmrc/mrlr/nrs/oopc/godae/HiResSST/). Our group has been developed, in the middle of 2001, the new generation SST (NGSST), which is daily, high-spatial resolution, quality-controlled cloud-free SST products merging AVHRR, GMS and TRMM SSTs. Since each of the satellite products are tuned against SSTs of the drifting buoys, they have a common observational basis for data merging. Using the hourly GMS solar radiation and the surface winds from SeaWinds, SSMI and TRMM, diurnal effects are eliminated to adjust all SSTs acquired at different times in a day to the daily minimum SSTs at around 1m depth. Then, all SSTs are merged using an objective analysis for one year, October 1999 to September 2000. The diurnal variation is not treated explicitly, but implicitly involved in the product generation process. The generated data and information are opened through http://www.ocean.caos.tohoku.ac.jp/~adeos/sst/ .The second version NGSST has been developed after the release of first version products. The strong signal of diurnal variation at 1m-depth appears in the western equatorial Pacific, where the TAO/TRITON buoys are densely deployed. Examination of the signals shows a common feature of SST increase in the morning to noon, which is parameterized by the diurnal SST amplitude. In contrast, the SST decrease pattern from its peak in the afternoon is rather variable. Introduction of the diurnal pattern enables us to produce the SST at any time in a day. The Version 1.0 products were examined by comparing against moored buoy SSTs at 1m depth. Wavelet analysis shows that the decorrelation scales of SST field are seasonally/regionally dependent. They are obtained for the sea south of Japan, and used in the production of second version of NGSST (NGSST-2.0). The processing procedure of NGSS2.0 is modified largely from the first version to the second version. Validation of the NGSST-2.0 using the buoy observations shows that the accuracy of NGSST does not change, but the SST patterns are improved.The global microwave SSTs are now available from the AMSR-E/Aqua and AMSR/ADEOS-II. The NGSST-2.0 is now tested using the AMSR SSTs, which will be released through the NASDA GODAE SST server for the GODAE research community in a day after their global observations. Real-time generation system of the NGSST-2.0 is now under development, and planned to be functioning early in 2003.

THE GODAE HIGH-RESOLUTION SEA SURFACE TEMPERATURE PILOT PROJECT

Craig J. DONLON[1], Chelle L. GENTEMANN[2] ([1]EC Joint Research Centre - Institute for Environmental and Sustainability, [2]RSMAS - University of Miami)

The Global Ocean Data Assimilation Experiment (GODAE) High-Resolution Sea Surface Temperature Pilot Project (GHRSST-PP) has been established to provide international focus and coordination for the development of a new generation of global, multi-sensor, high-resolution, sea surface temperature products provided in near real time. Its primary aim is to oversee the development, assembly and processing of high-quality, global scale, SST products at a fine spatial and temporal resolution, and timely delivery for the diverse needs of GODAE. Regional Data Assembly Centers (to be located in Japan, Europe, and the US) will provide collated, quality controlled, individual satellite retrievals. These data streams are to be integrated together at a Global Data Analysis Center, responsible for providing the global merged analysis in near real time. A Diagnostic Data Set, with sites distributed throughout the global ocean, will provide an easily assessable sub-sample of all data sets for validation purposes. Cool-skin effects, diurnal warming, multi-sensor data fusion methodologies, and validation studies are under deliberation by the Science Team. Status of these analyses and progress of the GHRSST-PP will be presented.

JSP06/07A/B21-006   1120

SEA SURFACE SALINITY IN THE TROPICAL PACIFIC AND THE ENSO OBSERVING SYSTEM

Thierry DELCROIX[1], Michael MCPHADEN[2], Kentaro ANDO[3] ([1]IRD / LEGOS, [2]NOAA / PMEL, [3]JAMSTEC)

Sea Surface salinity (SSS) in the tropical Pacific, despite the relative paucity of the observations, has proven to be valuable for describing and understanding climate variability, for assessing and improving numerical model performance, and for improving ENSO prediction lead times in statistical models. The importance of SSS in the climate system has also motivated the development by European and US space agencies of dedicated satellite missions to enhance global SSS observations.This presentation will aim at : a) reviewing the scientific rationale which justify the value and utility of SSS observations as part of the ENSO observing system, b) describing the present SSS measurements collected from thermosalinograph instruments installed onboard merchant and research ships and on the TAO/TRITON mooring arrays, and c) discussing possible evolution of the time/space sampling strategy based on computed SSS time and space scales.

JSP06/07A/B21-007   1140

AQUARIUS/SAC-D AND SMOS: FUTURE ADDITIONS TO THE SATELLITE OCEAN OBSERVING SYSTEM TO MEASURE GLOBAL SEA SURFACE SALINITY AND STUDY THE COUPLING BETWEEN THE WATER CYCLE, OCEAN CIRCULATION AND CLIMATE

Gary S.E. LAGERLOEF[1], Jordi FONT[2], Chester KOBLINSKY[3], Raul COLOMB[4] ([1]Earth and Space Research, Seattle, USA, [2]Institut de Ciències del Mar, Barcelona, Spain, [3]NASA Goddard Space Flight Center, USA, [4]Comision Nacional de Actividades Espaciales, Argentina)

Two new satellite missions to map sea surface salinity (SSS) are now being developed for launch in 2007. Systematic global SSS observations are required to study processes that link climatologic changes in the water cycle to the dynamics of ocean currents and air-sea interactions.   These include how SSS variations influence the ocean?s overturning thermohaline circulation, ENSO dynamics, and closure of the net air-sea water and heat flux budgets. Present day SSS observations are very sparse, with large ocean areas (>24%) devoid of measurements. The satellite data will provide the first synoptic global coverage on weekly to monthly time scales to measure the global mean field, the seasonal to interannual variability and to test climate models. The European Space Agency Soil Moisture Ocean Salinity (SMOS) mission is a dual land/ocean science mission using the 1.4 GHz passive microwave channel suitable to measuring both parameters. The sensor is a technically complex two-dimensional phased-array system designed principally for soil moisture retrievals. The SMOS program includes a focused effort to retrieve salinity data over the ocean. The observatory will provide global coverage every 3 days and ~50 km resolution for a 3-5 year mission. The salinity data will be averaged over broader scales to reduce measurement error. Aquarius/SAC-D is a dedicated salinity mapping mission being developed by the US and Argentina for a three-year baseline mission. The principal salinity sensor will be a high-precision 1.4 GHz radiometer system plus radar backscatter measurements to correct the large effects of surface wind roughness. The focus of the Aquarius/SAC-D design is to optimize the salinity retrieval accuracy for global climate studies. Aquarius/SAC-D will provide global maps every 8 days at 100 km resolution with a three-beam push-broom configuration of 60-90 km single-beam footprint. Measurement errors will meet the mission?s key science objectives with an rms uncertainty <0.2 psu on monthly time scales globally and closer to 0.1 psu in the tropics. A strong collaboration exists between the Aquarius/SAC-D and SMOS projects for both science and calibration. The latter will rely heavily on SSS measurements provided by the Global Ocean Observing System (GOOS).

RECENT ADVANCES IN THE TRITON PROJECT: SURFACE MOORING ARRAY IN THE WESTERN TROPICAL PACIFIC AND EASTERN INDIAN OCEANS

Yoshifumi KURODA (JAMSTEC)

JAMSTEC has developed a surface moored-buoy system named TRITON (TRIangle Trans-Ocean buoy Network) for the better understanding of ENSO and the Asian monsoon. The TRITON buoy can measure wind velocity, air temperature, relative humidity, shortwave radiation, atmospheric pressure, precipitation, current vector, subsurface temperature and salinity. It enables us to measure surface heat and fresh water flux, and also subsurface salinity changes to elucidate the heating and water mass mixing process. The four TRITON buoys along 156E were deployed in 1998 in the western tropical Pacific Ocean. TAO buoys west of 156E were replaced with TRITON buoys, and the TAO/TRITON array for monitoring ENSO was officially started in January 2000 harmonized with TAO array. The TRITON array was extended in the western most Pacific along 130E and two TRITON buoys were deployed in the eastern Indian Ocean in October 2001. At present in January 2002, eighteen TRITON buoys are working. The following topics will be presented,(1) development of TRITON array,(2) data quality of surface meteorological and subsurface temperature and salinity sensors,(3) data distribution,(4) scientific applications focusing on TRITON salinity

IA

data: e.g., water mass mixing process off the New Guinea coast; and water mass variations in the eastern Indian Ocean.

JSP06/07P/B21-002 1420

THE ARGO PROJECT: OBSERVING THE GLOBAL OCEAN IN REAL-TIME

Dean H. ROEMMICH (Scripps Institution of Oceanography)

The Argo profiling float project (http://argo.jcommops.org) is a key global element in the ocean observing system, measuring large-scale temperature and salinity (T/S) variability in the upper ocean for climate research and other applications. As of January 2003 there were 620 active Argo floats, drifting at 1-2 km depth and collecting a T/S profile and a measurement of mid-depth current every 10 days. When fully implemented in 2006, Argo will include 3000 profiling floats covering all of the world's ice-free, deep oceans. Data are made publicly available through the GTS and internet (http://www.usgodae.org or http://www.ifremer.fr/coriolis/cdc/argo.htm), usually within 24 hours of collection. Argo is an international effort endorsed by the IOC and WMO, and is a part of WCRP/CLIVAR and GODAE. Floats are being contributed by many nations, including Australia, Canada, China, Denmark, the European Union, France, Germany, India, Japan, Korea, New Zealand, Norway, the Russian Federation, the U.K. and the U.S., with coordination by the international Argo Science Team.   Scientific studies with Argo float data have begun, based on the extensive float arrays   in the North Atlantic and North Pacific and the developing arrays in the tropics and   Southern Ocean. Recent and ongoing studies by a number of international investigators are reviewed to illustrate the wide uses of the Argo array: - Subtropical Mode Water Formation in the northwest and the southeast Pacific   - Detection of mid-depth T/S variability in the southern Indian Ocean   - Local and regional heat balances in the North Atlantic and North Pacific   - Combination of Argo data with satellite altimetry   - ENSO variability in the salinity of the tropical Pacific and eastern Indian Ocean Argo has many applications in basic oceanographic research and operational oceanography through its measurements of the physical state of the upper ocean on large spatial scales. Argo by itself will describe patterns of broadscale variability in upper-ocean temperature and salinity globally, and will enable interpretation of the subsurface expression of sea surface height variability observed by the Jason satellite altimeter. Argo together with other elements of the observing system will better reveal the role of the ocean in the climate system and will provide the necessary data for powerful new data assimilation and forecast models, to satisfy a broad range of applications.

JSP06/07P/B21-003 1450

QUALITY OF ARGO SALINITY DATA MAINTAINED BY DELAYED-MODE QUALITY CONTROL

Taiyo KOBAYASHI[1], Shinnya MINATO[2], Toshio SUGA[1] ([1]Frontier Observational Research System for Global Change, Japan Marine Science and Technology Center, [2]Ocean Observation and Research Department, Japan Marine Science and Technology Center)

Argo, one of the key components of the global ocean observing system, consists of a global array of autonomous temperature/salinity profiling floats. How to calibrate the sensors, especially salinity sensors, of these floats is a major concern because direct comparison between the float data and any standardized data is not usually available. It has been agreed to use the "PMEL_QC method" (Wong et al., 2003) as the standard delayed-mode quality control procedure for Argo salinity data.This method evaluates and corrects the Argo salinity data by comparing the float data with the local climatology at float locations estimated from nearby historical data by an objective mapping technique. This method will perform well when the float data are compared in the deep where natural variability of temperature-salinity relation is relatively small. Although the Argo Programme recommends that temperature-salinity profiles should be measured down to 2000dbar, quit a few floats with their deepest profiling depths are shallower than 2000dbar have been deployed mainly for technical reasons including the limitation in buoyancy control capacity. It is thus important to examine how the precision of salinity data by corrected by the PMEL_QC method depends on the maximum depths of the observed profiles. We perform the PMEL_QC method to several sets of the real profiling data reaching to 2000dbar and compare the results with another results for the same data when the profiles become artificially shallower to 1500dbar or 1000dbar. As the profiling depths become shallower in the subtropical region, estimation errors of the salinity correction increase; they are lower than ±0.01psu, about ±0.01-0.015psu, and about ±0.02-0.04psu for the profiling depths of 2000dbar, 1500dbar and 1000dbar, respectively. Estimation errors in the subarctic region are generally larger than those in the subtropical and tropical regions; about ±0.01-0.015psu, about ±0.015-0.03psu, and about ±0.02-0.05psu when profile depth is 2000dbar, 1500dbar, and 1000dbar, respectively. It is because the temperature range effectively used for the salinity correction becomes narrower in the subarctic regions. Therefore, in order to maintain the data quality which almost satisfies the goal of the Argo Programme (accuracy of salinity ±0.01psu) with PMEL_QC method, the profiles measured by Argo floats should reach as deep as 1500dbar at least constantly in the subtropical and tropical region, but have to reach as deep as 2000dbar constantly in the subarctic region.

JSP06/07P/B21-004 1510

GLOBAL ARGO DATA REPOSITORY: A GATEWAY TO ARGO DATA, INFORMATION, AND SERVICE

Charles SUN (U.S. National Oceanographic Data Center/NOAA)

A long-term archive for Argo data, developed at the U.S. National Oceanographic Data Center (NODC), is presented in this paper. Argo data include real-time and delayed-mode profiles of ocean temperature and salinity (and conductivity, if any) measured by the Argo profiling floats. The purpose of this paper is to describe the development of a system for acquiring, preserving, and disseminating Argo data and information to the public. In the year 2000, a global array of approximately 3,000 free-drifting profiling floats, known as the Argo Ocean Profiling Network, was planned as a major component of the ocean observing system. Argo originated from the need to make climate predictions on both short and long time scales and has led to international participation and collaboration to ensure global coverage. All Argo data are publicly available in near real-time via the GTS (Global Telecommunications System) and in scientifically quality-controlled form with a few months delay. Two Argo Global Data Assembly Centers (GDACs), the US GODAE (Global Ocean Data Assimilation Experiment) Argo server and the French IFREMER (Institute for Research and Exploitation of the Sea) Argo server, are established to assemble the near real-time Argo data and provide them to the Argo users in a timely manner. The U.S. National Oceanographic Data Center (NODC) operates the long-term archive, also known as the Global Argo Data Repository (GADR), for Argo data. The GADR has the responsibilities for (1) preserving the data passed to the US NODC, (2) managing updates to Argo data that are re-analyzed some time later and for which corrections may be applied and (3) providing high quality Argo data to a wide variety of users in a timely and useful manner. Argo data are available both online to clients with high speed Internet access and on CD-ROM discs to

those who have poor Internet connections. The data served by the GADR are in the NODC netCDF format (fully compatible with ncBrowse) and the tab-delimited spreadsheet text format (compatible with Java OceanAtlas and Ocean Data View). The clients will use a ˝Web browser˝ to browse the Argo CD-ROM discs and ˝Acrobat Reader ™˝ to view, navigate, and print documents in the Adobe Portable Document Format (PDF) within a web browser. The CDs will be platform and operating system independent and inter-operatable among browsers as well. It will provide assertive technology accommodations and services to persons with disabilities and ensure people with disabilities have equal access to Argo data and information.

JSP06/07P/B21-005 1600

THE PACIFIC HIGH RESOLUTION XBT/XCTD NETWORK:MEAN AND TIME-VARYING MASS AND HEAT BALANCE OF THE TASMAN BOX

Dean H. ROEMMICH[1], John GILSON[1], Josh WILLIS[1], Ken RIDGWAY[2], Richard BAILEY[2], Philip SUTTON[3] ([1]Scripps Institution of Oceanography, [2]CSIRO Marine Research, [3]National Institute of Water and Atmospheric Research - New Zealand)

Since the late 1980's, a network of zonal and meridional High Resolution XBT/XCTD (HRX) transects has been occupied through a multi-national collaborative effort, spanning the Pacific basin on a quarterly basis (http://www-hrx.ucsd.edu). With a scientist or technician on board, tight probe spacing resolves boundary currents and eddies in order to measure seasonal to interannual variability in temperature, salinity and geostrophic circulation from the mesoscale to the basin-scale. The Pacific HRX dataset covers up to 17 years along some transects, and is a valuable resource for climate-relevant research. As an example of HRX research, the seasonal-to-interannual balance of mass, heat, and salt in the southwestern Pacific is described. There, an 11-year HRX time-series has been collected along the perimeter of a region we call the Tasman Box. The region contains the South Pacific's subtropical western boundary current system. The East Australian Current carries about 15.6 Sv southward in the upper 800 m (referenced to 2000 m) near Brisbane, separating from the coast to form recirculations plus eastward flowing filaments in a region of strong mesoscale variability. Net geostrophic plus Ekman transport of waters warmer than 20.5-degrees C is about 6.3 Sv southward into the box across the Brisbane-Fiji line, with about 4.4 Sv warmer than 15.5-degrees C flowing eastward out of the box across Auckland-Fiji. Net water mass conversions in the upper ocean - inflow waters averaging about 26-degrees C and 35.4 psu, balanced by outflow averaging 18-degrees C and 35.7 psu - reflect the net evaporation and heat loss in the formation of Subtropical Mode Water. Transports are seasonally varying with a range of about 4 Sv in each transect, and maxima about March in both the southward inflow and eastward outflow. Interannual variability is also substantial. The 11-year mean heat balance shows good agreement between ocean heat transport into the box (averaging 40 w/m**2) and heat loss to the atmosphere (35 w/m**2). The seasonal balance is between air-sea flux and storage, with a smaller contribution from transport. The interannual balance shows substantial anomalies in all three terms of the heat budget, with largest interannual variability (30 w/m**2) in ocean transport and interior storage. Maxima in the heat transport into the box occurred in 1993, 1997 and 2001.

JSP06/07P/B21-006 1620

MERIDIONAL TRANSPORT OF NORTH PACIFICINTERMEDIATE WATER ACROSS 37N BASED ON THEOBJECTIVE ANALYSIS OF LOWERED ACOUSTIC DOPPLERCURRENT PROFILER DATA

Hiroshi YOSHINARI[1], Ichiro YASUDA[2], Motoyoshi IKEDA[1] ([1]Graduate School of Environmental Earth Science, Hokkaido University, [2]Department of Earth and Planetary Science, Graduate School of Science, University of Tokyo)

The Meridional transport and the origin of North Pacific Intermediate Water (NPIW) in the Kuroshio-Oyashio interfrontal zone (K/O zone) were examined using hydrographic and directly-measured velocity data with LADCP (Lowered Acoustic Doppler Current Profiler) along 37°N in the observation performed in July 1998. The optimal interpolation method was applied to objectively derive transports and their spatial-interpolation errors. A statistically significant northward transport of 12.0±4.6 Sv was observed in the density of 26.6 −27.5σθ from coast (141°E) to the Shatsky Rise (157°E). In the upper part of NPIW (26.6 −27.0σθ), total transport was 4.1±1.2 Sv, of which Kuroshio component was 3.0±0.7 Sv and Oyashio 1.1±0.5 Sv. In the lower NPIW (27.0 −27.5σθ), the total transport was 7.9±3.4 Sv, of which Kuroshio was 4.7±1.9 Sv and Oyashio 3.2±1.5 Sv. A southward transport of 4.4±3.6 Sv was observed from the Shatsky Rise to 179.5°E in the density of26.6 −27.5σθ. In the region west to the Shatsky Rise, the Oyashio mixing ratio derived from temperature and salinity in the K/O zone is larger than the ratio in the Oyashio and the Kuroshio transports, implying the southward transport of 1 Sv Oyashio water across the Oyashio Front in the upper NPIW. On the other hand, both kind of ratios is almost same in the lower NPIW, suggesting that the lower NPIW in the same region is maintained only by the northward transport of the NPIW formed near the Kuroshio Extension.

JSP06/07P/B21-007 1640

BASIN-SCALE OCEANOGRAPHIC PROBLEMS OF THE ARCTIC OCEAN AND A MONITORING SYSTEM FOR THEIR SOLUTION

Andrey PROSHUTINSKY, John TOOLE, Richard KRISHFIELD (Woods Hole Oceanographic Institution)

It is common perception now that the recent history of the Arctic is characterized by:a significant change in circulation, sea ice thickness and extent, heat and salt content.But these changes could be erroneous because observations in the Arctic Ocean arescarce and there are huge gaps in the data in space and time.In order to fill these gaps in future studies, we propose an observational Arctic OceanMonitoring System (AOMS) that can serve for sustained, long-term efforts to documentand understand variability in the ocean and sea ice.Building on the successful Moored Profiler technology, we propose to initiate development ofan automated, long-lived, ice-tethered buoys capable of returning high-vertical-resolutionprofiles of upper ocean temperature and salinity in the Arctic Ocean during all seasons.

JSP06/07P/B21-008 1700

NEAR-GOOS DATA SYSTEM

Takashi YOSHIDA (Japan Meteorological Agency)

The North-East Asian Regional - Global Ocean Observing System (NEAR-GOOS) is a regional pilot project of GOOS in the Western Pacific region, presently with the participation of China, Japan, the Republic of Korea and the Russian Federation, with a view to demonstrating the usefulness of a regional ocean observing system within the framework of GOOS. The essence of NEAR-GOOS in its initial phase is to promote free oceanographic data exchange in real-time through Internet in support of daily mapping of sea conditions in

marginal seas bordered by NEAR-GOOS participating countries, benefiting a wide range of marine users. In order to promote the data exchange, a data exchange system called NEAR-GOOS data system has been established by the four participating countries. The system started its operation in 1996 and oceanographic data not only in the NEAR-GOOS region but also in the global ocean have been distributed through the system. It consists of Regional Real Time and Delayed Mode Data Bases (RRTDB and RDMDB) and national real time and delayed mode data bases. RRTDB and RDMDB are in charge of distributing all oceanographic data in the region. National data bases are in charge of distributing oceanographic data obtained in each country. One of the major data sources of RRTDB is the Global Telecommunication System (GTS), which interconnect meteorological telecommunication centers in order to exchange meteorological and oceanographic data in real time. Marine weather observations from voluntary observing ships and buoys, subsurface temperature and salinity profiles observed by ships of opportunity, research vessels, buoys and profiling floats are exchanged through GTS. RRTDB, which is operated by the Japan Meteorological Agency, retrieves those oceanographic data from GTS and provides them to registered users. RDMDB, which is operated by the Japan Oceanographic Data Center (JODC), serves to provide secondhand RRTDB data and other oceanographic data gathered by JODC and archive them. Even though the data system has been successfully operated, the data exchanged through it are still limited. Extension of the types and volume of the exchanged data should be given high priority in the future NEAR-GOOS activity.

GLOBAL MEAN SEA SURFACE HEIGHT MODE BASED ON SATELLITE ALTIMETRY DATA

Jianguo HU[1], Jiancheng LI[2], Weiping JIANG[2] ([1]Chinese Academy of Surveying and Mapping, [2]Wuhan University)

Nowadays, global environment change is one of the most import questions we mankind pay attention to. There are many factors which have influence on environment, for example, weather change, sea level change, gravity filed change, volcano activity, El Nino and so on. As a focus of geo-science and environment science, mean sea surface height (MSSH) is one of these questions. In the paper, the overall editing criteria for altimetric data are considered and the geophysical correction model is improved. The datum for various altimetric data is also unified, and the method of a full-combined crossover adjustment for different altimetric tracks is used to improve the radial orbits of Geosat, ERS-1 and ERS-2 data. The data used to compute MSS include 8 years of Topex/ Poseidon data (cycle 11 to 284), 2 years of Geosat ERM data (cycle 1 to 44), 5 years of ERS2 data (cycle 1 to 52) and all ERS-1 168-day data. The MSS is determined with a grid resolution of $2¢´2¢$ within the $±82º$ latitude and its precision is better than 0.05m. Moreover, $3.75¢´3.75¢$ CLS_SHOM98.2 MSS, $3¢´3¢$ GFZ MSS95A and $3.75¢´3.75¢$ OSU MSS95 are compared with the computed MSS to test the model in this paper.

A NEW FALL-RATE EQUATION FOR THE JAPANESE T-5 XBT PROBES

Shoichi KIZU, Kimio HANAWA (Department of Geophysics, Graduate School of Science, Tohoku University, Aramaki Aza Aoba, Aoba-ku, Sendai 980-8578 JAPAN)

The expendable bathythermograph (XBT) is a free-fall instrument, which is dropped from air into water and measures temperature at a fixed sampling rate as it falls through the water column. Due to its simple, could be automatic, operation, XBT has become very popular throughout the world for the temperature measurement of the upper ocean. However, since it carries no pressure sensor, we always need to infer the depth of measurement from the time elapsed, using the time-depth conversion equation (fall-rate equation). The manufacturer supplied different equations for different models of XBT probe to take account of their different shapes and weights in water, but the reliability of the supplied equations has been a matter of debate for a long time. T-5 XBT can reach the greatest depth (nominally 1850 meters) among all XBT models in the market. Here we investigated the accuracy of the manufacturer´s fall-rate equation for the model, about which the past studies showed inconsistent results. More than 200 pairs of XBT-CTD (Conductivity-Temperature-Depth profiler) temperature measurement were collected from various oceans on the earth, and the depth error is estimated by the method of Hanawa et al. (1995) with modifications. We found that the manufacturer´s fall-rate equation does not seem to have bias when applied to the T-5 XBT by Sippican, Inc., in USA, the largest supplier of the instrument, while it overestimates depth when applied to T-5 by TSK, Co. Ltd., in Japan, the second largest and the dominant supplier to the Asian countries. It is found that the depth error increases approximately linearly with depth and approaches one hundred meters at the deepest part of measurement. Based on these results, we propose a new fall-rate equation for T-5 XBT by TSK, which is $D(t) = 6.4751\ T - 0.00175\ T^2$, where D is the depth in meters at time, T, in seconds.

OCEAN OBSERVATIONS IN CLIVAR

Michael SPARROW, Katy L. HILL, Howard CATTLE, Roberta BOSCOLO, Zhongwei YAN (International CLIVAR Project Office)

CLIVAR, the Climate Variability and Predictability study of WCRP started in 1995 with an ambitious plan to explore coupled climate variability and predictability at global scales from seasons to centuries. The structure of CLIVAR is based around different principal research areas. These range from the study of ENSO, Asian-Australian and American Monsoon and African climate variability on seasonal to interannual timescales to Atlantic, Pacific, Indian and Southern Ocean climate variability on decadal to centennial time scales, and anthropogenic climate change. Each principal research area is distinct, in its aims, phenomenological base, geographical region of interest and, in some respects, scientific approach required. Ocean observations are a key element of the CLIVAR programme. CLIVAR aims to establish the appropriate mix of measurement platforms and synthesis techniques to determine the full suite of ocean variables, including air-sea fluxes, required for CLIVAR research, taking into account existing and new technologies. To achieve this CLIVAR is working, amongst others, with the emerging operational observing systems of the Global Ocean Observing System, the implementation activities of the Joint Commission on

Oceanography and Marine Meteorology and its panels, the Ocean Observations Panel for Climate and the Partnership for Observation of the Global Ocean. The planning of CLIVAR ocean observations is mainly coordinated through the CLIVAR Ocean Observation Panel and the regional basin panels: The Atlantic, Pacific, Southern Ocean Panels and the Asian-Australian Monsoon Panel (which currently has responsibility for the Indian Ocean). CLIVAR's needs for sustained ocean observations to enable implementation and development of its programme are described in this poster, with illustration of their application to ongoing and planned activities in the ocean basins.

FERHRI PRESENT ACTIVITY WITHIN NEAR-GOOS AND RELATED PROJECTS

Evgeniy Viktorovich KARASEV[1], Aleksander Nikolaevich MAN'KO[2], Evgeniy Petrovich URAEVSKIY[3], Nikolay Afanasievich RYKOV[4] ([1]Vice-direcor, Far Eastern Regional Hydrometeorological Research Institute, [2]Department of Oceanography and Marine Ecology, Far Eastern Regional Hydrometeorological Research Institute < RUSSIA, [3]Department of Mathimatical Analisys, Far Eastern Regional Hydrometeorological Research Institute, RUSSIA, [4]Department of Oceanography and Marine Ecology, Far Eastern Regional Hydrometeorological Research Institute, Russia)

EVGENIY KARASEV, Aleksander Man´ko, Evgeniy Uraevskiy, Nikolay RykovFar Eastern Regional Hydrometeorological Research Institute, Vladivostok, RussiaThe Russian Hydrometeorological Service carries problems of operative information management on ocean to the paramount questions demanding constant attention. On the Russian Far East the given problem, alongside with other divisions of Hydrometeorological Service, Far Eastern Regional Hydrometeorological Research Institute (FERHRI) is engaged in the decision. The decision of a problem of operative maintenance is carried out by the information on ocean in two ways. The first way is the decision of a problem within the framework of the national program of creation of uniform system of the information in the World Ocean (USIWO). The main goals of the system are directed to engineering such modules as operative supervision, transfer, gathering and distribution of the information to users on uniform principles for all Russian Federation, with use of technical decisions and development of normative documents. Creation of the special centers is stipulated, one of which is planned to organize in FERHRI for realization of system of accumulation and distribution of the information. The second way is direct participation in the international projects, which objective includes operative reception of the information on ocean. FERHRI is one of participants from the Russian side of project NEAR-GOOS, which is regional component of GOOS. Within this project FERHRI conducts the national operative database being a part of system of operative maintenance by the information on ocean in area of NEAR-GOOS responsibility. Web-site regarding NEAR-GOOS project is created in FERHRI both in English and Russian versions. While development of the ARGO project FERHRI makes the big efforts for connection of Russia to this program. Decision on Russian membership in ARGO project will be defined this year. Last October, FERHRI as the representative of the Russian side has carried out start of two floats in the NW Pacific, it is created Web-site ˝Russian-ARGO˝, researches in a direction of active mastering the information received during performance of the program are carried out. Realization of the specified programs will allow Russia to play more active role in operative maintenance with the information on ocean in the North Pacific.

THE TROPICAL ATLANTIC OBSERVING SYSTEM

Silvia Lucia GARZOLI[1], Jacques SERVAIN[2], Gustavo Jorge GONI[1] ([1]National Oceanic and Atmospheric Administration, Atlantic Oceanographic and Meteorological Laboratory, [2]Center IRD de Bretagne)

The oceanic in-situ data base in the Atlantic has been derived primarily during the last decades from volunteer observing ship (VOS) programs, coastal and island tide gauge stations, and a small number of drifting buoys. However, VOS measurements of surface meteorology and subsurface temperatures are concentrated mainly along well-traveled shipping routes, among which there are large data gaps. Satellite estimates of some key variables are available over the whole Atlantic basin with more uniform spatial and temporal resolution. However, satellites do not deliver direct measurements of the subsurface thermal structure in the ocean, which is essential for understanding processes affecting the evolution of SST and the thermocline depth. Since 1997 a program, called PIRATA, of moored measurements has been under development in the Atlantic provide high-resolution measurements of surface heat, moisture fluxes, temperature and salinity. Simultaneously to the start of the PIRATA moorings, and to the global Drifter Array, a program was started at NOAA/AOML to significantly increase the deployment of surface drifters in the tropical Atlantic. The purpose of the program is to observe the basin-wide scale tropical Atlantic current and SST fields on seasonal to inter-annual time scales. Currently, 80 drifters per year are deployed from ships of opportunity and research vessels providing an accurate picture of the surface current field and filling up gaps for needed observations of SST. Together with the existing observations provided by the ships of opportunity, the PIRATA array and the surface drifters constituted the initial tropical Atlantic Observing System. In the year 2000, two new and important components were added: a new high density XBT line (AX08) that runs between Cape Town, South Africa and the north-eastcoast of the US and the ARGO program. The main objective of AX08 isto measure the upper ocean thermal structure and to characterize both the mean and the time-dependent upper ocean properties of the tropical portion of the MOC and of the shallow subtropical cell in the Tropical Atlantic. The resolution along the line is 30 km between 10S and 10N and 40 km between 20S and 10S and 10N and 20N. This line is occupied four times per year, in four different seasons. ARGO is an international program whose goal is to deploy an array of 3,000 free-drifting profiling floats in a period of five years. Approximately 700 floats will be operating in 2003 in the Atlantic, of which about one third will be in the tropical basin. These profiling floats measure the temperature and salinity of the upper 1000 to 2000 m of the ocean.

ON THE MEAN AND FLUCTUATING TEMPERATURE FIELD IN THESUBTROPICAL NORTH ATLANTIC OCEAN

Molly O'Neil BARINGER, Dennis MAYER, Gustavo GONI (NOAA/AOML)

High density XBT sections along tracklines from the Gibraltar Straitsto the Straits of Florida (AX7) and from New York to Puerto Rico (AX10) starting in 1995 and 1997 respectively with average spatial sampling of 30-40 km show representative features seen on many previous hydrographic surveys in the area. The improved resolution along these sections provides a new look at the spatial scales of variability and improves estimates of heat transport. The spatial variability is diagnosed by examining an ensemble of Fourier transformed temperature data as a function of depth and examining the amount of variance contained in the mean versus the perturbation (mesoscale) fields. This resulted in scales of about 600 km that distinguish the large scales from the mesoscale in both the meridional and horizontal directions. At the depth of the main thermocline along AX7, the scales increase rapidly,

reaching gyre scale (on the order of6000 km) by 800 m and characterize an intrinsic anisotropy consistent with the gyre structure, implying that mesoscale features are increasingly important with depth. Decorrelation scales, computed by a structure function analysis, showed that the perturbation temperatures have much smaller scales (less than 100 km). Implicit in these findings is that the large scales require XBT sampling of 200-600 km and perturbation scales require sampling of order 30-50 km (2-3 XBTs per length scale). To assess how this increased spatial sampling has improved estimates of heat transport, we examined errors in baroclinic heat transport for reduced sampling. We found that the average baroclinic heat transport was -0.87 +/- 0.21 PW southward, consistent with earlier hydrographic estimates near this latitude.The errors incurred by reducing the station spacing rapidly increase with increased station spacing. Errors of about +/- 0.2 PW occur forspacing between 150-600 km (i.e. sampling of the synoptic and mesoscale structure), including a - 0.05 PW mean bias. Errors reduced ramatically for spacing less than 150 km, where the mesoscale field is resolved (as determined by the decorrelation analysis).

NEAR-GOOS RDMDB AND THE RELATED JODC ACTIVITIES

Satoshi SATO (Japan Oceanographic Data Center)

The first phase of NEAR-GOOS (North-East Asian Regional GOOS) was intended to provide a regional framework for gathering and distributing oceanographic data. Based on the recommendation of the NEAR-GOOS Coordinating Committee, the Japan Oceanographic Data Center (JODC) has operated the NEAR-GOOS Regional Delayed Mode DataBase (RDMDB: http://near-goos1.jodc.go.jp/) since 1996. RDMDB is an on-line data retrieval system. It receives and archives the oceanographic and marine meteorological data from the Regional Real Time DataBase (RRTDB) operated by the Japan Meteorological Agency 30 days after they are collected. RDMDB also receives oceanographic data and products from other sources, e.g., the National Delayed Mode DataBases of the member countries. Such data are provided through Internet without charge. JODC has operated another on-line database, J-DOSS (JODC Data On-line Service System: http://www.jodc.go.jp/service.htm). JODC has fulfilling the role of the synthetic marine data bank of Japan in acquisition of various oceanographic data obtained by research institutes and organizations in Japan. Those who need the oceanographic data in the world can search and download the data by using J-DOSS. At the present time, J-DOSS provides 12 kinds of data and information, serial station data, ocean current data, tide data (hourly value), marine biological data (plankton), 500m mesh depth-sounding data around Japan, 3 statistical data (temperature, salinity, and ocean current), NOPs (National Oceanographic Programs), CSRs (Cruise Summary Reports), IOC publications, and Oceanographic Abbreviation/Acronym Dictionary.

COMPARISON OF HYDROGRAPHIC AND ALTIMETER BASED ESTIMATES OF SEA LEVEL HEIGHT VARIABILITY IN THE ATLANTIC OCEAN

Dennis MAYER, Molly O'Neil BARINGER, Gustavo GONI (NOAA/AOML)

Our ability to understand the means by which mass and heat are exchanged between the tropics and subtropics is seriously compromised when using only sea level data because the exchange processes span a wide range of variability across the different dynamical regimes in our domain. Expendable bathythermograph XBT profiles and TOPEX/Poseidon T/P altimeter data are compared to temperature anomalies TA and to dynamic height anomalies DHA for the period 1993 through 1997 to determine how much can be inferred about the internal field of mass from sea level changes. Our focus is on the annual cycle along two well-sampled XBT sections on the western and eastern sides of the Atlantic Ocean from 10ºS to 40ºN. XBT profiles were matched time/location to Sea height anomalies SHA derived from T/P data, converted into DHA using TS relationships and then binned monthly into 2º of latitude by 4º of longitude boxes. The vertical mass distribution cannot always be inferred from SHA alone, unless there is a strong relationship between SHA and DHA and an understanding of the details of how temperature variability affects DHA. These relationships can be problematic if SHA are small. This occurs in zones of transition in the vicinity of troughs where small fluctuations in SHA belie the true nature of water column variability. These areas separate the mid-latitudes where surface buoyancy fluxes dominate from those in the equatorial region where ocean dynamics cause thermocline effects that dominate the forcing of sea level. Thus, the variability of SHA in transition regions tends to be small because both surface and thermocline variability may be significant but compensating in nature. This emphasizes how important direct observations in situ data can be in interpreting SHA correctly. Strong relationships between SHA and DHA are suggested where more than half of the SHA variance in the annual cycle can be accounted for by DHA approximately 30% of the positions along the two XBT sections. These relationships between SHA and DHA for residual variability obtained by removing the annual cycle are weak. The exceptions are in two areas of large sea height variability in the western basin where there is significant interannual variability. The first is in the tropics in the vicinity of the tropical gyre trough near 50ºW 8ºN. The second is in the Gulf Stream near 70ºW 38ºN. An analysis of Panulirus data at 32.2ºN, 64.5ºW suggests that in situ data may be needed down to at least 1000m where interannual variability accounts for about 40% of the SHA variance.

PATHWAYS OF NORTH PACIFIC INTERMEDIATE WATERS

Yuzhu YOU (The University of Sydney Institute of Marine Science (USIMS), University of Sydney, Australia)

Updated hydrographic data are used in a water mixing scheme to identify the spreading paths of North Pacific Intermediate Waters (NPIWs) in the subtropical gyre. The mixing scheme comprises two NPIW formation sources from the subpolar regions, Okhotsk Intermediate Water (OIW) and Gulf of Alaska Intermediate Water (GAIW), and a transformed aged NPIW (aNPIW)in the northwestern subtropical gyre southeast of Japan. Three conservative variables, potential temperature, salinity and potential vorticity are used as model input signals. The NPIW layer is spaned by four neutral density surfaces, sigma_N=26.5, 26.9, 27.2 and 27.4. Mixing fractions as model outputs on neutral density surfaces imply spreading paths of NPIW.Results show that NPIW source waters enter the subtropical gyre mainly from the northeastern subtropical gyre. The shift of the axes of NPIW salinity minimum, changed from dominantly westward in the southern rim of the subtropical gyre on sigma_N=26.5 to northeast-southwestward crossing the gyre on sigma_N=26.9,is the cause of forming the subtropical NPIW.

ANNUAL TO INTERANNUAL VARIABILITY IN THE GLOBAL INTEGRAL OFUPPER-OCEAN HEAT CONTENT

Josh K. WILLIS, Dean ROEMMICH, Bruce CORNUELLE (Scripps Institution of Oceanography, University of California, San Diego)

Because of its large heat capacity and organized circulations, the ocean plays important roles in the Earth´s climate system through the storage and transport of heat. As globally averaged atmospheric temperature rises, it becomes increasingly important to quantify the ocean´s ability to absorb and sequester excess heat, as well as to understand how a heated ocean affects the atmosphere and cryosphere. Describing variability in globally averaged, upper-ocean heat content is therefore an important step toward understanding the ocean´s role in the global heat budget. A time series of upper-ocean heat content from 1993 to the present is calculated using a combination of *in situ* temperature profiles and satellite altimetry data. The time series is calculated using a new technique to combine *in situ* and satellite data (Willis et al., *JGR*, submitted Dec., 2002) that results in substantially less error than estimates made from either data set alone. The time series shows annual to interannual variability of heat content in the upper 800 m of the water column, averaged over the globe, including inland and marginal seas. Maps of the yearly heat content anomaly will also be presented. The merged TOPEX/Poseidon - ERS product from AVISO was used to provide altimetry data for the estimate. By compiling data from several different sources, approximately 950,000 temperature profiles were found for the time-period from 1992 to the present. This includes a large number of profiles taken by subsurface floats as part of the Argo program. In recent years, subsurface floats have begun to contribute a substantial fraction of the globally available profiles as well as to provide data in historically data-sparse regions such as the Southern and Indian Oceans. In addition to quantifying interannual variability on a global scale, this work also illustrates the importance of maintaining continuously updated monitoring systems that provide global coverage of the world´s oceans. Such ongoing projects, like the TOPEX/Jason satellite altimetry program and the Argo float program provide a critical foundation for characterizing variability on regional, basin, and global scales and quantifying the ocean´s role as part of the climate system.

COMBINED USE OF ALTIMETRY AND IN-SITU DATA FOR OCEAN CLIMATE MONITORING

Shiro IMAWAKI[1], Hiroshi UCHIDA[2], Daisuke AMBE[3] ([1]Research Institute for Applied Mechanics, Kyushu University, Kasuga, Fukuoka 816-8580, JAPAN, [2]Japan Marine Science and Technology Center, Natsushima, Yokosuka 237-0061, JAPAN, [3]Interdisciplinary Graduate School of Engineering Sciences, Kyushu University, Kasuga, Fukuoka 816-8580, JAPAN)

Satellite altimeters can measure the sea-surface dynamic topography down to the oceanic mesoscale and provide irreplaceable information for ocean climate monitoring. The altimeter data can be utilized much more efficiently by being combined with in-situ oceanographic data. Here are shown two examples; one is the surface flow field of the North Pacific derived by combined use of altimeter and surface drifter data, and the other is the Kuroshio transport estimated from altimeter data by using empirical relationship between the transport and sea-surface height difference, which has been obtained from in-situ intensive observations. Example 1: The surface flow field. In the altimeter data processing, the information on the temporal mean topography is lost. Here, the mean surface flow field is estimated by combining anomalies of sea-surface dynamic topography obtained from altimeter data with in-situ surface velocities estimated from trajectories of surface drifters, as follows. Sea-surface velocity may be divided into the temporal mean and anomaly. The velocity anomalies are derived from satellite altimeter data with geostrophic approximation. Where a drifter measured the surface velocity, the temporal mean velocity can be estimated by subtracting the altimeter-derived velocity anomaly at that time from the drifter-measured surface velocity. The method is applied to the surface flow field of the North Pacific, using TOPEX/POSEIDON and ERS-1/2 altimeter data (CLS gridded data), and WOCE-TOGA surface drifter data obtained from October 1992 through August 2001. The temporal mean velocity field is estimated with a resolution of quarter degrees in both latitude and longitude. The instantaneous velocity field is estimated by summing up the temporal mean velocity field and velocity anomalies, every ten days during the nine-year period of 1993-2001. The instantaneous flow field shows energetic variability of the Kuroshio Extension vividly. Example 2: The Kuroshio transport. In 1993-1995, the ASUKA (Affiliated Surveys of the Kuroshio off Cape Ashizuri) Group carried out intensive observations of the Kuroshio south of Japan, including direct current measurements and frequently repeated hydrographic surveys along a subsatellite track of TOPEX/POSEIDON. Velocity sections are obtained by geostrophic calculation using the hydrographic survey data, referenced to velocities observed at mid and abyssal depths. Estimated transports of the Kuroshio have a high correlation with sea-surface height differences across the Kuroshio. Having this relationship and using the altimeter data, we obtained a time series of Kuroshio transport over nine years (1993-2001) at ten-day intervals. The Kuroshio transport, excluding contributions by local recirculations, is estimated to be 43 Sv on average. The range of annual fluctuation is found to be much smaller than that of transport expected from the interior wind stress curl.

UPPER OCEAN DYNAMICS IN THE TROPICAL AND SOUTH ATLANTICFROM HIGH DENSITY XBT LINES AX08 AND AX18

Gustavo Jorge GONI[1], Molly O'Neil BARINGER[1], Silvia Lucia GARZOLI[1], Qi YAO[2], Claudia SCHMID[1] ([1]National Oceanic and Atmospheric Administration, Atlantic Oceanographic and Meteorological Laboratory, [2]University of Miami, Rosenstiel School of Marine and Atmospheric Science,CIMAS)

We present results obtained from two high densityXBT lines that run across the Atlantic Ocean, from Cape Townto New York City (AX08) and from Cape Town to Buenos Aires (AX18).A total of six and two realization were carried in linesAX08 and AX18, respectively, by January 2003.XBTs are deployed in high densitymode (every 30-40 km), except along AX08 north of 20N where theyare deployed in low density (every 100-150 km) mode.Additionally, profiling floats arealso deployed to obtain salinity profiles in some transects.The temperature sections reveal themajor ocean currents in the upper 800 m.The

five AX08 transects are used to compute the water mass transportsof the major currents in the tropical Atlanticand to investigate their spatial and temporal variability.The two temperature sections across the SouthAtlantic (AX18) are used to estimate the upper ocean contributionto the Meridional Overturning Circulation by integrating the geostrophictransport across the subtropical gyre.In both lines, dynamic heights are computed using the XBTtemperature profiles with salinity derived from historical T-Srelationships. The dynamic heights estimated by combiningaltimeter data with climatological dynamic height fieldsare compared with the XBT-derived values. Theerror in XBT-derived dynamic height introduced by usinghistorical T-S relationships instead of synoptic salinity datafrom profiling floats are of the order of 1.5 cm in the tropicalAtlantic. The structure exhibited in the dynamic height and inthe altimeter-derived sea height fields do not reveal all thecomponents of the upper ocean current system, making thetemperature sections presented here critical for computingtransports and investigating the temporal and spatial variability ofthe upper ocean dynamics. Four and two transects are expected tobe carried out each year in lines AX08 and AX18, respectively.Data and preliminary results from these and other AOML-maintainedhigh density XBT lines can be found in:http://www.aoml.noaa.gov/phod/hdenxbt/

OPERATIONAL ALTIMETRY : SSALTO/DUACS READY FOR GODAE

Pierre-Yves LE TRAON (CLS Space Oceanography Division)

The near real time (NRT) processing of altimeter data was developed by CLS as part of DUACS (Developing Use of Altimetry for Climate Studies), a European Commission 3-year project which started in February 1997. DUACS was coordinated by CLS, and gathered four of the major climate research teams in Europe. Since the end of DUACS, the system has continued to provide NRT altimeter data for operational oceanography applications. During that time period, a new version of the system was also developed and has been operational since early 2002. The new system called SSALTO/DUACS is part of the CNES SSALTO multi-mission ground segment and is funded by CNES and the Midi-Pyrénées regional Council. It incorporates several improvements in the processing algorithms and is able to process TOPEX/POSEIDON (TP), ERS-2, GEOSAT Follow On (GFO), Jason-1 and ENVISAT data. The most recent geophysical corrections are applied and improved orbit error and long wavelength error reduction schemes are used. SSALTO/DUACS now provides MERCATOR, GODAE and climate forecasting centers with directly useable, high quality NRT altimeter data. Delayed mode high quality data are also produced for reanalysis activities. An overview of the SSALTO/DUACS system will be given and its main applications and users will be described.

GODAE: THE GLOBAL OCEAN DATA ASSIMILATION EXPERIMENT

Neville Ross SMITH (BMRC, Bureau of Meteorology)

The Global Ocean Data Assimilation Experiment (GODAE) was conceived in 1997 as apath-finding initiative for operational oceanography. While several agencies already had operational models and services, in general the community lacked the observational power and sophisticated model and data assimilation systems to fully exploit the accrued knowledge and recognized potential. The vision behind GODAE is that new societal and economic advantages can be provided through a global system of observations, communications, modelling and assimilation, that will deliver regular, comprehensive information on the state of the oceans in a way that will promote and engender wide utility and availability of this resource for maximum benefit to society. GODAE is a practical demonstration of feasibility and utility and of near-real-time, routine global ocean data assimilation. Through 2002, individuals and groups have formed a partnership to develop both regional and global prototype systems and have worked with relevant agencies to develop the infrastructure needed for GODAE. This year marks the beginning of the Demonstration Phase (2003-2005) and already many groups are routinely producing ocean analysis and forecasting products, ranging from short-range marine environmental predictions to sophisticated estimates of the ocean climate circulation. This presentation will review the strategy, discuss different aspects of the implementation of GODAE, and provide a context for GODAE within the general context of ocean and climate research. GODAE has a sound technical and scientific basis. Comprehensive integrated, global measurement networks provide the observational foundation, with satellites and Argo playing crucial roles. Full functionality depends on improvements in data management and data and product serving technology and GODAE is fostering innovative solutions to meet these needs. Ocean models and data assimilation provide the power to interpret and extrapolate complex observations into ocean products of broad utility. Several applications will be described, with the focus on value-adding and user products.

THE ECCO ROUTINE GLOBAL OCEAN DATA ASSIMILATION SYSTEM

Ichiro FUKUMORI, Tong LEE, Dimitris MENEMENLIS (Jet Propulsion Laboratory, California Institute of Technology)

An ocean data assimilation system producing regular analyses isestablished so as to monitor global ocean circulation and to betterunderstand processes underlying the ocean´s seasonal-to-interannualchanges. The data assimilation system is a product of the consortium"Estimating the Circulation and Climate of the Ocean (ECCO)" and is acontribution to GODAE. The system is based on a near-global primitiveequation model of high resolution (1-deg telescoping to 0.3-deg with10m near surface layers). Measurements from satellite altimetry(TOPEX/POSEIDON, Jason-1) and in situ hydrography (XBTs, moorings,floats, and climatology) are assimilated. The assimilation is basedon a hierarchical approach that consists of 1) a Green´s functionmethod to adjust gross characteristics of the model, 2) a partitionedKalman filter and smoother for routine assimilation and analysis, and3) an adjoint method for periodic rigorous optimization. Analyses areregularly updated and are available via a Live Access Server athttp://www.ecco-group.org/las. The data assimilation system will bereviewed and examples of its applications will be described.

Location: Site B, Room 17

JSP07/08A/B17-001   Invited   0900
STUDYING BIOGEOCHEMICAL PROCESS ON THE MID-ATLANTIC CONTINETAL SHELF USING AN OCEAN OBSERVATORY

Oscar SCHOFIELD, Scott GLENN, Robert CHANT (COOL, Rutgers University)

The Ocean Sciences Decadal Committee in laying out oceanography´s future suggested "The very few existing time-series stations paint a compelling picture of important oceanic changes in physics, chemistry and biology. Yet these stations capture the time domain at only a single point. New strategies for observing the appropriate spatial correlation are required." The question confronting the community is how do we get there? Key enabling technologies are opening the door. These include: (1) long-duration moorings or cabled observatories for subsurface time, (2) high-frequency RADARs providing real-time surface current maps over shelf scales, (3) a growing international constellation of high-resolution ocean color satellites, and (4) an emerging class of long-duration remotely-controlled Autonomous Underwater Vehicles (AUVs). These technologies, operated in an integrated manner, form the backbone of the New Jersey Shelf Observing System (NJ-SOS). This observationally rich environment changes the relationship between models and observation. In the well-sampled ocean, forecast errors are dominated by uncertainties in the model formulations or boundary conditions, and ensemble forecasts with differing parameterizations can be compared to observations so as to improve our understanding of errors associated with various model assumptions. The new paradigm of an observationally rich environment will in the near future feed ensemble biogeochemical models allowing us to assess many critical assumptions in elemental cycling on continental shelves. These approaches will fundamentally alter how biologists and chemists study the ocean processes.

THE CAROLINA COASTAL OCEAN OBSERVATION AND PREDICTION PROJECT

Lian XIE, Leonard J. PIETRAFESA, John M. MORRISON (Department of Marine, Earth and Atmospheric Sciecnes, North Carolina State University)

This presentation will introduce the Carolinas Coastal Ocean Observing and Prediction System (Caro-COOPS) and preliminary results from the 2001-2002 activity. This project is founded upon a partnership -- led by the University of South Carolina´s Belle W. Baruch Institute (USC), with North Carolina State University (NCSU), and the University of North Carolina at Wilmington (UNCW) -- and establishes the capacity to monitor and model estuarine and coastal ocean conditions in the Carolinas, USA. It will provide a capability for real-time predictions and ultimately forecasts to mitigate natural hazards, support management of living resources and marine ecosystems, and facilitate safe and efficient marine operations and support national security efforts. The central goal of Caro-COOPS is prediction of coastal ocean processes. The overall objectives are to: a) integrate information on the causal biological, chemical, and physical processes in the CarolinasÆcoastal ocean to provide a thorough understanding of how physical forcing and biological responses are coupled on regional spatial scales and seasonal and inter-annual time scales; b) assess the predictability of specific coastal processes and events; c) develop accurate forecasting models; and d) create tools for applying and evaluating these predictions in the context of "end-to-end" early warning systems. Caro-COOPS will represent a wholly integrated system for coastal observations and their application to user-driven research, societal, and economic needs. Moreover, it will provide three major advances in observing system capacities and capabilities: 1) It will establish an extensive array of instrumented moorings in the South Atlantic Bight, which currently receives extremely sparse coverage compared with other significant coastal regions, such as the Gulf of Mexico, New England coast, and the Chesapeake Bay. 2) It includes the development of a comprehensive data management system, essential for access to, and integration of, high quality, real-time data; the system will be designed to maximize flexibility and utility, with a view towards serving as a model and/or support for other coastal ocean observing systems; 3) It incorporates an advanced suite of integrated models that will markedly improve the predictive capacities of real-time physical data from coastal ocean instrumentation.

THE EUROPEAN SEA LEVEL SERVICE (ESEAS):A CONTRIBUTION TO THE COASTAL OCEAN OBSERVING SYSTEM

Hans-Peter PLAG (Geodetic Institute, Norwegian Mapping Authority, Kartverksveien 21. N-3511 Honefoss, Norway)

This abstract describes work carried out by the ESEAS and the ESEAS Research Infrastructure project (ESEAS-RI) teams (to be found at http://www.eseas.org). The ESEAS started its work in June 2001 and has the major objective to provide sea-level and sea-level related information for the European waters to scientific and non-scientific users both from inside and outside Europe. The ESEAS aims to achieve this goal in cooperation with other relevant orgaanisations such as the PSMSL, EuroGOOS, GLOSS, EUREF and IGS. The ESEAS strives to guarantee and co-ordinate the long-term monitoring activities and data exchange along the entire European coastline. This includes but is not limitted to tasks like setting up standards for observations and data processing, quality control of the large European database of hourly sea level data, upgrading of the ESEAS Observing Sites, collocation of tide gauges with CGPS, and provision of derived products such as secular trends and estimates of extremes. The EU-funded ESEAS-RI project started on 1 November 2002 with 25 institutions from 17 countries included. The project will run over three years and provides substantial resources for improving the observational network as well as the tools for exploitation of the data. In particular, Work Package (WP) 1 (Quality Control of Sea Level Observations) will make available a quality-controlled data set of hourly tide gauge data from most ESEAS Observing sites. WP2 (Absolute sea level variations) will concentrate on the determination of vertical crustal motion at the ESEAS Observing sites. WP3 (Decadal to inter-decadal sea level variations) will produce as main result an empirical model of the sea level variations in the Eurepean Seas for the last hundred years and give coherent estimates of long-term trends along the European Coasts. Finally, in the frame of WP4 (Improving the sea level observing system), a number of ESEAS Observing Sites will be upgraded and/or augmented with CGPS.

AN INTEGRATED OBSERVING AND MODELING SYSTEM FOR TAMPA BAY, FLORIDA

Mark E. LUTHER, Steven D. MEYERS, Sherryl A. GILBERT, Vembu SUBRAMANIAN (College of Marine Science, Univ. of South Florida)

The USF College of Marine Science has developed an integrated observing system and circulation, wave, sediment transport, and water quality model. The model system ingests

IA

real-time observations of the physical forcing functions for Tampa Bay to produce three-dimensional fields of circulation, temperature, salinity, wave spectra, sediment resuspension, sediment transport, and turbidity, A water quality module is under development. The hydrodynamic model is fully operational in either a nowcast-forecast mode or a hindcast mode and is described on our web site (http://ompl.marine.usf.edu/TBmodel). The integrated observing and modeling provides a decision support tool that is used to enhance safety and efficiency of maritime transportation, to guide search and rescue efforts, and to evaluate the bay ecosystem response to environmental stressors. Such stressors include severe storms, seasonal and interannual changes in fresh water input, as well as human impacts, such as hazardous material spills, river withdrawals, nutrient loading, changing land use patterns, and alterations in bay bathymetry. In addition to its routine use by the Tampa Bay Pilots and the US Coast Guard, the model system has been used to support management decisions in several environmental issues affecting the bay. For example, the model was used to investigate the effects of concentrate discharge from a seawater desalination facility recently built on Tampa Bay for the regional water supply authority; to simulate the trajectory of partially treated process water discharged from the Piney Point phosphate plant for the Florida Department of Environmental Protection; to predict trajectories of raw sewage spills into the bay for the Pinellas County Health Department; and to evaluate changes in salinity and estuarine residence time in the Palm River and McKay Bay for the Southwest Florida Water Management District. The Tampa Bay integrated observing and modeling system is being coupled to a similar integrated ocean observing system for the West Florida Shelf coastal ocean (see http://comps.marine.usf.edu).

A NEW TECHNOLOGY FOR THE COASTAL-SEA ENVIRONMENT MONITORING-COASTAL ACOUSTIC TOMOGRAPHY (CAT)-

Arata KANEKO[1], Noriaki GOHDA[1], Hong ZHENG[2], Keisuke YAMAGUCHI[1], Ju LIN[1], Fadli SYAMSUDIN[1], Hidetaka TAKEOKA[3], Masaji MATSUYAMA[4], Yoshio TAKASUGI[5] ([1]Graduate School of Engineering, Hiroshima University,1-4-1 Kagamiyama, Higashi-Hiroshima, Hiroshima 739-8527, Japan, [2]SEA Corporation, IU Bldg 4F, 2-23 Shiohama, Ichikawa, Chiba 272-0127, Japan, [3]Center for Marine Environmental Studies, Ehime University, Bunkyo-machi, Matsuyama, Ehime 790-8577, Japan, [4]Tokyo University of Fisheries, 4-5-7 Konan, Minato-ku, Tokyo 108-8477, Japan, [5]National Institute of Advanced Industrial Science and Technology, 2-2-2 Hiro-Suehiro, Kure, Hiroshima 737-0197, Japan)

The deep-sea acoustic tomography has a two-decade history as a three-dimensional mapping tool of mesoscale sound speed (temperature) and current velocity structures. The acoustic tomography is recently applied to the semi-enclosed coastal sea as have been seen with continuous effort of Hiroshima University group since 1994. The first 5 km-scale experiment using five sets of self-contained type coastal acoustic tomography (CAT) systems was successfully carried out on March 1999 in the Neko-Seto Channel of the Seto Inland Sea, Japan where a strong tidal jet induces a pair of vortices. A rapid process of initiation, growth, translation and decay of the vortices was well mapped every five minutes through the reciprocal sound transmission and receiving of 5.5-kHz sound among five stations equipped with a transmitter and a hydrophone. This CAT system is extended to an advanced system with a two/four-hydrophone array to catch baroclinic structures of current, and the number of the system is increased up to eight. Seven two-hydrophone systems were deployed to Uwajima Bay of the Seto Inland Sea, Japan with a horizontal scale of about 10 km in late summer of 2002 where most active fish and pearl aquacultures exist. The CAT surface buoy is floated up inside the raft of fish aquaculture or beside the surface buoy of pearl aquaculture. In early winter of 2002 the four-hydrophone systems were used in Tokyo Bay for measuring the winter circulation in the 20-km scale bay. Major part of the CAT system was put on the land near the vertical wall of wharfs and piers at eight sites surrounding Tokyo Bay, and the transmitter and hydrophone array were suspended down into water along the vertical wall. An overview of the advanced CAT system and the recent observational results will be presented in the symposium.

JSP07/08A/B17-006   1120

WAVEFORM RETRACKING OF T/P ALTIMETER IN CHINA SEAS AND ITS VICINITY

Lifeng BAO, Yang LU, Hou-Tse HSU (Institute of Geodesy and Geophysics of Chinese Academy of Sciences)

Just as in the open ocean, the altimeter data in the coastal zone can provide valuable information on wave heights, structure of the geoid and the associated gravity field, and dynamic sea surface topography. Because of this wealth of information, many scientists are seeking to extend the use of altimeter data to the shoreline. There are many different methods described in the literature that are available for retracking altimeter waveform data. All the various retracking algorithms have their own unique advantages and disadvantages, and it is generally accepted that no single algorithm can meet the diverse needs of all altimetry data users. To obtain accurate altimeter data in offshore of China Sea and its vicinity, we have reprocessed the raw Topex/Poseidon altimeter waveform data using more sophisticated algorithms, based on a fit of the waveform to a 5 or 9 parameter function, than those implemented in the altimeter hardware. Retracking altimetry data is done by computing the departure of the waveform´s leading edge from the tracking gate of altimeter and correcting the satellite range measurement accordingly. On the base of colleagues´ experience, reprocessed Topex/Poseidon altimeter waveform data is used to generate a time series of sea surface height. The post-processed altimeter waveform data is compared with the data from several tide gauge stations in China Sea, which close to the ground tracks of satellite, and Topex/Poseidon GDR data. The comparison shows that the post-processing data based on a nonlinear 5 parameters function is more accurate than post-processing data based on a nonlinear 9 parameters function in China Seas and its vicinity. With post-processing data, shallow water areas can be investigated with much more data and closer to the coastal line than the official products. It is shown that waveform retracking can extend the altimeter derived sea surface topography several kilometers shoreward in China seas and its vicinity.

JSP07/08A/B17-007   1140

MONITORING OF OIL POLLUTION WITH MOBIL AUTONOMOUS LANDER PLATFORMS AS A PART OF THE COASTAL OCEAN OBSERVING SYSTEM

Alexei Evgenievich KONTAR, Leopold Isaevich LOBKOVSKY (Laboratory of Seismology and Geodynamics, P.P. Shirshov Institute of Oceanology, Russian Academy of Sciences)

The present generation of submarine oceanographic hydrocarbon discharge field programs are fundamentally limited by too few measurements, taken too slowly, at too great a cost. One approach to provide more extensive access to oil pollution on the sea floor is to use robotic mobile lander platforms to characterize hydrocarbon seepage and the distribution of pollution on the seabed at different spatial and temporal resolutions. The term ˝lander˝ in sub-sea technology refers to vehicles that descend to the sea floor, carry out a series of tasks autonomously for a period of days to years storing data on board, and then ascend to the surface at the end of the mission for recovery by a surface ship. A typical lander

comprises a chassis, buoyancy module, recovery module and ballast with release mechanism. One or more scientific payloads can be attached, depending on the size of the lander, for monitoring processes in the surface layers of the sediment and the bottom water. Landers have evolved from conventional oceanographic instrument moorings such as current meters or sediment trap arrays but are characterized by an instrument package standing or suspended close to the sea floor such as seismographs and geophons. Environmental monitoring systems like those described above have applications beyond oceanographic science. A range of mobile lander platforms is under development, from a relatively fast survey vehicle, to a much slower but longer endurance buoyancy driven system. However, the design of sampling strategies to make the best use of mobile lander platforms is an unsolved problem for all but the simplest circumstances. Such strategies are necessary because even with the increase in sensing capability provided by many small lander platforms, most processes will still be under sampled. Thus the emerging challenge is to determine the most effective use of available observational assets to obtain the desired information, given the physics of the phenomena under study and the constraints of the lander platforms and sensors available for detecting of oil pollution on the sea floor. This presentation will review some emerging paradigms for employing the lander platforms for seabed environmental monitoring as a part of the coastal ocean observing system and will present results from field experiments in the Black Sea.

MORPHODYNAMIC CHARACTERIZATION OF THE FORESHORE USING PERODIC DGPS OBSERVATIONS:THE AVEIRO LAGOON BEACH CASE

Paulo BAPTISTA[1], Luisa BASTOS[1], Cristina BERNARDES[2], Oscar FERREIRA[3], Alveirinho DIAS[3] ([1]Astronomical Observatory, University of Porto, [2]Departament of Geosciences, University of Aveiro, [3]Marine Geosciences, UCTRA, University of Algarve)

The Aveiro Lagoon Littoral sandy beach that extends along 50 Km from Ovar to Mira, in central coast of Portugal, is exposed to the highly energetic North Atlantic Ocean. The coastal erosion usually associated to the action of storm events has strong impacts in the anthropic activities creating some difficulties in coastal management. The mean annual significant offshore wave height is about 2.2m, with an average peak period of 11.3s. As the foredune erosion and consequent destruction by overwashes are related with the foreshore and backshore morphology, the study of the morphodynamic evolution of these areas of the beach is of special interest. In the scope of the RIMAR project (Natural Hazards related with sea level changes), the changes that have taken place in the foredunes, backshore and foreshore areas are being monitored since 1998. The survey method presently used is based on a prototype system developed at the Astronomical Observatory. It consists of a two GPS antenna system installed on a four-wheel motor quad. The observation methodology consists in the establishment of grids along long stretches of the coast that are surveyed in DGPS kinematic mode. The accuracy of this system is under centimetre level, which makes it adequate for morphodynamic studies. One stretch with about 10 kilometres extension has been monitored since November 2001, with near monthly re-observations. The computed volumetric and slope changes along the study area were used for a macroscale morphodynamic characterisation using the most common morphodynamic parameters namely the *surf scalling parameter* and the *surf similarity parameter* . The establishment of correlations between the morphological data and wave data provides new insights on the volumetric recovery period of the beach along the year and after storm events. For the prediction of the erosion and coastal retreat associated with storms, the *Kriebel and Dean* convolution model was used, which has been tested previously with good results for the Portuguese coast. By applying the convolution model to wave data, obtained offshore, and to information from the monitored beach profiles, it is possible to establish a relation effect between storm and beach erosion. The results obtained show that the implemented methodology can be very useful for the characterisation of the beach behaviour and the prediction of beach erosion.

MODELLING: MORE QUESTIONS THAN ANSWERS?

Paul TETT (School of Life Sciences, Napier University)

Most models of marine ecosystems can be seen in terms of a set of equations of standard form: $\{\partial Y/\partial t = -\nabla \Phi_y + \beta_y\}$ and their numerical solutions. In the equation, Y is a state variable belonging to a set that could include, for examples, temperature, velocity, energy, and concentrations of nutrients and organisms. The first right-hand term is the divergence of physical transport flux vectors at a given spatial location and time; this term conserves the quantities totalled over a simulation domain except for boundary fluxes. The second right-hand term summarises the sources and sinks of each variable at a given location and time. It is not required to be conservative for any single variable, although conservation laws (e.g. for total energy, total nitrogen) may be introduced to constrain conversions between variables. Instances of this equation range from the simple first dynamical plankton model of Riley (1946) to modern, complicated, models such as ERSEM and COHERENS-PROWQM. This paper will consider two fundamental questions: 1) Is marine modelling largely an engineering problem - i.e. taking established scientific truths and using them to build models that can be used for system diagnosis and prognosis - or part of the scientific process - using models as tools for testing hypotheses? We know less than we think about marine ecosystem dynamics, and so need to continue making and testing hypotheses. Nevertheless, there is a pressing practical need for models that can be diagnostically and prognistically. 2) What are the entities which are quantified by the Y variables? The paper will explore how the idea of microplankton (comprising all pelagic bacteria and protists, both autotrophic and heterotrophic) can be used to develope efficient parameterisations of marine pelagic ecosystems at several levels of model complexity. These complicated simplifications can be further simplified to make a model that looks much like the original model of Riley, and can in turn be developed into to a steady state solution embodying the precautionary principle that is practically useful in diagnosing or predicting the trophic status of water bodies. Examples will draw on modelling work carried out in several EC supported projects: CANIGO, COHERENS, OAERRE and PROVESS.

VARIABILITY OF SOLAR TRANSMISSION AND RADIANT HEATING RATE IN THE COASTAL OCEAN: OPTICAL IMPACTS

Grace C. CHANG, Tommy D. DICKEY (Ocean Physics Laboratory, University of California Santa Barbara)

Understanding solar energy transmission is important for quantification and modeling of ocean radiant heating and primary productivity. Solar transmission and ocean radiant heating affect the intensity and depth of upper water column stratification. Stratification can

impact upper ocean ecology by limiting or facilitating vertical motion of phytoplankton; nutrient entrainment and availability; and movement of riverine inputs, suspended matter, and pollutants. The variability of solar transmission is dependent on the in-water spectral solar attenuation coefficient and the sea surface albedo, which are both influenced by meteorological and upper ocean physical processes, and bio-optical parameters. Past experimental and modeling studies of ocean radiant heating and solar transmission have primarily been executed for the open ocean. Studies regarding the impacts of coastal ocean processes on solar transmission have been limited until recently. An extensive physical and bio-optical time series data set, coupled with radiative transfer simulations, is used to characterize the processes and parameters that contribute to the variability of spectral solar transmission, sea surface albedo, and upper ocean radiant heating rates (RHR) in coastal waters. The data were collected from a mooring off the east coast of the United States in 24 m water depth in summer 2001. Three different analyses are utilized: (1) time series statistical analyses; (2) examination of processes and parameters affecting solar transmission, sea surface albedo, and RHR using radiative transfer simulations; and (3) investigation of bio-optical effects on RHR and heat content. (1) Quantitative coherence analyses suggest that cloud cover, chlorophyll concentration, and colored dissolved organic matter (CDOM) have the greatest impacts on solar transmission in the upper ocean in the visible wavelengths. All of these parameters are significantly coherent (negative phase) with solar transmission on a scale of about 1 week. Empirical orthogonal function (EOF) analyses show that the mixed layer depth (MLD) exhibits the strongest inverse correlation with solar transmission and RHR. (2) Radiative transfer simulations indicate that chlorophyll concentration, followed by absorption and attenuation coefficients, have the most significant impact on solar transmission variability. Solar angle and cloud cover greatly influence sea surface albedo. (3) Our data demonstrate that solar transmission is 14% lower and albedo is 1% higher for waters with higher concentrations of chlorophyll (~5 µg l⁻¹) as compared with lower chlorophyll concentration (~1 µg l⁻¹). In addition, the heat content of the upper mixed layer can increase by orders of magnitude during periods of deep mixing. For a shallow mixed layer (2 m), the mean hourly heat content is 90 W m⁻² as compared to 280 W m⁻² for a deeper mixed layer (6 m).

JSP07/08P/B17-003   1450
SPATIAL GRADIENTS IN BIOGEOCHEMICAL FLUX TO THE SEABED IN TIDE-STIRRED SHELF SEAS

Colin F. JAGO, Sarah E. JONES (School of Ocean Sciences, University of Wales Bangor)

A hypothesis is presented that the combined impact of dynamics, nutrients, and suspended matter produces enhanced biogeochemical fluxes to the seabed on the stratified side of tidal mixing fronts in tide-stirred shelf seas. In summer much of the algal production in the euphotic zone takes place in the thermocline and the greatest production occurs near tidal mixing fronts. This probably results from in situ growth of plankton due to optimal combination of light and nutrients: nutrient renewal during the summer, due to mixing by tide and wind, and surface stabilisation and reduction of the mixed layer optical thickness during fairweather and neap tides. A chlorophyll maximum is observed at the thermocline and at fronts. The optimal conditions for rapid algal growth are at fronts since lateral mixing across a front is greater than vertical mixing across the thermocline. Organic matter generated by algae is incorporated in suspended particulate matter (SPM) with most of the mass in large aggregates which settle to the seabed. Aggregation is facilitated by carbohydrates produced by the algae. In mixed waters, aggregated matter is frequently resuspended by tides so that significant remineralisation takes place in the water column. In stratified waters, low turbulence at the base of the thermocline provides conditions for aggregation and export of organic matter to the seabed where there is only limited resuspension; but remineralisation takes place as SPM sinks through the extended water column. Remineralisation therefore limits biogeochemical supply to the seabed in both mixed and stratified waters. In frontal zones, the potential for remineralisation is reduced due to rapid settling and limited resuspension. Combination of enhanced algal production, rapid settling of aggregates, and limited resuspension means that fluxes of aggregated biogeochemical components per unit area of seabed are greatest under fronts. However, resuspension in combination with cross-frontal mixing in summer and storms in winter should disperse benthic SPM away from fronts. Net deposition of this material is most likely on the stratified side of the frontal regions. The end result is that there should be spatial gradients in the supply of biogeochemical components to the seabed across mixed, frontal, and stratified zones. This is important because deposition of aggregates as benthic fluff controls redox conditions at the seabed and determines whether biogeochemical exchanges are oxic or anoxic. Temporary anoxia occurs even in mixed regions but it is particularly marked on the stratified size of frontal zones. High benthic oxygen demand occurs near the Frisian frontal, compared with the mixed, zone of the southern North Sea. Biogeochemical gradients also impact on the biota. Spatial gradients in dinoflagellate cysts and foraminifera in sediments occur across the Celtic Sea front. It is likely that the proposed biogeochemical gradient has significant impacts on benthic and pelagic biota and exchanges in tide-stirred shelf seas.

JSP07/08P/B17-004   1510
EXAMINATION OF SILICATE LIMITATION OF PRIMARY PRODUCTION IN JIAOZHOU BAY, NORTH CHINA IV TRANSECT OFFSHORE FROM THE COAST WITH THE ESTUARIES

Dongfang YANG (college of Fishery Science,Shanghai Fisheries University)

Jiaozhou Bay data collected from May 1991 to February 1994, 12 seasonal investigations, and provided the authors by the Ecological Station of Jiaozhou Bay, were analyzed to determine the characteristics, dynamic cycles and trends of silicateThe results indicated that the rivers around the Jiaozhou Bay supplied the rich silicate to the whole Bay so that the silicate concentration varied with the flow varying. The horizontal variation of silicate concentration transect offshore from the coast with estuaries showed that after the flow's carrying plentiful silicate into the Bay, the longer the distance was from the coast with estuaries, the lower the silicate concentration is in the waters. The vertical variation of silicate concentration transect offshore from the coast with estuaries showed that silicate sank and deposited to the marine bottom by the action of phytoplankton take-up and death, and zooplankton excretions. In this way, silicon would endlessly be transferred from terrestrial sources to marine bottom. The characteristics and transferences of diatoms and the ingestions and excretions of zooplankton elucidated the biogeochemical process of silicon, which showed the reason of phytoplankton's being lack of silicon. These results further proved that nutrient silicon is a limiting factor of phytoplankton growth.

A REVIEW TO DISTRIBUTION OF MACRO-MEIOFUNA AND SUBSTRATE CHARACTERISTICS IN IRANIAN CASPIAN SEA SHORES OFF GUILAN PROVINCE

Alireza MIRZAJANI (Department of Ecology, Caspian Sea Bony Fishers, Research Center)

The Caspian sea is a limited and brackish water that 724 species and 566 species microbenthos distributed in Caspian sea .In Iranian water of Caspian sea, the Hydrology and hydrobiology studies was started from late decade 1980. The study area was Caspian Sea at Guilan province on the 30 transect and 4 depths. Distribution of macrobenthic biomass had not a large changes for many years. During study of autumn 1995 to summer 1996 on 9 transect and 4 depths (10, 20, 50, 100 meter) the biomass was various from 1.69 to 65.45 gr/m2. The groups of Pseudocumidae, Amphipoda, Tubificidae, Chironomidae, Amphatridae, Nereidae, Cardidae and Scrobiculidae were studied. Generally the highest biomass was shown in a small region with biomass of higher than 18 gr/m2. The biomass was larger in 10 meter than another depths and the biomass had not the significant difference in all season. The study of meiofuna showed that Bivalva, Foraminifera, Nematoda, Ostracoda, Copopoda were dominate from 12 identified groups. The Foraminefera and Bivalva were the most abundant groups. There was a significant difference between average abundance of meiofouna at 4 depths, That 20 meter had the most average that it decreased in 50 and 100 meter depths. The average abundance of meiofouna varied from 825 to 29315 ind./cm2 in 100 and 20 meter respectively while the frequency of meiofouna was various from 80 to 133382 ind./10cm2. The most frequency was shown in small part of the west study area with higher than 3000 ind./10cm2 however the most frequency percentage had been seen with frequency of lower than 150 ind./cm2. Results of substrate characteristics studies showed that the organic matter was the most in 50 meter and it was the lowest at 10 meter depth. Fig. 4 shows the distribution of T.O.M. in study area that the most surface belong to 4-8 % organic matter, however a large surface of study area have belong to organic matter percentage of higher than 12 > % .The silt percentage was the most than other grain size (1, 0.5, 0.25, 0.076 mm) in all of depths and percentage of grain size for different depths for 0.076 mm size was more in 10 meter than other depths. The comparison of macrobenthic biomass distribution maps with fish catch data showed a positive relation. Also the overlapping of meiofauna abundant map on organic matter and grain size maps showed that the most abundant of meiofauna was in 4-8 % organic matter and there was a negative relation between meiofauna and silt values.

PECHORA SEA'S MICROPHYTOBENTHOS AT LATE AUTUMN AND ITS RELATIONS WITH TIDAL CYCLE

Filipp Vjacheslavovich SAPOZHNIKOV (P.P.Shirshov Institute of Oceanology)

Extremely high biomass rates benthic diatom algae had been occurred at summer and autumn 1998 in Pechora sea. Material was collected during the cruises of the RV "Academic Sergey Vavilov" and hydrographic vessel in the south-east part of Barents sea – the Pechora sea. The biomass of microphytobenthos was ranged from some tens to several hundreds grams per square meter on the depths 6-15 m. Usually, the biomass of microalgae in subtidals sediments of Arctic seas is about several grams. Extremely high biomass of microalgae – over 1 kg/m2- was found on a single shallow-water. Samples were consist mainly of plankton species (63,36 %). The most abundant was *Coscinodiscus cf. stellaris*. But mean density of plankton assemblage was about thousands cells per liter and some hundreds milligrams per liter. Sedimentation of cells from high light reach horizon makes considerable influence on formation of bottom community in before winter period. However, number of phytoplanktonic organisms was not reach enough to support a high density of bottom diatoms. It could be suggested, that near the bottom exist some specific density populated sestonic assemblages. This communities in particular consist of plankton diatoms, which actively utilize organic sediments. Most of cells of *Coscinodiscus* and *Thalassiosira* had viable chromatofores in the moment of fixing. Some of them were in process of cell division. Its important that during the collecting a material in this region penetration of light wasn't very deep. It was because of plentiful suspension. That's why we think that benthos microalgae use in general heterotrofic type of nourishment. Its possible, that sedimentation on bottom of alive plankton diatoms of high-performance seston assemblages accounts lashings of this creature in benthic communities. The most high density of alive diatoms was on depths 13-15 m. Biomass of cells approximately was more then 0,5 kilogram per sqeare meter. At that time the number of cells was ranged from 20 to 40 millions per sqeare centimeter of surface of bottom. Benthic diatoms were largely represent to. That all demonstrate the high concentration of organic substance on this depths. This substance is used by diatoms. We think, this phenomenon - high density of microphyts - can be supported by termoclins' and picnoclins' passing on researching depths. Perhaps, high density of diatoms in that conditions is connected with fluctuation of termoclins' level during the process of tidal cycle. With a tidal the termoclin is getting up. Cold waters with high salinity come to bottom layer. That waters are rich with organic substance and biogenic elements. This time, diatoms, which live in high horizon of sediments and, perhaps, in seston actively use organic substance which are necessary for grow. Then starts a low tide. And termoclins level falls down. The same time, thickness of water layer is reducing above the communities. On account of that the light impenetrate deeper. That makes the cells of diatoms to reproduce oneself.

MESOSCALE FEATURES IN A MEDITERRANEAN COASTAL AREA REVEALED BY A HF RADAR

Giorgio BUDILLON, Marco TRAMONTIN (Istituto di Meteorologia e Oceanografia. Universita' di Napoli PARTHENOPE)

A HF Coastal Dynamics Application Radar (CODAR) has been used to study the seasurface circulation in the coastal area between Ancona and Senigallia (NorthernAdriatic Sea) throughout one year of measurement (July 07th 1997 - July 06th1998) over a 30 x 30 km area including 401 grid points having a spatialresolution of 1.5 Km. Preliminary results show the well-known southeastward (i.e. alongshore) coastaljet that extends its influence as far as 10-15 Km from the coast; fartheroffshore a cyclonic eddy, with a diameter of 10-20 km typically occurs. This circulation can be occasionally reversed showing an anticyclonic eddythat forces a northward coastal current with a far less energetic signature. The spectral analysis reveals a propagation of the semidiurnal frequenciesfrom NW to SE according to the propagation of a Kelvin wave theory; converselyan exponential increase from the coast to offshore has been identified for thenear-inertial frequencies. An analysis of the mean kinetic energy during both ' Bora and ' Scirocco wind episode, from north-east and from south-eastrespectively, describes the typical dynamic of a surface layer driven by aninpulsive atmospheric forcing. In this work the CODAR velocity data have been used to perform also anEmpirical Orthogonal Function (EOF) analysis and principal modes and varianceare reported.

JSP08/09A/B19-002   0930
STUDYING THE WATER CIRCULATION ALONG THE EGYPTIAN MEDITERRANEAN COAST USING THREE DIMENSIONAL NUMERICAL MODEL

Sayed H. SHARAF EL-DIN, Khaled A. ALAM EL-DIN, Omneya M. IBRAHIM (Departement of Oceanography, University of Alexandria)

The water circulation along the Egyptian Mediterranean Coast was studied using three dimensional numerical model. Numerical simulation was achieved using the Princeton Ocean Model (POM) with horizontal resolution of 2` grid interval and 14 vertical sigma levels. The bathymetric map of the Egyptian coast was digitized with high resolution from the Admiralty charts which is updated by the Egyptian Government Survey Authority and Egyptian Navy. The initial fields of temperature, salinity and current used to run the model were taken from MODB dataset. The surface momentum, heat and fresh water fluxes were taken from ECMWF monthly data for the period 1986-1992. The simulation results showed that the surface circulation of the Egyptian Mediterranean waters is dominated by the easterly flow along the coast. Mersa-Matruh anticyclone occupies the area between 27°E to 28°E longitude. Also a cyclonic gyre takes place between 28°E and 30°E longitude. In the central region, a weak anticyclone persists in front of Nile Delta. In the Eastern part, El-Arish cyclonic gyre exists intensively.

THE RESPONSES OF THE WEST FLORIDA CONTINENTAL SHELF TO THE WINTER STORMS

Ruoying HE, Robert WEISBERG (College of Marine Science, University of South Florida)

Two large extra-tropic storm systems produced significant coastal ocean responses on the West Florida continental shelf in March 2001. Taking the month of March 01 as the study window, we describe the shelf circulation responses to the evolution of these two storms with in-situ measurements of winds, sea levels and currents. The responses of the west Florida shelf circulation are found to be sensitive to the wind direction primarily due to the variations of the coastal line orientation facing the ocean. Driven by NCEP EDAS winds and surface pressure only, a three-dimensional coastal ocean circulation model is used to simulate the west Florida shelf circulation in March 01 by assuming the remote forcing of deep ocean boundary current (i.e., Loop Current) is secondary. Model/Data comparisons indicate that the coastal ocean model is highly skillful and that the shelf circulation during this period indeed responds primarily to the local wind forcing.

CURRENT STRUCTURE AND BEHAVIOR OF THE RIVER PLUME IN SUO-NADA, JAPAN

Shinya MAGOME, Atsuhiko ISOBE (Department of Earth System Science and Technology, Kyushu University)

The behavior of the river plume in Suo-Nada is studied using a primitive equation numerical model, Princeton Ocean Model. Special attention is given to the current structure and behavior of the anticyclonic eddy (bulge) induced by high freshwater inflow changing in a timescale of one week. First, in order to investigate the fundamental process on the bulge, the freshwater is supplied from a river to a rectangular basin with a simple topography. An anticyclonic bulge near the river mouth and a coastal current in the direction of the Kelvin wave propagation are revealed after the river discharge increases. The anticyclonic bulge has the upwelling (downwelling) inside (along the fringe of) the bulge. When the river discharge subsides after reaching its peak value, the bulge propagates upstream (i.e., opposite to the direction of the Kelvin wave propagation). Next, in order to investigate the behavior of the bulge in Suo-Nada, the freshwater is supplied from major eight rivers to the basin with the realistic topography. The less saline water mass in the southern part of Suo-Nada propagates to the west (i.e., upstream direction) after the river discharge increases. It is consistent with an observational fact that the less saline water mass appears in the western part of Suo-Nada, suggesting that the upstream propagation of the bulge is possible in the real ocean. On the basis of the results of the model with the simple topography, a cause of the upstream propagation is considered. Onshore currents appear in the bottom layer beneath the bulge, propagating upstream. They produce an anticyclonic barotropic eddy due to the conservation of the potential vorticity. The current component associated with the eddy crosses normally to the isohaline in the upper layer, and therefore transports the bulge upstream. Other current component (surface current velocity minus vertically-averaged value) is not responsible for the upstream propagation of the bulge.

QUANTIFICATION OF CONTAMINANT FLUX IN AN IMPACTED ESTUARY, WINYAH BAY, SOUTHEASTERN USA

Yong Hoon KIM, Mary CATHEY, George VOULGARIS, Miguel GONI, Richard STYLES (Department of Geological Sciences and Marine Science Program, University of South Carolina)

A multidisciplinary approach was used to examine the dynamics of flow-particles-contaminants in an impacted estuarine environment. An intensive suite of field measurements was acquired along the upper region of Winyah Bay estuary, southeastern USA during October 2001 (low river discharge condition). Our work was focused on examining the relative importance of advection versus remobilization of contaminants within the estuarine turbidity maximum (ETM) as processes controlling their overall fate. Concurrent measurements of hydrographic properties, currents, sediment concentration and particle size distribution were combined with the geochemical analyses of water samples. Water samples were filtered to measure the concentrations of total suspended sediments

(TSS), particulate and dissolved organic carbon (POC and DOC), and particular nitrogen (PN), as well as stable carbon isotopes, and polycyclic aromatic hydrocarbons (PAHs). The tidal and residual circulation pattern and its influence on suspended sediment distribution are established for the prevailing conditions using the physical data. Residual current along the main channel axis shows typical estuarine circulation, outward flow near the surface and inflow near the bottom. The magnitude of landward-directed flow is much higher than seaward flow. Analysis of suspended sediment concentration exhibits a tidal asymmetry with higher concentrations during the flood (up to 0.94 g/l). Geochemical analyses of water samples show that POC concentrations were significantly lower (1-4 mg/L) than DOC (5-9 mg/L). At all stations POC concentrations increase with depth, showing a strong positive relationship with current. In contrast, the highest DOC concentrations precede peak flood by several hours. The trends in the POC/PN and stable carbon isotope ratios measured in POC indicate differential transport of organic materials during distinct periods of the tide. In addition, during flood tide, resuspension of vascular plant derived OM appears to occur, as evident by shifts towards typical terrestrial POC/PN ($>$20) and $\delta^{13}C_{org}$ (-28 ‰) values. The results show that net landward fluxes of suspended sediments and POC over a tidal cycle, indicating that Winyah Bay is flood dominated during low discharge. The overall consequence of this behavior is a significant input of organic material from the lower reaches of the bay towards the ETM.

CURRENTS AND TURBULENT EXCHANGE PROCESSES IN LAKE ONTARIO

Ram Rao YERUBANDI (Environment Canada-NWRI)

The coastal circulation and turbulent exchange processes during spring and summer stratification in Lake Ontario has been examined using concurrent measurements of velocity profiles from moored broadband ADCPs, and ship based transects. Temperature profiles at two thermistor moorings provided data on the thermal structure during the summer period. During May ship based ADCP transect data clearly shows the circulation associated with the thermal bar. During the summer period energy spectra of currents and temperature shows a primary peak located at 10-12 day period due to large scale circulation and a secondary peak at near-inertial frequency-band. The horizontal turbulent exchange parameters during summer stratification shows non-isotropic conditions in the surface layers and isotropic conditions in the bottom layers at the offshore location. The alongshore exchange coefficients are generally higher than cross-shore components. Upwelling and downwelling of isotherms are a common feature during the summer stratification. It is observed that during upwelling horizontal exchange coefficients are reduced in the surface layers while they are increased in the bottom layers. Near bottom layers are affected by intense turbulence associated with increased vertical current shear. During downwelling events with migration and intersection of the thermocline with the bottom, the vertical exchange coefficients are relatively small due to strong static stability.

TEMPORAL AND SPATIAL ASYMMETRIES IN THE TIDAL RESPONSE OF SHALLOW INLETS AND BACK-BARRIER BASSINS

Emil V. STANEV, Joerg-Olaf WOLFF (ICBM, University of Oldenburg)

In this paper we study water exchange between tidal basins and open ocean using data from observations and numerical simulations. The study area covers the East Frisian Wadden Sea, which consists of seven tidal basins. The major interest is focused on the tidal basins in the vicinity of the islands Spiekeroog and Langeoog and the inlets connecting them with the open ocean. We analyze the contribution of hypsometric control and Stokes transport to the overall dynamics of well-mixed tidal basins. The theoretical concepts are compared against results of direct observations and simulations with a numerical model. The data have been collected during the period 1995-2000 and consist of cross-channel ADCP transects. The numerical simulations are based on the 3-Dprimitive equation General Estuarine Transport Model (GETM) with a horizontal resolution of 200 m and terrain following vertical coordinates. The results ofthe observations and simulations reveal a distinct difference between transports in the upper layer, which is dominated by the Stokes drift and the deep layer being dominated by the hypsometric properties of the intertidal basin. The difference between these two transports gives rise to the existence avertical overturning cell: net inward motion in the upper layer and net outward motion in the deeper parts of the tidal channels. This vertical circulation is also well documented in our numerical simulations, and shows a clear dependency of transport patterns on the local depth. The interplay between transports and turbulence explains the major trends in the transport of sediment.

JSP08/09A/B19-008   1140
SEASONAL VARIABILITY OF NUTRIENTS SUPPLY TO THE PULICAT LAKE, EAST COAST OF INDIA

Jaya Raju NADIMIKERI (sri venkateswara university)

SEASONAL VARIABILITY OF NUTRIENTS SUPPY TO THE PULICAT LAKE ,EAST COAST OF INDIADetailed studies of the nutrients of the pulicat lake have shown that the Northern and Channel parts differ considerablyin the way that nutrients are supplied and regenerated . The Channel part is very much under the influence of the Baycurrent, and is affected both by upwelling at the shelf-break,and by the advection of warm ,nutrient -poor surface waterfrom perturbations along the land ward edge of the current. This leads to the establishment of a two layer system formuch of the year, with the thermoclines intensifying during the summer.The Northern part,in contrast, is ,more away from the upwelling region of the Bay. Here ,deep mixing during monsoonis favoured by the fresh water inflow ,wind stress and thermoclineformation during the summer is less intense. Bottom water supply appears to be from the Bay rather than the fresh waterinflow form the land and localised patches of oxygen-depleted water are formed as a result of lowered advection. The variability in source waters and the forcing fields over the two regions of the lake leads to differences in the nutrient concentrations in the surface waters. These, in turn, affect the productivity of the region and the attendant biodiversity in general and fish stocks in specific.

DEVELOPMENT OF A SEMI-SPECTRAL COASTAL OCEAN MODEL AND ITS APPLICATION TO THE NEKO SETO SEA IN THE SETO INLAND SEA

Masazumi ARAI (Graduate School of Engineering, Hiroshima University)

For studying coastal ocean processes such as tidal vortices, frontal instability of the Kuroshio and Kyucho, a new ocean model is developed based on the semi-spectral method using the primitive equations with hydrostatic balance on a sigma-coordinate system. The feature of the present model is that the vertical mode is used as a basis, which is different from the previous work of Haidvogel et al. (1991). As a first step of the development of the model, the Fourier cosine series is used as a basis by assuming that the reference density is

homogeneous or linearly stratified. To test the performance of the model with homogeneous density, the model is applied to the regional model of the Neko Seto Sea in the Seto Inland Sea. In the Neko Seto Sea, a tidal vortex is generated due to the barotropic instability of a strong tidal jet, so this is a suitable region to test a homogeneous model. Here the model tidal current is driven by the tide imposed at the boundaries of the model domain. The model result is intensively compared with the observational result of ADCP by the research group of Hiroshima University (Yamaoka et al. 2002). For the barotropic component of velocity, the correlation between the model result and ADCP result is quite high. The correlation coefficient is 0.84 (0.65) for the eastward (northward) component. Since the position and magnitude of the tidal jet is well simulated in the model, the correlation coefficient of the eastward component is higher. The vertical structure of the horizontal component of velocity is also compared with ADCP. The core structure of the tidal current passing through the narrow strait is well realized in the model. To test the accuracy of the baroclinic pressure gradient term, the linearized model with density stratification is applied to the seamount problem proposed by Beckmann and Haidvogel (1993). The maximum velocity associated with the pressure gradient error in a sigma-coordinate system is comparable to those of the previous models. The above results demonstrate the good performance of the present model. The model will be applied to the model of the Bungo Channel for studying the mechanism of Kyucho.

WEAK WIND-WAVE/LOW-FREQUENCY CURRENT INTERACTION WITH DUE REGARD FOR BOTTOM MOBILITY

Boris KAGAN[1], Oscar ALVAREZ[3], Alfredo IZQUIERDO[2], Rafael MANANES[2], Begonia TEJEDOR[2], Luis TEJEDOR[2] ([1]Shirshov Institute of Oceanology, Russian Academy of Sciences, St.Petersburg Branch, 30 Pervaya Liniya, 199053 St.Petersburg, Russia, [2]Departamento de Fisica Aplicada, Universidad de Cadiz, Apdo. 40,, [3]Departamento de Fisica Aplicada, Universidad de Cadiz. Unidad Asociada Oceanografia Interdisciplinar UCA-CSIC. Apdo. 40,)

The formulation of weak wind-wave/low-frequency current interaction is extended to the moveable rough bottom case using the bottom roughness predictors of Nielsen (1983) and Tolman (1994). This ´extended´ formulation is then implemented in a 2D depth-averaged, non-linear, high-resolution hydrodynamic model and the modified model is applied to study the changes in the tidal dynamics of Cadiz Bay due to wind-wave/tide interaction and bottom mobility. The inclusion of the second of these factors leads to noqualitative changes in the fields of tidal characteristics compared to those obtained with allowance for the first one alone. Certain quantitative changes, however, occur. These are such that an agreement between the predicted and observed tidal elevation amplitudes and phases tends to be improved if both of the above factors are accounted for. It is shown that quantitative distinctions between the solutions derived when employing Nielsen´s (1983) and Tolman´s (1994) bottom roughness predictors are not so much as might be expected from comparison of the appropriate values of the mobility parameter. That is because the mobility parameter defined as the ratio of the wave-induced change in the bottom roughness length to the wave reference bottom roughness length appears in the expression for the drag coefficient not by itself, but in combination with the ratio between the wave and tidal reference bottom roughness lengths (bottom roughness lengths in the immobile rough bottom case). It is for this reason that these lengths cannot be set equal to each other. Otherwise, the solution becomes unreasonable: the drag coefficient increases to an extent that the tidal elevation and velocity inthe region of interest either degenerate in part when using Nielsen´s (1983) bottom roughness predictor or are too reduced to be realistic when using Tolman´s (1994) bottom roughness predictor. The fields of other tidal characteristics are also transformed beyond recognition.

SEA-BREEZE-MODULATED SEASONAL VARIABILITY IN THE K1 TIDAL DYNAMICS IN NEARSHORE REGIONS

Oscar ALVAREZ[1], Begonia TEJEDOR[3], Luis TEJEDOR[3], Boris KAGAN[2] ([1]Department of Fisica Aplicada, University of Cadiz. Unidad Asociada Oceanografia Interdisciplinar UCA-CSIC, [2]Shirshov Institute of Oceanology, russian Academy of Sciences,, [3]. Departament of Fisica Aplicada, Universidad de Cadiz, Apdo.40, Puerto Real, Spain)

The role of sea breezes in the development of nearshore wave climate, diurnalcurrent velocity and sea surface elevation, and beach topography has beenextensively studied (see, e.g., O´Brien et al, 1977;Rosenfeld, 1988; Craig,1989; Chen and Xie, 1997; Pattiaratch et al., 1997, Militello and Kraus, 2001;Hyder et al., 2002). The same cannot be said in respect to the influence of seabreezes on tidal dynamics in coastal waters. All we know is that sea breezesare responsible for the formation of the S1 solar diurnal tide. This viewpointwas held by a number of tidalists, including Shureman (1941), Munk andCartwright (1966) and Zetler (1971). There were, however, dissenters. So,Godin (1990) speculated that the S1 tide, even though its gravitationalpotential is weak, is of gravitational origin and determined by a diurnalinequality in the tide-generating force due to a slight asymmetry in theshape of geoid. We show that sea breezes may be considered as a major sourceof the seasonal variability in the K1 tidal dynamics in near-coastal shallowregions. This fact is explined as follows: if the K1 tidal response toboundary forcing is subjected to the sea-breeze impact, the superposition ofthe K1 signal and the S1 signal, independent of what is its origin, willproduce a seasonal modulation of the K1 tidal dynamics and, hence, seasonalvariations in the K1 tidal characteristics. This finding results from thewell-known expression for an amplitude- and phase-modulated oscillation.It is also supported by simulating the response of Cadiz Bay to sea-breezewind stress and tidal boundary forcing - individually and in combination - through a 2D depth-averaged, non-linear, high-resolution hydrodynamic model.

NET SAND TRANSPORT BY TIDAL PUMPING IN A MACROTIDAL ESTUARY

Colin F. JAGO (School of Ocean Sciences, University of Wales Bangor)

Data are presented which provide sand fluxes and sedimentation rates in a macrotidal estuary on tidal to decadal time scales. The dynamics of the Taf Estuary in Wales (UK) are established by a macrotidal regime with a tidal range up to 10 m. The tidal wave is asymmetric with a short flood tide of <3 h and fast spring tide currents exceeding 2 m s[-1]. The estuary is sandy and characterised, at low water, by intertidal sandflats and shallow channels and, at high water, by a well mixed, or partially stratified, water column. Freshwater input is small (mean discharge 7 m³ s[-1]) in comparison with saltwater input (mean tidal prism 10⁷ m³). The estuary is exposed to large waves from the North Atlantic but much of the wave energy is dissipated across a wide shoreface before waves reach the estuary mouth. The fast tidal currents generate intense sand transport and rapid morphological change. A unique 30 year time series of sedimentation rate has been obtained. The sand budget has been

determined by periodic surveys of the sand flats at low water. Levelling of fixed transects across the estuary over a 30 year period shows that the estuary has been infilling with sand at a mean annual sedimentation rate of 0.02 m. Mineralogical analysis of the sand proves that it is sourced from offshore rather than via river input. A testable hypothesis is that the landward transport of marine sand is due to tidal pumping associated with the time-velocity asymmetry of the tidal currents rather than to storm events. The very fine sand of the sandflats is entrained into suspension for most of every tidal cycle. Bed load transport is minimal, and total sand transport can be quantified by measurement of the suspended sediment load. The suspended sand flux has been determined by measurements of current velocity and suspended sand concentration (SSC) along 2 transects across the estuary. Measurements were made through the water column over several tidal cycles, during fair-weather conditions, using profiling transmissometers for SSC. Flood sand flux exceeded ebb sand flux on all tides; hence there was a net landward flux on all tides. Relationships between sand flux and tidal height were determined and used to extrapolate the annual flux and annual sedimentation rate. The annual sedimentation rate is 0.014± 0.036 m. This ignores any forcing other than tidal. The long term budget and short term flux measurements provide very similar estimates of the sedimentation rate in the estuary. This provides compelling evidence that the high sand fluxes and sedimentation rates of the estuary are determined predominantly by the tidal regime. It is concluded that the hypothesis that tidal pumping, rather than storms, controls net sediment transport is correct.

COASTAL ESTUARINE-LAGOON SYSTEM BEHAVIOUR IN RESPONSE TO TYPHOON EVENTS, EASTERN HAINAN ISLAND, CHINA

Shu GAO (Department of Geo-Ocean Sciences, Nanjing University)

A series of estuary-lagoon systems are distributed along the eastern Hainan Island coastlines. Here, coastal development for tourism has become progressively intense, because of the clean air and water. However, this section of coastlines is also subjected to typhoons, which often result in sequential disasters. During a typhoon event, strong winds damage forests and houses, large storm waves erode the shoreline, typhoon induced heavy rain causes flood in the drainage basins, and combined action of storm surge and increased river flow leads to flooding in lagoonal areas. Boao Harbour, now being developed into a middle-sized coastal city, provides a good example. The sand spit that semi-encloses the lagoon to form an estuarine / tidal inlet system was breached at its northern section three times during storms in the past sixty years; these resulted from the storm waves, together with strong river flow inside the lagoon. The timing of the large river water discharge into the lagoon tends to match the storm-induced high water (because the rivers are relatively short); hence flooding in the low-lying lagoonal areas occurs once every two to five years. Human activities add further risks to flooding. For instance, at the Xiaohai inlet, the entrance channel was artificially narrowed for navigation purposes. This engineering work has hampered the river discharge into the open sea, causing an extremely severe flooding in 2000. Recently, artificial modification to the entrance channel to Boao Harbour has been proposed. For such an engineering scheme, however, additional flooding risk assessment must be carried out. Based upon analyses of the regional patterns of typhoon-induced sequential disasters and the related processes and mechanisms, the risk of flooding will be enhanced by inappropriate modifications to the entrance channel. Numerical studies indicate that the shape of the designed entrance channel for navigation is an important factor for the modified flood water levels.

ESTIMATION OF LONGSHORE SEDIMENT TRANSPORT RATE OFF DAMIETTA HARBOR, EGYPT

Sayed H. SHARAF EL-DIN, Fahmy Mohamed EID, Farid AbdelRahman ABDALLA (Departement of Oceanography, University of Alexandria)

Using the wave and longshore current data which collected by the coastal Research Institute during the period from Aug. 1997 to Dec. 1998 along Damietta area, the sediment transport rate is estimated at three places, east, west of Damietta harbor and west of Damietta mouth using two common models and field measurements. The results revealed that: The predominant direction of sediment transport takes place eastward. The gross transport is very large during winter, while it is low during spring and summer seasons. The average sediment transport rate is about 543 x 10₃ m³/year. The results of streamer sediment traps showed that, the sediment flux and sediment transport rate density have their maximum value at the east of study area than the western side. Using the fluorescent tracer grains, the result showed that, the amount of sediment transport moving on the eastern side is more than at western side of study area. Also, the percentage of occurrence of sediment transport from onshore to offshore during spring is more than that occurs in the autumn. In addition, the comparison between the different methods of estimation of sediment transport rate was done.

JSP08/09P/B19-004   1510
UNSTEADY DYNAMICS OF EDGE WAVES

Efim PELINOVSKY[1], Andrey KURKIN[2] ([1]Laboratory of Hydrophysics, Institute of Applied Physics, [2]Department of Applied Mathematics, Nizhny Novgorod State Technical University, 24 Minin Street, Nizhny Novgorod, RUSSIA)

Wave propagation in the coastal zone can induce both scattering and capturing of wave energy. The latter phenomenon is of great interest due to the weak attenuation of waves over long distances. Trapped waves are an important component of sea disturbances produced by cyclones moving along coastlines and their existence explains the non-uniform character of tsunami height along the coastline. Edge waves may be generated from normally incident wind waves due to the strong nonlinearity of wind waves and many field observations demonstrate the occurrence of these edge waves in coastal environments. Edge waves are often considered as the major factor in the long-term evolution of irregular coastal morphology, forming rhythmical crescentic bars. There is good agreement between the characteristic scales of these morphological features when measured in laboratory experiments and the natural environment. However, the energetics of the wave processes is poorly understood and the sediment transport rates associated with the edge wave field has neither been estimated nor measured. The main goal of this paper is to study the unsteady dynamics of the progressive and standing edge wave propagation above a sloping beach. In particular, the mechanism of the spatial–temporal focusing (dispersion enhancement) of multi-modal edge waves in the shelf zone is investigated in the framework of shallow water theory both analytically and numerically. The asymptotic solution is derived for the wave evolution above a sloping beach smoothly varied in along-shore direction. The unusual appearance of the coastal flood tongue is demonstrated in the framework of developed theory.

STATISTICS OF EXTREME WINDS; STORM SURGES AND OCEAN WAVES ALONG THE NORTH SEA COASTLINE, 1960 UNTIL TODAY

Hans VON STORCH[1], Ralf WEISSE[1], Arnt PFIZENMAYER[1], Frauke FESER[1], Saskia ESSELBORN[2], Trygve ASPELIEN[1] ([1]Institute for Coastal Research, GKSS Research Center, Geesthacht, Germany, [2]Geoforschungszentrum Potsdam, Germany)

The evolution of storm surge statistics along the North Sea coasts during the past 50 to 100 years is reconstructed using statistical and dynamical models with and without data assimilation. It turns out that the mean water level has increased since the 1960s by a few centimeters along the southern and eastern coast lines, but that the variations relative to the annual mean have undergone hardly any changes. This sea level rise is reflecting the tendency of the last decades for more frequent westerly wind conditions, which is not only associated with higher water levels in the southeast of the North Sea, but also with increased wave energy reaching the eastern shoreline as well as higher waves in the German Bight.

JSP08/09P/B19-006 — 1620

CLIMATOLOGY OF STORM SURGES IN THE ARCTIC OCEAN

Andrey PROSHUTINSKY[1], Igor ASHIK[2], Tatiana PROSHUTINSKY[3] ([1]Woods Hole Oceanographic Institution, [2]Arctic and Antarctic Research Institute, [3]University of Alaska Fairbanks)

The shore of the arctic seas are generally of low relief and the combination of waves and high water levels during late summer and fall storms before the development of significant sea-ice cover can be particularly damaging to shorelines. Gravel barrier beaches can be overwashed and eroded while bluffs consisting of unlithified ice-bonded sediment and segregated ice can fail and retreat. Storm surge climatology of the arctic marginal seas is investigated based on observational data and a 2-Dcoupled ice-ocean barotropic model results. Meteorological forcing is calculated based on NCAR/NCEP reanalysis data for 1948-present period. The spatial resolution of the model is 13.89 km. The sea ice conditions (concentration and thickness) are prescribed on the mean monthly basis. The model was calibrated based on the most strong storm surges observed in the Kara, Laptev, East-Siberian, Chukchi and Beaufort Seas. Simulation results are in relatively good agreement with observations of sea level heights and ice drift. Detailed studies showed that the spatial and temporal resolution of the NCEP/NCAR sea level pressure data (2.5x2.5 degree, 6 hours) are too low and can not reproduce well extreme conditions in the relatively small polar cyclones but storm surge event frequency is reproduce very well. The results of this study can be used to aid current and future scenario risk assessments of coastal flooding and costal erosion rates.

THE DEVELOPMENT OF A STORM SURGE MODEL INCLUDING EFFECT OF WAVE SET UP FOR OPERATIONAL FORECASTING

Nadao KOHNO[1], Masakazu HIGAKI[2], Tatsuo KONISHI[2] ([1]Typhoon Research Department, Meteorological Research Institute, JMA, [2]Climate and Marine Department, Japan Meteorological Agency)

Storm surges often lead to enormous disasters in coastal areas, and accurate predictions are crucial for disaster prevention. Recently storm surge predictions using numerical models have advanced and been operationally used in several countries. JMA operates a 2-dimensional linear storm surge model with horizontal grid resolution of 1 minute in each direction, which is much finer than those of weather models. Accuracy of this model is reasonable for inland bay areas, since the topographies of coasts and water depth mainly determine storm surges in inland bay.On the other hand, it is difficult to estimate storm surges accurately along coasts and islands shores where high waves tend to hit, even using a 3-dimensional storm surge model. This reason could be due to effects of ocean waves like wave set-up, which is not included in conventional storm surge models. A development of a storm surge model, which includes effects of ocean waves, is necessary. We have developed such a storm surge model for operational predictions. It consists of a storm surge model based on Princeton Ocean Model (POM) and the third generation wave model MRI-3 originally developed at MRI. Radiation stresses are calculated in the wave model and used in storm surge calculation. The expression of stress to storm surge is parameterized, since grid resolution is coarser than the scale of wave set-up phenomena. In August 2000, TY KIROGI (0003) passed by Hachijo Island located in the Pacific Ocean and a large storm surge of almost 250cm is observed at the Yaene tidal station located on the western coast of Hachijo Island. We simulated this case by this new model. The maximum storm surge at Yaene tidal station simulated by a conventional storm surge model was much lower (about 50cm) than the observation. The effect of wind set-up is not crucial since Yaene Port is quite small bay with rather deep water depth. From our wave calculation, quite high waves (wave height of 7 m) hit Yaene Port when the storm surge occurred. As a result, wave set-up must play a significant role in the storm surge. Our new model estimated maximum storm surge of about 170cm, and the value of about 120cm is improved by considering wave set-up. This value still indicates underestimation and it seems to result from some factors like grid resolution or wind estimation.We simulated other cases and the results of the simulations indicate that improvements are quite well. We have a plan to put this model into operation in near future.

LOICZ-RELATED STUDY IN THE CHINESE ACADEMY OF SCIENCES

Fan WANG, Dunxin HU (Laboratory of Ocean Circulation and Wave Study, Institute of Oceanology, Chinese Academy of Sciences)

Supported by the Chinese Academy of Sciences (CAS), the research into the Land-Ocean Interactions in the Coastal Zone (LOICZ) was initiated in China in 1997. Two CAS projects, "Land-Ocean Interactions in the China Seas and Their Environmental Impacts" (1997-2000) and "Study on Land-Ocean Interactions in the Chinese Main Estuaries and Adjacent Continental Shelf" (2000-2003), were successively carried out and led by the Institute of Oceanology, the CAS. The projects focused on some important issues in the Chinese coastal seas involved with the LOICZ, such as the variability of materials discharged from the Yangtze and Yellow Rivers, the processes of circulation and transportation of water, fine material and nutrients on the East China Sea (ECS) and Yellow Sea (YS) continental shelves, the distribution and variation of primary production limiting factors in the ECS, the contributions and their evolutions of the Yangtze River diluted water and Taiwan Warm Current to the nutrient supply of the Zhoushan Fishery Ground, and the sand transport dynamics in the Yellow River Estuary. Many progresses have been made and are reviewed in this paper.

JSP08/09P/B19-009 — 1720

TODOS OS SANTOS BAY: AN OCEANOGRAPHIC CHARACTERIZATION BASED ON IN SITU DATA AND NUMERICAL SIMULATIONS

Mauro CIRANO, Guilherme Camargo LESSA (Centro de Pesquisa em Geologia e Geofísica)

The Todos os Santos Bay (TSB) is the second largest coastal bay in Brazil, with an area of approximately 1270 km ^{2}. The tides in the bay are semidiurnal, with a mean range of 2 m, and a slight distortion that favors stronger ebb-tidal currents. The bay average depth, volume and tidal prism are 5.2 m, 12.5 x 109 m³, 3.36 x109 m³, respectively, and average fresh water input from all catchments is calculated as 111.10 m³/s. Fresh water discharge is three orders of magnitude smaller than the estimated average spring-tidal discharge at the bay mouth (1.30 x 105 m³/s). Under these circumstances, mixing of the water column appears to be effective throughout the year. Based on a massive data collection campaigns during two different seasons (summer and winter), a characterization of the circulation of TSB and its interaction with the associated continental shelf is provided. The hydrographic data collected during each season includes 17 current-meter stations (involving the deployment of 27 mechanical and electromagnetic current meters, as well as 2 ADCPs), 8 tide-gauging stations, 3 wind-gauging stations and 12 water-column profiling stations (CTD samplings during 1 spring and 1 neap tidal cycle). Currents inside the TSB are tidal driven, with average values between 10-30 cm/s, and residual velocities varying from 1-4 cm/s. The residual currents directed landward in the low water column may help to explain an extensive deposition of a several meters thick layer of mud in the shallower, inner half of the bay, where a turbidity maximum zone might exist. Outside the TSB, the inner shelf stations show higher values of residual velocities (4-14 cm/s) as well as a change in direction depending on the season, which indicates the influence of other forcing mechanisms in the area. Temperature and salinity gradients between the adjacent shelf and the innermost region of TSB can be as high as 2.7˚C and 3.6 psu respectively and according to the season. Based on all the data available, the Princeton Ocean Model was run in its three-dimensional model, and a comparison of the results from the in situ data and the numerical simulations is presented as part of this oceanographic characterization.

EFFECTS OF WINDS, TIDES, AND STORM SURGES ON OCEAN SURFACE WAVES IN THE JAPAN/EAST SEA

Wei ZHAO[1], Shuyi S. CHEN[1], Cheryl Ann BLAIN[2], Jiwei TIAN[3] ([1]Division of Meteorology and Physical Oceanography, University of Miami, Miami, Florida, USA, [2]Oceanography Division, Naval Research Laboratory, Stennis Space Center, MS, USA, [3]Laboratory of Physical Oceanography, The Ocean University of China, Qingdao, P. R. China)

Ocean surface waves are strongly forced by high wind conditions associated with winter storms the Japan/East Sea (JES). They are also modulated by tides and storm surges, especially near the coasts. The effects of the variability in surface wind forcing, tides, and storm surges on the waves are investigated using a wave model, a high-resolution atmospheric mesoscale model, and a hydrodynamic ocean circulation model. We conduct three month-long wave model simulations to examine the sensitivity of ocean waves to various wind forcing fields, tides, and storm surges during January 1997. Comparing with observed mean wave parameters (i.e., significant wave heights and wave periods), our results indicate that the variation in the wave fields is mainly caused by the variability of wind forcing. Tides and storm surges seem to have a significant impact on the waves near shores when mean water depth decreases sharply from a few hundreds of meters to less than 10 m along the west coast of Japan. Improving surface wind forecasts will be crucial for the prediction of surface waves and storm surges in JES, especially near the coastal regions.

ECOLOGICALLY SUSTAINABLE INTEGRATED COASTAL DEVELOPMENT IN BANGLADESH: PRESENT PRACTICES, ITS CONSEQUENCES AND A POLICY FRAMEWORK

Md. SALEQUZZAMAN (Ph.D. Candidate and Researcher, Institute for Sustainability and Technology Policy (ISTP), Murdoch University, Australia, and Associate Professor, Environmental Science Discipline, Khulna University, Bangladesh)

Coastal environment is highly valued and greatly attractive on its richness of various resources. Presently these coastal resources are critical to global sustainable development, particularly in developing countries like Bangladesh. Evidence suggests that activities in a variety of different sectors like energy, agriculture, industry, health and overall other coastal resources work better when these resources are ecologically integrated across disciplines and boundaries upon a strongly participatory and decision-making approaches and processes. Community can create authentic choices to achieve sustainable development by adopting integrative frameworks that could balance social, economic, and ecological concerns. Bangladesh belongs to a vast coastal area with a long coastal belt, most of which are protected by embankments and sluice gates. This coastal area possesses many resources and regarded as productive zone. But presently most of these resources are managed in an unplanned and unsustainable way. Although coastal environment of Bangladesh has had a good history of ecologically sustainable development practiced in the past. The main causes of present unplanned and unsustainable development are the lack of integration and lack of vision of future development. Among integration, electricity is an important indicator of modernisation, industrialisation and sustainable development. Presently this electricity is completely absent in coastal Bangladesh. The research identified tidal ranges in some areas of coastal Bangladesh are an important resource for the production of small-scale tidal energy. Thus the paper will briefly describes the various components necessary to integrating tidal energy in coastal Bangladesh. However, the core aim of integrated coastal development is to guide coastal area development in an ecologically sustainable fashion. Therefore the paper also identify factors responsible for ecologically sustainable integrated development through the examination of past environmental, socio-cultural and economical history of coastal Bangladesh. On the other hand, integrated coastal development is holistic and interdisciplinary in nature, especially with regard to science and policy. Therefore finally the paper will give a policy

recommendation that ´how coastal Bangladesh could be developed on ecologically sustainable manner´.

BLACK SAND CONCENTRATIONS AND COASTAL PROCESSES OF AZEMMOUR BEACH AND OUM ER RBIA ESTUARY, MOROCCAN ATLANTIC COAST

Nadia MHAMMDI[1], Addi AZZA[2] ([1]Département Physique du Globe, Universit?EMohammed V, [2]ministère de l'Energie et des Mines, PB 6208, rabat Instituts, Maroc)

Heavy-mineral sand-deposits are the main sources for the world supply of rare metals as zirconium and titanium. Concentrations of these minerals are known to occur in beach and dune sands. The economic importance of the Black Sands is attributed to their contents of industrial minerals such as ilmenite, hematite. magnetite, zircon, garnet and monazite. These deposits usually may visually be recognized by a darker colouring of the sands.Since heavy-mineral concentrations are often found in beach ridges it is generally accepted that the concentration took place by the selective removal of the lighter minerals such as quartz during erosion along a sandy coast. The presence of heavy minerals in beaches and dunes can therefore be used as an indicator for coastal development processes (erosion).The studied sector is situated on the Atlantic coast of Morocco about twenty km to the Northeast of El Jadida, near of Azemmour town. It belongs to the Moroccan Meseta crossed by the Oum Er-Rbia river. Climate, geomorphology, hydrology and geology of the Oum Er Rbia basin control the morphology and the sedimentation on this area. The climatically regime of this basin is under the influence of a Mediterranean climate of semi-arid type.Sand samples (thirty) were collected along of perpendicular beach profiles to the shore (river and sea) spaced of 50m to left of the river and 200m along of the beaches in order to examine the sorting patterns of heavy minerals that develop during cross-shore and alongshore sediment transportGrain-size analysis quartz morphology, heavy mineral and CaCo3 content analyses were performed on all the samples. The heavy fraction was separated from the light fraction by the gravity separation method. Selected samples for the analysis include the polished thin-sections prepared for modal analysis and isomagnetic separeted fractions were investigated.

MEASUREMENT AND PARAMETERIZATION OF AIR-SEA FLUXES: RECENT DEVELOPMENTS IN BULK FLUX ALOGORITHMS

Chris W. FAIRALL (Clouds, Radiation and Surface Processes Division)

Direct measurement of air-sea fluxes remains a technological challenge that is practiced by only a few research groups around the globe. Accurate measurements of fluxes from ships and buoys in a routine, unattended mode are still not practical. Thus, virtually all estimates of global or regional fluxes are obtained from bulk flux models, which use more easily obtained near surface meteorological data. Ultimately, bulk model coefficients must be traced to direct measurements obtained in very demanding intensive field programs. In the last decade great progress has been made on several technological fronts to improve the quality of the direct flux data. Similarly, several theoretical advances in representations of interfacial and boundary-layer processes has removed earlier pathological problems and linked the parameterizations more closely to the underlying physics. In 1996 version 2.5 of the COARE bulk algorithm was published and has become one of the most frequently used in the air-sea interaction community. In this talk we describe steps taken to improve the algorithm and a comparison with new data. This new version of the algorithm (COARE 3.0) was based on published results and 2777 one-hour covariance flux measurements in the ETL inventory. To test it, we added 4439 new values from field experiments between 1997 and 1999, which now dominate the database, especially in the wind speed regime beyond 10 m/s where the number of observations increased from 67 to about 800. In the paper we will discuss measurement issues, how these results compare with classic results from other field programs and models, and prospects for extending beyond 20 m/s.

REAL-TIME ON-BOARD AIR-SEA FLUX MEASUREMENT SYSTEM WITH EDDY COVARIANCE METHOD

Osamu TSUKAMOTO[1], Satoshi TAKAHASHI[1], Ken'ichi OKADA[1], Hiroshi ISHIDA[2] ([1]Okayama University, Department of Earth Sciences, [2]Maritime University of Kobe/ Frontier Observational Research System for Global Change)

Air-sea fluxes of momentum, energy or trace gases are key parameter to understand the air-sea interaction. A lot of approaches are carried out including satellite remote sensing. However most of the sea surface flux estimates are based on bulk aerodynamic formulas. While, the bulk algorithm includes bulk transfer coefficients, which are experimentally determined and some uncertainty remains in the transfer coefficients.Eddy correlation method or eddy covariance method are rather direct method for surface flux measurement without any assumptions or experimental coefficients. Now it is widely applied over land surface flux measurements (e.g.GEWEX, FLUXNET... The application of the eddy covariance method over open sea is rather complex as the platform(ships or buoys) sways with surface waves. Some research groups have already succeeded in the ship motion correction and on-board flux measurements are reported. Our group is one of them and unique in Japan. Present authors have installed the eddy flux system on R/V MIRAI, JAMSTEC and operating throughout a year as her all cruises in the Pacific since June, 2000. Her cruise extended from the Arctic to the tropics and encounters a lot of atmospheric and sea state conditions. A large amount of the dataset was analyzed and air-sea fluxes of sensible and latent heat were evaluated until the end of 2001. However, the data needs detailed quality control to remove noises and unfavorable conditions due to ship operations. The selected results are reported and compared with bulk fluxes.Now our measurement system evolved into a second generation since 2002. A open-path CO2 gas flux sensor was introduced and air-sea CO2 flux are now available as eddy covariance values. The sensor(LI-7500) also measures water vapor flux and humidity sensor was replaced as more long-life instrument. It can be used more than a year without special maintenance. Another development is the autonomated data processing system as real-time in-situ display system.

Our previous system requires off-line data processing job after the cruise. Now our on-line system can show you air-sea flux time series as real-time operating system. The present flux system can be applied to many cruising ships and more accurate air-sea fluxes are available in global scale. It should be helpful for the sea truth of satellite remote sensing or numerical model outputs.

CONSTRAINING THE INERTIAL DISSIPATION METHOD USING THE VERTICAL VELOCITY VARIANCE

Genevieve M. DARDIER[1], Alain WEILL[2], Helene DUPUIS[3], Christine GUERIN[2], William M. DRENNAN[4], Sidonie BRACHET[2], Fabienne LOHOU[3], Rodrigo PEDREROS[2] ([1]Stevens Institute of Technology, 711 Hudson Street, Hoboken, NJ 07030, [2]CETP, 10-12 av. de l'Europe, 78140 Velizy, France, [3]DGO, Universite Bordeaux I, UMR58, av. des Facultes, 33405 Talence, France, [4]RSMAS, University of Miami, 4600 Rickenbacker Causeway, Miami, FL, 33149, USA)

The Inertial Dissipation Method (IDM) is commonly used to measure turbulent fluxes over the ocean. It has the advantage over more direct methods in that it depends on the turbulent fluctuations only in the high frequencies of the so-called inertial subrange. These frequencies are above those of typical ship motions, and are considered to be relatively unaffected by flow distortion. However, a drawback in applying the method is that the problem is underdetermined: estimation of the fluxes requires knowledge of the Obukhov length L, which is itself a function of the fluxes. The problem is typically solved by iteration, using an initial L estimated from bulk formulae. This introduces a possible dependency on the initial bulk estimate and problems of convergence. To avoid this problem, IDM algorithms use an iterative approach, using an estimate of L as a 'first guess'. This initial estimate is typically derived from bulk relations or using the bulk Richardson number. The latter approach has been found to improve convergence but there remains the problem that for a significant number of cases the method does not converge. Also, the solution can be dependent on the initial estimate. We explore an alternative approach to the problem. In order to constrain the equations resulting from the IDM, we use the vertical velocity variance, σ_w, measured from the research vessel, l'Atalante and an ASIS buoy, both deployed during the 1998 FETCH experiment. These data are compared to several parameterisations of σ_w on stability derived in experiments over land. For unstable cases, the data are found to be well described by the Panofsky and Dutton [1984] parameterisation, although the scatter of the data is higher for swell conditions than for pure wind sea, indicating a likely sea state effect. Using measured values of σ_w, and this parameterisation, the inertial dissipation problem is fully specified. The convergence of the method is satisfactory, and it offers u* estimates independent of bulk formulae.

SEA STATE AND SURFACE CURRENT MEASUREMENTS WITH X-BAND MARINE RADAR ABOARD THE EXPLORER OF THE SEAS

Hans C. GRABER[1], Katrin HESSNER[2] ([1]University of Miami, [2]OceanWaves, GMBH)

The Wave Monitoring System **WaMoS II**, a real time ocean wave and surface current monitoring system designed for operational measurements under harsh environmental conditions, has been installed aboard the Royal Caribbean International cruise ship *Explorer of the Seas*. Standard methods are applied to derive directional wave spectra from a sequence of nautical radar images and then compute standard wave parameter like significant wave height, peak wave period, peak wave direction and peak wavelength. The measurement and data analysis takes about 2 minutes for standard, commercial nautical radars and sea state parameters are available in real time. A minimum wind speed of 3 m/s is required to obtain good wave measurements. The ship sails weekly on a seven-night Eastern Caribbean itinerary from Miami and cross the Gulf Stream to the major passages between the Atlantic Ocean and Caribbean Sea and the tradewind region. This ship´s repetitive cruise trackallows scientists to collect wave and surface current information continuously during weekly cruises. These observations will eventually provide improved descriptions of seasonal to interannual variability of the sea state and surface currents in this tropical regime. Results will show sea state information such as directional wave spectra, significant wave height, wave period and wave direction along the cruise track. The data is used to study wave-current interaction in the Florida Current and the effect of sheltering and diffraction around islands.

INFRARED INTERFEROMETRIC MEASUREMENTS OF THE AIR-SEA TEMPERATURE DIFFERENCE

Peter J. MINNETT[1], Kevin A. MAILLET[1], Brian J. OSBORNE[2] ([1]University of Miami, [2]University of Wisconsin-Madison)

The use of a well-calibrated, high-accuracy Fourier-Transform Infrared (FTIR) Interferometric Spectroradiometer on ships permits the derivation of many atmospheric parameters. Included amongst these is the air-sea temperature difference. Downward-looking measurements in transmissive parts of the infrared atmospheric absorption spectrum provide measurements of the surface skin temperature of the ocean, and upward-looking measurements in the less transmissive parts give air-temperature. Thus the air-sea temperature difference can be measured accurately with a single instrument. The Marine-Atmospheric Emitted Radiance Interferometer (M-AERI) has been deployed on several ships in a wide range of environmental conditions. The characteristics of the air-sea temperature difference revealed by radiometric measurements are different to those derived from conventional data, especially in the tropics. The larger variability in the conventional measurements is not surprising, but the presence of spurious mean signals in the conventional measurements may have significant and misleading consequences on our understanding of air-sea coupling. The interferometric measurement technique is presented with examples of at-sea measurements; the differences between these and conventional measurements are discussed along with some of their consequences.

SHIP-BASED MEASUREMENTS OF AIR-SEA FLUXES

Sergey K. GULEV (P.P.Shirshov Institute of Oceanology, RAS)

We discuss the major problems of the development of the global and regionalclimatologies of sea-air surface fluxes on the basis of Voluntary ObservingShip (VOS) data. Uncertainties inherent in the individual variables and fluxcomponents are quantified using the COADS (Comprehensive Ocean-Atmosphere DataSet) collection of VOS observations for a couple of decades. The main sourcesof uncertainties are the use of different parameterizations of fluxes,the accuracy of the meteorological variables used for the flux computations,and insufficient sampling. These uncertainties have different impacts on theclosure of the surface ocean heat balance and on the adequate representationof the climatic variability of surface

IA

fluxes. In particular, sampling problemmay have a time-dependent nature and, thus, can seriously affect variabilitypatterns on regional scales. Intercomparison of VOS-based flux products withthose available from numerical weather prediction (NWP) systems and remotesensing is presented in order to identify strengths and weaknesses of VOSwith respect to the other flux data sources. Approaches to minimize differentuncertainties are overviewed. These approaches are based on the applicationof the advanced objective analysis methods (to overcome the sampling problems)and the usage of the alternative information about the regional energy balances. Some perspectives in the use of VOS data for the computations ofadvanced sea-air flux parameters (e.g., sea-state-based wind stress and albedo) are discussed.

AIR-SEA HEAT AND FRESHWATER FLUXES: A NEW APPROACH FOR VALIDATION AND ESTIMATION BASED ON THE TIME-DEPENDENT ENERGY AND BUOYANCY BUDGETS OF NATURAL VOLUMES

Huai-Min ZHANG[1], John M. TOOLE[2], Michael J. CARUSO[2] ([1]NOAA/NESDIS/National Climatic Data Center, [2]Woods Hole Oceanographic Institution)

Accurate knowledge of air sea fluxes is central to advancing climate study and improving weather prediction, but currently available products have large uncertainties. Error is manifested by intercomparisons of various flux products, but such cross checks cannot determine which product is superior. And while validation against direct flux measurements is of great value, such estimates are rare and of limited temporal span; resultant flux adjustments based on these data are possibly location dependent. Here we propose application of oceanic heat and buoyancy conservation to evaluate air sea heat and freshwater fluxes, demonstrated with the heat flux into the tropical warm water pools. If the average oceanic vertical mixing is known at the base of such a control volume (physically the mixing must be down gradient), the method can be used to reduce air-sea flux errors/offsets. The method will be of greater value for freshwater flux when the satellite mission for SSS (Aquarius) is launched in the near future. The heat flux technique builds on the work of Niiler and Stevenson (1982) and Walin (1982) by examining the heat budget for natural control volumes defined by an isotherm. We applied the method to the tropical warm water pools of the Indo-Pacific and Atlantic Oceans, sites of intense convection in the atmosphere and thus key areas of air sea interaction. The dominant terms in the energy budget include time rate of change in pool heat content, net air pool heat flux over the whole pool surface, and turbulent and penetrating radiative heat fluxes integrated over the pool base. We find that the SOC and unconstrained COADS annual climatologies are most consistent with the mean annual march of ocean heat content in that consistently down gradient turbulent ocean heat fluxes are inferred, with relatively constant dia-thermal diffusivity of 2.8 cm²/s for the 28°C Indo Pacific pool and 1.5 cm²/s for the 27°C Atlantic pool. In contrast, other air sea flux climatologies (constrained COADS, NCEP and ECMWF) show inconsistencies with oceanic energy change in some seasons. On the mean annual cycle we find a dominant two term balance between seasonal changes in air pool heat exchange and change in pool energy content. On interannual time scales, all terms in the pool energy budget contribute, but high correlation is obtained between the air pool heat flux (estimated from the unconstrained COADS climatology) and the inferred turbulent ocean flux (as well as with the inferred diffusivity). We hope to explore this further in the context of coupled ocean atmosphere models where the turbulent fluxes can be estimated directly from model quantities.

JSP09/10A/B20-008 1130

BALANCING THE HEAT BUDGET OF THE SOC AIR-SEA FLUX CLIMATOLOGY THROUGH AN INVERSE ANALYSIS WITH OCEAN HEAT TRANSPORT CONSTRAINTS

Simon A. JOSEY, Jeremy P. GRIST (James Rennell Division, Southampton Oceanography Centre)

The Southampton Oceanography Centre (SOC) air-sea flux climatology, in common with other ship-based climatologies, exhibits an imbalance of 30Wm-2 in the global ocean heat budget. We have attempted to balance the climatology using linear inverse analysis. Up to ten hydrographic measurements of ocean heat transport from the Atlantic and North Pacific Oceans have been used as constraints. An additional constraint that the global mean net heat flux lies in the range 0±2 Wm-2 was also utilized. A solution is obtained with all ten transport constraints but without the requirement of global closure in which the global net heat bias is reduced to -5Wm-2. This change is largely due to a 15% increase in the latent heat flux and a 9% reduction to the shortwave flux. When the global constraint is included with the hydrographic constraints the solution requires increases in the latent heat flux, the longwave flux and the sensible heat flux of 19%, 9% and 7% respectively and a decrease in the shortwave flux of 6%. This solution results in an adjusted climatology with a global net heat flux of -2 Wm-2. It also provides good agreement with recent estimates of the global ocean heat transport obtained using residual techniques and from atmospheric model reanalyses. However, additional comparisons of the adjusted fluxes with measurements made by various Woods Hole Oceanographic Institute research buoys indicate that significant regional biases still exist. Results of ongoing research, aimed at identifying the causes of these biases, will be presented.

JSP09/10A/B20-009 1145

DIURNAL VARIATIONS OVER TROPICAL OCEANS AND THEIR IMPLICATIONS FOR AIR-SEA INTERACTIONS

Aiguo DAI, Kevin E. TRENBERTH (National Center for Atmospheric Research (NCAR))

We have analyzed high-resolution surface meteorological and oceanic data from TOGA COARE, Tropical Atmosphere-Ocean (TAO) buoys, WHOI buoys, and Nauru99 R/V Mirai to quantify the diurnal cycle at tropical ocean surfaces and determine the factors controlling the oceanic diurnal cycle. We have found that the diurnal (mean-to-peak) amplitude of sea surface skin temperature (Tskin) can be over 4 deg.C under calm (< 2 m/s winds) and clear-sky conditions in the Tropics. Under windy (> 4 m/s) conditions, the amplitude is less than 2 deg.C. Tskin peaks around 1-2 pm. Sea surface temperatures (SSTs) within the top 2m depth have a diurnal amplitude of 0.2-2.5 deg.C, with the maximum around 3-4pm. Surface air temperatures (Ta) have a diurnal amplitude of 0.4-5.0 deg.C with high values in the afternoon (2-4pm). The Ta amplitude increases with diurnal amplitudes of surface specific humidity, wind stress, sensible and latent heat fluxes, but is not correlated with daily mean wind speeds and maximum solar radiation. Time-averaged diurnal amplitudes are much smaller than those of individual days. Amplitudes of monthly SSTs are about 0.3-0.6 deg.C on the Equator and 0.1-0.3 deg.C off the Equator in the Pacific. Using daily mean wind speed or SSTs results in large errors in surface latent (up to 60 W/s) and sensible (up to 12 W/s) fluxes on hourly time scales.

JSP09/10A/B20-010 1200

AN ASSESSMENT OF THE SURFACE TURBULENT HEAT FLUXES FROM THE NCEP REANALYSIS OVER THE WESTERN BOUNDARY CURRENTS

Kent MOORE[1], Ian RENFREW[2] ([1]Department of Physics, University of Toronto, [2]British Antarctic Survey)

With the completion of the NCEP and ECMWF reanalyses there are now global representations of air-sea surface heat fluxes with sufficient spatial and temporal resolution to be useful in characterizing the air-sea interaction associated with individual weather systems, as well as in developing global-scale oceanic heat and moisture budgets. However these fluxes are strongly dependent on the numerical models used, and as a result, there is a clear need to validate them against observations. Accurate air-sea heat flux estimates require a realistic representation of the atmospheric boundary layer, and the implementation of an appropriate surface flux parameterization. Previous work at high latitudes has highlighted the shortcomings of the surface turbulent heat flux parameterization used in the NCEP reanalysis during high wind speed conditions; especially when these are combined with large air-sea temperature differences. Here we extend this result through an examination of the air-sea heat fluxes over the western boundary currents of the North Atlantic and North Pacific Oceans. These are also regions where large transfers of heat and moisture from the ocean to the atmosphere take place. A comparison with in-situ data shows that the surface-layer meteorological fields are reasonably well represented in the NCEP reanalysis, but the turbulent heat flux fields contain significant systematic errors. It is argued that these errors are associated with shortcomings in the bulk flux algorithm employed in the reanalysis. Using the NCEP reanalysis surface-layer meteorological fields and a more appropriate bulk flux algorithm, adjusted fields for the sensible and latent heat fluxes are presented that more accurately represent the air-sea exchange of heat and moisture over the western boundary currents.

JSP09/10A/B20-011 1215

FRESH WATER FLUXES AND SEA SURFACE SALINITY

S.Daniel JACOB[1], Chester J. KOBLINSKY[2] ([1]GEST, NASA GSFC/ UMBC, [2]NASA GSFC, Greenbelt, MD 20771, USA.)

Oceanic fresh water transport has been shown to to play an important role inthe global hydrological cycle. With more than 70% of global evaporation andprecipitation occuring over world´s oceans, it has also been pointed outthat small changes in these will cause major changes in the terresterialwater budget. Sea Surface Salinity (SSS) is representative of the surfacefresh water fluxes and the upcoming NASA Aquarius mission will provideexcellent spatial and temporal SSS coverage to better estimate the nettransfer. However, SSS is also controlled by advection and mixing processes,therefore the main objective of this study is to understand and quantifyvarious mechanisms controlling SSS in relation to surface fresh water fluxesover interannual time scales. Using a near-global HYbrid Coordinate Ocean Model (HYCOM) configured with different mixing schemes SSS variability and controlling mechanisms are investigated in this paper for different forcing data sets. Results suggest significant variability in the tropical and subtropical ocean regions due to differences in forcing climatologies.

JSP09/10P/B20-001 Invited 1400

THE WHOI DAILY FLUX PRODUCT AND ITS COMPARISON WITH IN SITU FLUX MEASUREMENTS AND THE SOC CLIMATOLOGY

Lisan YU[1], Robert A. WELLER[1], Simon A. JOSEY[2] ([1]Department of Physical Oceanography, Woods Hole Oceanographic Institution, [2]James Rennell Division, Southampton Oceanography Centre, UK)

Efforts have been taken at the Woods Hole Oceanographic Institution (WHOI) to develop high-quality, gridded, time-dependent surface turbulent and radiative fluxes to support studies of climate variability and predictability under the auspices of the NOAA CLIVAR Atlantic program. The emphasis of this presentation will be on the newly constructed latent and sensible fluxes product and its comparison with in situ flux buoy measurements and the SOC climatology. The product has daily, 1° by 1° resolution and covers the period from 1988 to 1999. It is developed by using a weighted objective analysis approach to improve the estimates of flux-related basic surface meteorological variables (e.g., wind speed, air humidity, air temperature, and sea surface temperature) through synthesizing data from satellite retrievals and outputs from NCEP and ECMWF global analysis/forecast models. The state-of-the-art COARE bulk flux algorithm 2.6a is then applied to compute the flux fields. Two types of errors can affect the representativeness of a flux product, i.e., the systematic error that influences the mean and the random error that influences the variance. Therefore, the two aspects at the heart of the comparison study are the mean and variability of flux fields. The primary reference data used in the comparison are high accuracy in situ buoy measurements. Comparisons are also made with the analysis of the Southampton Oceanography Centre (SOC) flux climatology. The latter provides high-quality depiction of global air-sea heat exchanges on climatological mean basis, while the former, though available for only limited locations and short spanning periods, provide the benchmark time series to identify regional biases. Good agreement is found between the new WHOI flux product and the independent research buoy measurements. The analysis also shows that the mean field structure and year-to-year variations of the WHOI latent and sensible fluxes are very similar to those obtained from the SOC fluxes, despite the different methods used to produce the two datasets. The buoy and SOC comparisons show that the WHOI synthesis is a considerable improvement over those of the ECMWF and NCEP2 outputs and the improvement comes not only from the use of a better flux algorithm but more importantly from the use of improved estimates of bulk variables.

JSP09/10P/B20-002 1430

AIR-SEA INTERACTION ASSOCIATED WITH GREENLAND TIP JETS

Rebekah E. MARTIN[1], G.W.K. MOORE[1], Ian A. RENFREW[2] ([1]Department of Physics, University of Toronto, [2]British Antarctic Survey, Cambridge U.K.)

High wind speed events are a frequent occurrence downstream of Cape Farewell, Greenland in synoptic situations characterized by low-level westerly/northwesterly flow. It has been suggested that the dynamics of these so-called tip jets are governed by the conservation of the Bernoulli function, which leads to an acceleration as air parcels undergo orographic descent on the eastern (leeward) side of Greenland. In addition, it has been proposed that the air-sea interaction associated with tip jets plays a role in triggering deep oceanic convection in the lee of Greenland. Recent work has however shown that the surface layer parameterization in many numerical models have roughness length

formulations for heat and moisture that are biased high in conditions such as those associated with tip jets. In this presentation, we will show results of one such event from a numerical model whose surface layer parameterization has been validated against observations in conditions similar to those observed during tip jet events.

JSP09/10P/B20-003   1445

SST FORCING TO SURFACE WIND SPEED OVER THE MALVINAS/BRAZIL CONFLUENCE AND NORWEGIAN SEA

Hiroki TOKINAGA, Youichi TANIMOTO (Graduate School of Environmental Earth Science, Hokkaido University)

Over most of the mid-high latitudes, sea surface temperature (SST) is cold (warm) under the strong (weak) surface wind on basinwide scales. This negative correlation between SST and surface wind speed anomalies indicates that SST changes over the mid-high latitudes are mainly dominated by an atmosphere-to-ocean forcing. However, the positive SST-wind correlation is detected over the Malvinas/Brazil Confluence and Norwegian Sea in the South and the North Atlantic, respectively. The cold northward-flowing Malvinas Current encounters the warm southward-flowing Brazil Current east of Argentina. The confluence of these currents forms a sharp SST gradient all through the year, leading to a remarkable cold (warm) tongue west (east) of the SST gradient, where the annual mean surface winds are westerlies under the influence of the subtropical jet. High-resolution satellite datasets clearly depict that surface wind speeds are weak over the colder flank of the SST gradient while strong over the warmer flank all through the year. This relationship between SST and surface wind speed is indicative of an ocean-to-atmosphere forcing. In addition, we detect that such a positive SST-wind correlation is explained by the vertical mixing mechanism, using difference between SST and surface air temperature from high-resolution in-situ datasets. The same relationship between SST, surface wind speed and surface air temperature is identified in the Norwegian Sea.

JSP09/10P/B20-004   1500

INTERCOMPARISON OF HEAT FLUXES IN THE SOUTH ATLANTIC: PART II: INTERANNUAL VARIABILITY

Fabrice M. VAUCLAIR, Ilana WAINER (Dept. of Physical Oceanography, University of São Paulo)

Inter-comparison of the interannual variability of sea surface temperature, net heat and latent heat flux, for 2 observation based products (DaSilva, SOC), output of the two major atmospheric model reanalysis (NCEP, ECMWF) and the results for the NCAR CCSM coupled model are examined in order to gain an improved understanding of the South Atlantic characteristic spatial patterns. Their spatial structure and associated temporal variability, related ocean dynamics evolution are also discussed. The key regions of the Brazil-Malvinas confluence, Agulhas retroflection and Benguela upwelling region off Africa were chosen for a closer examination of the fluxes. These key regions were identified as being the regions with the highest variance in the South Atlantic. Preliminary results show significant interannual variability from each data product, but large differences among them. The merchant ship based interannual patterns are highly dependent of the spatio-temporal data distribution. Interannual patterns of the CCSM are coherent with the reanalysis products.

AN EXTENDED ASSOCIATE PATTERN ANALYSIS OF ENSO

Maochang CUI[1], Jun MO[1], Yongqiang YU[2] ([1] Institute of Oceanology, Chinese Academy of Sciences, [2]LASG, Institute of Atmospheric Physics, Chinese Academy of Sciences)

To further study the causes of El Niño events Extended Associate Pattern Analysis (EAPA) is adopted again with monthly sea surface wind stress and precipitation besides sea level pressure (SLP) and sea surface temperature(SST) in or over the Pacific and related seas in present paper sine 1979 in present paper. The results show that El Niño events mean a SST redistribution covering almost the whole Pacific that needs a huge amount of energy provided by air-sea interaction in the most Pacific regions; It is the west burst and wind convergence, coming from meddle latitudes directly, instead of Kelevin waves that produce the strong SST warm signal in Nino regions; Two negative SLP anomalies in middle of the North and South Pacific, most likely produced by the average air pressure decreasing effect of explosive cyclones through precipitation, and the positive SLP anomaly over the Asia-Australia land bridge, coming mainly from the south hemisphere with a little influence from the Asian continent, are the three major causes for El Niño onset, they work together to produce the west bursts, wind convergence in Nino regions and anomalous westerly in the middle Pacific that results in a warm tongue and cold pincers gearing together; Basically, during its early stage the oceanis forced by the atmosphere, while during its late stage the atmosphere is forced by the ocean.

JSP09/10P/B20-006   1530

INFLUENCE OF TRANSIENT ATMOSPHERIC CIRCULATION ON THE SURFACE HEATING AND TEMPERATURE OF THE PACIFIC WARM POOL

Ming-Dah CHOU[1], Shu-Hsien CHOU[1], Pui-King CHAN[2] ([1]NASA Goddard Space Flight Center, [2]Science Systems & Applications, Inc.)

Analyses of data on clouds, winds, and surface heat fluxes show that the transient behavior of basin-wide large-scale circulation has a significant influence on the warm pool sea surface temperature (SST). Trade winds converge to regions of the highest SST in the equatorial western Pacific. These regions have the largest cloud cover and smallest wind speed. Both surface solar heating and evaporative cooling are weak. The reduced evaporative cooling due to weakened winds exceeds the reduced solar heating due to enhanced cloudiness. The result is a maximum surface heating in the strong convective and high SST regions. Data also show that the maximum surface heating in strong convective regions is interrupted by transient atmospheric and oceanic circulation. Due to the seasonal variation of the insolation at the top of the atmosphere, trade winds and clouds also experience seasonal variations. Regions of high SST and low-level convergence follow the Sun, where the surface heating is a maximum. As the Sun moves away from a convective region, the strong trade winds set in, and the evaporative cooling enhances, resulting in a net cooling of the surface. During an El Nino, the maximum SST and convective region shifts eastward from the maritime continent to the equatorial central Pacific. Following the eastward shift of the maximum SST, the region of maximum cloudiness and surface heating also shift eastward. As the atmospheric and oceanic circulation returns to normal situations, the trade winds increase and the surface heating decreases. We conclude that the evaporative cooling associated with the seasonal and interannual variations of trade winds is one of the major factors that modulate the SST distribution of the Pacific warm pool.

DENSE WATER GENERATION IN THE NORTH ADRIATIC: THE ROLE OF SURFACE FLUXES AND RIVER DISCHARGES

Ivica VILIBIC[1], Nastjenjka SUPIC[2] ([1]Hydrographic Institute, [2]Centre for Marine Research)

The analyses of winter thermohaline properties of the North Adriatic were performed at the transect Po-Rovinj in the 1967-2000 interval, based on the data of temperature and salinity collected primarily at two stations: the first positioned near the Po River mouth (station 5) and the second located close to the eastern shore (station 2). The analyses comprised single and double correlation analyses between temperature, salinity and sigma-t values in February as outputs to the surface fluxes (temperature versus heat flux, salinity versus water flux, density versus buoyancy flux) calculated for the North Adriatic and Po River discharge values as inputs. The February was chosen as the minimum in temperature and maximum in density have been measured then. Winter thermohaline properties are predominantly influenced both by Po River discharge and advection of warmer and saline waters from the southeast; therefore, bottom temperature is always lower near the western shore whereas the salinity is higher close to the eastern flank in general, but such distribution can be reversed during the years when the Po River plume is detached from the shore. Correlation analyses indicate that bottom water properties in February are driven dominantly by fluxes in September (salinity versus water flux) and in June, October and December/January (temperature versus heat flux) at the station 2, and in February/March (salinity versus water flux and Po River discharge) and October (density versus buoyancy flux) at the station 5. The strongest influence on the west side has the pycnocline destruction that usually occurs in October, bringing warmer and less saline waters to the bottom. Correlation for sigma-t values is calculated to be significant at 99.99 % level, but correlation vanishes at station 2, due to the impact of the advective processes there. Correlation with February/March Po River discharges is a consequence of deepening of the waters influenced by Po River, which can be brought to the bottom during the period of vertical instability (February/March), then spreading in the bottom layer and reaching eastern side after a month (April). Finally, it should be pointed out that thermohaline properties at the bottom of the North Adriatic are not correlated to the dynamics that occurs at the zero phase lag (February) as one should expect, due to temporal characteristics of the fluxes and strong vertical stratification in January/February near the Po River delta.

SIGNATURES OF AIR-SEA INTERACTIONS IN A COUPLED ATMOSPHERE-OCEAN GCM

Jin-Song VON STORCH (Institute of Meteorology, University Hamburg, Germany)

Various types of air-sea interactions are studied based on the generalproperties of cross covariance function and the well-defined shapes ofthese functions obtained from conceptual models. The analysis isapplied to sea surface temperature and surface fluxes obtained from along integration with the coupled ECHAM3/LSG model. The resultssuggest that the atmosphere plays a dominant role in generating thecoupled variability. Covariances between SST and wind stress are close to zero when SST leads, suggesting that SSTanomalies, once being generated, do not feed back to the atmosphere.The interactions between SST and tropical wind stress involve varioustypes of feedbacks. For heat flux, the antisymmetric shape of crosscovariance functions indicates that heat flux anomalies generate SSTvariations and the interaction tends to reverse the sign of theearlier SST anomalies. The atmosphere plays also an important role ingenerating coupled variations of SST and evaporation, and of SST andextratropical precipitation. The most dominant role of the ocean isfound in the tropics. The results can be used to verify simpleatmospheric models, which are used in ocean-only modellingstudies. Cross covariance functions found in such simple coupledmodels should be similar to those found in a fully coupledatmosphere-ocean GCM, if the simple models produce the sameinteractions found in fully coupled GCMs.

JSP09/10P/B20-009   1630

AN ACTIVE ROLE OF EXTRATROPICAL SEA SURFACE TEMPERATURE ANOMALIES IN DETERMINING ANOMALOUS TURBULENT HEAT FLUX

Youichi TANIMOTO[1], Hisashi NAKAMURA[2], Takashi KAGIMOTO[3], Shozo YAMANE[3] ([1]Frontier Research System for Global Change and Graduate school of Environmental Earth Science, Hokkaido University, [2]Frontier Research System for Global Change and Department of Earth and Planetary Science, University of Tokyo, [3] Frontier Research System for Global Change)

Relative importance among observed anomalies in sea surface temperature (SST), surface air temperature and wind speed in determining the anomalous turbulent heat fluxes is assessed through linearizing flux anomalies calculated from individual ship reports contained in Comprehensive Ocean-Atmosphere Data Set (COADS). Over the central basin of the North Pacific, changes in the atmospheric variable associated with basin-scale changes in mid-latitude westerlies, including air temperature and wind speed, are primarily responsible for the generation of local SST variations by changing turbulent heat flux, which supports a conventional view of extratropical air-sea interaction. In the westerern North Pacific along Kuroshio and its extension where ocean dynamics is much important in forming SSTAs, in contrast, SSTAs that have been formed in early winter play the primary role in determining mid- and late-winter turbulent heat flux anomalies, indicative of the SST forcing upon the overlying atmosphere. Specifically, both decadal scale SSTAs in the western Pacific subarctic frontal zone and El Nino related SSTAs south of Japan are found to be engaged actively in such forcing on the atmosphere. The atmospheric response to this forcing appears to include the anomalous storm track activity in the northwestern portion of the North Pacific. Fidelity of these observational results is discussed with NCEP/NCAR reanalysis data.

AIRCRAFT OBSERVATIONS OF AIR MASS MODIFICATION OVER ADVANCING ICE COVERIN THE SEA OF OKHOTSK

Jun INOUE, Masayuki KAWASHIMA, Yasushi FUJIYOSHI, Masaaki WAKATSUCHI (Institute of Low Temperature Science, Hokkaido University, Japan)

In order to investigate a role of leads in advancing of ice cover,turbulent heat transport processes over the ice-covered Sea of Okhotskwas studied by use of aircraft observations during two cold-air outbreakevents. One case is characterized by a heterogeneous ice concentrationcontaining numerous wide open leads, and the other one occurred overrelatively narrow leads. By using the technique of joint frequencydistribution, it is found that the buoyancy flux is mainly generated bythe rising thermals over the upwind leads for each case. The sensibleheat flux by these thermals abruptly decreases from 600 W/m^2 to 100W/m^2 with increase of accumulated fetch-width of upstream leads up to 5km within the ice cover. These results suggest that the role of theaccumulated open water is as important

as that of coastal polynyas forthe new-ice formation and resultant advance of sea-ice extent in theseasonal ice zone during cold-air outbreaks.

JSP09/10P/B20-011   1700

THE MODIFIED CLOUD PHYSICAL ASPECTS OF A COLD AIRMASS CROSSING OVER THE JAPAN SEA AND ITS COASTAL REGION

Xueliang GUO[1], Ronghui HUANG[1], Hiroshi NIINO[2] ([1]Institute of Atmospheric Physics, Chinese Academy of Sciences, [2] Ocean Research Institute, University of Tokyo, Tokyo, Japan)

The modification process of a cold airmass crossing over the Japan Sea and its coastal region on 29 January 1993 was simulated using a three-dimensional compressible non-hydrostatic cloud model with detailed microphysics coupling with a simple first-order boundary layer parameterized model. The microphysical characteristics of the shallow convective snow clouds formed in association with the cold airmass as well as the heat and moisture transfer processes between air and sea were investigated. The simulation of the cold airmass was initiated based on the rawinsonde soundings taken from middle of Japan Sea (42N, 135E) at 00Z on 29 Jan 1993. The domain size for the simulation was 36 x 36 km in the horizontal and 19 km in the vertical. The grid intervals were *x=*y=1 km, *z=0.5 km. A cold pool placed in the center of model domain with size of 8 x 8 km in the horizontal and 2 km in the vertical was used to initiate convection in the cold airmass (Tao et al., 1990). The peak temperature perturbation in the center of thermal bubble was 0.5 K. is assumed to be homogeneous in the horizontal and keep constant during the simulation time. The maximum lifting velocity of is taken as 0.1 ms-1. The 10°C and 0°C of temperatures are used in the simulation for the sea and land surface, respectively. The simulation results show that the simulated clouds experience three pronounced phases while crossing the Japan Sea and its coastal region, which is the same as that observed. The first stage is shown as a rapid intensification of the simulated radar echo due to the formation of a considerable number of snow aggregate particles in the clouds over the warm sea. In the second stage the snow clouds appear as a rapid decrease of radar echo due to the heavy snowfall along the coastal region. The third stage shows that the snow clouds become gradually intensive again due to the production of a limited number of graupel particles after landing the Japan Islands. The echo structure is changed from the isolated type to the diffused type during landing process.

JSP09/10P/B20-012   1715

IDENTIFICATION FOR INTERACTION BETWEENATMOSPHERE AND SEA SURFACE DEVELOPMENT CONDITIONS ABOVEINDONESIAN REGION DURING THE RAINY SEASON 2002(FROM JANUARY TO MARCH 2002)

Edison KURNIAWAN (Meteorological and Geophysical Agency)

The weather-pattern above the Indonesian region has been vary and fluctuation for physic-dynamic atmosphere related to the interaction between atmosphere and sea surface conditions. From those conditions, some regions in Indonesia received the big impact which is caused from natural disaster such as floods and landslides. Based from the unstable-weather which is occurred for the months before, some descriptions about the analysis including its impact will be summarized by observing the atmosphere and sea surface development conditions above the Indonesian region from January to March 2002. All of the weather parameters which is analysed such as air-pressure, relative humidity, sea surface temperature, cloud activity and wind circulation-pattern from surface and beyond. Besides that, the developing of water vapour above sea surface has been counted related to the warming of sea surface on the Indonesian ocean. In this case, the formation of cloud could became the rainy day in the earlier 2002. The identification for interaction between atmosphere and sea surface development conditions above the Indonesian region during the rainy season 2002 from January to March 2002 has been done using the daily-weather parameters i.e. air-pressure above the northern hemisphere and southern hemisphere, the analysis of cloud activity from GMS satellite, wind circulation from surface and beyond, sounding-data, sea-surface temperature and SOI Index. Those parameters will give the illustration about the conditions of atmosphere on the Indonesian region. The yields from this research has shown the fluctuation of dynamic-physic atmosphere and sea surface condition along those periods. It caused the extreme-weather which is being impact such as floods and landslides in all of Indonesian provinces. The results obtained from this reserch will be presented in this papper.

WIND ENERGY INPUT TO SURFACE WAVES

Wei WANG[1], Rui Xin HUANG[2] ([1]Physical Oceanography Lab. Ocean University of China, [2]Department of Physical Oceanography, Woods Hole Oceanographic Institution, Woods Hole, MA 02543)

Wind energy input into the ocean is primarily produced through the surface waves. The total rate of this energy source, integrated over the world oceans, is estimated at 60TW, based on empirical formula and results from a numerical model of surface waves. Thus, surface wave energy input is about 46 times largerthan the energy input into the surface geostrophic current (1.3TW) and 17 timeslarger than the total tidal dissipation rate (3.5TW). Most of the sueface waveenergy input is concentrated within the Antarctic Circumpolar Currents. The total energy input through surface waves is transferred into other formsand locations by three mechanisms: wave-current interaction, wave-wave interaction,and dissipation. The amount of energy going through wave-current interaction isunclear. The wave-wave interaction transfers energy from short waves into longwaves. All the input energy is either trandferred into other form of energy, suchas currents, internal waves and turbulence, or eventually dissipated. The dissipationis primarily through two channels: wave breaking in the open ocean dissipatesabout 36TW of energy and waves breaking and dissipation along the beaches take upabout 20TW of energy.

STATISTICAL CHARACTERISTICS OF WAVES AND CURRENTS IN FRONT OF THE COASTAL WATER OF DAMIETTA, EGYPT

Fahmy M. EID, Sayed H. SHARAF EL-DIN, Farid A. ABDALLA (Department of Oceanography, University of Alexandria)

The data of waves and currents which are measured off Damietta area throughout the period from Aug. 1997 to Dec. 1998 are analyzed in details to give a clear picture on sediment transport along the coast or in the on/offshore direction. The results of this analysis showed that: The main wave direction is mainly from NNW for all months with the highest maximum wave height of about 4.3 m during winter. The average significant wave height and period were approximately 0.46 m and 6.4 second respectively. The current speed in winter were greater than that at the other seasons with a maximum values of about 69.9 cm/sec. The current direction off Damietta area lies between NE and ENE direction. The current direction beyond breaker zone in front of Damietta Nile branch mostly tending westward and

accompanied with a rip current on the western side which is responsible to remove sediment from onshore to offshore direction and thus execrate coastal erosion in this area. The predominant direction of long shore current is from west to east. Littoral Current velocity are higher during the winter than in other seasons due to the stormy waves prevailing during winter and swells in summer.

OCEAN-ATMOSPHERE COUPLING OBSERVED FROM SPACE

W.Timothy LIU[1], Xie XIAOSU[1], Shang-Ping XIE[2] ([1]Jet Propulsion Laboratory, MS 300-323, [2]IPRC, Univ. of Hawaii)

The ocean is forced at the surface largely through the exchanges of water, heat, and momentum. The exchanges drive the transport and change the storage of heat, water, and greenhouse gases, and thus moderate the world´s climate. The ocean feedback to climate changes must be manifested through these exchanges, without which the Earth would be a more hostile habitat. Adequate observations at significant temporal and spatial scales can only be achieved from the vantage point of space. An overview of present spacebased sensors that contribute to the estimation of these exchanges will be presented. The manifestation of ocean-atmosphere coupling, as the correlation between two well-established spacebased measurements - sea surface temperature and surface wind, has long been studied. Two perspectives on the correlation will be presented - atmosphere or the ocean as the driving force. Negative lag correlations are found between seasonal changes of curl of wind stress and sea surface temperature caused by monsoons, and at the wake of tropical cyclones, largely because of wind-driven Ekman pumping and vertical mixing in the ocean. Negative lag correlations are also observed between wind-driven evaporative cooling and sea surface temperature in both annual and interannual time scales over global oceans. In these cases, the atmosphere drives the ocean. The case of ocean driving the atmosphere is best demonstrated in the two mechanisms that sustain the double intertropical convergence zones (ITCZ). The stronger ITCZ occurs when the northerly trade winds meet the southerly trade winds over water with sea surface temperature above threshold for deep convection. The weaker ITCZ occurs over cooler water and is caused by the deceleration of the surface winds as they approach the cold upwelling water near the equator. Decreases in vertical mixing and increases in vertical wind shear in the atmospheric boundary layer are suggested to be the causes of the deceleration of the trade winds as they move from warmer to colder water. This boundary instability mechanism is ubiquitous and may be the dominant mechanism for air-sea coupling when SST is below deep-convection threshold. The resultant positive contemporary correlation has been observed in tropical instability waves, in the cold wake of tropical cyclones, and in bathymetry induced and warm-current induced SST fronts.

JSP09/11A/B20-002   0900

THE SECOND VERSION OF THE HAMBURG OCEAN ATMOSPHERE PARAMETERS AND FLUXES FROM SATELLITE DATA (HOAPS-II): IMPROVEMENTS AND NEW ANALYSIS CAPABILITIES

Stephan BAKAN[1], Karsten FENNIG[2], Christian KLEPP[2], Joerg SCHULZ[3] ([1]Max-Planck-Institut f. Meteorologie, [2]Meteorologisches Institut, Universität Hamburg, [3]Meteorologisches Institut, Universität Bonn)

This paper presents the new version of the Hamburg Ocean Atmosphere Parameters and Fluxes from Satellite Data set (HOAPS), its improvements, and new analysis capabilities. HOAPS-II contains global fields of turbulent heat fluxes, precipitation, evaporation minus precipitation, and all basic state variables needed for the derivation of the fluxes. The climatology is enhanced by new atmospheric parameters like the total precipitable water and the cloud liquid water content that are also derived from SSM/I data using standard retrieval schemes. All variables are derived over the ice free ocean and delivered in a variety of temporal and spatial resolutions. The HOAPS-II time series is now extended to December 2001. Through the use of earlier HOAPS data in various climate studies and comparison activities a few accuracy issues and data problems emerged and are fixed now. HOAPS-II utilizes all SSM/I data available at the same time in a multi-satellite average, which required an inter-calibration of the SSM/I measurements from different platforms. This has been achieved by using 10 day mean values of brightness temperatures during overlapping periods. The mean correction factors turned out to be only about 1K in each channel, indicating a stable on-board calibration of the radiometric measurements. The resulting sampling frequency is not the same for each year as the number of SSM/Is in space was increasing from one in the beginning to four at the end of the nineties. In Remarkable biases in the precipitation and longwave net radiation products mainly over mid-latitude oceans have been experienced in the earlier HOAPS version due to the failure of the 85GHz channel on the DMSP F08 platform during 1989 and 1990. This has been corrected by adjusting the replacement retrieval regression coefficients during periods with available 85 GHz channel and applying these new values to the years in question. This correction reduces precipitation estimates over mid-latitude oceans considerably, making them far more realistic. HOAPS-II is provided as two different data sets serving different application areas. HOAPS-S is a scan-wise oriented data set containing instantaneous estimates of the parameters. This data set should be most useful for case studies and nowcasting applications. HOAPS-G is a gridded data set with temporal resolutions ranging from daily to monthly and spatial resolutions compatible with major global circulation models. This part of HOAPS-II is ideally suitable for climate studies and the evaluation of re-analysis data sets.

JSP09/11A/B20-003   0915

THE SURFACE ENERGY BUDGET FOR TROPICAL OCEANS FROM TRMM

Bing LIN, Alice FAN (Langley NASA)

Tropical Rainfall Measuring Mission (TRMM) is a joint projectbetween the US National Aeronautics and Space Administration(NASA) and National Space Development Agency of Japan to measurethe tropical rainfall distribution. Data collected from CERES,VIRS, and TMI instruments onboard the TRMM satellite can be used toretrieve the major heat fluxes at sea surface, top of atmosphere,and within atmosphere simultaneously. The major heat energy values includeshortwave (SW) and longwave (LW) radiation fluxes, and turbulentlatent heat and sensible heat, and rain induced sensibleheat fluxes in air-sea interface.This study investigates the major flux components over tropical oceans(30N to 30S). The LW and SW net fluxes are estimated by CERES project(Weilicki et al. 1996) with an accuracy of ~2 and ~3 W/m**2 at thetop of atmosphere and ~8 and ~15 W/m**2 at sea surfaces, respectively.The turbulent latent and sensible heat fluxes are calculated fromTRMM Microwave Imager (TMI) retrievals of near sea surface wind speeds,air humidity, and temperature using bulk formulae derived from TOGACOARE experiment. The turbulent fluxes are compared to those of GoddardSatellite-Based Surface Turbulent Fluxes (GSSTF)

version 2 productsderived from SSM/I data collected by Defense Meteorological SatelliteProgram (DMSP) satellites with a difference of less than 7 W/m^2 formonthly mean values. The rain induced sensible heat fluxes are estimatedfrom the level 2 TMI Profiling rainfall data assuming that raindroplets are in thermal equilibrium with the environments, and havethe wet bulb temperatures of surface air when they hit oceansurfaces. Depending on the season and region, The monthly 1 by 1 degreegrid mean values vary from 0 to 300 W/m^2 for SW net flux, from 0 to 100W/m^2 for LW net flux, from 0 to 300 W/m^2 for latent heat flux, andfrom 0 to 30 W/m^2 for turbulent sensible heat, and 0 to 3 W/m^2 forrain induced sensible heat. The positive tropical total surface netfluxes is generally balanced by the loss of fluxes in higher latitudes.This study provides instantaneous, hourly, daily, monthly, and seasonalgridded and zonal means for the major components of the ocean surface heatfluxes. The monthly and seasonal variations will be examined. AlthoughTRMM is designed for precipitation sciences, this study expand it to anentire new research area.

JSP09/11A/B20-004   0930

IMPACT OF IMPROVED FLUX ESTIMATES DERIVED FROM SCATTEROMETER WINDSON THE TROPICAL PACIFIC HEAT BUDGET

LuAnne THOMPSON[1], Kathryn A. KELLY[2], Chuanli JIANG[1] ([1]School of Oceanography, University of Washington, [2]Applied Physics Laboratory, University of Washington)

In addition to improving ocean circulation, scatterometer winds can beused to improve the upper ocean heat budget. Three distinct effects ofthe winds have been identified: changes in the latent and sensible heatfluxes from wind speed, ocean heat flux divergence associated withchanges in the currents, and changes in mixed layer depth which in turnaffect SST. Comparisons with NCEP (National Center for EnvironmentalPrediction) wind stress and NCEP-derived fluxes show substantialdifferences with the scatterometer-derived heat and momentum fluxes,particularly in the equatorial Pacific near the IntertropicalConvergence Zone.To test the impact of the scatterometer winds on a modeled tropicalPacific Ocean, we run a three-dimensional isopycnal general circulationmodel with a domain from 30S to 30N at 0.5 degree resolution. Themodel has 16 layers in the vertical and includes an active mixedlayer. The model is forced with NCEP stress for spinup, and thenparallel runs are done using the NCEP and QuikSCAT stress fields. Thesurface thermal boundary condition is calculated from the COARE bulkformulae, using the model SST with NCEP atmospheric variables andeither NCEP stress or QuikSCAT stress. There are significantdifferences between the two model runs, with QuikSCAT winds generallygiving better performance relative to observations both in the meanmodel oceans and in the variability. Along the equator, the QuikSCATruns show a smaller SST gradient and a lower maximum SST, both of whichmatch the observations better. The mixed-layer temperature budget onintraseasonal time scales also compares well with a previousobservational analysis. Both of these results can mostly be explainedby significant differences in the mixed-layer depth in the easternequatorial Pacific. Additional model experiments are performed to test whether thedifferences come about from changes in dynamics or fromthermodynamics. To do this, we perform one model run where we use NCEPfor all model fields except for the momentum flux (wind stress); onemodel run with all NCEP fields except for latent and sensible heatflux; and finally, one model run with all NCEP fields except for windmixing (u*). The QuikSCAT winds show promise in improving ourunderstanding of tropical ocean circulation and the upper ocean heatbudget during the ENSO cycle.

JSP09/11A/B20-005   0945

DIURNAL SEA SURFACE TEMPERATURE MODELING WITH SATELLITE DATA

Chelle Leigh GENTEMANN[1], Peter J. MINNETT[1], Craig J. DONLON[2], Gary A. WICK[3] ([1]RSMAS, University of Miami, [2]EC Joint Research Centre, Institute for Environmental Studies, [3]NOAA/ETL)

The formation of a near-surface diurnal warm layer, particularly in regions with low wind speeds, is clearly present in daytime satellite sea surface temperature (SST) measurements. This has consequences for ocean-atmosphere heat flux calculations. The satellite retrievals reveal significant diurnal amplitudes covering large oceanic regions, with regional distribution and amplitude of warming varying significantly within annual cycles. Additionally, the diurnal amplitudes are shown to have inter-annual variability correlated to ENSO events. Analysis of TMI, AMSR-E, AVHRR satellite SSTs reveal that the onset of warming sometimes begins as early as 8 AM and generally peaks near 3 PM., with a magnitude of 2.8 C during favorable conditions. After this peak, the signal decays, but sometimes extends until 11 PM. A simple empirical model was calculated from satellite SSTs, satellite wind speeds, and modeled insolation. Diurnal warming is measurable for wind speeds less than 10 m/s, with daily-average insolation values greater than 96 Wm^{-2}. The character and magnitude of diurnal variability witnessed by ship-based observations are compared with both the empirical model and physical warm layer models.

JSP09/11A/B20-006   1000

THE DIFFERENCE BETWEEN INFRARED SEA SURFACE TEMPERATUREAND PASSIVE MICROWAVE SEA SURFACE TEMPERATURE AND ITS RELATIONSHIP TO LATENT HEAT FLUX

William J. EMERY, Sandra CASTRO, Gary A. WICK (Univ of Colorado)

Global differences between thermal infrared sea surface temperatures (SST's) and passive microwave SST's are found to have similar spatial patterns as do climatological estimates of latent heat flux computed from historical averages of bulk formulae observations. A comparison with global patterns of passive microwave estimates of atmospheric water vapor demonstrate that this is not the cause of the observed SST differences. Comparisons between these same SST differences and in situ measurements of accurate eddy correlation fluxes also show a good correspondence between latent heat flux and the SST differences. This correspondence also occurs between these SST differences and latent heat fluxes computed from TAO moored buoy bulk aerodynamic observations. These correspondences are found to hold throughout the seasonal cycle with equivalent changes in spatial distributions occurring in both the SST differences and in the latent heat flux distributions. Earlier comparisons between bulk and skin SSTs exhibited similar spatial patterns. Statistical and numerical physical models of the upper ocean skin and mixed-layer stratification are used to explain these correspondences between latent heat flux and satellite SST differences. In addition, other skin-bulk comparisons will be used to evaluate the satellite SST differences.

JSP09/11A/B20-007   1015

ESTIMATION OF WIND-DRIVEN OCEANIC TRANSPORT IN THE SUBTROPICAL GYRE BY SCATTEROMETER WIND PRODUCT

Kunihiro AOKI (School of Marine Science and Technology, Tokai University)

Product of gridded surface wind-stress constructed by satellite scatterometer (ERS-1/2) data is used to estimate wind-driven transport in the subtropical gyre of the North Pacific and

Atlantic Oceans and to verify the Sverdrup balance in the interior region. Zonally-integrated Sverdrup transport at 30°N in the North Pacific, corresponding to the transport of the western boundary current, calculated from 8-year (1992-99) mean field by ERS-1/2 is about 32 x 106m3s -1(Sv). The value is larger than by that(27 Sv) by the ECMWF product and smaller than the NCEP's(42 Sv), meaning that the estimated wind-driven transport is sensitive to the selection of wind product. Using dynamic height field (referred to 1000db) calculated from the World Ocean Atlas(WOA) 98 database, we also estimate the meridional component of geostrophic transports in the interior region of the subtropical gyre and compare them with the wind-driven ones. Wind-driven transport by the ERS wind product at 30°N in the North Pacific is 0.3-0.4 Sv between 165°E and 150°W, close to that by the WOA98, which suggests the validity of the Sverdrup balance in this region. On the other hand, the estimate (0.45-0.5 Sv) by NCEP winds is larger than those, suggesting overestimation of wind-driven transport using the NCEP field. A similar approach for the zone of 25°N in the North Atlantic reveals that the values by the ERS and NCEP winds are not only closer to each other (0.3-0.45 Sv) but also similar to that by WOA98 database.

JSP09/11A/B20-008   Invited   1045

INTERCOMPARISON AND VALIDATION OF LATENT HEAT FLUX OVER THE GLOBAL OCEAN

Masahisa KUBOTA, Hiroyuki TOMITA (School of Marine Science and Technology,Tokai University)

Latent heat flux plays an important role in the global climate system. Though it was difficult to globally monitor latent heat flux over the ocean for many years, the situation is rapidly changing by the use of satellite data. Since a bulk formula is used to estimate turbulent heat flux using satellite data, we need wind speed, sea surface temperature and specific humidity data. Various satellite sensors can accurately observe wind speed and sea surface temperature. On the other hand, it is not easy to accurately estimate specific humidity using satellite data. Now several algorithms for estimating specific humidity have been proposed and applied to construct latent heat flux data sets. Latent heat flux data sets derived from satellite data such as J-OFURO, HOAPS and GSSTF are available at present. Since the algorithm and used satellite data are not the same between them, the characteristics of each data set may be different. Therefore, it is important to clarify the difference between each data set and investigate the cause of the difference in latent heat flux estimates. In this paper we summarize the present state of the art with regard to the turbulent heat flux estimation by using satellite data. Also we present the comparison results of latent heat flux fields including not only satellite-derived flux fields but also analysis fields. Moreover, we investigate the accuracy of the various data sets by comparison with buoy observation data.

INTERCOMPARISON OF LATENT HEAT FLUXES OVER GLOBAL OCEANS

Shu-Hsien CHOU[1], Eric NELKIN[2], Joe ARDIZZONE[3], Robert M. ATLAS[1], Ming-Dah CHOU[1] ([1]NASA Goddard Space Flight Center, [2]Science Systems and Applications, Inc., [3]Science Applications International Corporation)

Turbulent fluxes of momentum, moisture, and heat at the air-sea interface are essential for climate studies. Version 2 Goddard Satellite-based Surface Turbulent Fluxes (GSSTF2) has been derived from the Special Sensor Microwave/Imager (SSM/I) radiance measurements. This dataset, covering the period July 1987-December 2000 over global oceans, has a spatial resolution of 1 degree x 1 degree lat-long and a temporal resolution of 1 day. Turbulent fluxes are derived from the SSM/I surface winds and surface air humidity, as well as the 2-m air and sea surface temperatures (SST) of the NCEP/NCAR reanalysis, using a bulk aerodynamic algorithm based on the surface layer similarity theory. The GSSTF2 bulk flux model, and retrieved daily wind stress, latent heat flux, wind speed, and surface air humidity validate well with ship observations of ten field experiments over the tropical and mid-latitude oceans during 1991-99. The global distributions of 1988-2000 annual- and seasonal-mean turbulent fluxes show reasonable patterns related to the atmospheric general circulation and seasonal variations. Latent heat fluxes and related input parameters over global oceans during 1992-93 have been compared among GSSTF1 (version 1), GSSTF2, HOAPS (Hamburg Ocean Atmosphere Parameters and Fluxes from Satellite Data), NCEP/NCAR reanalysis, and one based on COADS (Comprehensive Ocean-Atmosphere Data Set). Our analyses suggest that the GSSTF2 latent heat flux, surface air humidity, surface wind, and SST are quite realistic compared to the other four flux datasets examined. However, significant differences are found among these five flux datasets. The GSSTF2, available at http://daac.gsfc.nasa.gov/CAMPAIGN_DOCS/hydrology/hd_gsstf2.0.html, is useful for climate studies

UNCERTAINTIES IN MEAN AND SEASONAL STRESSES OVER THE OCEAN CAUSED BYERRORS IN SUB-WEEKLY WINDS

Rui M. PONTE, Richard D. ROSEN (Atmospheric and Environmental Research, Inc.)

Variability in surface winds on synoptic time scales can have aneffect on the mean and seasonal stress on the ocean, owing to thenonlinear dependence of stress on wind speed. We use multi-yearsatellite-derived and operational wind products to show that theimpact of these rapid wind signals is indeed important and mostpronounced at mid and high latitudes, in regions of strong synopticactivity. Using differences in various wind products as a proxy forerror, we find that uncertainties at sub-weekly periods can lead tosubstantial errors in the mean and seasonal ocean stresses. Resultspoint to the importance of accurately determining wind variability atsub-weekly periods, thereby placing constraints on sampling strategiesfor observing winds over the ocean.

JSP09/11A/B20-011   1145

ESTIMATION OF SAMPLING ERRORS IN ALTIMETER WAVE MEASUREMENTS

Gavrikov Alexander VLADIMIROVICH[1], Sergey Konstantinovich GULEV[1], David WOOLF[2], Andreas STERL[3] ([1]P.P.Shirshov Institute of Oceanology, RAS, [2]Southampton Oceanography Centre, Southampton, United Kingdom, [3]Royal Netherlands Meteorological Institute, De Bilt, The Netherlands)

Remotely sensed observations from space now provide measurements of the basic wind wave variables for the period of about 15 years. These data are influenced by sampling uncertainty, resulting from the relatively sparse separation of satellite tracks and some irregularity of these tracks in space and time. Sampling uncertainty may have an influence on the reliability of climatological characteristics derived from the space-based observations. In order to estimate sampling uncertainty in altimeter wave measurements we used Ku-band altimeter wave data from GEOSAT, TOPEX/POSEIDON and ERS-1/2 crafts for the period overlapping with the ERA-WAM wave hindcast. Despite possible biases inherent into the model wave data, they provide regularly high sampling over the globe. Model data were sub-

IA

sampled in accordance to the locations and time of individual satellite tracks. Then these ˝undersampled˝ wave fields intercompared with (i) original model data to assess the effect of sampling and (ii) with altimeter data in order to obtain reliable estimates of the differences in wave parameters between satellite measurements and model hindcast. The derived sampling uncertainties were compared with sampling errors in visual wave observations derived from Voluntary Observing Ship (VOS) data.

VARIDATION OF QUIKSCAT OCEAN SURFACE DATA BY A SMALL ISLAND DATA

Tetsuo NAKAZAWA, Shunsuke HOSHINO (Meteorological Research Institute)

The ocean surface wind by QuikSCAT is compared with the in-situ data. It is really difficult to find a validation wind dataset for speeds greater than 25 m/s. We chose a small island in the western Pacific, Okinotorishima (20°25'N, 136°04'E), to check the QuikSCAT high-wind data. There are two datasets at the Observatory, operated by the Japan Marine Science and Technology Center: one is 30 min. averaged wind, and the second is the 4-sec averaged maximum wind during each 30 min. The QuikSCAT data we used in this study were obtained from the Remote Sensing Systems(RSS), http://www.ssmi.com. The data period is from July 1999 through December 2000. The study shows that the difference between the QuikSCAT data and the in-situ observation has a small bias with large scattering. It may be due to the time averaging. The QuikSCAT data is instantaneous and the in-situ data is the averaged one in 30 min. The strongest wind at the site was about 31 m/s. Thus we need more data in high-wind regime to verify the accuracy of the QuikSCAT data.

OCEAN CURRENTS INFERRED FROM DIFFERENCES BETWEEN QUIKSCAT AND TAO WINDS

Kathryn A. KELLY[1], Suzanne DICKINSON[1], Gregory C. JOHNSON[2] ([1]Applied Physics Laboratory, University of Washington, [2]Pacific Marine Environmental Laboratory, NOAA)

Differences between the winds from the Tropical Atmosphere-Ocean (TAO)buoys and from the QuikScat scatterometer are used to estimatetime-varying ocean surface currents. The scatterometer measuresbackscatter from centimeter waves caused by the wind blowing over theocean; when ocean and atmosphere move together, no waves are generated.Thus, the scatterometer measures the motion of the air relative to themoving ocean surface, the quantity needed to estimate surface stress.On the other hand, an anemometer measures the motion of the airrelative to a fixed platform. Therefore, the difference between ananemometer wind and a scatterometer ``wind˝ is primarily the oceansurface current.Estimates of currents from TAO anemometer winds minus NSCAT or QuikSCATscatterometer winds show good agreement with carefully collocatedcurrent measurements from moored current meters on the equator and fromacoustic Doppler current profilers (ADCP) mounted on ships servicingthe TAO array. For this comparison currents in the South EquatorialCurrent (SEC) are about 1.2 m/s westward and currents in the NorthEquatorial Countercurrent (NECC) are about 0.6 m/s eastward. Neglect ofthese strong tropical currents in this region of relatively weak winds(5-7 m/s) leads to errors in stress of 25-50\% and to even largererrors in wind stress curl.In addition we estimate time-varying surface currents over 3 years and comparewith the current estimates derived from drifters, ADCP, and the altimeter. The seasonal cycle of the estimate of zonal winds is in excellent agreementwith the other measurements, particularly the altimeter, which also givesa surface current. The meridional winds are much noisier, as is the case for all the other current measurements, but show reasonably good agreementwith an estimate of the Ekman current component off the equator. Onthe equator, current estimates show surprisingly good agreement with a simple model of forced motion.

STUDY FOR ESTIMATION OF AIR-SEA CO2 GAS TRANSFER BY WAVE BREAKING MODEL USING SATELLITE DATA

Naoya SUZUKI[1], Naoto EBUCHI[2], Takahiro OSAWA[3], Yasuhiro SUGIMORI[3] ([1]Center for Air Sea Interaction, Rosenstiel School of Marine and Atmospheric Science, Division of Applied Marine Phisycs, University of Miami, [2]Institute of Low Temperature Science, Hokkaido University, [3]Center for Environmental Remote Sensing, Chiba University)

CO2 transfer velocity at air-sea interface associated with different mechanisms such as turbulence and wave breaking, which are closely related with wind speed, has been studied from satellite data in this work. The determination of wind friction velocity from satellite-derived wind data will take an important role in computation of CO2 flux transfer. It is necessary for relation between wind speed and wind friction velocity to determine that of relation between non-dimensional roughness length and wave age, included with all parameters (wind, wave). Because of the large variation of the non-dimensional roughness length, it is difficult to describe wave influence by the single wave age. In this study we observed directional wave spectra at the Hiratsuka Tower of National Research Institute for Earth Science and Disaster Prevention (NIED) in Sagami Bay, Japan. As the result, the data set was separated into two kinds of directional spectrum types, Case 1 contains only swell and wind waves, but Case 2 consists of a lot of component waves due to several different wind fetch in the bay. The results show that Case 2 is associated with the large variation in the relation between non-dimensional roughness length and wave age. As wave age is associated with fetch, and a new relationship between non-dimensional roughness length and wave age was proposed, based on in situ wind and wave data after considering wind fetch effect. A new method was proposed to estimate u*, which is based on the new relationship between non-dimensional roughness and wave age, after considering fetch and wave directionality. We estimated the wave frequency from two methods: 3/2 powers law (Toba, 1972) and WAM model (WAMDI, 1988). The results are compared with the results estimated from Charnock formula (1955), and the influence of wave effects on the wind stress is also discussed. A new relationship was established to determine CO2 exchange coefficient based on whitecap model (Monahan and Spillane 1984), using U10-u* relationship in the North Pacific Ocean, satellite data of NOAA/AVHRR (SST) and DMSP/SSM/I (wind speed) in Oct., Nov., and Dec. 1991. The CO2 exchange coefficient estimated by other models (Wanninkhof, 1992; Liss and Merlivat, 1986; Tans et al., 1990) is also compared with these results. Also, we investigated wave effect for CO2 exchange coefficient in numerical simulation using Whitecap model (Monahan and Spillane, 1984) and the new relationship between non-dimensional roughness length and wave age. These results show the importance of wave breaking effect.

SENSITIVITY OF THE EQUATORIAL PACIFIC OCEAN CIRCULATION TO CHLOROPHYLL MODULATION OF PENETRATIVE SOLAR IRRADIANCE IN AN OGCM

Kyozo UEYOSHI[1], Detlef STAMMER[1], Shoichiro NAKAMOTO[2], Bulusu SUBRAHAMANYAM[3], Prasanna KUMAR[4], Kei MUNEYAMA[5] ([1]SCRIPPS INSTITUTION OF OCEANOGRAPHY, UNIV. OF CALIFORNIA, SAN DIEGO, [2]Advanced Earth Science and Technology Organization, Bussan Bldg. Annex, 1-1-15 Nishi-shinbashi, Minato-ku, Tokyo 105-0003, Japan, [3]Center for Ocean Atmospheric Prediction Studies, Florida State University, Tallahassee, FL 32306-2840, USA, [4]Physical Oceanography Division, National Institute of Oceanography, Dona Paula, Goa 403 004, India, [5]Japan Marine Science and Technology Center, 2-15 Natsushima-cho, Yokosuka, 237, Japan)

The sensitivity of the dynamics and thermodynamics to details in the vertical profile of short-wave radiative heating rate is investigated in the MIT z-coordinate ocean general circulation model with initial focus to the tropical Pacific. In this study we examine the hypothesis that surface chlorophyll pigment induces geostrophic current at subsurface level in the equatorial Pacific ocean, proposed by Nakamoto et al.(2001).For this purpose the biological vertical heating rate parameterization of Morel and Anotine(1994) is used to simulate the effects of space-time varying phytoplankton content in the upper ocean in conjunction with monthlymean SeaWifs chlorophyll pigment concentrations. The results from this simulation are compared to those from a control run in which a clear water body is mimicked by assigning a minimum constant pigment concentration value in the same parameterization scheme. The difference between these two simulations is regarded as the effects of phytoplankton on the penetration of solar radiation in the model ocean. A year-round, higher concentration of chlorophyll pigment in theequatorial Pacific leads to a decrease of the mixed layerdepth due to heat accumulation in the mixed layer accompaniedby equatorward shoaling of mixed layer base. In the central equatorial Pacific between 5N and 5S,anomalous geostrophic currents are generated which balance with the slope of the mixed layer shoaling toward the equator.Anomalous eastward currents are seen along the isopycnal surface of~26 sigma t, extending from the ~200 m depth in the western equatorial Pacific (160E) to the surface level in the eastern equatorial Pacific at 90W. The divergence of anomalous surface currents in the eastern equatorial Pacificis accompanied by meridional convergence in the level below,consistent with the enhanced water mass in the equatorial undercurrents inSeaWifs chlorophyll pigment ocean. Anomalous vertical velocity induced by modulated penetration of solarradiation by phytoplankton leads to upwelling of cold water along the equatorextending from the eastern equatorial Pacific towards the dateline.This upwelling is associated with surface divergence and subsurface convergence due to heat localization and subsequent geostrophic balance in the equatorial Pacific. Our results with SeaWifs chlorophyll pigment data generally support the hypothesis of Nakamoto et al. (2001) that phytoplankton in the equatorial Pacific induces subsurface currents that merges into the equatorialundercurrents, resulting in biomass-induced upwelling in the eastern equatorial Pacific. The results from several different absorption models for the shortwave solar radiation are currently being examined and will also be presented.

AIR-SEA FLUX ESTIMATION IN HIGH WIND BOUNDARY LAYERS: PLANS AND INITIAL RESULTS FROM THE HURRICANE COUPLED BOUNDARY LAYER AIR-SEA TRANSFER (H-CBLAST) EXPERIMENT

Peter Gerard BLACK (Hurricane Research Division, NOAA)

The USA Office of Naval Research (ONR) in collaboration with the National Oceanic and Atmospheric Administration's Hurricane Research Division (NOAA/HRD) is conducting a 5-year Coupled Boundary Layer Air-Sea Transfer (CBLAST) experiment designed to improve the accuracy of typhoon and hurricane intensity prediction through an improved understanding of the air-sea flux processes at high winds. The specific objective of this experiment is to develop a new surface wave-dependent flux parameterization for the high wind hurricane boundary layer containing secondary (roll-vortex) circulations over fetch limited seas in the presence of sea spray and one or more swell components from an airborne platform. We will test the following hypotheses: 1) that surface momentum exchange coefficients increase with wind speed for moderate winds (>30 m/s), are enhanced by fetch-limited waves or opposing swell, but level off or decrease above a high wind threshold (>45 m/s), especially in quadrants where swell has a significant downwind component, 2) that compensating mechanisms for enhanced surface air-sea enthalpy fluxes over and above current parameterizations must exist for storm maintenance and growth above some high-wind speed threshold, and3) that candidate mechanisms are separable and can be estimated, such as a) enhanced turbulent fluxes due to wave interactions, b) spray evaporation and c) secondary flow circulations (roll-vortex type).To begin the process of examining these hypothesis, instrument testing and calibration as well as aircraft flight plan experimentation were conducted in 2002. Observations on both sides of the air-sea interface were made concurrent with surface wave spectra. Intensive experimental work is planned for the Atlantic hurricane seasons of 2003 and 2004. The airborne in-situ and remote sensing instrumentation suite used for this purpose is briefly described along with the planned array of air-deployed drifting buoys and subsurface floats. Recent tropical cyclone flux estimates are described, and new studies on the variation of air-sea exchange coefficients with wind speed are summarized.

ATMOSPHERE-WAVE-OCEAN COUPLING IN TROPICAL CYCLONES

Shuyi S. CHEN, Wei ZHAO, Joseph E. TENERELLI, Mark A. DONELAN (RSMAS, University of Miami)

Over the last a few decades tropical cyclone (TC) track forecasts have improved significantly, whereas very little progress made in TC intensity forecasts. The lack of the skill in the intensity forecasts may be attributed to deficiencies in the current prediction models: insufficient horizontal resolution, inadequate surface and boundary layer formulations, and no full coupling to the ocean. The extreme high winds, intense rainfall, large ocean waves, and copious sea spray push the surface-exchange parameters for temperature, water vapor, and momentum into untested new regimes. To resolve the TC eyewall structure, crucial in intensity forecasting, the horizontal resolution need to be at ~1-2 km. The air-sea interaction in the eyewall region is largely unknown with very little observations. While TCs draw energy from the ocean surface, they cool the ocean by wind-induced surface fluxes and vertical mixing. The enthalpy and momentum exchange coefficients under the high-wind conditions are difficult to determine. The stress is supported mainly by waves in the wavelength range of 0.1-10 m, which are unresolved by wave models. Rapid increase in computer power and recent advance in technology in observations have made it possible for us to develop a strategy for the next generation of high-resolution TC prediction models. We begin by examing key parameterizations including effects of the wave spectral tail on drag coefficients, the source term for sea spray, and subgrid-scale turbulence property at 1-2 km resolution. The components of the coupled model system are the PSU/NCAR MM5, WAVEWATCHIII, and the University of Miami HYCOM. Model simulation of the Hurricane Floyd (1999) is compared observations of surface wave spectra, surface fluxes, and vertical

profiles of atmospheric boundary layer hurricane field programs. Remotely sensed SST, surface winds, and rainfall are used to evaluate and validate model simulations, develop parameterizations of the air-sea interface, and initialize the models over the open ocean. Model simulated TC intensity change is very sensitive to various paramterizations of the air-sea interface. For example, maximum surface wind speeds differ by 10-30 m/s using different wind-wave coupling parameters.

JSP09/11P/B20-005   1515

EFFECTS OF OCEANIC MIXED LAYER ENTRAINMENT CLOSURE ON THE AIR-SEA FLUXES DURING A TROPICAL CYCLONE PASSAGE

S. Daniel JACOB[1], Chester J. KOBLINSKY[2], Lynn Keith SHAY[3], George R. HALLIWELL[3] ([1]GEST, NASA GSFC/ UMBC, [2]NASA GSFC, Greenbelt, MD 20771, USA, [3]RSMAS, University of Miami, Miami, FL 33149, USA)

Upper ocean heat content is an important factor in the rapid intensficationof tropical cyclones. During storm passage, a large fraction of upper oceancooling and reduction in heat content is due to entrainment of cooler lessturbulent water from below the oceanic mixed layer. Analysis ofhigh-resolution measurements acquired during the passage of hurricaneGilbert (1988) in the western Gulf of Mexico revealed that the heat and massbudgets strongly depended upon the entrainment scheme used. In this paper,the time evolution of mixed layer quantities for different entrainmentclosure schemes during Gilbert is investigated using a high resolutionnumerical model with realistic forcing fields and the results are comparedto observations. The main objective is to understand the upper ocean heatand mass budget variability due to the various entrainment closure schemes. The HYbrid Coordinate Ocean Model (HYCOM) initialized with observational data and realistic forcing is used in this study. This model is configured with fourentrainment mixing schemes. Results indicate qualitatively similar pattern of oceanic mixed layer temperature and depth changes, but the entrainment rates differ for these schemes confirming observational findings. Simulated fields are compared to observations to identify a scheme that performs well. This is crucial for the upper ocean and coupled response studies and the resulting air-sea fluxes during storm passage.

JSP09/11P/B20-006   1545

OCEANIC AND ATMOSPHERIC MEASUREMENTS ACQUIRED IN TROPICAL CYCLONES ISIDORE AND LILI

Lynn K. SHAY[1], Thomas M. COOK[1], Scott A. GUHIN[1], Peter G. BLACK[2], Eric W. UHLHORN[2], Joseph J. CIONE[2], Sean R. WHITE[2], Michael L. BLACK ([1]Division of Meteorology and Physical Oceanography, RSMAS, University of Miami, [2]National Oceanic and Atmospheric Administration, Hurricane Research Division, Miami)

As part of a National Science Foundation and NOAA sponsored research project, coupled ocean and atmosphere measurements were acquired during the passage of Tropical Cyclones (TC) Isidore (18-25 Sept 2002) and Lili (28 Sept- 4 Oct) from the NOAA WP-3Ds in the Caribbean Sea and Gulf of Mexico. For both TCs, the aircraft-based strategy sampled pre-storm, storm and post-storm current, temperature and salinity conditions in the Caribbean Sea and the Gulf of Mexico in and north of the Yucatan straits using airborne expendable ocean profilers. Profiles of temperature, wind and humidity were acquired simultaneously during the storm flights to examine the atmospheric boundary layer structure as well as remotely sensed surface conditions of waves and winds.As Isidore moved along the periphery of pre-storm ocean grids across the Yucatan Straits, he intensified to a Category 3 storm. Preliminary results suggest that upwelling and vertical mixing processes were balanced by the horizontal advection of thermal gradients by the Loop Current. Thus, no significant cooling was observed in the straits. By contrast, the water over the Yucatan shelf significantly cooled as the storm made landfall on the Yucatan Peninsula as the TC was downgraded to a tropical storm. The storm subsequently moved northward and created an area of broad cooling with ~28oC SSTs prior to landfall in Louisiana on 25 Sept. Lili (28 Sept) formed in the northwest Caribbean Sea and followed Isidore's track. Due to deep, warm layers in this oceanic regime, no significant SST cooling was observed from the ocean profilers. Lili then moved over the western tip of Cuba and into the Gulf of Mexico directly over the pre- and post-Isidore ocean grids. During this period, she intensified to a Category 4 hurricane just north of the Loop Current boundary. As in the Isidore case, no significant cooling was observed in the Loop Current, however, north of this boundary, SSTs decreased by an additional ~2oC due to shear-induced ocean mixing processes. As Lili interacted with the cooler wake induced by Isidore a few days prior in the northern Gulf of Mexico, she suddenly weakened in strength prior to landfall on 4 Oct. In this context, the 3-dimensional upper ocean heat budgets were important in documenting processes that affected air-sea fluxes and hence TC intensity changes in these two storms.

JSP09/11P/B20-007   1600

OCEAN EFFECTS ON TROPICAL CYCLONE INTENSIFICATION IN A MINIMAL THREE-DIMENSIONAL COUPLED MODEL

Hongyan ZHU, Wolfgang ULRICH, Roger K. SMITH (Meteorological Institute, University of Munich)

The interaction between a tropical cyclone and the ocean is investigated using a minimal three-dimensional tropical-cyclone model coupled with a two-layer ocean model.Two representations for entrainment into the ocean mixed layer are compared: one based on the assumption that the velocity scale for entrainment is the surface friction velocity, the other on the assumption that this scale is the magnitude of the mean velocity difference across the base of the mixed layer. On a beta-plane with no background flow, the model cyclone moves towards the northwest. With ocean coupling, it leaves a cold wake behind it, mostly to the right of its track. The cooling reduces the heat flux from the ocean and thereby the moist static energy in the boundary layer. As a result, the cyclone is less intense in the mature stage than in the case without cooling. The magnitude and distribution of the cooling depends strongly on the method for representing entrainment. The method based on the surface friction velocity is more effective in reducing the heat flux from the ocean to the storm under the eyewall region and leads to a greater reduction of the tropical cyclone intensity. With ocean coupling,the surface heat flux and moist static energy in the boundary layer are reduced mainly in the rear-right quadrant of the cyclone core. The region of convergence in the lower troposphere in the coupled experiments rotates counterclockwise from the rear quadrant of inner core to the east of the core, presumably in response to the change in the distribution of moist static energy in the boundary layer. In addition, the region of maximum upward motion in the core region shifts from the rear-right quadrant to the front-right quadrant. These changes are associated mainly with changes in the divergence pattern in the lower troposphere rather than in the boundary layer.

AIR-SEA INTERACTIONS DURING PASSAGE OF A WINTER STORM OVER THE GULFSTREAM: A 3-DIMENSIONAL, COUPLED, ATMOSPHERE-OCEAN MODEL STUDY

Huijie XUE[1], Yongping LI[2], John M. BANE[3] ([1]School of Marine Sciences, University of Maine, [2]Shanghai Typhoon Institute, [3]Dept. of Marine Sciences, University of North Carolina)

A three-dimensional, regional, coupled atmosphere-ocean model with full physics is developed. The model performs well in simulating the cyclone that developed off the Carolina coast and traveled over the northwestern Atlantic Ocean on 19-20 January 1998. Model diagnosis is used to examine the air-sea heat and momentum exchanges and the responses in the upper ocean. Maximum heat flux appears over the Gulf Stream in the South Atlantic Bight (SAB), which results in rapid deepening of the cyclone off the Carolina coast. After the cyclone leaves the SAB, the heat flux maximum moves to over the Gulf Stream off Cape Hatteras and later northeast of Hatteras, which in turn enhances the wind locally. Oceanic response is closely related to the wind direction. Southerly and southwesterly winds tend to strengthen the Gulf Stream at the surface, whereas the northeasterly winds reduce the Gulf Stream and also generate the southwestward flows on the shelf. Running the atmospheric model alone with unchanged SST overestimates the oceanic effect on the cyclone, with the surface wind being about 5 to 10 per cent stronger. Large differences in the surface heat flux appear near the Gulf Stream mender troughs due to wind-driven lateral shifts of the stream, which in turn enhance the local northeasterly winds.

JSP09/11P/B20-009   1645

SYNOPTIC VARIABILITY OF OCEAN-ATMOSPHERE TURBULENT FLUXES ASSOCIATED WITH ATMOSPHERIC CYCLONES

Olga ZOLINA[1], Sergey GULEV[2] ([1]Meteorologishes Institut, Universitaet Bonn, [2]P.P.Shirshov Institute of Oceanology, RAS)

We analyse synoptic scale variability in the air-sea turbulent fluxes in the areas of mid-latitudinal western boundary currents. In the Gulf Stream area ocean-atmosphere fluxes on synoptic space-time scales are clearly coordinated with the propagating synoptic scale atmospheric transients. Statistical analysis of 6-hourly resolution sea level pressure and surface turbulent fluxes from the NCEP/NCAR Reanalysis for the period from 1948 to 2000 in the area of strong sea surface temperature gradients in the Gulf Stream give a strong proof for the association between the propagating cyclones and synoptic patterns of surface turbulent fluxes. We show that sea-air interaction in this area is controlled by the sharpness of surface temperature gradients in the ocean and by the intensity of the advection of the air masses in different parts of cyclones during the cold-air and warm-air outbreaks. A simple parameter based on the joint consideration of the characteristics of sea surface temperature and sea level pressure fields is used to characterize synoptic variability of air-sea turbulent fluxes. Effectiveness of the relationship between surface temperature and surface pressure on one side and air-sea flux anomalies on the other vary from year to year in phase with variability in the frequencies of deep atmospheric cyclones in the Gulf Stream area. The limits of applicability of the approach, its sensitivity to higher resolution sea surface temperature data, and the possibility of its further applications are discussed.

A STUDY OF HIGH-FREQUENCY AIR-SEA INTERACTION PROCESSES

Chung-Hsiung SUI[1], June CHANG[2] ([1]Institute of Hydrological Sciences, National Central University, [2]National Center for Ocean Research, Taiwan)

The focus of this study is air-sea exchange processes of momentum, heat and fresh water from the diurnal to intraseasonal time scales in various regions including western Pacific, Kuroshio current, and S. China Sea. In particular, a systematic investigation on the effects of such air-sea exchanges on typhoon and intraseasonal oscillations (ISOs) at both regional and local scales is being performed. The regional-scale study concerns region-wide effects of surface winds, warm SSTs, air-sea exchanges, and upper-ocean thermal/dynamic structures on typhoons and ISOs. The local-scale study concerns air-sea exchange processes in general, and particularly in high wind speed (>35 ms-1) and ocean surface wave conditions. The research tasks basically consist of three steps. First, oceanic mixing processes in response to observed surface forcing will be carried out using mixed layer ocean models and 3-D ocean models. Second, the atmospheric response to the same observed surface forcing will be performed using an atmospheric model. Then the atmospheric model will be coupled with the ocean models for fully coupled study. In this meeting, I will report a preliminary analysis of observed surface fluxes based on ECMWF operational assimilation data and TRMM data for the summer of 2000 and 2001, and the upper-ocean response to the observed forcing. The latter is based on two 1D-ocean mixed layer models: a Kraus-Turner type mixed layer model and a Mellor-Yamada type model. For typhoons in the South China Sea and Western Pacific, the effect of shear-induced turbulent mixing and Ekman upwelling on the upper ocean is being evaluated carefully. For tropical intraseasonal oscillations, the relative role of heat fluxes to wind stresses in affecting upper ocean heat content is being analyzed.

LARGE-SCALE EXPERIMENTAL STUDY OF THE FORMATION OF ZONAL JETS IN CONVECTIVELY-DRIVEN GEOSTROPHIC TURBULENCE ON A TOPOGRAPHIC BETA-PLANE

Peter Leonard READ[1], Stephen LEWIS[1], Paul WILLIAMS[1], Yasuhiro YAMAZAKI[1], Kuniko YAMAZAKI[1], Joel SOMMERIA[2], Adam FINCHAM[2], Henri DIDELLE[2] ([1]Department of Physics, University of Oxford, [2]LEGI-Coriolis, Grenoble, France)

One of the most striking aspects of the appearance of the gas giant planets in the outer solar system is the persistent and stable organisation of their upper cloud decks into zonal-

oriented belts and zones, in association with a pattern of strong latitudinally-alternating zonal winds. Since the early numerical model simulations of Williams (1978), it has been suggested that this zonal organisation of the atmospheric circulation on these planets arises from highly nonlinear interactions between convectively-driven eddies in the background potential vorticity gradient produced by the rotation and spherical curvature of the planet (the so-called 'Rhines effect'). More recent numerical studies have qualitatively confirmed this effect under various circumstances, and shown to lead under some circumstances to strongly anisotropic spectra and transfers of energy and enstrophy. Until recently, however, experimental confirmation of this effect in the laboratory has been sparse, owing mainly to the extreme conditions needed to access the relevant flow regimes. In a new set of experiments, carried out on the 13m diameter Coriolis Platform in Grenoble, convective geostrophic turbulence was driven by a uniform buoyancy flux introduced at the free surface of the rapidly-rotating tank by a continuous spray of dense, salty water. The resulting flow was allowed to develop in the presence of a conical lower boundary, and was visualised and measured over periods of up to 5-6 hours. In this talk, we describe the experimental setup and report on new results which demonstrate the formation of up to 5 alternating zonal jets across the domain, depending on the strength of background rotation, topographic slope and the intensity of buoyancy forcing.

RECONSIDERATION OF EQUATORIAL INERTIAL INSTABILITY

Hiroshi TANIGUCHI, Masaki ISHIWATARI (Graduate School of Environmental Earth Science, Hokkaido University)

Planetary-scale zonally non-symmetric temperature disturbances(called as ``pancake structures´´) appear near the equatorialstratopause in winter hemisphere. The disturbances are usuallyinterpreted as inertial instability (Hitchman *et al.*, 1987and Hayashi *et al.*, 1998, Hayashi *et al.*, 2002).However, so-called ``inertial instability´´ is a symmetricinstability in rotating system (Boyd and Christidis, 1982,Dunkerton, 1981,1983, and Stevens, 1983). It has not beendiscussed neatly whether non-symmetric pancake structurescorrespond to symmetric inertial instability. The purpose ofthis study is to examine the physical mechanism of unstablenon-symmetric modes and unstable symmetric modes in equatorialatmosphere. The linearized non-dimensional primitive equations on theequatorial beta plane are solved for investigating the linearstability problem on latitudinal shear flows. Values of Lamb´sparameter, E, are from 0.0031622 to 31622777. The results showthat non-symmetric unstable modes appear for $E > 0.1$ and thatsymmetric unstable modes appear for $E > 1.204$. Symmetric modesare most unstable for E greater than 16, otherwisenon-symmetric modes are most unstable. In order to consider the physical difference of calculatedunstable modes, dispersion relations of modes are examinedfrom the viewpoint of resonance between neutral waves, thatis, the discussion that instabilities are caused by theresonance between modes with positive pseudomomentum and modeswith negative pseudomomentum (Cairns, 1979; Iga, 1993,1999).For small values of E in which only non-symmetric modes areunstable, resonance between equatorial Kelvin-wave mode andcontinuous modes occurs. This result suggests thatnon-symmetric instabilities are caused by unstable equatorialKelvin waves, and is consistent with the discussions of Boydand Christidis (1982) and Natarov and Boyd (2001).Unfortunately, for larger values of E in which both ofsymmetric and non-symmetric unstable modes appear, it is difficultto identify modes which are resonant since their dispersioncurves are hidden by superimposed dispersion curves ofcontinuous modes. However, the changes of dispersion curvesof most unstable mode with changing the values of E can beobserved. This suggests that the combination of neutral modeswhich are resonant are different for different values of E. The future problem is to identify neutral modes hidden bycontinuous modes and to give physical interpretation on thedifference between symmetric modes and non-symmetric modes.

SUPPRESSION OF THE RHINES-EFFECT BY STRONG HORIZONTAL DIVERGENCE IN A SYSTEM GOVERNED BY THE CHM EQUATION ON A BETA-PLANE

Akira OKUNO, Akira MASUDA (Dynamics Simulation Research Center, Research Institute for Applied Mechanics, Kyushu University)

An investigation is made on the effect of strong stratification, or horizontal divergence, on almost freely decaying geostrophic turbulence on a β-plane. In the periodic domain of a model ocean, the surface layer is assumed to be active above the quiet deep layer, so that barotropification was prohibited *a priori* to purify the effect of horizontal divergence. In other words the Charney-Hasegawa-Mima equation is adopted as the governing equation. Spectral evolution is accelerated numerically by an adjustment to keep kinetic energy constant against the retarding effect of horizontal divergence. First, numerical experiment is carried out for small or moderate horizontal divergence as control runs for comparison; $UF/β < O(1)$, where U is the characteristic velocity of turbulence and F the squared inverse of the radius of deformation. As has been reported repeatedly, the β-effect induces a highly anisotropic field characterized by a band of zonal currents, which phenomenon is known as the Rhines effect. It is confirmed also that kinetic energy has a one-dimensional spectrum approximately proportional to k^5 at high wavenumbers k. A moderate value of $UF/β$ slightly increases the preferred meridional scale of the zonal currents. Then, horizontal divergence is enlarged enough so that $UF/β >> 1$, for which geostrophic turbulence turns out to behave just as on an *f*-plane: (1) the field becomes isotropic with no significant zonal currents; (2) the inverse cascade of energy is not hindered by the β-effect though it takes a longer time for turbulence to transfer energy to longer scales; and (3) the one-dimensional spectrum of kinetic energy (not total energy) is proportional to k^3 at high wavenumbers. An argument based on the physics of long baroclinic Rossby waves is presented to explain why strong horizontal divergence suppresses the β-effect. Furthermore a transform of variables leads to a modified governing equation, which clearly shows that the β-effect should disappear for large horizontal divergence. This argument is confirmed by additional experiments based on those different forms of governing equations; the resulting spectra cannot be distinguished one from another, indicating the total suppression of the β-effect for strong horizontal divergence.

SHEAR INSTABILITY IN SPEHRICAL SHALLOW WATER SYSTEM

Shin-ichi IGA, Yoshihisa MATSUDA (Dept. of Earth and Planetary Science, Univ. of Tokyo)

Shear instability in spherical linear shallow water system is investigated using wind profiles observed near Venus cloud top. Results from two different wind profiles are presented. The first profile has a uniform zonal wind velocity between 60N and 60S with wind decreasing poleward of these latitudes; it is barotropically and inertially stable. The other has a zonal wind velocity of 100ms⁻¹ at the equator and high-latitude jets of 160ms⁻¹ at around 60N and 60S; it satisfies sufficient condition for both barotropic and inertial instability. For the former profile, the most preferred growing mode appears at a zonal number of m=2 and $(gH)^2(2a\Omega)^{-1}$ =0.11. It has an e-folding time of about 100 days and an equivalent depth corresponding to a vertical wavelength of ~1km near the cloud top. In a frequency - Lamb-parameter diagram,

---

this mode corresponds to an intersection of the Kelvin mode curve and the continuous modes region, which ranges from the frequency corresponding to minimum basic angular velocity to that of maximum basic angular velocity. The intersections of eastward propagating gravity mode curves and continuous mode region sometimes generate another growing mode, whereas the intersections of westward propagating gravity mode curves and continuous mode region do not generate growing mode. For the latter profile, the most preferred growing mode appears at a zonal number of m=1 and $(gH)^2(2a\Omega)^{-1} > 0.1$. It has an e-folding time of about 2 days and an equivalent depth corresponding to a vertical wavelength of below ~2km near the cloud top. This mode corresponds to an interscion of modified Rossby mode curve and continuous modes region. In these growing modes, angular momentum is conveyed equatorward. This particular feature is expected for explaining the superrotation of Venus atmosphere. Using the concept of resonance between different neutral modes, the cause of these growing modes is discussed. For the former profile, for example, the eastward propagating gravity modes and Kelvin mode having positive pseudo angular momentum resonate with continuous modes, which originally have negative (i.e. opposite sign) pseudo angular momentum. On the other hand, the westward propagating gravity modes, which originally have negative pseudo angular momentum cannot resonate with continuous modes with negative (i.e. same sign) pseudo angular momentum.

INSTABILITIES OF INTERNAL SHEAR LAYERS IN ROTATING FLUIDS

Nathanael SCHAEFFER, Philippe CARDIN (LGIT, Observatoire de Grenoble)

Many free shear layers can be found in rotating systems, like atmosphere motion,oceanic currents, core dynamics or gaseous planets.We study the shear layer produced by differential rotation in cylindrical or spherical shells,numerically and experimentally. The quasi-geostrophic model we developped is not linited to small-slope containers,accounts for global mass conservation, and fully includes the Ekman pumping effects.It has been developped to simulate as well as possible our experiments in spherical shells,involving water, sodium or galium; thermal convection or mechanical forcing; magnetic field or not. When the depth is constant, the destabilization follows a local Reynolds number criteria, and iswell understood. However, when the depth is not constant, the instability has to break theProudman-Taylor constraint, and thus the slope plays a major role in determining the threshold.Furthermore we show that in the latter case, the instability is a Rossby wave. A first experiment consists of two corotating disks in a spherical shell, which drive a shearlayer. We study the stability threshold, and the instabilities that take place. We obtain asymptotical laws, supported by simple theoretical considerations, as well as numerical results.A second experiment uses an ˝inner core˝ that is differentially rotating to generate the shear layer.Again, the stability threshold is studied and asymptotical laws are exhibited. Recently, we found that such quasi-geostrophic flows are able to produce magnetic fields.Taking advantage of the quasi-geostrophic nature of the flow, we are writing a numerical codethat could be able to lower both Ekman and Prandtl number significantly compared toregular geodynamo simulations.

ON THE FORM DRAG CAUSED BY TOPOGRAPHICALLY FORCED ROSSBY WAVES IN A BAROTROPIC BETA CHANNEL

Keisuke UCHIMOTO, Atsushi KUBOKAWA (Graduate School of Environmental Earth Science, Hokkaido University)

It is well known that form stress is exerted on fluid when fluid flowsover the uneven topography. It is thought that the form drag isimportant in the Antarctic Circumpolar Current. When the primary sinkof the momentum is the form drag, how is the mean steady velocity of aβ channel flow driven by a surface-wind stress determined? Thisstudy addresses this question using a nondimensional barotropicquasi-geostrophic β-channel model, which consists of the zonalmomentum equation and the vorticity equation. The applied wind stressis spatially uniform eastward one. The momentum equation includes onlythe wind stress term and the form stress term, and the mean zonalvelocity, U, is determined by the two terms. The potential vorticityequation includes horizontal diffusion. Both the length and the widthof the channel are π. The bottom topography η is one of thesimplest forms; η=η₀sin 2x sin y. First, we perform numerical experiments applying a constant windstress. The initial conditions are quiescent. The solution behaviordepends on the magnitude of the wind stress. When the wind stress isweak, the final U is determined well by the viscous linearsolution. When the wind stress is too strong, U is infinitelyaccelerated. When the wind stress is between some values, U approachesa certain value almost independent of the magnitude of the windstress. The solution driven by a weak wind stress has a similar structureas that of the linear viscous solution or nonlinear inviscid solutionin which a cyclonic circulation exists over the elevation of ηand an anticyclonic one over the trough. In the solution in which Uis almost independent of the wind stress, the circulations reverse. In order to interpret the experimental results, we numericallyobtain steady solutions for given values of the mean zonal currentspeed, U, by the revised Marquardt method. From these computations,it is found that there are two types of steady solution; one of themis similar to the linear solution which gives a small form drag, andthe other is strongly nonlinear, giving a large form drag. Thestructures of the solutions are similar to those obtained by thenumerical experiments. The transition between the two types of the solution occurs at acertain U. This certain velocity corresponds to a speed of a Rossbymode. Although the wave number is not the same as that of thetopography, we refer to this velocity as a ``resonant velocity´´.When the amplitude of the bottom topography is higher, the transitionoccurs at the resonant velocity of a higher mode. Around the``resonant velocity´´, the nonlinear interaction between the modesbecomes active, and transition to the solution with large form dragoccurs. The present result suggests that the mean zonal current speedis not necessarily proportional to the magnitude of the wind stress.

TOPOGRAPHIC EFFECTS ON WIND DRIVEN OCEANIC CIRCULATION

Sebastien BIGORRE, William K. DEWAR (Florida State University)

A large scale oceanic anticyclone has been recently observed above theZapiola Drift in the Argentine Basin. Its transports are comparableto those of the Gulf Stream. Its proximity to the Malvinas-Brazilcurrent confluence renders it potentially important to severalaspects of the South Atlantic oceanic climate.A conceptual multilayer turbulent quasigeostrophic model simulated acomparable anticyclonic circulation in the presence of an isolatedtopography. The model is able to generate an upslope eddy mass flux,in agreement with downgradient eddy potential vorticity diffusion. Maps of EKE are consistent with the eddy kinetic energy minimumobserved by TOPEX above the Zapiola Drift. This paper investigates the time dependent dynamics of the flow, froma 150 years long simulation. Compared to the flat bottom case, thespectrum over the bump is redder, a multi-year (7 years) band isenergized, and a decadal or multi-decadal oscillation created. Thepresence of the decadal oscillation is variable and connected to an apparent tendency for the flow regime to switch between ″stable″ and ″unstable″ states.During unstable periods, the phenomenology of the oscillation consistsof the slow development of a large potential vorticity anomaly abovethe seamount driven by surface Ekman pumping. This is followed by a rapidejection phase. In stable regimes, the potential vorticity anomaly canpersist for longer periods and is accompanied by a stronger eddyvariability. Eddy potential vorticity fluxes show that relativevorticity flux, caused by vortex tube stretching along the slope ofthe seamount is dominant.A low order relaxation oscillator model has successfully reproducedthe results of the turbulent numerical model.

NONHYDROSTATIC SIMULATIONS OF THE IMPACT OF PLANETARY ROTATION ON CROSS-SLOPE FLOWS

Patrick Charles GALLACHER, Steve PIACSEK (Oceanography Division, Naval Research Laboratory)

Barotropic tides can generate internal waves that propagate up the continental slope and force deep water onto the continental shelf. Also dense water formed by winter cooling on the shelf flows down the continental slope to the deep ocean. Canyons are preferred locations for these cross-slope flows because the slopes are steeper than the average, thus accelerating the flows. Since cross-slope flows have an inherent vertical acceleration, they are nonhydrostatic. Hence these flows should be poorly simulated in hydrostatic models. We used a nonhydrostatic model to study the effects of slope, canyon width and planetary rotation on these cross-slope flows and their mixing and entrainment of ambient water. We will compare and contrast the results to those obtained with hydrostatic and quasihydrostatic models. Previous simulations of internal bores over flat topography have demonstrated that nonhydrostatic models are required to obtain the correct dynamics of the head, the mixing region and the large amplitude internal waves of the bore.

CHAOTIC ADVECTION IN BACKGROUND CURRENTS MODELS OF GEOPHYSICAL HYDRODYNAMICS

Konstantin V. KOSHEL, Vadim Fedorovich KOZLOV (Laboratory of geophysical hydrodynamics, Pacific Oceanological institute)

The concept of background currents is offered in the example of barotropic quasigeostrophic model. The background currents are characterized by constant value of potential vorticity, which minimize a kinetic energy of a system. The proposed approach allows to unambiguously defining background currents in areas with known boundary conditions as the sum of stationary vortical planetary-topographical and non-steady nonvortical flow components. Hamiltonian character of fluid particles motion equations allows to apply such models to study of chaotic advection. Instances of problems for a half-disk with linear bottom relief and a system of a source - sink in angular points of boundary line, about developing chaotic advection in unidirectional pulsing flow above a seamount of the Gaussian form, about effect of an anisotropy the localized submarine elevation on evolution of process, about roles of rectilinear boundary line in a neighborhood of point vortices are considered. Mainly with the help of numerical experiments and developed in the theory of dynamic systems technique of quantitative characteristics construction the processes of passive tracers carry out from a vortex region to flowing region are studied as functions of frequency, phase and relative amplitude of the background current flowing component oscillations. The geophysical interpretation of proposed models is presented.

OCEANIC FLOWS DRIVEN BY AN EKMAN PUMPING DIPOLE IN A QUASI-GEOSTROPHICMODEL

Atsushi KUBOKAWA, Atsushi MOTOKI, Keisuke UCHIMOTO (Graduate School of Environmental Earth Science, Hokkaido University)

Recent observations by satellite boarded micro-wave scatterometers have revealed that the surface wind field contains small scale shears.If the small scale wind shear is persistent, it will affect ocean current.For example, Xie et al. (2001, Science 292, p.2057-) showed that thedipole-shaped wind-stress curl produced by interaction between theeasterlies and the Hawaii islands can drive an eastward current similar to the Hawaiian Lee Counter Current (HLCC). Although wind-driven currents are usually explained by the Sverdrup theory, the nonlinearity of such a current might be too strong for the Sverdrup theory to be applied, because of the small horizontal length scale and strong wind shear. On the other hand, the subpolar/subtropical gyre system might be able to be regarded as a current system driven by a large scale dipole-shaped wind stress curl. It is not very clear, however, how the current

structure in the west of the forcing region depends on the horizontal length scale and strength of the forcing. Motivated by this issue, we investigate the structure of the oceaniccurrent driven by a dipole-shaped Ekman pumping velocity in which the Ekman pumping velocity is positive in the north and negative in thesouth, using a 3-layer quasi-geostrophic model. The parametersconsidered here are the strength of the Ekman pumping (nonlinearity) and the ratio of the lateral length scale of the forcingregion to the baroclinic deformation radius. A series of numerical experiments in a wide range of parameters suggeststhat the parameter space can be classified into several domains. Forexamples, in a domain with O(10) nonlinearity and O(1) horizontal scale,modon type vortex pair appears, and in a domain with O(1) nonlinearityand O(1) horizontal scale, active eddies appear in the west of theforcing region and eastward flow in the far west is significantlyweakened in comparison with that expected from the Sverdrup theory. Forlarge scale forcing, a domain in which the eastward current is separatedinto two jets is also found. A theoretical arguments are given based on the instability criteria and wave mode propagation, and it is shown that the domain where the double jets occur corresponds to theparameters for which the second baroclinic mode cannot propagate westward along the central latitude of the model after the lower mode adjustments are completed.

AN ASSESSMENT OF BOUNDARY LAYER PUMPING IN THE INVISCIDLY BALANCED APPROXIMATION EQUATION SYSTEM: LINEAR TRANSIENT PROBLEM

Shin-Ichi ISHIDA, Takahiro IWAYAMA (Graduate School of Science and Technology, University of Kobe)

It is well known that a boundary layer pumping is one of the importantdecaying mechanisms of vortices in the free atmosphere. After the pioneering work by Ekman (1905), many formulae for theboundary layer pumping have been proposed. In this study, the boundary layer pumping in the inviscidly balanced(IB) approximation equation system that is recently proposed by Kanehisa(2000) is examined following the linear transient study of Bannon (1998).The IB system is compared with four approximation equation systemsderived from the primitive equation on the f plane. Bannon (1998) concluded that in the case of the decaying vortex thesemigeostrophic (SG) approximation equation system is the most accurateapproximation of the primitive equation system, and in the case of thedeveloping vortex SG and Ekman momentum (EM) approximation equation systemsare the best.However, the geostrophic momentum (GM) approximation system is notbetter than the SG and EM systems. In this study, it is shown by the concept of an equilibrium flow thatthe IB system is equivalent to the GM system.Therefore, the pumping in the IB system is not good approximation.It is also pointed out that the energy equation in the IB systemcontains unphysical contribution from Coriolis force.This is a major failure of the IB system.

A NEW TYPE OF ISLAND RULE FOR THE ABYSSAL CIRCULATION BASED ON THE VOLUME TRANSPORTS IN BOUNDARY LAYERS AND ITS APPLICATION TO THE WIND-DRIVEN CIRCULATION IN AN OCEAN WITH MULTIPLE ISLANDS

Akira MASUDA, Akira OKUNO (Dynamics Simulation Research Center, Research Institue for Applied Mechanics, Kyushu University)

A new type of island rule is developed for the abyssal circulation of the Stommel-Arons scheme. The island rule is formulated so as to determine two unknowns of volume transports in the boundary layers west of the northern and southern tips of an island, using two conditions of mass conservation and the circulation law. No stream functions need to be assumed in this island rule. These features are to be contrasted with those of previous island rules, which are concerned with the one unknown of the stream function around an island, based on the circulation law. The derivation and the resulting formulas are compared with those of previous ones. In comparison with Pedlosky´s island rule, the present derivation does not go into details of boundary layers, though their presence was assumed as in the classical theory of the abyssal circulation by Stommel and Arons. Furthermore the present formulas apply to equatorial regions, where the approximation of the quasi-geostrophic stream function is inadequate. Two kinds of island rules are presented in different forms, but they turn out to be equivalent with each other. Also either Godfrey´s or Pedlosky´s island rule is shown to agree with the present island rule when there exists a stream function. To confirm the validity of the present island rule, numerical experiments were carried out with a diffusive reduced-gravity model, in which the upwelling velocity from the abyssal layer is determined autonomously through diffusive stretching. The experiment confirmed the prediction of the present island rule in particular for the equatorial abyssal circulation. Further the island rule is applied to the wind-driven circulation in an ocean with multiple islands. This problem was once studied numerically by Nakajima, who pointed out that the circulation depends not only on the wind stress curl, but also on the wind stress itself. The circulation in the interior region is determined away from the Sverdrup relation, but the boundary currents must be calculated using the island rule. A recursive formula is obtained to relate the volume transports in the boundary layers one another. The equation is solved to yield an analytical formula, which clearly shows that the volume transports in the boundary layers surely depend on the wind stress itself. Finally the total circulation of the ocean is represented as the superposition of the interior flow and the boundary layer current. The latter is expressed by the structure function of the boundary layer (which depends on the properties of the boundary layer, in particular on the principal dissipative process there) multiplied by the amplitude or the volume transports in the boundary layers. These arguments were confirmed as well by numerical experiment based on the diffusive reduced-gravity model.

EXPERIMENTAL AND NUMERICAL INVESTIGATION OF LABORATORY VORTICES WITH DATA ASSIMILATION

Martin Paul GALMICHE[1], Joel SOMMERIA[1], Emmanuelle THIVOLLE-CAZAT[1], Jacques VERRON[2] ([1]Coriolis, Laboratoire des Ecoulements Géophysiques et Industriels, [2]MEOM, Laboratoire des Ecoulements Géophysiques et Industriels)

Meso-scale vortices play a crucial role in the transportof heat, mass and momentum in the ocean. The behaviour ofun stable, two-layer vortex in a rotating fluid is hereinvestigated at the laboratory scale using experimentalmeasurements, numerical simulations and data assimilation. The experiments are performed on the Coriolis turntable(Grenoble, France). The large dimensions (13m diameter)enable oceanic processes to be reproduced with a good levelof similarity. To generate the vortex, a cylinder isintroduced across the interface of the two-layer fluid,the interface is displaced inside the cylinder and the cylinderis removed at t=0. After a short adjustment period, a vortex isformed which, when unstable, undergoes baroclinic instability andsplits into two or more new vortices. The velocity field ismeasured with high precision and resolution in both layersusing Particle Image Velocimetry but the interface elevation is notmeasured and, therefore, no potential vorticity measurement isavailable. In order to obtain more information on the flowevolution, numerical simulations are thus performed usinga two-layer, shallow-water model and data assimilation ofthe

experimental velocity data is used to drive the modelclose to reality. The assimilation scheme is a Kalman filtersimilar to the sequential filters used in real-scalesimulations of the ocean. The use of data assimilation for experimental purposes is anovel technique and has many applications. First, the combinedexperimental and numerical data provide a complete and realisticdescription of the flow. In particular, the potential vorticityanomaly can be computed, a quantity that is generally impossibleto measure but which is crucial to a better understanding of thebaroclinic instability (behaviour of fronts, propagation ofpatches, ...). The obtained flow field can also be used as ainitial condition to test the numerical model. This makes itpossible to quantify the systematic forecast errors. In the presentstudy, the forecast errors are mainly due to the hydrostaticapproximation. Lastly, the properties of the assimilation schemecan be analysed in details, in particular when only a reduced set ofvelocity data is assimilated. For instance, it is possible to test theaccuracy of the assimilation scheme when only surface velocity dataare available. This is clearly of practical interest because verticalextrapolation of the measured surface quantities is a great challengein oceanography.

INSTABILITY OF A COLUMNAR VORTEX IN A STRATIFIED FLUID

Benjamin CARITEAU, Jan-Bert FLOR (LEGI-CNRS)

We investigate a columnar vortex generated by a rotating flap around a vertical axis in a linearly stratified fluid. This flap was accelerated and subsequently decelerated to create an intense Gaussian vortex with Reynolds number Re=UR/v~1000, with U its maximum azimuthal velocity and R the corresponding radius. The vortex instability was explored as a function of the Froude number Fr=U/(RN), with N the buoyancy frequency, which was varied between 0.5 and 5. Experimental observations reveal a slow developing elliptical instability of the core as well as the centrifugal instability at the rim of the vortex. In addition, for approximately 1 $\angle$: Fr $\angle$ 2 a helical wave was observed to develop near the radius of maximum azimuthal velocity, which leads to quasi-horizontal co-rotating vortices dislike the mushroom-shaped vortices observed for centrifugal instability. The wavelength of this instability increases with the Froude number. The sinusoidal oscillation of the core has a wavelength 2R which and grows exponentially until the core breaks down into vortex lenses. We discuss the different instabilities that occur.

SPONTANEOUS FORMATION OF STEP-LIKE STRATIFICATION DUE TO DIFFUSIVEINSTABILITY

Takashi NOGUCHI, Hiroshi NIINO (Ocean Research Institute, The University of Tokyo)

A mechanism of spontaneous formation of multi-layered convection dueto double-diffusive convection in an unbounded uniformly stratifiedfluid was investigated. The fluid is unbounded and initially atrest and is stratified in ˝diffusive˝ sense (*i.e.*, both temperatureand salinity decrease linearly with height). A linear stability analysis predicts that there are growing modeswhen the ratio of the density gradient due to temperature to thatdue to salinity, γ, is larger than 0.876. The fastest growingmode (FGM) has a thin columnar shape which extends infinitely in thevertical direction and exhibits oscillation with increasingamplitude with time. A direct nonlinear numerical simulation in two-dimensional (*x-z*)plane was performed for γ=0.88. In this numerical simulation,the perturbations from the basic state are assumed to be periodicboth in horizontal and vertical directions. A white noise withrandom phase was introduced to velocity field to initiate thecalculation. The initial growth of disturbances were consistentwith the linear theory, but eventually overturning motions commenceand a series of well-mixed region was formed. These well-mixedregions gradually started to organize into multi-layered convection.The convective motions which resemble Rayleigh-Benard convectioncells at a high Rayleigh number and the well-mixed layers weresandwiched by thin diffusive interfaces which have very sharpdensity gradient. Based on the results of the direct simulation, we analysed thedetailed nonlinear evolution of the disturbances that led to thelayer formation. First, the disturbances were decomposed intoFourier modes and nonlinear energy transfer among modes wereexamined. During the period right before the layer formation, it isfound that the interactions among four modes play an essensial rolefor the layer formation. These four modes include: (A) FGM of the linear stability analysis (k, m) = (k_0, 0), (B) a growing mode (k_0, m_1), (C) a layer mode (0, m_1), and (D) a mode which corresponds to the resulting layer (0, $2m_1$), where k and m arehorizontal and vertical wavenumber, respectively. Note that modes Cand D are decaying modes according to the linear analysis. A truncated model which considers only the nonlinear interactionsamong the four modes turned out to reproduce succesfully the growthof layer modes C and D. Layer modes C and D are shown to gainenergy from the growing modes A and B through nonlinearinteractions, grow and finally catch up with FGM (mode A). Once theamplitude of mode C or D becomes as large as that of A, it is foundthat vertical diffusion acting on the disturbed stratification,starts to enhance the layered stratification, thus leading to thelayer formation.

INERTIA-GRAVITY WAVE GENERATION FROM UNSTABLE CURRENTS

Marie-Pascale G. LELONG, Timothy J. DUNKERTON (NorthWest Research Associates)

Inertia-gravity wave generation resulting from the instability of an energeticocean current is investigated by means of high-resolution numerical simulations. We consider the efficiency of the generation mechanism as a function of current intensity, structure, position relative to lateral and bottom boundaries and atmospheric forcing. We identify preferred regions of wave generation on the evolving instability wave. The structure of the resulting wave field, its dependence on the characteristics of the unstable current and its tendency to radiate away from the source region is investigated.We also compare our results to those of Ford (1995) and Ford et al (2000).

EXTENDED JETS PRODUCED BY A FREE OSCILLATING BODY ON A NEYTRAL BUOYANCY HORIZON IN A CONTINUOSLY STRATIFIED LIQUID

Yuli D. CHASHECHKIN, Vladimir V. LEVITSKIY, Yuri V. PRIKHOD'KO (Laboratory of Fluid Mechanics, Institute for Problems in Mechanics of the Russian Academy of Sciences)

We study experimentally a flow pattern around a free falling and then oscillating body on a neutral buoyancy horizon in a continuously stratified brine in a laboratory tanks with sizes 50 (length)x 15 (width)x 50(height) cm and 70 x 25 x 70 cm filled with a linearly stratified salt brine (buoyancy period is T= 5.7; 9,8; 13,4 s). The spheres with diameter 3,1; 4,5; 6,7 cm and vertical circular cylinder with flat tips (with diameter 3.2 cm and length of 5.5 cm) are used in the experiments. The flow pattern is visualized by the different method (conventional "vertical slit-Foucault knife", Maksoutov's "slit-thread˝, "natural rainbow" colour schlieren and schlieren interferometric) by the schlieren instrument IAB 458. A conductivity probe

measures particle displacements in the emitted internal waves. We have measured the body displacements, time series of its variable velocity, length scales of structural elements, wave amplitudes. We have compared experimental data with conventional theory and found rather large discrepancies. We have found that the pattern of flow around the body besides of the downstream wake with immersed vortices, boundary layer on the body surface, emitting transient internal waves contains elongated regular jets, forming in vicinity of trajectory turning point in the space regions where the body did not come. These mushroms like jets firstly with convex and then with concave head are formed in result of interaction of the upstream blocked fluid with emitting internal waves. They are bounded by a high gradient envelope. The narrow jets move directly to the body supporting its oscillatory motion. It is precisely inside this area that we can observe the maximum values of the velocities and displacement amplitudes of the fluid particles. The jets appearance and disintegration correlate with body oscillations. The length of these secondary jets increases with the their number. They are placed in the region of the body first diving even if the body is not symmetric and displaces from its initial position. Time series of the body displacements shows that firstly amplitude of oscillations relaxes rather fast and then the rate of oscillations damping dramatically decreases. The tips of the jets act as instantaneous source of transient internal waves, which do not contact with the body surface directly. Usually the upper set of jets is shadowed by the downstream wake and become visible only if the initial body displacement from the neutral buoyancy level is small and the wake is characterized py a simple structure. As a whole, the simplicity of the sphere trajectory does not reflect the complexity of observed non-stationary flow pattern. Similar effects can affect on accuracy of the ocean parameter measurements from submerged buoys that is from neutral buoyancy tracers.

A FINE STUCTURE OF A STRATIFIED FLOW AROUND A HORIZONTAL STRIP UNIFORMLY MOVING IN A CONTINUOUSLY STRATIFIED FLUID

Vladimir Y. MITKIN, Yuli D. CHASHECHKIN, Roman N. BARDAKOV (Laboratory of Fluid Mechancs, Institute for Problems in Mechanics of the RAS)

We study theoretically and experimentally 2D problem of generation of macro- and micro- disturbances by a plane horizontal strip uniformly moving in a viscous exponentially stratified fluid. We have neglected by diffusion effects and constructed an exact solution of the completely linearized problem with right boundary conditions that are no-slip for velocity and decay of all disturbances on infinity. We have applied an integral transforms method taking into account all set of roots of a dispersion relation. The solution describes upstream transient and downstream stationary (lee) internal waves as well as a set of boundary layers on the moving strip and on the rigid surface beneath it. We have visualized the fields of vector (velocity, vorticity, density gradients) as well as scalar parameters (density, pressure) numerically and calculated the same parameters asymptotically in an approximation of weak stratification and small viscosity. We have compared different solutions between themselves and have drawn fields of differences between exact and asymptotic data. We have visualised side view of flow pattern in stratified brine by different schlieren methods (´slit and knife´, ´slit and thread´, ´colour rainbow method´) and have measured wave displacements by a conductivity probe. Profiles of upstream velocity are visualised by long density markers that are produced by wakes past vertically ascending small gas burbles or descending sugar crystals. Asymptotic methods give qualitatively compatible data with exact solution and the laboratory study results only in limited areas past the obstacle. Ahead of the body both the exact solution and laboratory data describe transient waves with sloping rays and asymptotic solutions shows stationary horizontal wave columns. Pattern of attached internal waves past the obstacle is displaced in asymptotic representation. Patterns of exact solutions and laboratory observations correspond between themselves rather good. With increasing of towing velocity the horizontal boundary layer split on sub-layers and motion of sloping streaky structures is observed. In supercritical regimes downstream vortices are formed and density wake become wavy. Extrapolation on an environmental condition is discussed.

GENERATION OF 3D PERIODIC INTERNAL WAVE BEAMS BY A COMPACT SOURCE IN AN EXPONENTIALLY STRATIFIED FLUID

Aleksey Yu. VASILIEV, Yuli D. CHASHECHKIN (Laboratory of Fluid Mechanics, Institute for Problems in Mechanics of the RAS)

We study generation of 2D and 3D periodic internal wave beams in continuously stratified viscous liquid basing on a complete set of governing equations and exact boundary conditions that is no-slip for velocity and attenuation of all disturbances at infinite distance from the source. The linearized governing equations are solved by an integral transform method. A total set of dispersion equation roots contains terms corresponding to internal waves and additional roots describing two kinds of periodic boundary layers. The first one is a viscous boundary layer and has an analogue in a homogeneous fluid that is a periodic or Stokes´ flow. Its thickness is defined by a kinematic viscosity coefficient and a buoyancy frequency. The second one, an internal boundary layer, is a specific feature of stratified flows. Its thickness besides the Stokes´ scale contains additional factor depending on relative wave frequency and geometry of the problem. The thickness depends on the local slope of emitting surface and a direction of the wave propagation. We have constructed exact solutions of linear problems describing generation of 2D and 3D periodic waves by a strip and a rectangular with an arbitrary ratio of sides moving along or normally to a plane, which are placed on the sloping plane. We also calculated the wave pattern generated by a part of a vertical cylinder surface with different ratios of intrinsic scales that is of cylinder radius, thickness of the boundary layer and internal viscous scale. All solutions are regularly matched between themselves in limiting cases. The spatial decay of the waves depends on the dimension and geometry of the problem. Non-linear generation of internal waves by interacting boundary layers on an arbitrary moving vertical strip is investigated too. We found conditions of generation of the main frequency and its harmonics. In experiments periodic waves beams from different described above sources are visualised by the schlieren instrument and measured by conductivity probes. The probes are dynamically calibrated before each set of experiments. Calculated parameters of periodic internal wave beam are able to fit the best recent experimental data exquisitely well. Extrapolation on the environment is discussed.

NUMERICAL SIMULATION OF THE CIRCULATION PATTERN OF THE LEVANTINE BASIN

Khaled A. ALAM EL-DIN, Sayed H. SHARAF EL-DIN, Omneya M. IBRAHIM (Departement of Oceanography, University of Alexandria)

Numerical modeling was used to study the circulation pattern under climatological conditions and the understanding of the relative importance of the forcing functions of the Levantine basin. The model domain extends from 25.6° E to 36° E longitudes and from 30° N to 37° N latitudes. The numerical simulation was performed using 3D hydrodynamical Princeton

Ocean Model (POM). The horizontal resolution was about 5` grid interval with 14 vertical sigma levels and a number of grid points of about 121x 85. The model bathymetry was obtained from the MODB data bathymetry. The initial fields of temperature, salinity and current used to spin up the model were taken from MODB Med4 dataset. The surface momentum, heat and fresh water fluxes were taken from ECMWF monthly data for the period 1986-1992. The model results can successfully show the well-known flow phenomena of the Levantine basin (North African current, Rhodes cyclonic gyre, Mersa-Matruh anticyclonic gyre, El-Arish cyclonic gyre and Shikmona anticyclonic gyre).

ULTRASOUND SCATTERING FROM STRATIFIED WAKES PAST A 2D BODY AND SINGULAR CIRCULAR VORTEX

Viktor E. PROHOROV, Yuli D. CHASHECHKIN (Laboratory of Fluid Mechancs, Institute for Problems in Mechanics of the RAS)

We study experimentally scattering of the ultrasound pulses (operating frequency 1 MHz, ping duration 40 microseconds, repetition period 0.16 s, acoustic pattern angle 2 degree) from the downstream wakes past different 2D bodies and horizontally moving singular vortex rings. The experiments have been performed in the laboratory tank with dimensions 240 (length)x40 (width)x60(height) cm filled with continuously stratified brine. Pattern of the flow is visualized by schlieren instrument. Different optical techniques (conventional, Maksutouv's slit thread, natural rainbow colour methods) are used. The experiments with the horizontally moving cylinder of different diameters (0.8, 1.5, 2.5, 5.0 and 7.6 cm) are conducted over a range of the flow parameters corresponding to laminar wake bounded with two sharp envelopes, with central sharp interface surrounded with microstructure region, also wake with vortex bubbles periodically dispensed along the trajectory. As has been shown from the backscattering experiments, the intensity scattered by sharp high gradient envelopes exceeds by several orders the entire scattering created by volume microstructures. Scattering indicatrix measured by bistatic configuration is subdivided into three parts. The middle one is a narrow resonance region of sound wave numbers corresponding to the specular scattering, and is a direct consequence of the reflection by the sharp interface. This region is adjacent by the ranges of volume scattering. Intensity of the reflection is larger by two orders of magnitude than that of volume scattering. To extend laboratory data to marine environment, a production of scattering volume cross section by the sound wavelength is employed. According to the estimation, the scattering of the pure microstructural inhomogeneities is comparable with that created by biota in the ocean. Pattern of the flow around horizontally moving vortex ring is similar to flow around a solid body, and includes upstream disturbances, set of internal waves and downstream wake with the finest elongated laminas. Microstructural components, which are responsible for volume scattering from the wake past the vortex, are characterized by internal boundary scale, which is analogous to the Stokes scale and defined by square root from kinematic viscosity over the buoyancy frequency. Experimentally the scale of the microstructural components is obtained from acoustic measurements of the buoyancy frequency extracted from the energetic spectra of the scattered signals. Additionally, the scales of the small-scale components are obtained from the schlieren images of the vortex wakes. The scales measured both acoustically and optically are very close. This testifies that the singular interfaces produced by internal boundary currents are the main contributors to the sound scattering. The internal boundary currents can separate from the rigid boundaries and can be formed directly inside the continuously stratified liquid without any solid bodies.

THE DISPERSION RELATION FOR MID-LATITUDEOCEANIC PLANETARY WAVES IN THE PRESENCEOF MEAN FLOW AND TOPOGRAPHY

Peter Douglas KILLWORTH, Jeffrey Ralph BLUNDELL (Southampton Oceanography Centre)

A great deal of research concerning phase and group speeds of oceanic planetary waves has taken place since the discovery from satellite altimeter data that such waves are ubiquitous, but travel somewhat faster than predicted by linear theory. Almost all of this research has concentrated on **long**, i.e. geostrophic, waves for simplicity. In this work we consider the dispersion relation for planetary waves of **any** wavelength, subject only to the requirement that the wave frequency be small compared with the Coriolis parameter, when the wave is propagating through a mean background flow, varyingstratification, and with a sloping bottom. In most cases, a new wave mode appears for short waves which is essentially non-dispersive, concentrated around some mid-depth value, and is evanescent towards surface and floor. This mode is approximately Doppler-shifted with the local mean flow component along the wavevector.

WAVE-PACKET RESONANCE : ATMOSPHERIC STORM TRACKS DYNAMICS

Mankin MAK, Yi DENG (Department of Atmospheric Sciences, University of Illinois at Urbana-Champaign)

Localized and persistent jets are ubiquitous in the atmosphere and oceans. The instability of a three-dimensional localized jet over western North Pacific Ocean in winter gives rise to the so-called Pacific storm-track. The disturbances associated with such a storm track are three-dimensional propagating wave-packets. It is hypothesized that the intensification mechanism can be succinctly interpreted as resonant interactions among the constituent potential vorticity anomalies associated with a representative unstable wave packet in the presence of such a jet. Those interactions give rise to mutual influences among the PV anomalies due to their individual advection of the background potential vorticity field. Supporting evidence from a model analysis for this hypothesis will be presented. It is also instructive to distinguish barotropic resonant interactions from baroclinic resonant interactions. A complementary diagnosis of the local energetics of an unstable disturbance will be reported, further delineating how such general instability takes place. Furthermore, the maintenance of a storm track will be discussed on the basis of an analysis of the nonlinear simulation.The intensity of the Pacific storm track is also known to be distinctly weaker in mid-winter, when the jet is strongest, than in early- or late- winter. If time permits,

---

a dynamical account for this counter-intuitive phenomenon known as 'mid-winter suppression will be proposed.

LIMITATION OF THE BALANCED DYNAMICS IN THE F-PLANE SHALLOW WATER SYSTEM

Norihiko SUGIMOTO, Shigeo YODEN (Department of Geophysics, Kyoto University)

The limitation of balanced dynamics which contain the coupling of slow Rossby mode and fast gravity mode are investigated in the *f*-plane shallow water system. First, we investigate the linear stability of zonal jets in this system, and compare the stability characteristics with those obtained in the quasi-geostrophic system for a wide range of Rossby *Ro*, and Froude *Fr*, numbers. As for the maximum growth rate, quasi-geostrophic approximation is good for a wide parameter range of $Fr^2/Ro^2 > 1$ and $Fr < 1$, even for high *Ro*. However, unstable modes in this parameter range are different between high *Ro* and low *Ro*. In low *Ro* ($Ro < O(1)$), there is a regime in which geostrophic balance is dominant. In this regime, the ratio of the amplitude of divergent component ψ to that of rotational one φ, $|φ|/|ψ|$ is proportional to Ro/Fr^2, and φ is symmetric to the center of jet. On the other hand, in high *Ro* ($Ro > O(1)$), another regime does exist. Here dominant balance is related to the basic flow. $|φ|/|ψ|$ is proportional to $1/Fr^2$, and antisymmetric component in φ is dominant. In addition, for high *Ro* and *Fr* ($Ro > O(1)$, Fr $> O(1)$), there is a regime of gravity-wave instability. These all results can be explained by order estimate of the linearized equations. Second, gravity wave radiations from balanced Rossby flow are investigated in the *f*-plane forced-dissipative shallow water system. We use two types of basic flow; zonal jets and hurricane-like vortices. Unlike the well known linear Rossby adjustment problem, gravity waves are continuously and intermittently radiated from these basic flows. Furthermore, these radiations are occurred for small *Ro* and *Fr*. Therefore, it is fundamentally different from gravity-wave instability which is found in the linear stability analysis for the case of high *Ro* and *Fr*. We analyze these radiations in detail for a wide range of parameters.

EFFECT OF THERMAL FORCING ON THE GENERAL CIRCULATION ANDMEAN_FLOW EDDY INTERACTIONS

Oliver STENZEL, Jin-Song VON STORCH (Institute of Meteorology, University Hamburg, Germany)

The classical laboratory simulations suggest that the generalcirculation of a rotating fluid is determined both by the rotationrate and by the differential diabatic heating. As these laboratoryexperiments only crudely represent the atmosphere, it is worthwhile tofurther quantify the effect of the two external forcings usingnumerical models. So far numerical experiments have been mainlyfocused on the role of the earth's rotation rate. As acomplementation, this paper studies the impact of the latitudinalheating from the sun on the general circulation. A 'dry' atmosphericGCM is used for this purpose. The diabatic forcing is parameterizedby a Newtonian forcing. With this parameterization, the strength ofthe net latitudinal differential heating is controlled by thepole-to-equator difference in the restoring temperature, DT. To studythe effect of differential thermal forcing on the general circulation,the model is integrated using different DT.It is found that an increase in the differential heating leads tostrengthen the general circulation. The strengthening is characterizedby regimes with different types of mean-flow eddy interactions. Forextremely weak differential heating, the general circulation isdescribed by a Hadley circulation with no eddy activity. As thedifferential heating increases, an indirect circulation in conjunctionwith large-scale waves emerges at the mid-latitudes and a weak polarcell appears in the polar region. The most pronounced waves aresynoptic ones, and have wave number 6 and 7. As the differentialheating further increases, the indirect circulation increases both instrength and size and covers the entire mid-latitude and polarregion. This change is accompanied by a change in waves. The waveshave now larger spatial scales with the dominant wave number being 3.The changes in the general circulation and the mean-flow eddy regimescan be summarized from an energetic point of view. The increase indifferential heating leads to an increase in available potentialenergy, which is then transferred into the mean kinetic energy(i.e. the energy of the mean circulation). As long as the meancirculation is weak and stable, as generated by a weak differentialthermal forcing, the available potential energy generated by thedifferential forcing will be entirely used to generate and maintainthe mean circulation. Once the mean circulation becomes unstable, theavailable potential energy will also be used to 'feed' the eddies. Inthis sense, the different mean-flow eddy regimes represent differentways of a fluid to adapt to an increase in available potential energy.

BAROCLINIC GEOSTROPHIC ADJUSTMENT IN A ROTATING CIRCULAR BASIN

Geoffrey W. WAKE[1], Gregory N. IVEY[1], Jörg IMBERGER[1], N.Robb MCDONALD[2] ([1]Centre for Water Research, University of Western Australia, [2]Department of Mathematics, University College London)

A weakly nonlinear baroclinic geostrophic adjustment in a rotating basin is investigated in a laboratory study. The adjustment process is separable into a linear phase followed by a nonlinear phase on the basis of scaling arguments. This work describes in detail the hydrodynamics and energetics of the linear phase of the adjustment process from an initial step height discontinuity in the density interface ΔH to a final response consisting of geostrophic and periodic components. For a forcing length scale r_i equal to the basin radius R_0, the geostrophic component consists of a double gyre while the periodic component is composed of baroclinic Kelvin and Poincaré waves. The Burger number S = R_i/r_i (R_i = baroclinic Rossby radius of deformation) and the scaled depth ε = $ΔH/H_1$ (H_1 = the upper layer depth) characterise the response of the adjustment process.In particular, an excellent agreement between an analytical solution and the laboratory measurements is observed for times $τ < 1/2 ε^{-1}$, indicating this is the duration of the linear phase of the adjustment process. Over this timescale, the analytical solution can thus be used to calculate the energetics of the baroclinic geostrophic adjustment in a rotating basin. The results of this energetics study are found to compare favourably with previous studies with partitioning of energy between the geostrophic and periodic components exhibiting a strong dependence on S.

SIMPLE FRONTAL MODELS OF BAROCLINIC INSTABILITY

Mateusz K. RESZKA[1], Gordon E. SWATERS[2] ([1]Department of Physics, University of Toronto, [2]Department of Mathematical and Statistical Sciences, University of Alberta)

A class of layered mesoscale models is presented, relevant for oceanographic studies of baroclinicfrontal instabilities and propagation of coherent structures. The models allow for finite thicknessvariations in the frontal layer and continuous stratification in the ambient

IA

layer(s). The governingequations are derived in a formal asymptotic reduction of the primitive equations, assumingsubinertial dynamics and leading-order geostrophy. The resulting systems are not quasigeostrophic(QG), however, since they allow for vanishing thickness of the frontal layer. The linear stability problem is solved for idealized and realistic steady basic states, in thepresence of linearly sloping topography. Linear stability criteria suggest that introduction of ambientstratification reduces the size of the stable region of parameter space. Indeed, perturbation growthrates associated with the linearized equations are shown to increase with the stratification number,in agreement with previous laboratory experiments. For monotonic frontal profiles, the bottomtopography tends to be a stabilizing influence when the interfacial and bottom slopes are of thesame sign. This trend is consistent with traditional QG stability results, however, the present modelsare better suited than QG theory to the description of true fronts, which intersect the topography orfluid surface. Dependence of the instability characteristics on the width and relative thickness of theassociated current is also investigated. Oceanographic and experimental applications of the frontal models are discussed, withparticular emphasis on instability of the Denmark Strait Overflow and laboratory investigations ofaxisymmetric buoyancy fronts. Long-term numerical integration of the models demonstrates plumeformation and ejection of coherent vortex features, in agreement with similar primitive-equationstudies of coastal processes. In contrast to some previous studies, however, irregularities in thecoastline or topography are not necessary for the onset of instability.

JSP10/09A/B21-007   1120
NONLINEAR GEOSTROPHIC ADJUSTMENT OF DENSITY FRONT

Alexandre STEGNER[1], Pascale BOURUET-AUBERTOT[2], Thierry PICHON[3] ([1]LMD, IPSL, Ecole Normale Superieure, [2]LODYC, IPSL, Universite Paris 6 Jussieu, [3]UME, ENSTA Palaiseau)

This study deals with the non-linear cyclo-geostrophic adjustment of a circular density front in a two-layer fluid. Laboratory experiments have been performed to investigate the dynamical evolution of a fixed volume of buoyant water, initially confined within a bottomless cylinder, which is quickly released in a dense rotating fluid. This configuration corresponds to a rapid input of potential energy in a geostrophic fluid layer and reproduces some dynamical processes which occur during oceanic upwelling or stratospheric warming events. We focus our efforts on the visualisation techniques in order to have simultaneous and independent measurements of both the horizontal velocity field and the vertical density field. We thus obtained, for the first time, quantitative measurements of the potential vorticity and the flow balance after a geostrophic adjustment process. The density profile of the mean adjusted state observed in the experiment is in good agreement with the prediction of the standard adjustment theory based on lagrangian conservation of potential vorticity except in the frontal region. There, strong three-dimensional motions (plume structures, shocks and rapid transient instabilities) take place during the early stage of adjustment. These transient three-dimensional motions could dissipate up to 50% of the initial energy of the system, especially when the size of the initial density anomaly is close or larger than the deformation radius. Therefore, it significantly changes the velocity and the energy budget predicted by the standard Rossby adjustment. Both the kinetic energy of the mean adjusted state and the energy transferred to inertia-gravity waves modes are reduced by theses transient dissipative processes. During the adjustment, an important part of the initial potential energy is released to inertia-gravity waves modes. Theses modes exhibit a non-trivial structure where the kinetic energy fluctuations are concentrated in the frontal region while significant potential energy fluctuations may occur in the central region. For all the case studied, the first deviation of the density interface oscillate at the inertial frequency. Hence, the energy released to the wave modes during the adjustment is mainly concentrated at the inertial frequency. Afterwards, frequency doubling could occur for large amplitude wave.

THE STABILITY OF ALONG ISOBATH CURRENTS FOR A SHELF-CONTINENTAL SLOPE OROGRAPHY

Don L. BOYER[1], Andjelka N. SRDIC-MITROVIC[1], Sergey A. SMIRNOV[1], Peter G. BAINES[2], Joel SOMMERIA[3] ([1]Environmental Fluid Dynamics Program, Dept. of Mechanical and Aerospace Engineering, [2]CSIRO Atmospheric Research, Aspendale VIC 3141, Australia, [3]LEGI Equipe Coriolis, Universite Joseph Fourier-CNRS-INPG Grenoble, France)

Mesoscale numerical models have difficulty in representing oceanic flows past steep topography. Here we describe laboratory experiments for comparison with numerical models and to explore the character of instabilities that occur. The experiments were conducted for geometrically identical systems, on both a large turntable (13 m in diameter) and a smaller one (1.8 m in diameter) with the flow in the former being transitional or turbulent and laminar in the latter. The topography, which is placed in the center of the test cell, includes a vertical coastline, a horizontal shelf, a continental slope and a deep ocean. Experiments were conducted for both homogeneous and linearly stratified fluids that were initially in a state of solid body rotation. The motion relative to the topography was established by impulsively increasing (or decreasing) the rotation rate, to provide along-isobath, downwelling (upwelling) favorable currents. The flow properties depend on the Rossby, the Burger and to a lesser extent, the Ekman number. Spin-up or spin-down first develops on the spin-up timescale, and then possible instabilities develop. This baroclinic flow was either stable as evidenced by circular, along-isobath streamlines, or unstable, in the sense that the azimuthal motions began to develop small scale disturbances which eventually developed into basin-scale eddies which encopassed the entire test facility. These observations have been compared with theoretical model of the extended Eady type, and quantitative agreement between the two is highly satisfactory. These results show that baroclinic eddy formation occurs naturally as part of stratified spin-up/down, and may be a significant factor in producing eddies in coastal currents.

JSP10/09A/B21-009   1200
THE SPLITTING OF EDDIES BY ISLANDS

Harper L. SIMMONS[1], Doron NOF[2] ([1]International Arctic Research Center and Geophysical Fluid Dynamics Laboratory, [2]Florida State University)

Previous theoretical work has shown that, in an unbounded domain, anticyclones are prohibited from splitting on their own due to limitations imposed by the conservation of angular momentum. By explicitly considering the role of angular momentum exchange between eddies and boundaries (neglected by previous theories), splitting criteria for an anticyclonic lens colliding with a long and thin island are established analytically. The inviscid analytical model consists of an isolated patch of fluid in a reduced gravity regime. Nonlinear analytical solutions are constructed by connecting the initial and final states using conserved quantities. For the conceptual case of a lens pierced by a thin moving wall, the result is that, in order for a zero potential vorticity lens to split into two equal offspring, the wall length must be at least 1.19 of the lens´ radius. Even for infinitesimal splitting, which arises from weak collisions (where the wall merely ``brushes´´ the lens), the wall must be the order of the radius. This is because the ``parent´´ lens can split into two offspring only when the wall allows sufficient spreading of the lens, which increases its relative angular momentum, and

thereby enables the lens to form two distinct ``offspring.´´ Numerical experiments employing Lagrangian floats reveal that the splitting is accomplished by a jet that leaks fluid along the wall, forming a second lens. The fluid initially found along the rim of the parent lens occupies both the core and the rim of the second lens; the fluid found at an intermediate radius in the second lens is derived from fluid situated at an intermediate radius in the parent lens. In general, a very good agreement between the numerics and the analytical theory is found. The numerical simulations demonstrate that the integrated angular momentum is a far stronger constraint than energy conservation. Using the numerics, we extend the moving wall theory to the splitting of finite vorticity lenses and lenses on a β-plane. We find that the basic requirement of mass redistribution by a wall is relevant in all the regimes that we examined, and, therefore, is likely to also be relevant to collisions of eddies with actual islands. This supports our application of the theory to Meddy splitting by seamounts, where we find that the seamounts can provide the necessary torque for recently observed Meddy splitting and destruction.

JSP10/09A/B21-010   1220
EDDIES GENERATED BY A HUGE MOUNTAIN IN A ROTATING STRATIFIED FLUID

Yu HOZUMI[1], Hiromasa UEDA[1], Weiming SHA[2] ([1]Section of severe storms, Division of atmospheric disasters, Disaster Prevention Research Institute of Kyoto University, [2]Department of Science, University of Tohoku)

The numerical simulations of flows on a huge-scale are performed supposing a rotating stratified fluid so as to understand the effects of the interaction between flows and very large-scale obstacle. These include colioris forcing and a huge-scale obstacle in order that Rossby number is less than a unity, and the buoyancy frequency of the flow and mountain´s height are kept large in order Froude number with definition using mountain height keeps less than a unity. This situation includes the remarkable effects of stratification and rotation of the fluid, so the phenomena cause of interactions between flows and obstacle, concretely speaking a comparison the flow around mountain with over mountain and Taylor cap phenomenon, keep difficulties of understanding. A numerical model including primitive equations and no-slip boundary condition on bottom helps getting insights of a lot of effects, for example, the dynamical mechanism of a jet around a mountain and formation of an advecting cyclonic eddy near from mountain´s top. To make clear these mechanisms and relation between the phenomenon and non-dimensional numbers of this fluid, further simulation are carried out with some values of the buoyancy frequency and wind speed. Results of these simulations clarify that (a) the jet flows separated to left and right on looking downward are kept by different reasons each other, one of the cause is concerned with the quasi-geostrophic flow pattern and another is concerned with the downdraft from higher level flow releasing the potential energy, (b) the maximum value of advecting cyclonic eddy depends on the upward flow speed and the buoyancy frequency, and shows that eddy is made of the tilting effect with quasi-geostrophic theory and the horizontal shear by the confluent jets at leeward. These results have the applicability to the understanding of the flow pattern near an actual huge mountain and of the phenomena in the mid latitude.

GRAVITY CURRENTS AND LENSES IN A ROTATING STRATIFIED AMBIENT - NUMERICAL SIMULATIONS

Marius UNGARISH[1], Herbert E. HUPPERT[2] ([1]Computer Science, Technion, [2] Institute of TheoreticalGeophysics, DAMTP, University of Cambridge, Wilberforce Rd., Cambridge CB3 0WA, UK)

The behaviour of an axisymmetric high-Reynolds-number gravity current in a rotating frame which is released from a lock and then propagates over a horizontal boundary at the base of a stratified ambient fluid is considered. A finite-difference numerical code for the Navier-Stokes formulation is developed. The typical grid has 300 radial and 200 axial intervals (refined near the bottom to resolve the Ekman layer). The numerical results are compared with novel shallow-water approximations (also presented at this conference in a separate lecture) and with previous computations for non-stratified cases. The dependency on the dimensionless parameters predicted by theshallow-water formulation is confirmed. However, the numerical results of the stratified case display density waves that are not incorporated in the shallow-water formulation.

JSP10/09P/B21-002   1420
GRAVITY CURRENTS AND LENSES IN A ROTATING STRATIFIED AMBIENT - SHALLOW-WATER THEORY

Herbert E. HUPPERT[1], Marius UNGARISH[2] ([1]Institute of TheoreticalGeophysics, DAMTP , University of Cambridge, Wilberforce Rd., Cambridge CB3 0WA, UK, [2]Department of Computer Science, Technion, Haifa 32000, Israel)

The behaviour of an axisymmetric inviscid gravity current in a rotating frame which is released from a lock and then propagates over a horizontal boundary at the base of a stratified ambient fluid is considered. The one-layer shallow-water formulation is developed. This is an extension of recent theoretical investigations by the present authors of a gravity current in a non-rotating rectangular geometry which showed good agreement with corresponding experiments by Maxworthy et al (2002). The theory indicates that theinviscid flow is governed by (1) two dimensionless parameters, astratification number S (which varies from 0 for the homogeneous ambient to 1 for adensity at base equal to that of the dense fluid) and the initialheight ratio H of the ambient to the dense fluid (which varies from1 up to large values) and (2) a nose Froude number correlation betweenvelocity and pressure head (which is, apparently, not influenced by thevalue of S). In the rotating case an additional parameter, the ratioof Coriolis to inertia forces, C, appears. We assume that C is small. The time-dependent propagation is solved by a Lax-Wendroff schemeand compared with non-stratified and non-rotating cases. The results provide insights into the influence of the combined effects of stratification and rotations on the motion of the gravity current. In general, the stratification reduces the velocity of propagation and enhances the Coriolis effects in a rotating system. The shallow-water equations admit a steady-state lens solution,which is also investigated by numerical and asymptotical means. The problem of a lens in a stratifiedrotating fluid has been studied somewhat in the past, but the considered generating process wasa slow injection of fluid from a point source, not a true gravitycurrent. There is, however, good agreement between our results andprevious predictions concerning the aspect ratio of the lens. The present shallow-water formulations filters out the stratificationwaves, whose effect can be captured by numerical solutions ofthe Navier-Stokes equations (also presented at this conference in aseparate lecture).

STABILITY AND EVOLUTION OF DENSE CURRENTS ON SLOPING TOPOGRAPHY

Bruce R. SUTHERLAND, Kerianne YEWCHUCK, Joshua NAULT, Gordon E. SWATERS (Department of Mathematical and Statistical Sciences)

Driven by a need to understand the propagation and stability of abyssal ocean currents, there have been numerous idealised studies examining the dynamics in a rotating frame of reference of dense fluid on a slope underlying a less dense ambient fluid. This circumstance is characteristic, for example, of the Denmark Strait Overflow and the Western Boundary Undercurrent. A starting point of many theoretical and numerical studies is to assume the ambient is stationary and the current moves initially at a constant speed set by geostrophic balance. However, recent laboratory experiments (e.g. Lane-Serff and Baines (1998)) have shown that the continuous injection of a dense current from a localised source can significantly accelerate the ambient fluid and the consequent interaction between the two moving fluids cannot be neglected. We have performed a series of laboratory experiments designed to examine the temporal as well as spatial stability characteristics of the current. In these experiments a 90 centimetre diameter cylindrical tank on a rotating table is filled with fresh water. Dyed salt-water is injected uniformly through an annular slit on the conical-shaped bottom of the tank thus creating a uniform circular current. When instability occurs we observe a sinusoidal mode with phase speed approximately equal to that of the induced surface flow. The results are shown to be consistent with barotropic instability of the ambient rather than baroclinic instability of the dense current.

JSP10/09P/B21-004   1500

BAROCLINIC INSTABILITY OF COASTAL CURRENTS AND VORTICES IN LABORATORY EXPERIMENTS

Emmanuelle THIVOLLE-CAZAT, Joel SOMMERIA, Martin GALMICHE (LEGI/Coriolis)

Laboratory experiments are performed in the large Coriolis rotating tank in Grenoble (France) in order to study the development of coastal currents. The large dimensions of the turntable (13m diameter) provides large Reynolds and small Rossby numbers, allowing a good dynamical similarity with oceanic flows. A boundary current is produced by introducing light water over a heavier (more salty) fluid layer near a straight vertical wall. The fluid injector is shaped to produce a geostrophically balanced current. Measurements of horizontal and vertical velocity fields have been realized at different distances of the injector. The horizontal velocity field is measured by PIV (Particle Image Velocimetry) at two depths in the homogeneous water and in the current in a 2,5m x 2,5m domain. The vertical velocity field is also measured by PIV using a vertical laser sheet. The position of the density interface is controlled by ultrasonic probes downstream of the PIV domain. The unstable behavior of the current in the upper layer and in the lower one and the subsequent generation of meander and vortices or dipoles is analyzed. A comparison with the theory of baroclinic instability is performed, using the experimental analysis of perturbation phase and growth rate. Comparison with the baroclinic instability of a circular vortex is also discussed. A numerical model of the system is performed, using a two layer shallow water model (MICOM). Data assimilation (with the Singular Extended Kalman Filter) of the measured fields allows to capture the initial perturbations at the origin of the instability. Then a precise comparison between model and experiments can be performed.

WAVE GENERATION BY INTRUSIONS IN TWO-LAYER AND CONTINUOUSLY STRATIFIED FLUIDS

Morris R. FLYNN, Patrick KYBA, Bruce R. SUTHERLAND (University of Alberta)

Substantial mixing occurs near the margins of the ocean basin at the continental shelf. However, the dynamics by which this mixed fluid collapses and intrudes in the stratified ambient is not well understood, nor is the process of internal wave generation from such intrusions. As a starting point in examining these dynamics, in particular of an intrusion propagating along an interface such as the thermocline, we have performed a series of experiments in which a fluid intrusion is released along the interface of a two-layer fluid and also between a uniformly stratified fluid and a uniform fluid. In the former case, dye-tracking is used to measure transport and interfacial wave characteristics. In the latter case ``synthetic schlieren´´ is used to measure the amplitude of vertically propagating internal waves generated from the intrusion. We compare the intrusion speed with predictions by Holyer and Huppert (1980). They agree well with two-layer fluid experiments in which the density of the lock fluid is established by uniformly mixing the ambient fluid. However, when the lock fluid is made more dense by adding salt to the mixture, the resulting evolution of the intrusion, which generates large amplitude interfacial waves, is quite complex and is not captured by theory. In experiments with a stratified lower layer, schlieren reveals that internal waves are generated within a narrow frequency band.

A NUMERICAL STUDY ON MEDDY FORMATION

Hidenori AIKI[1], Toshio YAMAGATA[2] ([1]Frontier Research System for Global Change, [2]the University of Tokyo)

We have conducted a series of three-dimensional numerical experiments on a density current over a sloping bottom to study how Meddies (Mediterranean Water eddies) are generated off the Portuguese coast. It is demonstrated that the presence of a nominal cape can lead to periodic formation of anticyclonic lenses as part of baroclinic dipolar vortices. The size and rotation of the anticyclonic lens simulated in the model are in good agreement with the Meddies in the Iberian Basin. Noteworthy is the formation interval of about 30 days, which confirms the estimate that ten Meddies are shed per year near Cape St. Vincent (Bower et al., 1997). The transport of the density current is 0.5 Sv at the source region and 1.0 Sv past the cape. This downstream increase is associated with the entrainment of the ambient fluid; thereby the dense water on the bottom slope is converted into low potential vorticity water. The relative vorticity at the core of the dense water changes its sign from positive (cyclonic) to negative (anticyclonic), corresponding to the offshore ejection of the water parcels past the cape. We also discuss whether the surface cyclones are generated by the diapycnal volume flux due to the bottom water mixing. Additional experiments with reducing the mixing show no separated eddies from the density currents. To clarify some aspects regarding the generation of surface currents established in the above z-coordinate experiments, we simplify the problem of water intrusion and introduce a 5-layer model forced by a source/sink distribution of water mass. For an injection rate of 1.0 Sv, we observe the shedding of dipolar vortices which is remarkably similar to that observed previously. We find that the surface cyclones are generated as a result of the interaction between the coastal boundary current and the cape, rather than the density mixing near the bottom slope. It is demonstrated that the background current is induced by the passage of barotropic topographic waves associated with the subsurface water intrusion. We suggest that the background current is

essential for the subsurface lenses to drift far away from the source region (cf. Hogg and Stommel, 1990), thereby the eddy shedding event is repeated (cf. Nof and Pichevin, 1996). The overall results in this study suggest three necessary elements required for eddy shedding: a localized variation in the coastline as a trigger of cyclonic vortices, mixing of Mediterranean Water with the surrounding fluids leading to anticyclonic rotation of Meddies, and background currents which advect the detached vortices out of the source region.

ROTATIONAL SUPPRESSION OF RAYLEIGH-BENARD AND RAYLEIGH-TAYLOR INSTABILITY

Paolo ORLANDI (Dipartimento di Meccanica ed Aeronautica)

The retarding effect of rotation on the Rayleigh-Taylor instability is examined from the point of view of the vortex structures that develop during the instability. In numerical simulations, we found that it is possible to completely suppress RTI by the application of sufficiently strong rotation. To understand the role of viscosity and thermal diffusivity in this suppression, we turned to the more tractable Rayleigh-Benard problem. The linear dynamics of rotating RB convection has been investigated by Chandrasehkar[1] who numerically determined the marginal stability boundary for the onset of convection and overstability. Using a different approach, we are able to present remarkably simple analytical expressions for these boundaries. Finally, we find that if the fluid has either zero viscosity or zero diffusivity, the system is always unstable suggesting that both viscosity and diffusivity, as well as rotation, are necessary for the observed complete suppression. CONVECTION IN SMALL BASINS

William K. DEWAR (Dept. of Oceanography, Florida State University)

Convection in the world´s oceans often occurs in small, semi-enclosed basins where bottom slopes and nearby continental shelf breaks are commonplace. The evolution of convectively generated heat anomalies in such settings is studied using quasi-geostrophic finite difference and point vortex models. The displayed behaviors divide essentially into two categories: whole fluid column convection, in which bottom slope effects are felt immediately by the convective patch, and partial fluid column convection, in which the topographic effects can be delayed. In the latter, the sequence of events is somewhat richer and leads to differing scenarios involving bottom and lateral topography. In both cases, topography significantly modifies the evolution of convectively formed heat anomalies from that recently articulated for open ocean convection. It is suggested that topographic interactions are important to the preconditioning and dispersal phases of convection noted in water mass formation areas. Applications to the Labrador Sea and Mediterranean Seas are discussed.

TWO-DIMENSIONAL NONLINEAR HORIZONTAL CONVECTION IN A ROTATING STRATIFIED FLUID

Atsushi MORI[1], Hiroshi NIINO[2] ([1]Department of Astronomy and Earth Science, Tokyo Gakugei University, [2]Department of Physical Oceanography, Ocean Research Institute, The University of Tokyo)

Horizontal convection due to differential heating is one of the most basic problem in geophysical fluid dynamics. Typical examples in the atmosphere are heat/cool island circulations (hereafter referred to as HCIC) and land-and-sea breeze circulations. There have been extensive observational, numerical and theoretical studies on HCIC. However, they are mostly confined themselves to the steady-state circulations, and surprisingly small number of studies have been made on the formation processes of the HCIC. Recently, we have made a theoretical study on the time evolution of a non-linear HCIC in a non-rotating linearly stratified Boussinesq fluid (Mori and Niino, J. Atmos. Sci, 2002), where the temperature of a half of the infinite bottom is suddenly lowered by a certain amount and maintained thereafter. We have found that the time evolution of the resulting horizontal convection is clearly categorized into three distinct flow regimes; Diffusion Regime(DR), Gravity Current Regime(GCR) and Gravity Wave Regime(GWR). We have also found that there exists a self-similar solution in each regime, i.e., the flow pattern and the temperature field remain similar with time if they are suitably scaled by prescribed functions of the elapsed time; the scaling functions for the horizontal length scales in the three regimes are shown to be given by diffusive spread(DR), propagation distance of a gravity current(GCR) and propagation distance of a hydrostatic gravity wave(GWR), respectively. In the present study, we extended the above study to a rotating system. The results are summarized as follows: When the elapsed time is shorter than the inertial period, the time evolution of the flow field is similar to the non-rotating case. When the elapsed time becomes comparable to the inertial period, however, the horizontal length scale of the circulation ceases to increase and the flow fields become to be horizontally confined to a suitably defined ´radius of deformation´. As in the non-rotating system, there exist three regimes: DR, GCR and GWR. Accordingly, the radii of deformation for DR, GCR and GWR are scaled by diffusive spread, propagation distance of gravity current and propagation distance of gravity wave within one inertial period, respectively. Once the flow fields start to be confined to the radius of deformation, they start to expand upward and eventually approach a steady state. For the steady state in each regime, dominant dynamical balance above the Ekman layer found to be the thermal wind balance. We have also examined the momentum budget and the three-dimensional linear stability.

FLOW REGIMES OF NON-LINEAR HEAT ISLAND CIRCULATION

Hiroshi NIINO[1], Atsushi MORI, Takehiko SATOMURA, Kiyoka AKIBA ([1]Ocean Research Institute, The Univeristy of Tokyo, [2]Tokyo Gakugei Univeristy, [3]Geophysical and Planetary Sciences, Kyoto University, [4]Suntory Ltd.)

Heat island circulation is one of the typical examples of horizontal convections in geophysical fluids. The most fundamental configuration for the heat island circulation is such that a finite area of the lower boundary of a stably-stratified Boussinesq fluid with constant kinematic viscosity and thermal diffusivity is maintained at a constant temperature slightly higher than that of the rest of the boundary. It is known from laboratory and numerical experiments (e.g. Kimura, 1975) that the non-linear heat island circulation generated for such a configuration has two different flow regimes: The first regime (hereafter referred to as Regime E) is characterized by two maximums of updraft at both coastlines of the heat island, while the second regime referred to as Regime C by a single maximum of updraft at the center of the island. In the present study, a theoretical consideration is made to suggest that the flow for such a configuration is governed mainly by two non-dimensional parameters: a newly defined non-linear parameter N and a Prandtl number. Thus, when the fluid is specified, the

IA

flow regime is principally determined by the non-linear parameter. A numerical experiment is performed to confirm the theoretical prediction. The steady-state flow regimes obtained from the numerical experiment in fact belong to either Regime E or Regime C. In accordance with the theoretical prediction, the transition between two regimes occurs at a constant value of N. When N is larger (smaller) than this value, Regime C (E) is realized. The physical meaning of N has been interpreted based on our recent theoretical study (Mori and Niino, J. Atmos. Sci.; 2002) on the initial value problem of a non-linear horizontal convection. It is shown that when the non-linear parameter N is large, the gravity current initiated at the coastline reaches the center of the island before it experiences a transition to the gravity wave regime, so that Regime C is realized. The numerical experiments reveal that, however, there is a parameter range in which the flow never attains a steady-state but experiences a time-dependent state. The shape of the boundary curve that separates the steady-state and time-dependent state on the parameter space is shown to be well explained by an initiation of Rayleigh-Benard convections near the bottom boundary due to the boundary heating.

TRANSVERSE ROLL CONVECTION FORMED IN A ROTATING HORIZONTAL SHEAR FLOW

Yutaka YOSHIKAWA[1], Kazunori AKITOMO[2] ([1]Research Institute for Applied Mechanics, Kyushu University, [2]Graduate School of Science, Kyoto University)

The previous linear study by Davies-Jones (1971) showed that the horizontal velocity shear of background flow prefers parallel roll convection. However, our recent numerical experiment (Yoshikawa etal. 2001) suggests that the horizontal shear can organize convection into the roll whose axis is transverse to the background flow (transverse roll). This study is intended to make clear the effect of horizontal velocity shear on convection in detail. Numerical experiments are first carried out to examine whether transverse roll convection is actually formed in a horizontal velocity shear flow. We observe that the transformation of convection structure takes place in the linear stage of perturbation growth; In the nonrotating or slowly rotating case, the transformation from cellular to parallel roll convection occurs. In the rapidly rotating case, on the other hand, the transformation from cellular to parallel roll via transverse roll convection occurs. As a consequence, the transverse roll convection of finite amplitude is allowed to be formed in the rapidly rotating frame, if it becomes finite in amplitude when it is transformed into transverse roll. This transverse roll convection appears only for a short period of time just after its onset. This is the reason why the transverse roll convection was not found by Davies-Jones (1971), in which convection after a infinitely long time has passed is examined. The mechanism of the transformation is investigated by linear analysis. We formulated the problem so that the horizontal structure of the perturbation is sheared by the background flow as observed in numerical experiments. This formulation can significantly illuminates the underlying dynamics of the perturbation growth in the case where the advection speed of the perturbation is equal to the background flow. By this formulation, the perturbation is separated into the transverse mode (that is sheared by the background flow) and the parallel mode, and the governing equations change from partial to ordinary differential equations for perturbation amplitude with respect to time. Integration of the ordinary differential equations and complementary eigen analysis make it clear that in the rapidly rotating case where the Coriolis acceleration greatly changes the direction of the horizontal velocity vector to the right, the shearing of the perturbation by the background flow results in enhancing potential energy conversion of the transverse mode. As a consequence, the transverse mode dominates over the parallel mode. The present result might explain some aspects of transverse roll convection observed in the atmosphere of planets such as in the Jupiter.

ON ESTIMATING THE DIAPYCNAL DIFFUSIVITY IN THE PRESENCE OF DENSITY STRATIFICATION

Gregory N. IVEY (Centre for Water Research, University of Western Australia)

The future development of atmospheric and oceanic models requires improved description both of many fundamental flow processes and of the internal mixing. Recent laboratory and numerical studies have examined one aspect of this problem, the estimation of the diapycnal diffusivity in the presence of a stable background density stratification. The laboratory experiments were conducted in a closed system filled with a high Pr fluid with turbulent stirring by a horizontally oscillating vertical grid. Estimates were made of the rate of turbulent dissipation, turbulent lengthscales and diapycnal diffusivities over a very wide range of the turbulence intensities. In the energetic regime, for example, diffusivities were found to have both a different parameter dependence and to be smaller than predicted by traditional models. Some recent Direct Numerical Simulations in a density stratified shear flow at a Pr=0.7 provide an independent means of examining some of the predictions from these laboratory experiments. What emerges from the laboratory and numerical studies is a picture of how the diapycnal diffusivity smoothly makes the transition from the molecular value at very low turbulent intensities to very high diffusivities at the highest turbulent intensities attainable.

NUMERICAL EXPERIMENTS OF CONVECTION UNDER POLYNYA

Naosuke OKADA[1], Motoyoshi IKEDA[1], Shoshiro MINOBE[2] ([1]Division of Ocean and Atmospheric Sciences, Graduate School of Environmental Earth Science, Hokkaido University, [2]Division of Earth and Planetary Sciences, Graduate School of Science, Hokkaido University)

In the ocean partially covered by sea ice, nearly uniform atmospheric cooling can induce much more intense cooling through an open water area (polynya or lead), and hence, more rapid brine rejection from ice formation than the ice-covered portion. This non-uniform negative buoyancy flux produces a unique situation of convection: an area of convection is comparable with a convective plume. To investigate relationship between effects on the dense water formation of convection and external parameters (the horizontal length scale of the buoyancy forcing, the strength of the cooling, or rotation) in this situation, numerical experiments of convection driven by horizontally restricted forcing (isolated convection) are carried out. A three-dimensional ocean model is developed without a hydrostatic assumption. The model domain is a doubly periodic box 2560m square by 200m deep. The spatial resolution is 10m in both the horizontal and vertical direction. The buoyancy forcing region has a disc shape and is set at the center of the model domain. In this region, buoyancy loss is introduced by subtracting a decrement of density from top grid throughout the model integration. The initial density profile is neutral. Many experiments were conducted for the different sets of external parameters. From results of these experiments, the two dynamical regimes described in Jacobs and Ivey (1999): the baroclinically unstable convection and the

baroclinically stable convection is confirmed. These two regimes are distinguished by the Rossby number $R_{oR}=(B_0/f^3R^2)^{1/4}$. Here B_0 is the buoyancy flux, f is the Coriolis parameter, R is the radius of the forcing disc and H is the total ocean depth. In the baroclinically stable convection, it is found that the shift of the chimney is important, and the density scale of newly formed water has stronger dependency against the radius of the forcing disc than the previous studies. In the case where R_{oR} is high and R/H is low, multiple convective plume dose not fully developed. And, the density scale has nearly no dependency against the radius of the forcing disc. That is considered as a new regime. The change of the dependency of density scale is explained by scaling analysis. The term balance in the vertical plain vorticity equation is crucial to this change. The information about the density of newly formed water is useful for parameterizing dense water formation under the ice cover in a numerical model with a large (a few tens of km or larger) grid size.

EFFECTS OF UNSTEADINESS, INITIAL CONDITIONS AND MOELCULAR DIFFUSION ON THE SCALAR FLUXES IN STRATIFIED TURBULENCE

Hideshi HANAZAKI (Institute of Fluid Science, Tohoku University)

Turbulent fluxes of passive and active scalar in unsteady strongly stratified homogeneous turbulence are analyzed using the rapid distortion theory (RDT) [1]-[2]. Analytical solutions of the RDT equations demonstrate that the initial conditions, i.e., the initial cross correlation between passive scalar and active scalar (density), and the initial potential energy, make difference between the passive and active scalar flux in the vertical direction, giving difference between the turbulent diffusion coefficients for passive and active scalars. This is in contrast to the previous literature which usually assumed the same diffusion coefficient for the passive and active scalars. On the ohter hand, our results show that the zero initial correlation between passive and active scalars leads to complete correlation between the passive and active (density) scalar in a long time, in contrast again to the previous discussions in the literature that initial strong correlation is necessary for the final strong correlation. The difference between the passive scalar flux and active scalar (density) flux appears in the passive scalar flux in its components slowly oscillating at frequency N (N: Brunt-Vaisala frequency), while the active scalar flux has only the twice as rapidly oscillating components with frequency 2N. It is also found that the correlation coefficient between passive and active scalars is not a good measure of identifying the agreement or disagreement of the turbulent diffusion coefficients for these scalars, since if the passive scalar variance is initially large, final correlation coefficient becomes small even when the turbulent diffusion coefficients are equal for the active and passive scalars. The above results suggests the importance of the ´unsteady´ analysis and the ´initial conditions´ in the diffusion problem in stratified turbulence, which has been largely ignored in the previous studies. Effects of molecular diffusion of passive scalar (Schmidt number Sc) and density (Prandtl number Pr) show that if Sc $>2/(1+1/Pr)$, the slowly oscillating mode with half frequency N decays more slowly than the fast mode with frequency 2N. Then the difference between the passive and active scalar fluxes will become even more significant in a long time. This would be important in practical applications since in most practical conditions in the atmosphere/ocean Pr >0.7 and Sc $>>1$ hold so that the condition Sc $>2/(1+1/Pr)$ is usually satisfied. INTERNAL STRUCTURE OF PERIODIC BOUNDARY LAYERS IN A VISCOUS STRATIFIED FLUID WITH DIFFUSION

Anatolii V. KISTOVICH, Yuli D. CHASHECHKIN, Marina A. DAVYDOVA (Laboratory of Fluid Mechanics, Institute for Problems in Mechanics of the RAS)

We have applied two supplementary methods to solve the linearized problem of 3D disturbances generation in a viscous exponentially stratified liquid by a oscillating surface taking into account diffusivity effects. The source of disturbances is a part of vertical circular cylinder performing infinitesimal vertical or torsion periodic oscillations. We study the problem with both large and small Schmidt numbers. To calculate the fluid motion in the body vicinity we have applied the well-known method of singular boundary layers functions. The 3D spectral expansion technique is also used to calculate set of boundary layers on the solid surface and wave beams far from the source. We have found that in the general case produced set motions consist of emitting internal wave beams and three types of boundary layers even if the Schmidt number is equal to unity. The first one is a periodic Stokes boundary layer existing even in a homogeneous fluid. Its thickness is defined by kinematic viscosity and the frequency of the source oscillation. Two other layers, which are named internal viscous and diffusion boundary layers, are characterized by a more complex structure. Their thickness is defined besides intrinsic (Stokes) length scales by a similar scale including diffusivity coefficient, some derivative length scales and geometrical factors. In a limiting case of a weak viscosity and even more weak diffusivity the set of singular components of motion includes two types of split boundary layers. The ratio of their transverse sizes is proportional to the square root from the Schmidt number. The wave part of the solution describes internal gravity waves propagating along a wave cone as in an ideal fluid. To calculate wave fields far from the source, which satisfy right boundary conditions, we have used the spectral expansion method taking into account all set of regular and singular roots of the dispersion relation. The constructed exact solutions also describe the set of the same boundary layers and emitting 3D periodic internal wave beams. The transverse structure of the beam is defined by the ratio of the source size to intrinsic combined internal length scale. If the characteristic size of the generator is smaller than the combined internal length scale the beam is unimodal. In opposite case near the source the wave beam is bimodal. We have calculated the distance from the source where the bimodal beam transforms into the unimodal one. Constructed solutions present in the form adopted for comparison with the laboratory data. Given schlieren images demonstrate sections of wave cones and flows produced separating boundary currents from the periodically oscillating disks and rectangular in a continuously stratified fluid. Results of laboratory experiments a reasonable agreement with the calculations.

TWO-DIMENSIONAL TURBULENCE ON A BOUNDED DOMAIN

GertJan F. VAN HEIJST, Herman J.H. CLERCX (Department of Physics, Eindhoven University of Technology)

In contrast to its counterpart in the 3D world, turbulence in 2D is characterized by an inverse energy cascade. The presence of this inverse cascade in 2D turbulence is visible in the so-called self-organization of such flows: larger vortices and structures are observed to emerge from initially random flow fields. The lecture will address the evolution of 2D turbulent flows on a finite domain with no-slip walls. Results of both laboratory experiments and numerical simulations reveal the crucial role played by the unsteady boundary layers: the domain

boundaries act as important sources of large-amplitude vorticity filaments. In addition, spectral characteristics and some aspects of (chaotic) tracer transport will be highlighted.

JSP10/10A/B21-006   1100

WHY DOES A TURBULENT CHANNEL FLOW TEND TO HAVE A SHEAR ZONE OF ZERO ABSOLUTE VORTICITY IN A ROTATING SYSTEM?

Akira MASUDA, Yutaka YOSHIKAWA (Dynamics Simulation Research Center, Research Institue for Applied Mechanics, Kyushu University)

It has long been known that turbulent channel flows tend to have a zone of mean shear with nearly zero absolute vorticity in homogeneous rotating fluids. This feature was observed either in a numerical experiment for the Couette flow or in a tank experiment for the Poiseuille flow. This paper is intended to give a plausible account of how this curious property of turbulent channel flows is maintained in a rotating system, on the basis of an analogy between rotating and stratified fluids. The analogy itself has been well-known since Veronis. In reality, some arguments along this line have already been attempted for the presence of the shear zone of nearly zero absolute vorticity by such as Bradshaw and Tanaka et al. Nevertheless convincing explanation does not seem to have been proposed so far. Here the argument is improved first by showing that the zonally averaged flow in the rotating fluids is governed by the same equations as those for the zonally averaged flow in stratified fluids, even though the second moment may differ in the two systems. Then, as is usual, the shear zone of zero absolute vorticity in the rotating fluids is identified with nearly homogeneous layers in stratified fluids. The Couette flow in the rotating system corresponds to the thermal convection driven by cooling at the top and heating at the bottom. Likewise and remarkably the Poiseullie flow in the rotating system can be compared to the stratified fluid that suffers from steady body cooling along with the stabilizing heating from above. In order to confirm the validity of this analogy numerical experiments were carried out for the zonally averaged field in the stratified system to model the turbulent channel flows of Couette and Poiseullie types in the rotating system. In both cases, thermal convection yielded nearly homogeneous layers. The profile of the mean density profile in stratified fluids is translated to the mean zonal flow in rotating fluids including the linear shear due to the Coriolis parameter. The results showed a good agreement between the picture based on the analogy with stratified fluids and previous numerical or tank experiments in rotating fluids. Additional experiments were carried out, where fluctuating forms of body cooling were superposed to the inherent regular one in the stratified system corresponding either to the Couette or the Poiseuille flow in the rotating system. Even under the fluctuating body forcing, we observed the robust formation of nearly homogeneous layers that corresponds to the shear zone of zero absolute vorticity. The results suggest that the basic mechanism for maintaining the shear zone of nearly zero absolute vorticity is the inertial instability analogous to the gravitational instability in stratified fluids and that the maintenance of the shear zone of zero absolute vorticity does not depend on the details of turbulent motion.

INTERACTION OF DECAYING 2D TURBULENCE WITH RIGID BOUNDARIES: LABORATORY EXPERIMENTS

Yakov D. AFANASYEV, Jennifer WELLS (Department of Physics and Physical Oceanography.,Memorial University of Newfoundland)

Results from a new series of experiments on quasi-two-dimensional turbulence decaying in a rectangular container are presented. The flows are generated electromagnetically in a thin layer of conducting fluid when different configurations of permanent magnets are used to specify the initial characteristics of the flow. The Particle Image Velocimetry method is used to determine the velocity and vorticity fields. These fields are further used to determine the global characteristics of the flow such as the energy, enstrophy and the net angular momentum with respect to the centre of the container. The experimental results demonstrate that variations of net angular momentum occur due to the interactions of coherent vortex dipoles/jets with the walls of the container. The variation of the angular momentum of the system which occurs due to the action of stresses at the solid boundary can be obtained quantitatively if the initial linear impulse exerted by the magnets on the fluid is known. The analysis of external forces and torques allows one to predict that during the intermediate state of the flow evolution a pattern of the flow will be a rotating quadrupole.

SELF-SIMILARITY OF VORTICITY DYNAMICS IN DECAYING CHM TURBULENCE

Takahiro IWAYAMA[1], Theodore G. SHEPHERD[2], Takeshi WATANABE[3] ([1]Graduate School of Science and Technology, Kobe University, [2]Department of Physics, University of Toronto, [3]Department of System Engineering, Nagoya Institute of Technology)

In decaying 2D Navier-Stokes turbulence, Batchelor´s similarity hypothesis fails due to the existence of coherent vortices. However, it is shownthat decaying 2D turbulence governed by the Charney-Hasegawa-Mima (CHM) equation is well described by Batchelor´s similarity hypothesis forlength scales much greater than the Rossby deformation radius, suggesting that vortices in this regime are not really coherent. A theoryfor the self-similarity of energy and enstrophy spectral fluxes is also presented. It is argued that the possibility of complete self-similaritydepends on the choice of dissipation operators.

STRONG TURBULENCE OF INTERNAL NONLINEAR KELVIN WAVES

Vadim V. NOVOTRAYSOV (V.I.Il`ichev Pacific Oceanological Institute, FAR-EASTERN BRANCH OF RUSSIAN ACADEMY OF SCIENCES)

Turbulence at boundaries in rotating stratified fluids is supposed to beconsidered as a random field of weak nonlinear internal Kelvin waves (IKW).Theory of this turbulence is considered on the base of Burger´s equation.It is shown that the energy spectrum of this turbulences has a universalstructure: on the young-age stage the energy spectrum is proportional to thethird power of the frequency, on the old-age stage the energy spectrum isproportional to the second power of the frequency at small frequencies anddecreases exponentially at high frequencies. The coefficient of theproportionality is determined by the nonlinear effects on the initial stageof the propagation.We presented observations of the IWK in the coastal zone of Japan sea.Data collected from moored instrument and repeated profile measurementsduring the September 1999 show an energetic, large amplitude semidiurnalIWK. Spectrums of temperature, current variations and IWK are constructed.Comparison of IWK spectrum with model random nonlinear IWK spectrum hasrevealed their good agreement. Work supported by RFBR grants 02-05-64277.

NONLINEAR DYNAMICS OF A STRAINED VORTEX

Richard R. KERSWELL (Department of Mathematics, University of Bristol)

It is now well known that elliptically-distorted vortices are linearly unstable to pairs of inertial waves if the fluid viscosity is small enough. These growing inertial waves themselves become unstable beyond a threshold amplitude so that the resulting flow quickly grows in both spatial and temporal complexity. At this point, direct numerical simulation offers the only practical tool for probing the breakdown further. We will present the results of such an exploration for the closely related flow of a precessing vortex (Mason & Kerswell 2002). (The precessing vortex is a strained vortex in which the strain takes the form of a exp(i phi) perturbation as opposed to a exp(2 i phi) perturbation in an elliptical vortex.) This flow is more naturally simulated in a numerically-accessible plane layer model and is interesting in its own right having application to the Earth´s precessing outer core. The exact basic flow can be written simply as u_basic:=(-y,x-2*epsilon*z,0) in cartesian velocity components where epsilon measures the straining of the vortex in a frame rotating at an angular velocity of epsilon in the x-direction. The flow solution consists of `sheared´ circular streamlines where the line joining their centres is no longer perpendicular to their plane (the strain is out of the plane of motion). Numerical results confirm that the initial instability occurs through a pairwise inertial wave instability at epsilon_crit=O(E^1/2) where E is the Ekman number, and that a weakly nonlinear regime only exists for epsilon-epsilon_crit=O(E). Beyond this, secondary instabilities occur which lead to a multitude of co-existing solution branches, some of which are chaotic. Interestingly, all the nonlinear flow solutions found remain within O(epsilon) (in an energy norm) of u_basic. This indicates that the precessional instability is not able to remove energy from the underlying rotation of the vortex but instead merely feeds off the strain perturbation. Why this conclusion appears at variance with experimental realisations of precessing flows (Malkus 1968) and elliptical vortices (Malkus 1989, Eloy et al. 2000) will be discussed. THREE-DIMENSIONAL LINEAR INSTABILITY OF AN ELLIPTICALLY STRAINED VORTEX TUBE

Yasuhide FUKUMOTO (Graduate School of Mathematics, Kyushu University)

The global linear stability analysis for a straight vortex tube embedded in a pure shear flow is revisited. This problem was originally addressed by Moore and Saffman (1975) and Tsai and Widnall (1976), and the three-dimensional instability of an elliptically strained vortex tube is now well known as the Moore-Saffman-Tsai-Widnall instability. We restrict our attention to the case of uniform vorticity. Without shear, the basic flow is the Rankine vortex. The Rankine vortex supports neutrally stable three-dimensional waves called the Kelvin waves. A pure shear deforms the core into an ellipse and thus breaks the circular symmetry, causing a parametric resonance between right- and left-handed helical (bending) waves. Resonance instability is possible between any combination of the Kelvin waves with their azimuthal wavenumber difference being 2. Eloy and Le Dizes (2001) showed that this is indeed the case and that the resonances other than bending-bending wave interaction are equally dangerous. The results of Tsai and Widnall (1976) are simplified by providing an explicit expression for disturbance flow field, whereby an improvement in numerical accuracy is achieved. Given the wavenumber and the frequency of the intersection points of dispersion curves of Kelvin waves with azimuthal wavenumber difference 2, the growth rate is expressible solely in terms of the modified Bessel functions, and so is the unstable wavenumber range. The parametric resonance instability occurs at every intersection point. For bending-bending waves resonances, the amplification rate of non-rotating waves is by far larger than that of rotating waves. Direct relations of this static instability are established with the two-dimensional displacement instability in the long-wave limit (Moore and Saffman 1971) and with the elliptical instability in the short-wave limit (Bayly 1986; Waleffe 1990). For other resonances of higher azimuthal wavenumbers, amplification rate is larger at a particular sequence of intersection points of dispersion curves, which are the only surviving modes in the short-wavelength limit. Its growth rate approaches that of the elliptical instability. An account for this instability is given from the viewpoint of Hamiltonian spectra. The energy of the Kelvin waves is calculated by invoking Cairns´ formula. The instability result is compatible with Krein´s theory for parametric resonance in Hamiltonian systems; for instance, the non-rotating instability mode emerges as a result of collision of eigenvalues of zero-energy waves.

INTERACTION BETWEEN A Q-VORTEX AND EXTERNAL TURBULENCE

Naoya TAKAHASHI, Takeshi MIYAZAKI (Department of Mechanical Engineering and Control Systems)

Interactions between intense columnar vortices and surroundingturbulent motions are often produced in engineering and environmentalflows, and they occur naturally in most sheared turbulent flows, suchas circular jet, plane jet, and mixing layer. These interactions arethought to play an important role in the three-dimensionalization ofthe flow fields. It is, also, of practical interest to estimate thelifetime of trailing vortices under the influence of atmosphericturbulence. We investigate the instability of the columnar vortex with axialflow. embedded in ambientturbulence, using direct numerical simulation(DNS). We consider thecolumnar vortex of various values of swirling parameter q[1] (q=-∞, -3.0, -1.5 and -0.45). We produced an externalturbulence numerically by the Fourier-spectral method($R\lambda$ is about 120). In the case of q=-0.45, twist structures are formedinside the vortex core. Its growth rate is consistent with that of the linearinstability analysis [2]. After two revolutions, the secondaryinstability is excited. Then the columnar q-vortexcollapses, and many fine scale vortices appear abruptly.The mean energy density decreases, and thedisturbance energy density increases outstandingly after the vortexbreak down. The cases of q=-1.5 and -3.0 are less unstable.From Stewartson and Leibovich[3], we expect modes with $|m|$ muchlarger than 1 are stabilized for $|q|>$ square root of 2, then oursimulations are well resolved. In these cases, we find that generation of thin spiralstructures. These structures, generated around the surface of the core,are winded up by the columnar vortex, and they are stretched to bevery thin spirals. In the case of q=-∞ (a.k.a. Lamb-Oseen vortex),We find that the columnar vortex, which itself expands slightly, windsup the worms, which enhance energy dissipation considerably.Using the two-point energy-spectrum tensors, we capture such phenomena as the ´Blocking Effect´ (fluid particles cannot invade the core of the ordered vortex) and the excitation of bending and axisymmetric vortex waves. During these processes, we can alsoobserve suppression of the scalar diffusion by the core and

enhancement ofthe diffusion by fine scale structures. [1] Lessen, M. and Paillet, F.: J. Fluid Mech. **65** (1974). [2] Mayer, E.W. and Powell, K. G.: J. Fluid Mech. **245** (1992) 91. [3] Leibovich, S. and Stewartson, K.: J. Fluid Mech. **126** (1983) 335.

QUASIGEOSTROPHIC ELLIPSOIDAL VORTICES: INSTABILITY, INTERACTION AND SCALAR MIXING

Takeshi MIYAZAKI, Wei QIN, Kensei SAKAMOTO (Department of Mech. Eng. Control Systems, University of Electro-Communications)

In geophysical flows, coherent vortex structures persist for long time and their interactions dominate the dynamics of geophysical turbulence. Miyazaki *et al.*have derived a Hamiltonian dynamical system of *3N* degrees of freedom, describing the interactions of *N* ellipsoidal vortices, where each coherent vortex was modeled by an ellipsoid of uniform potential vorticity (Meacham *et al*). Chaotic motions are observed even in a two-body system. In this paper, direct numerical simulations based on a Contour Advective Semi-Lagrangian algorithm (CASL) are performed in order to investigate the instability and the interaction of ellipsoidal vortices. First, the instability of a tilted spheroidal vortex is investigated. A prolate spheroid becomes unstable against the third Legendre mode when the aspect ratio is less than *0.44* and the inclination angle is larger than *0.48*. An oblate spheroid may become unstable if the aspect ratio is larger than *1.62*, even if the inclination angle is very small.Weakly unstable prolate spheroidal vortices emit thin filaments from their top and bottom, whereas strongly unstable slender prolate spheroidal vortices are broken up into two pieces. Unstable oblate spheroids emit thin sheets of vorticity to become stable oblate (or prolate) spheroid. Secondly, the interaction of two co-rotating spheroidal vortices on slightly different vertical levels, which plays a key role in the turbulence dynamics, is studied.The Hamiltonian model can predict the critical distance of symmetric and asymmetric mergers well, although in asymmetric interactions vorticity exchange occurs (not ´two to one merger´) along the threshold determined by the Hamiltonian model. The smaller vortex loses some of its original volume, and the larger vortex expands slightly absorbing the filaments ejected from the smaller vortex. This is a new dynamical process linked with the energy and enstrophy cascades. Thirdly, the interaction of two counter-rotating spheroidal vortices on slightly different vertical levels. These vortices are quite robust, i.e., they keep the dipole structure by emitting filaments, even if they are placed within the model threshold initially. Finally, scalar transport around an ellipsoidal vortex(almost a tilted spheroid) is investigated analytically and numerically. When a spheroidal vortex is embedded in an otherwise quiesent fluid, it rotates rigidly with a constant angular velocity. A fluid particle moves along a streamline in the coordinate system rotating with the spheroid. There are two saddles and heteroclinic orbits conecting them on the horizontal plane through the vortex center. The heteroclinic orbits change into homoclinic orbits on the horizontal plane slightly off center (*z* >0). The Melnikov functions computed along the heteroclinic and homoclinic orbits intersect zero transversely, suggesting the occuerence of chaotic mixing of fluid particles. In fact, numerically computed stroboscopic Poincare plots scatter along the heteroclinic and homoclinic orbits even when the perturbations are very weak.

A LAGRANGIAN VIEW OF VORTEX MERGER

Oscar U. VELASCO FUENTES (Departamento de Oceanografia Fisica, CICESE)

Two circular vortices of equal size and strength in an otherwise quiescent fluidmay exhibit three types of behaviour depending on their relative position. Whenthe intercentroid distance *d* is much larger than the vortex radius *R* (*d/R* >3.45),the vortices rotate about one another quasi-steadily while undergoing somedeformation. When the distance is in the range *3.3* < d/R < 3.45 the vorticesstill rotate about one another, but they also approach and exchange mass. Finally,when the distance is smaller than the critical value *d/R ≈ 3.3* the vortices mergeinto a single vortex. These regimes are reviewed here using ideas and methods from the theory of transportin dynamical systems. The Lagrangian flow geometry (i.e., the hyperbolic trajectoriesand their asociated stable and unstable manifolds) is computed and analysed forinitial conditions in the range *3.2* < d/R < 3.5. It is observed that the regimetransitions are asociated with changes in the relative position of the stable manifoldswith respect to each other and with respect to the vortices´ edges. Finally, the results are contrasted with the conventional explanation for the regime transitions(namely, the vortex location with respect to a co-rotating streamfunction) whichuses an Eulerian point of view.

ON THE VERTICAL ALIGNMENT OF GEOPHYSICAL VORTICES IN STABLY STRATIFIED INVISCID FLUID

Michael Thomas MONTGOMERY[1], David A. SCHECTER[2], Paul D. REASOR[1] ([1]Dept. of Atmospheric Science, Colorado State University, [2]Dept. of Earth and Planetary Sciences, Harvard University)

Observations and numerical models demonstrate that a broad class of geophysical vortices freely evolve toward vertically aligned states. This intrinsic drive toward symmetry opposes destructive shearing by the environment and is believed an essential element in the robustness and emergence of coherent vortex structures. This talk presents new results on the vertical alignment and axisymmetrization of both weak (Rossby number much less than unity) and intense (Rossby number greater than unity) centrifugally-stable vortices in stably stratified inviscid fluid. For potential vorticity (PV) towers whose upper- and lower-layer PV cores overlap, the alignment dynamics can be represented accurately as the excitation and evolution of a three-dimensional ˝vortex Rossby wave˝ that evolves within the ˝slow-manifold˝ (balanced) subspace of the three-dimensional primitive equations. The wave, that is, the tilt, decays by two distinct pathways depending on the core Rossby number and the ratio of the horizontal vortex scale to the ambient Rossby deformation radius.Given these two parameters, the tilt decays either via sheared vortex Rossby waves, or an exponentially decaying vortex Rossby wave mode. Alignment in the latter case is controlled by the sign and magnitude of the radial PV gradient at a critical radius, where the fluid rotation is resonant with the mode. The decay rate of the tilt is shown to be sensitive to the form of the vortex. For the case of a ˝Rankine-with-skirt˝ vortex, the magnitude of the decay rate decreases (initially) with decreasing deformation radius. On the other hand, for the case of a ˝Gaussian˝ vortex, the magnitude of the decay rate increases with decreasing deformation radius. A discrete vortex Rossby wave can also resonate with an outward propagating inertia-buoyancy wave (Lighthill radiation), inducing BOTH to grow. At large Rossby numbers, this growth mechanism can be dynamically relevant. All balance models neglect inertia-buoyancy waves, and therefore ignore the possibility of a Rossby-inertia-buoyancy (RIB) instability. We show that a large radial potential vorticity gradient (of the proper sign) at the critical radius can suppress the RIB instability, and thereby preseve balanced flow, even at large Rossby number. The relationship of these results to the problem of robustness of tornado and hurricane vortices will be discussed.

RESONANT ROSSBY WAVE TRIADS AND THE SWINGING SPRING

Peter LYNCH (Assistant Director, Met Eireann)

The wave solutions discovered by Rossby are of fundamental importancefor atmospheric dynamics. The nonlinear interactions between thesewaves determine the primary characteristics of the energy spectrum.These interactions take place between triplets of waves known as resonanttriads and, for small amplitude, they are described by the three-waveequations. These same equations also govern the dynamics of a simplemechanical system, the elastic pendulum or *swinging spring*.This equivalence allows us to deduce properties, not otherwiseevident, of resonant triads from the behavior of the mechanical system.In particular, the characteristic stepwise precession of the swing-plane,so obvious from observation of the physical spring pendulum, is alsofound for the Rossby triads. This phenomenon has not been previouslynoted and is an example of the insight coming from the mathematicalequivalence of the two systems. The implications of the precession forpredictability of atmospheric motions are considered. The pattern ofbreakdown of unstable Rossby waves is very sensitive to unobservabledetails of the perturbations, making accurate prediction very difficult.

SPIN-UP FROM REST IN A STRATIFIED FLUID

Jan-Bert FLOR[1], John W.M. BUSH[2], Marius UNGARISH[3] ([1]LEGI-CNRS, [2]Department of Mathematics, MIT, Cambridge MA01239, USA, [3]Department of Computer Science, Technion, Haifa, Israel)

We present the results of an examination of spin-up from rest of a stratified fluid. A vertical cylindrical container of radius R and height 2H containing fluid of viscosity *v* and characterized by a constant buoyancy frequency N is set impulsively to rotate about its symmetry axis with angular speed Ω=f/2. The characteristic Ekman number E = $v/\Omega R^2$ is small and the Schmidt number S=v/D_s (where D_s is the diffusivity of salt) is large. The initial stage of the spin-up is characterized by an axisymmetric circulation driven by nonlinear Ekman layers adjoining the horizontal boundaries. Fluid is drawn by the boundary layers from the stationary, stratified interior and transported into corner regions. It is shown that the corner regions are restricted to a height of approximately *0.3Rf/N* from the horizontal boundaries, beyond which the fluid remains unperturbed apart from that spun up by diffusion of momentum from the side-wall boundary. Two distinct regions thus emerge: rotating corner regions, and a quiescent stratified core. After a time *1.3/(E$^{1/2}$N)*, the corner regions cover the bulk of the horizontal boundaries and the boundary layer suction is suppressed. Our study provides a framework for understanding the subsequent evolution of the spin-up process, which may be characterized by axisymmetry-breaking instabilities of the stratified core (Flor, Ungarish and Bush, 2002, J. Fluid Mech.**472**). The subsequent evolution of the central vortex depends critically on N$_c$/f, with N$_c$ the stratification in the core region. For N$_c$/f >1 and /R >1, the axisymmetry of the system is retained throughout the spin-up process: the central vortex attains a state of near solid body rotation by the diffusion of vorticity from the sidewalls. For N$_c$/f >1 and H/R<1, the central vortex breaks up into a series of vertical vortices that enhance transfer of angular momentum from the boundaries and so expedite the spin-up process. For N$_c$/f <1, the interface between the core and corner region is (mode two) unstable, leading to a simple tipping of the central stratified vortex. In a tall tank, the centerline of the central vortex is twisted from its vertical position, and the resulting instability gives rise to a stack of vortices.

INVARIANT PROPERTIES OF BASIC SETS OF GOVERNING EQUATIONS OF ENVIRONMENTAL FLUID MECHANICS

Vasiliy G. BAYDULOV, Yuli D. CHASHECHKIN (Laboratory of Fluid Mechancs, Institute for Problems in Mechanics of the RAS)

A main goal of given study is to test a level of compatibility of different mathematical models that are widely used in investigations of environmental flows. As the basis the Navier-Stokes equations supplemented by of the heat and mass transport together with an empirical equation of state are chosen. We compare sets of local symmetries of the basic and derivatives models using the continuous (Lie) groups theory and methods of symbolic calculations. To perform extended algebraic calculations symbolic system Maple has been adopted. We have investigated symmetry properties of a general set of multi-component stratified fluid governing equations and different well-known models: stationary ones, the Boussinesq approximation, 1D and 2D flows, elimina-tion of diffusion, temperature transport and viscosity effects, the boundary layer model and dif-ferent well-known models of turbulence. In general case we have performed detail investigation of the effects of algebraic equation of state on the symmetry properties of the set of governing equations. We found that the general set off governing equations is characterized by a set of symmetries, containing ten-parametric Galilean group of symmetry and infinite-dimensional sub-algebra of pressure shifts. Additional expansion groups can be found if the state equation is taken in a specific form. Diffusion impacts on invariant properties more essentially than viscos-ity. 1D transient and stationary problems are characterized by irreducible set of symmetries. One of specific generators corresponding to the expansion group of the heat conduction equation de-scribes set of diffusion induced internal boundary currents producing sets of boundary layers on a moving body and singular interfaces inside the liquid. Analysis of symmetries in the expanded space of jets including all known non-dimensional parameters reveal the number of non-dimensional parameters completely describing stratified flows. Model of isotropic turbulence does not satisfy the Galilean principle of relativity. Some more sophisticated energy-dissipation models of turbulence have no the rotational symmetries. We also have applied given methods for solutions some concrete problems. We have analyzed formation for the flow past abrupt begin-ning of motion of a horizontal cylinder in a stratified liquid. We have constructed complete set of eigen-functions of 3D periodic motion including a regular part (internal waves) and a singular part (boundary layers on bounding surfaces and internal boundary layers in a fluid interior. We have defined conditions of superposing of non-linear periodic and lee (attached) waves from several independent sources and presented recommendation for introducing of generalizes vari-ables and specific potentials to increase the stability of solutions with respect to errors and in-completeness of an initial data set. Results of laboratory experiments are used to illustrate main theoretical conclusions concerning structures of regular and singular components of motion in-side a stratified fluid.

MEAN-FIELD HYDRODYNAMICS FOR TURBULENT FLOWS SUBJECTED ROTATION

Arakel S. PETROSYAN, Denis TSYGANKOV (Space Research Institute, Russian Academy of Sciences)

Many turbulent flows that must be understood are subjected to a rotation. The present study is concerned with Reynolds Averaged Navier-Stockes equations for rotating system with and without convection. There are two basic observations: limited application of the turbulent viscosity hypothesis and possibility for turbulent viscosity to become negative in rotating systems. Our prime interest here is to find nontrivial parameterizations of Reynolds stresses describing contribution of turbulence to the large-scale momentum flux. For this purpose we use statistical perturbation methods to analyze the way the basic flow is modified by a weak large-scale perturbation. It is apparent that Reynolds stresses, expanded in the gradient Taylor series, contain term directly proportional to the large-scale velocity as well as that proportional to the large-scale velocity gradient. First mentioned term is precisely that term which can lead to nontrivial large-scale dynamics, while the second one describes eddy-diffusive modification of molecular transport of momentum. Our main concern here is to derive analytic expressions for nontrivial terms as well as turbulent viscosity terms. The global breaking of mirror symmetry in turbulence is often considered as probable cause of nontrivial dynamics. We consider model homogeneous helical turbulence as an initial basic state in Reynolds stresses computations. It is well known, that any large-scale perturbation of the velocity field in homogeneous helical turbulent flow will only dissipate in non-rotating system since non-zero helicity density implies low energy cascade from large wave numbers to smaller one. Nevertheless, nontrivial dynamics of large-scale flows exists when turbulence in rotating system has been treated. There are quite a lot of ways of closing the equations. Using the first-order smoothing approximation we have investigated the large-scale flow interaction with small-scale turbulence in linear approximation for two cases: with and without convection. It has been found that non-helical component of the turbulent field and the presence of the rotation leads to the additional terms in the Reynolds stress tensor. These terms are proportional to the first spatial derivatives and may cause an additional wave-like transport of momentum. Helical component of basic turbulence leads to the phase velocity difference of such wave-like motions in direct and backward propagating directions. In the presence of convection, described in Boussinesque approximation, we found the possibility for decreasing turbulent viscosity value in comparison with the rotating system without convection.

DECAYING GRID TURBULENCE IN A ROTATING STRATIFIED FLUID

Joel SOMMERIA, Olivier PRAUD (LEGI/Coriolis)

Rotating grid turbulence experiments have been carried out in stably stratified fluid at large Reynolds number (10000), using the ˝Coriolis˝ turntable in Grenoble. Under effects of rotation and stratification the flow degenerates into quasi horizontal motions. This regime is investigated using a scanning imaging velocimetriy which provides time resolved velocity in a volume. The most obvious effect of rotation is the inhibition of the kinetic energy decay which is in agreement with the quasi geostrophic model which predicts an absence of direct energy cascade, like in two dimensional turbulence. In the regime of small Froude and Rossby numbers, the results show that the dynamics are non-dissipativeand associated with a Kh^{-3} energy spectra and highly intermittent vertical vorticity field, involving intense vortices of both signs. For higher Rossby number, the results show fundamental differences with the quasi geostrophic model. A significant decay of kinetic energy which does not depend on stratification is indeed observed. Moreover, although both cyclones and anticyclones are initially produced, cyclones tend to dominate the flow.

ENERGY DISSIPATION IN LARGE WAVENUMBER REGION OF QUASI-GEOSTROPHIC TURBULENCE

Keita IGA (Research Institute for Applied Mechanics, Kyushu University)

Large scale motions in the atmosphere and in the oceans are well expressed using quasi-geostrophic systems. Simple one-layer quasi-geostrophic potential vorticity equation (also called Charney-Hasegawa-Mima equation as an equivalent) often describes the essential dynamics of such large scale motions. In turbulent motions governed by this quasi-geostrophic equation, the energy is transported upward to the small wavenumber region and thus coherent patterns are formed. The energy upward cascade is also observed in two-dimensional turbulence, but there are some quantitative differences such as the speed of the upward cascade. Dynamic scaling laws for quasi-geostrophic turbulence, which describes quantitatively this energy upward cascade, is developed by Watanabe et al. (1998) theoretically and by numerical simulations. However, in their theory, they evaluated a parameter necessary for the dynamic scaling law from the result of numerical calculation: a parameter which shows the total energy dissipation rate. In the quasi-geostrophic turbulence, most of the energy is transported to the small wavenumber region, but a small amount of energy is transported to the large wavenumber region owing to the small but finite dissipation. We estimated the energy dissipation rate based on the assumption that the total energy dissipation in this system is equal to the energy transported to the large wavenumber region. The shift of the energy spectrum to the small wavenumber region must be balanced with the energy transport to the large wavenumber region, and this relation enables us to evaluate the energy transported to the large wavenumber region from the wavenumber of the energy spectrum peak. This theoretical estimation complements the dynamic scaling laws of Watanabe et al. (1998): the parameter expressing the total energy dissipation which is left unknown and empirically determined in their study is theoretically derived. In numerical calculations with finite cut-off wavenumber, we use artificial hyperviscosity coefficients in order to avoid the pile-up of the cascaded energy near the cut-off wavenumber region. This estimation also suggests the means to determine the appropriate hyperviscosity coefficient used in numerical simulations. Considering that the artificial dissipation near the cut-off wavenumber region is a substitute of the energy which should have been transported beyond the cut-off wavenumber, we can determine the appropriate value of the hyperviscosity from the condition that the energy dissipated by the hyperviscosity should be the same as the energy cascaded to the large wavenumber region. In the numerical calculation by Watanabe et al. (1998), the energy spectrum has a too steep gradient in the large wavenumber region. The numerical calculation using the value suggested by the consideration here successfully derived the theoretically expected energy spectrum.

JSP10/11A/B21-003   0920
KINETIC ENERGY SPECTRUM IN STRATIFIED TURBULENCE AND ITS APPLICATIONTO THE ATMOSPHERIC MESOSCALES

Yuji KITAMURA, Yoshihisa MATSUDA (Graduate School of Science, The University of Tokyo)

It is known from observations that the horizontal kinetic energyspectrum follows a $k^{-5/3}$ power law in the mesoscale phenomena inthe upper troposphere. Nastrom et al. (1984) found the $k^{-5/3}$power law in the scales less than about 500 km from the observation inthe upper troposphere. From the aircraft observation, Cho etal. (1999) showed that this spectral slope

can be applied to theatmospheric motion with the hoizontal scales less than 100 km in thetroposphere except the boundary layer. Lilly (1984) attemped tounderstand the energy spectrum in the mesoscales from inverse energycascades in stratified turbulence. However the results from numericalsimulations of stratified turbulence indicate that inverse energycascades does not occur unless the Coriolis parameter f is extremelylarge (Herring and Metais; 1989, Metais et al., 1994). On the otherhand, Vallis et al. (1997) reproduced the above spectral slope in themesoscales with the regional model including water vapor and Koshykand Hamilton (1999) did with GFDL SKYHI GCM. These models include manyphysical processes so that it is difficult to understand their resultsas energy cascades in stratified turbulence. We conduct numerical experiments with a three dimensionalnonhydrostatic model assuming the Boussinesq approximationin in order toconsider upscale and/or downscale energy cascades in stratifiedturbulence. The results obtained in these experiments are asfollows. When the dynamical forcing function has a peak at thehorizontal scale of 20 km, inverse energy cascading due to interactionsbetween horizontal vortices is too weak to explain the spectral slopein the mesoscales, even if the amplitude of the forcing function andthe stratification are strong. When the forcing is given at the domainsize (400--800 km), the $k^{-5/3}$ spectral slope are formed as theresult of downscale energy cascades only if the forcing amplitude issufficiently large. However, in this case the spectral amplitude isabout two order larger than that obtained by the observationalstudies. For the weak forcing, the spectral slope tends to be steeperand this result is not improved by the smaller eddy viscosity. We also examine the Smagorinsky-Lilly parameterization and the 1.5order TKE parameterization, which are well known as subgrid-scaleturbulent parameterization. In both parameterizations, the kineticenergy at the grid scale is not sufficiently removed because of tooweak eddy viscosity at this scale, while the energy spectrum in thescales larger than 20--30 km is close to that of the observations. Wewill also discuss details of energy cascade processes and bettersubgrid-scale parameterization.

JSP10/11A/B21-004   0940
DYNAMICS OF THE SELF-SIMILAR SPECTRAL EVOLUTION OF QUASI-GEOSTROPHIC TURBULENCE ON AN F-PLANE AFFECTED BY HORIZONTAL DIVERGENCE

Akira MASUDA (Dynamics Simulation Research Center, Research Institue for Applied Mechanics, Kyushu University)

An investigation is made on the self-similar spectral evolution of quasi-geotrophic (QG) turbulence on an f-plane affected by horizontal divergence, which is proportional to the squared inverse of the radius of deformation. To purify the effect of horizontal divergence we adopt the Charney-Hasegawa-Mima equation as the governing equation. First, freely decaying turbulence is examined as a first step. In case of vanishing horizontal divergence, Batchelor provided a well-known theory for self-similar spectral evolution of two-dimensional turbulence. One more parameter of horizontal divergence invalidates such a purely dimensional argument as by Batchelor. A similarity form is proposed here including the effect of horizontal divergence. The formula is reduced to that of Batchelor when there is no horizontal divergence. On the other hand it turns out to agree with the spectral evolution discussed later for strong horizontal divergence. Next, spectral forms in inertial ranges are studied based on the balance of terms in the vorticity equation. In this argument the power of the stream function or kinetic energy is preferred to that of total energy. In reality the kinetic energy spectrum in the inertial subrange is shown to be the same irrespective of the strength of horizontal divergence: $k^{-5/3}$ for energy cascade and k^{-3} for enstrophy cascade with k being the wavenumber, just as in the ordinary two-dimensional turbulence without horizontal divergence. Finally self-similar spectral evolution is discussed in terms of the ordinary differential equations (ODEs) for the three variables of peak wavenumber, total energy and total enstrophy. The dynamics based on the ODEs gives quite a comprehensive and systematic explanation to the self-similar evolution of QG turbulence on an f-plane with and without horizontal divergence in various situations including the classical case of Batchelor. The method can be applied to both freely decaying and forced turbulence, which may suffer finite dissipation near the truncation wavenumber in numerical experiment. In order to examine the validity of the argument a numerical experiment was carried out, where the kinetic energy (not total energy) was kept constant by a rather artificial numerical adjustment for the case of strong horizontal divergence. Numerical experiment showed a good agreement with the prediction based on the dynamics that the spectral peak scale increases as a third power of time.

NUMERICAL STUDY OF STRUCTURES AND SPECTRA FOR STABLY STRATIFIED TURBULENCE

Yoshi KIMURA[1], Jackson R. HERRING[2] ([1]Graduate School of Mathematics, Nagoya University, [2]National Center for Atmospheric Research)

The structural and statistical aspects of stably stratified turbulence is studied by way of Direct Numerical Simulations (DNS) of the Navier-Stokes equations under the Boussinesq approximation. It is well-known that the structures generic to homogeneous isotropic turbulence are ˝vortex tubes˝ while ˝vortex pancakes˝ which are randomly scattered throughout the flow, are often observed for stably stratified turbulence. An issue here is whether vortex tubes are somehow part of the stably stratified flow or not. This problem is concerned with the universality of the production mechanism of small-scales in turbulence which is an essential assumption of most Large Eddy Simulations (LES) in meteorology. We shall report the results of DNS with 512^3 grid points for both decaying and randomly forced stratified turbulence. For the decaying case, it is observed that stratified turbulence leads to a near self-similar decay. It is also noticed that the decay rate of energy in large scales differ from the unstratified turbulence. For the forced case, two issues which are related with the aspect of energy transfer for stratified turbulence will be discussed; (1) a spectrum close to k^{-2}, steeper than $k^{-5/3}$ for homogeneous isotropic turbulence, is observed, and (2) large scale horizontal layers are formed rather suddenly at a later stage of the flow development.

UNBOUNDED ROTATING FLOWS WITH AND WITHOUT STABLE STRATIFICATION

Claude J. CAMBON (LMFA, Ecole Centrale de Lyon)

A statistically homogeneous three-dimensional (3D) turbulent flowis considered in a rotating frame and possibly in a stably stratified medium. Both angular velocity and mean density gradient are in thevertical direction, with constant system vorticity and Brumt Waisalafrequency. In addition to various DNS inperiodic boxes, a recent experimental study (Praud andFincham) has been performed in a very large rotating tank, giving access to much larger Reynolds numbers. The structure of isotropic turbulence is deeply altered by dominantrotation, with emergence of columnar structures (`cigar´ type), and with polarized sheets (`pancake´ type) if stratification is dominant . The mechanisms responsible for this structuring arebriefly reviewed here, and statistical theory/modelling is used, ranging fromwave-turbulence theory to EDQNM (Eddy Damped Quasi Normal Markovian).In the presence of rapid rotation, without stratification, the flowconsists of superimposed inertial

waves, which are weakly coupledthrough nonlinearity. Wave-turbulence theory is really relevant toexplore a transition from 3D to 2D structure with the Rossby numberbeing the small control parameter. By contrast, the well-known Proudmantheorem only says that the slow motion is the 2D one, butcannot explain the `nonlinear´ 3D to 2D transition. Using the slow amplitudes of the eigenmodes of thelinear operator as new dependent variables, an EDQNM technique is shownto be equivalent to an Eulerian wave-turbulence theory, at least in the limit of vanishingeddy damping. The energy transfer in Fourier space reduces to surfacic integrals along the surfaces of resonant triads.The spectral density ofkinetic energy appears to be governed by a strongly anisotropic energy flux,with evolution (in term of a `slow´ time) tending to concentrate thisenergy towards horizontal wavevectors. A complete two-dimensionalisation,however, cannot be achieved, but the trend is quantified in a reliableway. In the presence of stable stratification, things are different. The wave-turbulence theory is not valid ingeneral, since the eigenmodes decomposition includes a non-wavy mode:this is the part of the toroidal velocity field which correspondsto the quasi-geostrophic mode in geophysics. Except for pure poloidal turbulence,nonlinearity does not vanish with the Froude number, and resonant inertia-gravity waves are only marginally involved. Without rotation, the initially 3D flow is shown to evolve towards the slow mode (zero frequency) of gravity waves, but this slow mode (Fourier mode related to verticalwave-vector) has nothing to do with the 2D mode, and may be consideredas 1D instead. If the flow is initially quasi-2D or forcedin a quasi-2D manner, a good candidate for explaining a partial transition2D-1D is the zig-zag instability, evidenced at length by Billand andChomaz. An alternative scenario for the transition 3D-1D is proposedhere, based on consistent EDQNM/DNS results, with no fororganized vertical vortices in the initial data.

ON INSTABILITIES AND TURBULENCE IN STRONGLY STRATIFIED FLOWS

James J. RILEY[1], Kraig B. WINTERS[2], Stephen M. DEBRUYNKOPS[3] ([1]University of Washington, [2]Scripps Institute of Oceanography, [3]University of Massachusetts)

Recent laboratory experiments have suggested that turbulent mixing events in a stably-stratified fluid, unless provided with some external forcing mechanism, inevitably decay to a low Froude number regime in which the stratification effects dominate. For example, turbulent wakes evolve into remarkably stable, quasi-horizontal vortex patches of alternating sign in this regime. The Reynolds number in the low Froude number regime in the experiments is rather low, however, raising the question of whether the results scale up to geophysical scales. In this presentation we will report on high resolution direct numerical simulations and analytical scaling arguments which have been used to understand the dynamics of turbulence in the low Froude number regime, and to estimate the Reynolds number above which laboratory experiments must be conducted in order for the results to scale up to geophysical scales. It is found that the simulated quasi-horizontal flows evolve to a state with high vertical shearing of the horizontal velocity, leading to locally low Richardson numbers and susceptibility to shear instabilities. This occurs even though the nominal Richardson number is greater than order one. Kelvin-Helmholtz instabilities were observed to be one pathway to turbulence in the simulated flows. It is estimated that instabilities and turbulence in these flows will occur if the product of the local Reynolds number times the local Froude number squared is greater than order 1, where the local Reynolds and Froude numbers are based upon the horizontal motions.

A SPECTRAL MODEL FOR PROCESS STUDIES OF DENSITY-STRATIFIED, ROTATING FLOWS

Kraig B. WINTERS, Jen A. MACKINNON, Bren MILLS (Scripps Institution of Oceanography, University of California, San Diego)

The features and use of a spectrally based numerical model designed to provide approximate solutions to the Navier-Stokes equations for density-stratified fluids in a rotating reference frame will be presented. The code is freely available and is intended for use as a tool for process oriented simulations of stratified fluid flow, in particular for nonlinear interactions between internal gravity waves and transitional processes and instabilities resulting in disordered, three-dimensional motions. For our purposes here, we refer to this latter class of flows as turbulent. The algorithm is designed to be run on distributed memory multiprocessor computers using a data-parallel programming paradigm. Within the practical limits of memory and speed on the various platforms, the model can be run on machines ranging from Macintosh laptop computers, to workstation clusters, to large-scale community resources such as the Cray T3E. The code itself is portable and easy to configure for real problems via simple user-defined functions for initial conditions and time dependent forcing. Sub-models include a spectrally based Lagrangian particle tracker and auxilliary passive tracers. In this talk I will present some of the numerical techniques underlying the model, show results illustrating the types of problems that can be addressed using the model and demonstrate the ease of configuration for a study of stability of quasi-horizontal vortex motions.

WAKES IN STRATIFIED FLUIDS: PROGRESS DURING THE LAST TWENTY YEARS

Alan BRANDT (Johns Hopkins University Applied Physics Laboratory)

Oceanic turbulent wakes can arise in the lee of seamounts and other topographic discontinuities, at the shelf-break, and from the motion of ships, submarines and mobile ocean creatures, the latter ranging in size from plankton to whales. As such, stratified wakes can contribute to ocean mixing affecting local stratification, the distribution of nutrients, dissolved oxygen, and CO_2, thus affecting bio-feeding patterns, primary productivity, and global ocean balances.Wakes in stratified fluids embody many of the fundamental processes inherent to stratified flow dynamics that are of interest to this symposium, including: stratified mixing and collapse, internal wave generation, and the appearance of coherent, late-wake vertical vorticity. While all of these fundamental processes were known over twenty years ago, the review by Lin and Pao (Ann. Rev. Fluid Mech. 1979, 11: 317-38), focused on wake turbulence and collapse, giving only passing reference to late-wake eddies. The presence of the wake-generated internal wavefield was not mentioned. Since that time, laboratory and numerical studies have considerably furthered our understanding of these processes.The processes governing the evolution of stratified wakes have been found to be a function of the evolution time scale, which is related to the inherent period of oscillation of the ambient water column, the Brunt-Väsälä frequency. At early times the wake does not 'feel' the stratification and thus the wake behaves as though stratification were not present. At intermediate times there exists a 'non-equilibrium regime' where the wake collapses and potential energy is converted into kinetic energy. At late times the stratification causes a cessation of vertical motion and a quasi-two dimensional, horizontal motion persists. While wake turbulence results from the turbulent boundary layer on the body, the sources of the internal wavefield are more diverse. Internal waves are generated by displacement of the ambient fluid by the body itself, the overall collapse of the wake, and small-scale turbulent fluctuations within the wake. This review will discuss the processes extant in each of these wake flow regimes,

covering advances during the past twenty years, including some recent, hitherto unpublished findings. Recent results include studies on the coupling of the wake flows to the internal wave field at low Froude numbers, where this coupling is quite substantial, and on the nature of the three-dimensional density distributions in the early wake, which pose the initial conditions that drive the intermediate and late wake dynamics (and provide appropriate initial conditions for numerical simulations). Outstanding issues regarding our understanding of the evolution of stratified wakes will also be discussed.

JSP10/11A/B21-010   1210
CYCLONE-ANTICYCLONE ASYMMETRY OF GEOPHYSICAL VON KARMAN STREET

Alexandre STEGNER[1], Gaelle PERRET[1], Marie FARGE[1], Thierry PICHON[2] ([1]LMD, IPSL Ecole Normale Superieure, Paris., [2]UME, ENSTA, Palaiseau, France.)

Unlike the classical bi-dimensional Von-Karman street, geophysical vortex street are affected by the earth rotation and the vertical stratification. We performed laboratory experiments and numerical simulations to study the specific dynamics of Von-Karman street in a rotating shallow-water layer from small (150) to intermediate (1000) Reynolds number. It is shown that ageostrophic effects (finite Rossby number) or large-scale effects (small Burger number) both induce an asymmetric vortex street. These effects occur in an oceanic context especially when the island size becomes larger than the local deformation radius. On one hand, ageostrophic effects lead to elliptical cyclones which could enhance the mixing in the near wake behind the island. On the other hand, large-scale effects, induce a long tail behind the obstacle where no vortices emerge. The vortex shedding occurs far away from the island, leading to an asymmetric vortex street with triangular cyclones.

VARIABILITY OF MIXING EFFICIENCY IN STRATIFIED SHEAR FLOWS

Colm-cille P. CAULFIELD[1], W.Richard PELTIER[2] ([1]Department of Mechanical and Aerospace Engineering, University of California, San Diego, [2]Department of Physics, University of Toronto)

Flows where both the velocity and density vary with height (i.e. stably stratified shear flows) are ubiquitous in nature. Of crucial interest to appropriate description of the redistribution of heat, momentum and chemical species within such flows is a detailed understanding both of the fundamental processes that trigger transition to turbulence and also the mixing characteristics of the ensuing turbulence. Significant progress towards addressing this problem has been made through the relatively recent advent of adequately resolved three-dimensional simulations. When combined with innovative theoretical, experimental, and observational results, a detailed picture is beginning to emerge of the qualitative and quantitative aspects of the time-dependent irreversible mixing associated with small-scale disordered motion within such flows. Of particular importance is the efficiency of the mixing, i.e. the proportion of the kinetic energy that is lost by the underlying shear flow that leads to irreversible increases in the potential energy of the system. In this talk, we will review the characteristics of mixing within a range of stratified shear flows. We will focus on two important aspects. Firstly, we will analyze the time-dependence of the mixing, drawing a clear distinction between mixing associated with the coherent instabilities that develop within the flow and the (more important) later mixing associated with small-scale disordered motion after flow transition. Secondly, we will discuss the dependence of mixing on the bulk flow parameters in the parameterization of stratified mixing events. As we demonstrate, controlling parameters include flow Reynolds number, bulk Richardson number, and the particular structure of the velocity and density profiles. Since we show evidence for the non-monotonic dependence of the mixing efficiency on overall stratification, it appears that the generic end-state for a stratified shear flow has a layered density profile, with relatively thin regions of strong density gradient separating deeper well-mixed layers with weak density gradient.

HIGH REYNOLDS NUMBER LABORATORYMOUNTAIN-WAVE BREAKING

Olivier EIFF, Frederic HUTEAU (IMFT / Mété o-France)

Mountain-wave breaking was studied in the large linear salt-stratified towing tank of Meteo-France with a Gaussian-shaped quasi-twodimensional obstacle, attaining Reynolds numbers of about 10^4. To investigate the large-scale dynamics and turbulencegenerated by the wave-breaking, simultaneous velocity measurements were performed in two orthogonal planes via digital particle imagevelocimetry. The results have been compared to previous laboratory and direct numerical simulations obtained at low Reynolds numbers(10^2) but otherwise similar conditions. The comparison reveals a dynamically similar development leading to wave-breaking for a flow started from rest. In particular, atwo-dimensional roll-up of the steeping wave is observed which is rapidly followed by a threee-dimensional Rayleigh Taylor-likeconvective instability. This instability results in large-scale ring-like vortical structures encompassing the wave-breaking zone, as has beenfound at low Reynolds numbers. Preliminary estimates of the turbulence statistics in the wave-breaking region have also been evaluated.

JSP10/11P/B21-003   1510
WAVE-VORTEX INTERACTIONS IN A ROTATING STRATIFIED FLUID AND TRANSPORT THROUGH A DYNAMICAL BARRIER

Frédéric Y. MOULIN[1], Jan-Bert FLOR[2] ([1]Dynamic Marine Meteorology, Department of Physical Oceanography, Ocean Research Institute, Tokyo University, JAPAN, [2]THEO team, Laboratory for Geophysical and Industrial Flows (L.E.G.I.-CNRS), BP 53, 38041 Grenoble Cedex 09, FRANCE)

Edges of vortices are examples of dynamical barriers, and prevent fluid captured inside the vortex from mixing with the ambient. The existence of a cross-barrier transport material is relevant to large-scale geophysical flows, in which vortices are redundantly present. Breaking internal waves at the vortex edge can enhance such a transport. We have experimentally investigated wave-vortex interactions in a rotating stratified fluid, and address questions about wave induced mixing in the vortex and possible wave-vortex energy transfer. We consider the interaction of planar waves with baroclinic vortices, continuously forced by a small towing disk, and with freely evolving barotropic vortices initially generated by an elongated sink. Only cyclonic vortices are considered. The wave pattern observed in the experiments is well captured by numerical simulations of ray tracing, based on WKB theory. Waves interacting with a baroclinic vortex are trapped along inclined critical layers, where their wavelength decreases towards zero due to vertical shear without triggering wave breaking. Trapped waves are wrapped around the vortex centre and lead in some cases to a spiral-like pattern in the velocity field. Waves propagating against a barotropic vortex are trapped along almost vertical critical layers, leading to wave breaking in case the viscous damping time-scale is long compared to the typical time-scale over which the wavelength

decreases. A critical Reynolds number for wave breaking is introduced, based on these two competing time-scales. In the experiments with barotropic vortices, the wave breaking is due to a local inversion of the density field, which drives a buoyancy induced instability, and leads eventually to a deposit of negative azimutal momentum in the outer part of the vortex. Meanwhile, mixing is driven by two distinct processes: vortex streamlines are perturbed by periodic waves leading to bands where chaotic mixing occurs on a large time scale; wave breaking leads to turbulent patches of which the impact depends on the amount of energy provided by the breaking waves.

A LABORATORY STUDY OF VORTEX-INDUCED MIXING IN THE FRONTAL REGION OF BUOYANT SURFACE PLUMES USING PARTICLE-TRACKING METHODS

Thomas A. MCCLIMANS[1], Walman HUTAHAEAN[2], Oivind A. ARNTSEN[3] ([1]SINTEF Fisheries and Aquaculture, Trondheim, Norway, [2](1) Indonesian Institute of Sciences, Research and Development Centre for Oceanology (LIPI-P3O), Ancol, Jakarta, Indonesia, [3](2) Norwegian University of Science and Technology, Department of Civil and Transport Engineering, Trondheim, Norway)

Examples of buoyant plumes entering a large basin include the Indonesian throughflow in the Banda Sea, rivers flowing into bays and fjords and fjord water flowing into a coastal current. Mixing between the inflowing and ambient waters occurs along fronts between the masses. Elsewhere, energy from wind and tides often dominate the mixing and homogenizing of water masses. In larger quiescent regions, double-diffusion can also be important. Near the fronts, both buoyancy and rotation govern the type of processes that contribute to diapycnal mixing. The processes include Kelvin-Helmholtz instabilities and frontal instabilities that form eddies and sometimes intense frontal tornadoes. These latter processes have been studied in the 5-m diameter Coriolis basin at SINTEF/NTNU in Trondheim. Inflow of buoyant water from a strait to a wide basin was simulated at a Froude number near 1 and Rossby numbers from 1 to infinity. Particle tracking methods used to measure the flow fields are photogrammetry to obtain three-dimensional Lagrangian trajectories and particle image velocimetry (PIV) to obtain horizontal divergence and vertical vorticity. This combination allows us to answer questions of the nature of the plume circulation and mixing processes. Internal wave motions in the plume are seen in the photogrammetry and frontal tornadoes penetrating in the lower layer are revealed by the PIV. The analysis of these results for computing the dependency of entrainment and mixing on vortices is attempted.

JSP10/11P/B21-005   1610
LATERAL STIRRING BY THE RELAXATION OFDIAPYCNAL MIXING EVENTS

Marie-Pascale G. LELONG[1], Miles A. SUNDERMEYER[2] ([1]NorthWest Research Associates, [2]School for Marine Science and Technology, University of Massachusetts Dartmouth)

Analysis of a series of tracer-release experiments conducted during the latesummer stratification over the New England continental shelf has shown thatthe observed isopycnal dispersion cannot be explained by existing models oflateral dispersion (Sundermeyer, 1998; Sundermeyer and Ledwell, 2001). Similardispersion behavior was also found during the North Atlantic Tracer ReleaseExperiment in the pycnocline of the open ocean (Sundermeyer and Price, 1998).Using a 3d numerical model (developed by K.Winters) for the Boussinesq equations coupled with an advection/diffusion equation for a passive tracer,we performed numerical simulations of lateral dispersion.The objective of our study was to test the conjecture that observedrates of lateral dispersion can be explained by the presence of vorticalmotions created through the relaxation of diapycnal mixing events. The rates of vertical and lateral dispersion and their dependence onambient stratification, and vertical and horizontal scales of diapycnal mixing events were investigated.Our results indicate that lateral dispersion caused by vortical modes is morethan an order of magnitude larger than predicted theoretically by Sundermeyerand Ledwell (2003), can readily account for the dispersion on scales of1-10km observed during the Coastal Mixing and Optics (CMO) experiment andmay be significant in other regions of the ocean as well.

INTERACTION OF INERTIA-GRAVITY WAVES WITH A BAROCLINIC SHEAR FLOW

Chantal STAQUET[1], Neil R. EDWARDS[2] ([1]LEGI, University of Grenoble, France, [2]Climate and Environmental Physics, University of Bern, Switzerland)

The interaction of inertia-gravity waves (which are internal gravity waves modified by rotation) with a horizontal mean flow in a stably stratified fluid has received much attention when the mean flow is vertically sheared ($U(z)$). When the mean flow is horizontally sheared ($U(y)$), thus modelling the edge of an atmospheric vortex or an oceanic current, the problem amounts to the interaction with a dynamical barrier. The interaction process is addressed here when the horizontal mean flow also displays a vertical dependence ($U(y,z)$). WKB theory has been used as a preliminary step to analyse the problem, for a simple flow configuration: an inertia-gravity packet confined along the y and z directions propagates into a horizontal shear layer with a vertical dependence. Linear and fully nonlinear direct numerical simulations of the three-dimensional Boussinesq equations have also been conducted. Results concerning the wave-mean flow interactions will be presented for this hierarchy of models, along with the resulting transport properties across the barrier, if any.

PERIODIC MOTIONS PRODUCED BY CIRCULAR DISC PERFORMING TORSION OSCILLATIONS AND SUPERPOSED UNIFORM ROTATION IN A CONTINUOUSLY STRATIFIED LIQUID

Yuli Dmitrievich CHASHECHKIN (Laboratory of Fluid Mechanics, Institute for Problems in Mechanics of the RAS)

Pattern of flow around a horizontal or sloping circular disc performing periodic torsion oscillations with or without superposed uniform rotation with a permanent angular velocity in exponentially stratified brine is visualised by a schlieren instrument. Parameters of internal waves are measured by a 'single electrode' conductivity probe. The probes are statically and dynamically calibrated before each experiment. A set of boundary layers forming on upper and lower sides of a horizontal disk performing harmonic oscillations is observed. Outer edges of boundary layers contact with two monotonically growing circular rotating rings. When direction of the disc rotation is changed the rings are displaced by the new growing pair of rings and are separated from the disc. Separated rings are collapsed symmetrically under the action of a buoyancy forces. They lost their symmetry and tend to go uniformly to the central plane of the source. Their lower parts arise and upper parts sink producing set of long-loving closed structures. Both horizontal and sloping discs performing pure torsion oscillations generate separate periodic internal waves propagating along the wave cone. The angle the wave cone depends on frequency of periodic torsion oscillations. Experiments are performed in a wide range of the problem parameters (buoyancy period, diameter and the

angle of the disc slope to horizontal, circular velocities of permanent and periodic components of rotation) corresponding to laminar, transient and non-regular regimes. The system consisting from the disc and surrounding disturbances generates regular internal waves even if the complex irregular fluid motion is observed near the disc. The frequency of waves is larger in two times exactly than the frequency of periodic torsion oscillations. With increasing of angular velocity of superposed permanent rotation the waves with the main frequency of the disc torsion oscillations become more pronounced. For interpretation of experiments the non-linear problem of internal wave generation by the periodic boundary layer on the oscillating horizontal disc is solved analytically. Received expressions describe dependence of the internal wave beams shapes, value of the waves amplitude and their spatial attenuation as a function of the buoyancy frequency, the fluid viscosity, size of the disc and parameters of its motion. In a wide range of parameters calculations are in a good agreement with experimental data without any fitting factor. Diverges between theory and experiment with a large value of angular velocity is presented and discussed. The data can be used for testing of analytical and numerical models of boundary layers, vortices and 3D internal waves including problems of their generation and non-linear interaction.

TAYLOR-COUETTE FLOW IN A TWO-FLUID SYSTEM: INSTABILITIES AND MIXING

Evgueni V. ERMANYUK[1], Jan-Bert FLOR[2], Beatrice JANIAUD[2] ([1]Lavrentyev Institute of Hydrodynamics, Novosibirsk, Russia, [2]Laboratoire des Ecoulements Geophysiques et Industrielles, Grenoble)

Mixing in a density stratified fluid plays important role in numerous geophysical and engineering applications, being responsible for the transport of heat, nutrients and pollutants in ocean and atmosphere, as well as in various technical devices. In many cases the fluid flow may have a large vorticity component aligned with the main direction of the flow (a natural example of such a flow in the Ocean is known as Langmuir circulation). This report presents the experimental results on entrainment, mixing and instabilities in a particular case of non-isotropic turbulent flow, namely, a stratified Taylor-Couette flow in a two-fluid system, with the upper layer of pure water and the lower layer of salt solution in water. The fluid flow is driven by the rotation of the inner cylinder, with the outer cylinder held fixed. As the rotation rate of the inner cylinder increases, the flow in the smooth pycnocline between the upper and lower fluid layers undergoes the transition from wave regime (with waves propagating in vertical direction from the middle of the pycnocline toward its upper and lower boundaries) to the regime of stratified Taylor vortices. This transition is accompanied by the abrupt increase of the characteristic frequency of the time-dependent flow parameters measured at fixed locations. Vortical motion leads to the formation of fine multy-layer structure (with multiple clearly visible interfaces) inside the pycnocline. Experiments on mixing in the two-fluid Taylor-Couette flow were focussed on the case of large Reynolds numbers. At sufficiently high velocity of rotation the erosion of the initial density profile is extremely effectlive, leading to formation of a single sharp interface between the fluid layers. The resulting two-fluid system is ultimately destroyed by entrainment of salt across the density interface at the time-scale of several hours. Since the initial (two-fluid system) and final (homogeneous fluid) stages of the mixing process are well-defined, it is possible to estimate the overall mixing efficiency characterized by the flux Richardson number. The estimated values of the flux Richardson number are quite low (of order 0.01). Experimental data suggests that in the studied range of parameters the flux Richardson number is proportional to the Reynolds number.

JSP10/11P/B21-009   1740
INTERNAL WAVE GENERATION FROM A TURBULENT LAYER

Kathleen B. DOHAN, Bruce R. SUTHERLAND (Department of Mathematical and Statistical Sciences, University of Alberta)

High turbulent dissipation rates are observed in the ocean interior over mid-ocean ridges and are most likely attributed to breaking internal waves generated by tidal flows over the topography. The turbulence created by the rubbing of tidal currents over the rough topography may be an additional internal wave source, and may contribute to the high dissipation rates. We report on laboratory experiments that examine the properties of the internal wave field excited from an overlying oscillating grid-generated turbulent region. In the first of two non-intrusive visualization methods, dye lines are used to mark the vertical motions of isopycnal layers. The dye lines highlight large tank-scale wave modes which are generated from a large-scale circulation that develops in the turbulent region. The amplitudes of the isopycnal lines, A, vary with buoyancy frequency, N, as $A \sim N^{-1.5}$. The second visualization method, ``synthetic schlieren,´´ measures the entire wave field and allows us to isolate the properties of the strongest eddy-scale waves that propagate from the base of the turbulent layer. These waves have a narrow range of frequencies and vertical wavenumbers. The angles of wave propagation from the vertical for the eddy-scale waves lie in the range Theta=42-55 degrees. These waves are of large amplitude with vertical displacements from 2%-4% of their horizontal wavelength and follow a relation $A \sim N^{-1.68}$. We discuss a continuation of this investigation into wave-turbulence interaction through numerical simulations.

GEOPHYSICAL HAZARD AND HUMAN VULNERABILITY

Tom BEER (CSIRO Environmental Risk Network)

Earthquakes, volcanic eruptions, landslides, floods, droughts, tsunamis, storm surges, wildfires, tropical cyclones, tornadoes and extreme space weather events become major societal risks when they impinge on vulnerable populations. The growth in world population, its urbanization, and the possibility of climate change and global climate change exacerbate the vulnerability. Three factors that influence vulnerability are examined. Connectivity, susceptibility and resilience. We examine the role of these three factors for episodic disasters, such as those listed above, as well as for chronic hazards, such as air

IA

pollution.The IUGG Commission on Geophysical Risk and Sustainability intends to establish a webcyclopedia of geophysical risks and hazards to document the population-hazard interaction.

JSP11/07A/A10-002   0930

DRASTIC; A SYSTEMATIC APPROACH FOR GROUNDWATER VULNEARLIBILITY MAPPING

Sanjeev KUMAR[1], Shakeel AHMED[1], Shikha RAJPUT[2] ([1]I.F.C.G.R.,NATIONAL GEOPHYSICAL RESEARCH INSTITUTE, [2]KURUKSHETRA UNIVERISTY,INDIA)

The aim of this paper is to present a study on DRASTIC groundwater pollutionvulnerability assessment. Aquifer vulnerability mapping is the acquisitionand accumulation of aquifer attribute spatial data, placing the spatial datainto a database, and using the database in a Geographic Information System (GIS)to show where an aquifer is at risk to pollution. *GIS* is the dynamic toolfor study hydrologic setting and various parameters, which influence the groundwater vulnerability i.e., drastic parameters. The study area is located inHaridwar district,Uttaranchal,India. **DRASTIC** is a methodology foridentifying vulnerability to groundwater pollution. It uses seven parameters,which are a combination of geologic, hydrologic, geomorphologic andmeteorological factors, to relate an aquifer to the sources of its water and theconstituents within that water. The parameters (Depth to water, annual Recharge,Aquifer media, Soil media, Topography, vadose zone Impact, and hydraulic Conductivity) are weighted according to their relative importance in determining the abilityof a pollutant to reach an aquifer. The parameters are used to produceDRASTIC index numbers from which maps are constructed. The relative rankingscheme uses a combination of weights and rating to produce a numeric valuecalled he DRASTIC index, which helps to prioritize areas with respect topollution potential. *GIS*, due to its capabilities in terms of management, analysis, and manipulation of spatial data can be efficiently be used forgeneration of vulnerability maps for the study area. The vulnerability mapof study area indicates that different parts of the area are susceptible to ground water pollution to different degrees i.e. highly susceptible and leastsusceptible. The pollution risk to the study area drinking water systemwill increase as a result of urban sprawl. Thus, it is prudent to protectthe drinking water system by determining aquifer pollution risk throughmapping aquifer vulnerability prior to urban sprawl. The Drastic rankingscheme can then be applied enlightened layman for valid comparative evaluationwith acceptable results.

NONLINEAR GROWTH OF CUMULATIVE LOSSES FROM DISASTERS IS COMPATIBLE WITH THE CONCEPTION OF SUSTAINABLE DEVELOPMENT OF SOCIETY

Mikhail V. RODKIN, Vladilen F. PISARENKO (Geophysical Centre of the Russian Academy of Sci.)

It was noticed that the numbers of victims from natural disasters (earthquakes, floods, hurricanes etc.) as well as losses from disasters have a tendency to a non-linear increase with time. This effect is commonly related to the rate of population growth, to spreading of potentially dangerous technologies and to environment degradation. Thus, the process is assumed to be non-stationary which evidently interferes with the idea of the sustainable development of society. However, the alternative model of this effect can be suggested. We have shown that the non-linear growth of cumulative losses from earthquakes and floods is connected with the ˝heavy tail˝ in the loss distribution rather than with a change in distribution or occurrence rate of disasters, the latter being of minor importance. This effect occurs in the cases when distribution function F(x) of losses has a ˝heavy tail˝. In such cases it can be described satisfactorily by the Pareto distribution: $F(x)=1-(a/x)b$, where $b\ge 1$. This distribution law is often used for modelling both natural and man-made disaster data. For the Pareto law the cumulative sum of losses increases with time as ta, where $a=1/b > 1$. In this case, the process is fully stationary, and the tendency to the non-linear growth is caused by an increase of probability of realisation of a huge disaster with time. The regime of non-linear increase of losses should saturate at some time moment because of practical limitation of possible loss size. Methods of evaluation of saturation parameters are presented and obtained results are discussed in connection with the social and economic situation in different regions. Besides, it was shown that after proper normalisation by size of the population and by per capita income the losses have a tendency to decrease with the level of social and economic development. Thus, in contrast with the wide-spread opinion, the regime of losses from natural disasters is compatible with conception of the sustainable development of society, moreover, it can be considered as an example of realisation of this conception.

IMPACT OF TRAFFIC ON THE AIR QUALITY OF THE CITY OF BANGKOK AND ITS APPLICATION TO CLIMATE CHANGE IMPACT ASSESSMENT IN THAILAND

Suwannee ADSAVAKULCHAI (King Mongkut's University of Technology Thonburi)

The main atmospheric pollutants in Bangkok are total suspended particles (TSP), particle matter smaller than 10 microns (PM-10), carbon monoxide (CO), ground-level ozone (O3), nitrogen oxides (NOx) and sulphur oxides (SOx)-which contribute as greenhouse gases to global warming. Air pollution in Bangkok results from a combination of transport (diesel fuel) and industrial sources. SO2 Originates primarily from industrial processes. NOx and CO originate primarily from vehicles. TSP pollution is caused in large part by street dust blown from unpaved roads, open lands and eroded hillsides surrounding the city. Diesel buses and industrial sources also contribute significantly to PM-10 emissions. Conventional urban air pollutants are considered the most important problem. In addition, there is atmospheric pollution with toxic substances, such as hydrocarbons. This study contains the application of simple method for estimation of urban background pollution and the Street Pollution. Furthermore, a GIS-based is a model for automatic mapping of street pollution levels in an entire urban area. This method of city mapping is a powerful tool to investigate possible effects of street configuration on pollution concentrations in a city.

CERES-WHEAT MODEL APPLICATION UNDER CLIMATE CHANGE CONDITIONS OVER I. R. OF IRAN

Sohaila JAVANMARD, Ali KIANI, Javad BODAGHJAMALI (Climatological Research Institute (CRI), I. R. of Iran Meteorology Organization (IRIMO), P. O. Box 91735-491, Mashhad, Iran)

About 64 percent of the warming effect due to greenhouse gas increase during the last 200 years, is caused bay carbon dioxide. The global climate changr will affect all economic sectors to some degree, but the agricultural sector is perhaps the most sensitive and vulnerable. The impact of climate variabilityon agricultural production is important at local and regional, as well as global scales. In this research, the CERES-Wheat v.3.5 model after calibrationwas used to determine the vulnerability of current agricultural management in Mashhad city climatic conditions. In order to prediction of climate change due to doubling carbon dioxide concenteration on two wheat cultivars, Alamout and Alvand, NASA-GIS model was used.The results of the modeling showed that grain yield are increased by 7.5 and 11.7 percent, respectively for Alamout and Alvand cultivars.

GEOMAGNETIC HAZARD RESEARCH IN CANADA

Lawrence Richard NEWITT, Larisa TRICHTCHENKO, David H. BOTELER (Natural Resources Canada, Geomagnetic Laboratory)

Features of the Earth's natural electromagnetic environment have many practical applications, from navigation to HF radio communication. However, the same electromagnetic environment can also have negative consequences. Activities in near-Earth space, such as satellite broadcasting, Earth observation, GPS , and the International Space Station are vulnerable to sudden changes in the geomagnetic field and in the radiation environment caused by space weather events. Building long conducting networks such as power lines, pipelines, or telephone cables on the surface of the Earth changes the electromagnetic environment . Because of significant inductive coupling to the geomagnetic field, these networks became vulnerable to variations of magnetic field such as those that occur during geomagnetic storms. In extreme cases the disruptions in distribution of the electric energy, communications or unexpected degrading of the pipeline can lead to conditions hazardous to people. Effects on these systems are greater at higher latitudes where geomagnetic disturbances are especially severe. Canada, which is bisected by the auroral zone, is particularly vulnerable, which prompted Natural Resources Canada to begin research on geomagnetic hazards more than 25 years ago. Research has been directed into three areas: forecasting of geomagnetic activity; determining the geomagnetic climate in different regions of the country; and mitigating the effects of geomagnetic activity on power lines and pipelines by understanding the underlying physical processes.

DEGRADATION OF QUIET MAGNETIC ACTIVITY AND ITS IMPACT ON HUMAN CONDUCTIVITY

Tamara GULYAEVA (Institute of Terrestrial Magnetism, Ionosphere and Radio Wave Propagation)

Studies of the long-term trend of the geomagnetic aa-indices has revealed that occurrence probability of quiet magnetic conditions (aa $<$ 7 nT) has been gradually reduced during the 20th century from 50% to 10%. Similar trend of local magnetic k indices at Moscow during 2002 at the declining phase of the 23d solar cycle has been compared with electroacupunctural (EAP) measurements of human electrical conductivity carried out at Institute of Terrestrial Magnetism, Ionosphere and Radio Wave Propagation (IZMIRAN) since 1998 (http://helios.izmiran.rssi.ru/helioecology/index.html). Method of electroacupunctural diagnostics of health condition by R.Voll is used (M.V.Ragoulskaya, V.V.Lyubimov, Investigation of natural magnetic fields´ influence on human biological active points: methods, equipment, results. El. J.of Biomedical Electronics, Nov. 2000). Accumulation of k-index for 27 days (corresponding to rotation of the Sun) preceding day of EAP measurements is used for estimate the percentage occurrence probability of k-index (k $<$2 for quiet magnetic conditions and k $>$2 for disturbed magnetic conditions). It is shown that average daily human conductivity EAP index has been gradually reduced during 2002 correlated with the same trend of occurrence of quiet local k-index at Moscow and several other local and planetary estimated k indices. Our EAP results confirm that human conductivity is sensitive to reduced quiet (grown disturbed) magnetic activity. Technological developments may be required for human adapting to reduced quietness of magnetic field.

DIURNAL DYNAMICS OF RATS RESISTANCE TO HYPOXIA DURING VARIOUS GEOMAGNETIC ACTIVITY

Youry P. SIZOV[1], Maryam L. KHACHATURYAN[2], Mikhail M. TEJBLUM[3] ([1]Geoelectromagnetic Research Institute of RAS, [2]Russian State medical university, [3]Institute of rentgenoradiology)

The objective was to find the influence of geomagnetic activity (GMA) on diurnal dynamics of rats resistance to acute hypoxia. METHODS. The resistance to acute hypoxia of rats male Wistar (mass 150-180 g)was estimated by life time (LT) in sec after "rise" to "altitude" 11.5 km above sea level in different seasons of the year. The C=0,34 and C=0,66 quantiles of LT values distribution served as boundaries for LT of low (LR), middle (MR), high resistant to hypoxia rats (HR). The GMA for an hours of LT determination was assessed by K-indices : less than 3 – quiet (QGMA), from 3 to 5 – disturbed (DGMA). Time rows of LT values were studied by spectral analysis and cosinor-analysis. Nonparametric methods of statistics were used too: analysis of variance, correlation analysis, Dunn's method and X2. RESULTSLTS. diurnal dynamics was determined by circadian and ultradian rhythms. The influence of GMA and day time on LT was found (p $<$0,05-0,01), GMA alteration being accompanied by LT rhythms alteration. The basic rhythms during QGMA were chiefly circadian rhythms, more rarely ultradian ones. The part of ultradian rhythms increased (2.5 times), the part of circadian rhythms decreased (3.5 times) among LT basic rhythms during DGMA in winter and spring, the rats rhythms periods (except those of HR and MR in spring) being shorter than those during QGMA (1.2-4.0 times). About 70 % of the number of the circadian and ultradian LT rhythms revealed during QGMA changed during DGMA for the year as a whole. At different day periods of all seasons of the year LT decreased 2-3 times more often than increased. LT altered almost 2 times more often in the middle and at the end of the day than at its beginning. Stages of LT alteration were found as GMA disturbed during a day and a year and as well as after passing different time after its disturbance. CONCLUSION. GMA disturbance is accompanied by alteration of circadian and ultradian LT rhythms number and their parameters, that stipulated increase of fluctuating LT alterations during a day. During GMA disturbance life time of low Resistant more often decreases particularly in autumn.

SUSTAINABILITY OF WATER RESOURCES IN A COASTAL CITY IN A CHANGING ENVIRONMENT

Shadanan K. NAIR (Department of Physical Oceanography, Cochin University of Science & Technology)

Rapid urbanization is a complicated issue in many parts of the World, the effect more felt in developing counties with poor economies. Providing basic necessities, essentially safe water has become a difficult task. Coastal cities face additional problems like the saltwater

intrusion and pollution that deteriorates the water resources. The metropolitan city of Kochi situated in the southwest coast of India is a good example for this. It lies just one metre above mean level of the adjoining Arabian Sea. Western part of the city is separated from the mainland by the backwater lying within few kilometres and almost parallel to the Seashore. Monsoons and thunderstorms produce more than 300cm of annual rainfall. But, proximity to the backwater and sea, and pollution from industrial and domestic sources makes the surface and groundwater not usable, especially in the western parts of the city. Water has to be brought from the river from the point several kilometres upstream. Improper public water supply system and unexpected power failure always affect availability of water. Though the city has so many inter connected canals, high intensity of rainfall and unscientific design of sewage system block the water, resulting flooding and blocking the roads. Deposition of mud in the canals and careless disposal of solid wastes worsen the situation. Earth filling of paddy fields, ponds and wetlands has also affected the freshwater availability and wastewater outflow. Water-borne deceases have become a common hygienic issue. Increasing migration and worsening environmental conditions pose a serious threat to the life in the city. Present population density of the city is 6250/km2 with a decadal growth rate of 10.3%, excluding migratiuon. In this study, a comprehensive investigation on the problems related to water in Kochi – its availability, effect of environmental degradation, water logging and flooding – have been made. Extremes of weather and water conditions here during the last 100 years have been computed to provide guidelines for the overall development of the city.

JSP11/07P/A10-002   1430

GENPATSU-SHINSAI: CATASTROPHIC MULTIPLE DISASTER OF EARTHQUAKE AND QUAKE-INDUCED NUCLEAR ACCIDENT ANTICIPATED IN THE JAPANESE ISLANDS

Katsuhiko ISHIBASHI (Department of Earth and Planetary Sciences, Kobe University)

The most serious factor of civilized infrastructure that has maximized vulnerability to earthquakes in Japan is a cluster of nuclear power plants distributed all along the coastlines of the world's most earthquake-prone archipelago. At present, 16 commercial nuclear power stations with 52 large-scale reactors are being operated in tiny and densely-populated islands. The most dangerous nuclear power station is Hama'oka located just above the hypothesized huge fault plane of the impending M8-class Tokai earthquake on the Pacific coast of central Japan. If this earthquake, a nationwide concern and the subject of a special countermeasures act, happens, the seismic disaster will definitely be devastating in a broad area between Tokyo and Nagoya with officially estimated collapsed buildings of more than 200 thousands and huge tsunami. If this earthquake causes a severe accident to the Hama'oka station with massive leakage of radioactivities outside, then the rescue and restoration works in the earthquake disaster area becomes impossible, and at the same time, management of the nuclear accident and evacuation of inhabitants from radioactivity are extremely difficult due to the earthquake damages. Therefore, the nuclear accident would be left to expand to the maximum scale and victims of radiation exposure and ordinary earthquake disaster would become numerous. Even a few tens of million inhabitants around Tokyo, nearly 200 km away from Hama'oka, would be forced to evacuate. I call this disaster of earthquake-nuclear complex as ˝Genpatsu (nuclear power plant)-Shinsai (earthquake disaster),˝ which is a totally new type of natural-manmade disaster that the human beings have never encountered. Its final effect will be global as well as a fatal blow to Japan, and affect deeply future generations. The authorities concerned claim that the aseismic measures of Japanese nuclear power plants are perfect and all plants and related atomic facilities are safe against any kind of earthquake. But, construction of nuclear power plants in Japan was started around the early 1960's, just on the eve of the birth and spread of two basic theory of modern earthquake science, fault model of earthquakes and plate tectonics. Therefore, the official standards of aseismic design of nuclear facilities are oldish and insufficient in view of modern earthquake sciences. Not only Hama'oka but also most other nuclear power stations in Japan seem accident-prone due to large earthquake, because many are located in seismic gaps with clear active faults or just above subducted oceanic plate where large slab earthquakes may occur. These kinds of scientific matters were not taken into account during planning and construction of plants. In order to avoid Genpatsu-shinsai we should first face this problem squarely and assess its risk as objectively as possible. I think this serious vulnerability of modern society is not restricted in Japan but should also be a global concern.

JSP11/07P/A10-003   1500

THE FINAL STAGE OF PLATE DETACHMENT - THE CARPATHIAN MODEL

Victor I. MOCANU (University of Bucharest)

The Carpathian area is a key zone for understanding the post-collisional fate of subducted lithosphere which can only be observed and monitored on a very few spots on the Earth. The slab detachment (?) and the following sinking of the detached lithosphere slab into the deeper mantle is strictly restricted to a few million years. The detachment process itself is rarely observable and not really understood. It is not clear whether the detachment takes place in form of brittle failure suddenly removing the slab or whether visco-elastic processes play a relevant role, so that the detachment is not a real ˝break˝, but more likely a long-winded elongation and thinning of parts of the subducted lithosphere. The Vrancea region in the SE-Carpathians (Romania) is one of the regions where to study this geodynamic process. There, a nearly vertical hanging slab segment is probably breaking nowadays. Seismicity beneath Vrancea is characterized by the occurrence of intermediate depth earthquakes in very epicentral and hypocentral regions, with occurrence times of 10 years for Mw >6.5 and 50 years for Mw >7.4. A very complex approach is clearly necessary in order to shade light on the processes associated with this very active area. Seismic investigations of the Carpathian Orogen area form one component of a few multidisciplinary initiatives. The main objectives are: (1) the architecture of the Tertiary/Quaternary; (2) the presence and geometry of structural detachments; (3) the relationship between crustal structures related to basin evolution, especially neotectonic structures, with deeper (mantle) structure and seismicity; and (4) integration with complementary studies I the Carpathian region, the evaluation and validation of competing geodynamic models. A complex tomography experiment from 1999 shows a good resolution down to 350 km depth. As a preliminary result, the high velocity body extends between 70 km and more than 350 km, deeper than the deepest event (220 km). The 350 km are key for ocean closure reconstruction as it represents the entire lithosphere subducted in the area of SE-Carpathians. The earthquake hypocenters are concentrated at the eastern outer part of the high velocity body. The subduction of a foreland slab is associated to surface deformation as indicated by the crustal seismicity and by leveling comparison data. Repeated GPS measurements gives two basic kinds of information: the precise location of the present deformation, and the direction of velocities of block movements. The precise location of deformations has important implications for determination/confirmation of the main risked areas and therefore on the future development of the area. The measurement of the present-day deformationcan permit to propose an estimation of the locked surface and then an estimation of the importance of the next crustal earthquake. In particular, we try to answer if the subducted slab has detached from the foreland plate or not. We also have information on the origin of the convergence (eastern or western plate) and about the (de)coupling of the Carpathians with the foreland plate.

POPULATION DYNAMICS AND RISK VULNERABILITY IN INDIA

Ramesh P. SINGH, Anup K. PRASAD, Nilima BHOI (Indian Institute of Technology, Kanpur, India)

Population of India is presently more than one billion and it is expected that it will increase by 60 per cent by 2050. The Indian regions suffer with numerous natural hazards (earthquake, cyclone, floods, landslides, forest fire, subsidence, droughts, lightning, cloud bursts) from which loss of lives and properties occurfrom time to time. A review of various types of natural hazards in India will be presented. Efforts have been made to carry out GIS modelling to study the vulnerability of the Indian region based on the various types of hazards and their interactions with the Indian population. The present analysis show that the northern part of Indian region is one of the risk prone Indian regions.

JSP11/07P/A10-005   1620

SEISMIC MICROZONATION OF DELHI, INDIA: AN APPROACH USING SITE SPECIFIC RESPONSE

KAMAL .., Sriram. V., Mundepi A. K. (Wadia Institute of Himalayan Geology, Dehradun, INDIA)

Seismic microzonation of mega cities in India is the need of the hour in wake ofincreasing seismicity in the region. In last decade, India has seen many damaging earthquakes. The capital city, New Delhi and its surroundings are one of the most densely populated regions of the world. It is also located in one of the most seismically active area on the globe. This combination makes the city of New Delhi, India as the most seismically vulnerable place. A systematic survey using short period velocity transducers was carried out in the city, in order to designate areas of vulnerability during a future earthquake in Himalaya. Half of the city is located on the alluvial planes of the river Yamuna, which is susceptible to produce large accelerations during a mega event in Himalaya, thus exposing a large population to the damage. A brief account of the results obtained during the survey is presented. An attempt to delineate zones of vulnerablity is also made in the paper.

JSP11/07P/A10-006   1640

AN INTEGRATED FRAMEWORK FOR EARTHQUAKE DAMAGE ASSESSMENT OF REINFORCED CONCRETE BUILDING

Zengoing WEN, Hongshan LU (Institute of Geophysics, China Seismological Bureau)

Structural damage during recent earthquakes, such as Northridge, USA; Kobe, Japan; Taiwan, China demonstrates that it is necessary to develop a comprehensive model to estimate building damage as a kernel part of a seismic risk management system. Local site effects have enormous influence on the intensity and character of earthquake motion. The amplitude and frequency content of the ground motions from on earthquake can be greatly affected by properties and configuration of the near surface materials via mechanisms such as selective filtering (including resonance), damping and focusing. Building damage in earthquakes is frequently a direct result of the local site geological conditions affecting the incident ground motion. Consequently, any attempt of seismic damage assessment should take into account the local site conditions. This study is devoted to establish the procedure for seismic damage assessment of reinforced concrete building in seismic regions, which is integrated seismic environment and site condition into the framework of seismic response analysis and earthquake damage assessment. The model developed for earthquake damage assessment has four stages: i) probabilistic seismic hazard assessment at rock site, ii) site response analysis, iii) the seismic response estimation for reinforced concrete building, and iv) structural damage assessment. In this paper, a 24-story shear wall-structure in Beijing is selected as an example to demonstrate the procedure. The multi-degree-of-freedom lump mass systems are used to represent a high-rise reinforced concrete building. The one-dimension site response models using the equivalent linear analysis method for site seismic response analysis and the equivalent lateral force method for structure seismic analysis are incorporated to investigate the site effects on seismic response of building and building damage distribution among various damage states. By comparing the damage distribution under the acceleration response spectra with 63%, 10% and 2% probability of exceedance in 50 years at rock site and specific site, it can observed that the site effect is very important and seismic environment and site condition should be considered at same time.

JSP11/07P/A10-007   1700

NEW APPROACH TO PARAMETERIZATION OF THE DISTRIBUTION OF STRONG EARTHQUAKES: EVALUATION OF THE CROSSOVER POINT AND ITS CONNECTION WITH TECTONIC CHARACTERISTICS

Mikhail V. RODKIN, Vladilen F. PISARENKO (Geophysical Centre of the Russian Academy of Sci.)

Main losses from the earthquakes are caused by rare major events. Thus, the problem of risk assessment is connected essentially with the evaluation of probability of rare strong events. It was shown that for some seismic regions with a larger number of strong events (as well as for global catalogue too) the distribution law of major earthquakes differs from that of typical events. An important characteristic of distribution of moderate and major events is so-called crossover point, determining the passage of distribution tail to a more rapid decreasing rate. Several approaches to the evaluation of the crossover point are discussed and compared. First method is based on the use of the so-called Generalized Pareto Distribution (GPD) describing the limiting Peak Over Threshold (POT) distribution. The second approach is based on the Maximum Likelihood Estimation of the crossover parameter for a particular parametric model of distribution function possessing necessary smoothness. The third approach is connected with the change of the regime of growth of cumulative effects from the non-linear law typical of the moderate earthquakes to the linear one typical of major disasters. The statistical uncertainty of suggested estimates of the crossover parameter is derived. The obtained values of the crossover point and the tendencies in their change are discussed. It is shown that the crossover values depend on the tectonic characteristics in particular region. The revealed correlation of the tectonic parameters (velocity of subduction, plate age, etc) with the seismic regime is discussed in connection with the hypothesis of universality of the seismic moment-frequency law. The obtained results give possibility to characterize the specific character of distribution of major earthquakes in more details. Using this result the new method of parameterisation of the distribution of strong events was suggested. This method of parameterisation can be used in the seismic zoning problem.

GLOBAL HAZARD MAPS BASED ON UNIFIED SCALING LAW FOR EARTHQUAKES

Anastassia K. NEKRASOVA, Vladimir G. KOSSOBOKOV (IIEPT&MG, Russian Acad. Sci.)

The evident heterogeneity of patterns of seismic distribution and dynamics are apparently scalable according to the generalized Gutenberg-Richter recurrence law that accounts for the fractal nature of faulting. The results of our global and regional analyses imply that (i) the recurrence of earthquakes in a seismic region, for a wide range of magnitudes and sizes, can be characterized with the following law: Log N(M,L) = A - B (M - 5) + C Log L, where N(M,L) is the expected annual number of earthquakes of magnitude M within an area of liner size L (recently Bak et al. (2002) came independently to a reformulation of essentially the same ˝Unified Scaling Law for earthquakes˝); (ii) for a wide range of seismic activity, A, the balance between magnitude ranges, B, varies from 0.6 to 1.4, while the fractal dimension, C, changes from under 1 to 1.6; (iii) an estimate of earthquake recurrence rate depends on the size of the territory that is used for averaging and may differ dramatically when rescaled in traditional way to the area of interest. The confirmed multiplicative scaling of earthquakes changes the traditional view on the recurrence of earthquakes, the catastrophic ones in particular, and has serious implications for estimation of seismic hazard, for the Global Seismic Risk Assessment, as well as for earthquake prediction. We demonstrate the Global Seismic Hazard maps that display at resolution of one by one degree the A, B, and C for the recurrence of earthquakes.

JSP11/07P/A10-009 — 1740

HIGH-FREQUENCY HYDRO ACOUSTIC SIGNALS (40 - 110 HZ) DETECTED BEFORE THE EARTHQUAKES ON THE PACIFIC SHELF OF THE KAMCHATKA PENINSULA

Victor E. MOROZOV (Tsunami laboratory, Shirshov Institute of Oceanology RAS)

Kuril-Kamchatka arc is a well-known tsunami risk region. Almost all earthquakes in the region occur in the coastal zone. Many of such events can produce landslides and tsunamis. Early prediction of earthquakes is very important. The objective of this study is to make an attempt to forecast earthquakes using hydro acoustic signals, which can be recorded before the main shock. A joint analysis of the local Kamchatka earthquake catalogue data and hydro-acoustic measurements obtained during the Acoustic Thermometry of Ocean Climate (ATOC) experiment was carried out. Records were obtained from a horizontal cluster of hydrophones located on the shelf of the Kamchatka Peninsula in the Pacific Ocean. The 160 records available are about 22 minutes long each. They contain information from 14 smaller hydrophone clusters, which form the main cluster. The location of the source of acoustic signal can be found from the cross analysis of the data collected by different clusters of hydrophones. Acoustic noise was recorded from July 1998 to March 1999, thus the records contain seasonal variations in the noise. Spectral analysis of the main signal was carried out. In addition, the acoustic signals were analyzed by usual listening. The time series of acoustic records coincident with the earthquakes or measured immediately before the beginning of earthquakes were analyzed. The total period of the time series was divided into smaller parts and spectra were calculated for each of the small intervals. Changes in the form of the spectra with intensive peaks in the frequency range within 40-110 Hz were observed in many records preceding an earthquake. These changes could be also distinguished in the audio record of the signal as clearly recognized cracks. Two types of signals were distinguished from the hydro acoustic records: the micro-earthquakes, whose focuses were located in the same area as the seismic focus of main earthquake and the seismic noise, which appears before the main shock. The duration of micro-earthquakes was about several seconds. If the time interval between the hydro acoustic record and earthquake exceeded 4 hours no micro-earthquakes were observed. This hydrophone cluster was located in the region of high seismic activity; therefore we can evaluate the structure of micro-earthquakes and distinguish them from other non-seismic signals. We conclude that hydrophone records of the ocean noise can supply information about the processes, which occurred at the ocean bottom several hours before the beginning of an earthquake, and can make it is possible to forecast the area of the further main shock of the earthquake. A theoretical model of this process has been contrived to compare field data with the model.

ASSESSMENT OF TSUNAMI HAZARD FOR DIFFERENT COASTAL AREAS IN THE PACIFIC

Viatcheslav K. GUSIAKOV (Department of Geophysics, Institute of Computational Mathematics and Matematical Geophysics)

The paper describes a potential application of the Expert Tsunami Database (ETDB) for estimation of the long-term tsunami hazard. The ETDB has been developed and is being maintained at the Novosibirsk Tsunami Laboratory under the joint project of the IUGG Tsunami Commission (IUGG/TC) and the International Coordination Group for the Tsunami Warning System in the Pacific (ICG/ITSU). The concept of the ETDB is based on the integration of historical data, numerical models, processing and analyzing tools along with supporting mapping software. These components are embedded inside a specifically developed GIS-type graphic shell providing fast and efficient manipulation of maps, models and data. The ETDB is intended to be a comprehensive source of historical data on tsunami occurrence and coastal manifestation along with additional reference information related to the tsunami problem in the Pacific. Three main parts of the ETDB data storage subsystem are TSUNAMI database, EARTHQUAKE database and GEOGRAPHY database. The TSUNAMI database consists of the catalog of tsunamigenic events in the Pacific (Level I data) and the catalog of historical observations of tsunami run-up heights (Level II data). The collected data can be easily retrieved from the database by a number of criteria and are readily available for further display and analysis. Availability of this large amount of digital data on tsunami run-up heights enables us to develop a special application tailored to specific needs of coastal communities for having long-term estimates of tsunami risk. The approach to the long-term tsunami hazard assessment, implemented in the ETDB software, is based on the statistical analysis of historical run-up observations near a particular site and involves the following four basic steps: (1) selection of a particular coastal area within which available historical run-up observations can be considered as spatially correlated; (2) retrieval of historical run-up measurements from the database, displaying them along the time axis and analyzing their time-spatial relation; (3) plotting the data against the ˝wave height - frequency occurrence˝ diagram and obtaining the ˝height - frequency˝ relation by linear regression; (4) calculation of the so-called ˝hazard curves˝ for the estimation of probability that a particular wave height of H (m) will not be exceeded for the given time interval of T (years). For a particular coastal area, this type of analysis can be interactively made using a special pop-up menu and dialog windows. The results can be immediately displayed on the screen in the form of hazard curves and evaluated by an expert. This analysis can be easily repeated for different subsets of data in order to evaluate its

variability depending on the data quality and completeness. Some examples of the ETDB application for the tsunami hazard assessment in the different tsunamigenic areas in the Pacific are presented.

JSP11/08A/A10-002 — 0930

STRENGTHENING THE MAPPING SYSTEM OF JAKARTA (INDONESIA)FOR FLOOD HAZARD MITIGATION MANAGEMENT

Hasanuddin Zainal ABIDIN[1], Samsul HADI[2], Joenil KAHAR[1], Rudolf MATINDAS[3] ([1]Department of Geodetic Engineering, Institut Teknologi Bandung (ITB), Jl. Ganesha 10, Bandung 40132, INDONESIA, [2]Land and Mapping Office of DKI Jakarta, Jakarta, INDONESIA, [3]National Coordinating Agency for Survey and Mapping, Cibinong, Bogor, INDONESIA)

Jakarta is the capital city of Indonesia with a population of about 10 million people, inhabiting an area of about 25-km by 25-km. Due to several natural and man-made factors, Jakarta is yearly affected by flood. It causes a lot of damages and creates physical, social and economic impacts. Several approaches have been implemented for flood hazard mitigation in the area. One aspect that limits the effectiveness of the approaches so far is the lack of detail, comprehensive and up-to-date spatial information of Jakarta and its surrounding areas, both in forms of maps or GIS databases.This paper will review the status and development of mapping system in Jakarta. Strengthening analysis will be performed in order to make the system also useful for flood hazard mitigation manage-ment. Preliminary analysis concluded that for flood management at least there are five maps (databases) that their making have to be added to the system, namely height contour, watershed, drainage, water penetration, and land subsidence maps (databases). Social mapping should also be performed in order to map and identify the social and economic conditions of the peoples living in the flood prone areas. Strategic issues and problems related to this mapping system strengthening will be presented and discussed. Paper will be sum up with conclusions and recommendation along with plans for future activities.

JSP11/08A/A10-003 — 0950

LANDSLIDE HAZARD MONITORING AND SURVEY OF THE VITAL AREAS IN INDONESIA

Surono (Directorate of Volcanology and Geological Hazard Mitigation)

Landslide hazard in Indonesia has caused many victims of people killed and number of casualties. This was created by such geologic condition, climate and human factors. Especially for the areas, in which economic and transportation is vital, monitoring of landslide by using GPS has been done episodically. The result of monitoring for Bandung – Jakarta and Bandung – Jogyakarta main roads within 2 months period in rainy season, showed 5 cm road sliding was detected. Two dimensional resistivity imaging survey was done in understanding the degree of sliding slope and thickness of the upper layer. Usually for the upper layer of 3-5 m in thickness with slope of 20 degrees, causing the damage of building, roads and many other public facilities. The areas of those fulfill the above criteria was stated to be unlikely for human living, limited farmer activities and needs road maintenance with a special engineering technique.

JSP11/08A/A10-004 — 1010

SUSTAINABLE COASTAL DEVELOPMENT: PERSPECTIVES OF LOCAL KNOWLEDGE AND COMMUNITY-BASED CO-MANAGEMENT IN SOUTHEAST ASIAN COASTAL COMMUNITY

Md. SALEQUZZAMAN (Ph. D. Candidate and Researcher, Institute for Sustainability and Technology Policy (ISTP), Murdoch University, Perth, WA-6150, Australia & Associate Professor, Environmental Science, Khulna University, Bangladesh)

Coastal environment is the most resourceful and productive zone in the world. On the other hand, most Southeast Asian coastal communities are in great risk due to climate change and other anthropogenic disturbance. Therefore the coastal environment needs to become sustainable, because rest of the world human population depends on the sustainablity of the coastal environment. Local knowledge about the environment and natural resources is being shown to be an important asset in coastal communities. Such knowledge provides the basis for traditional community-based management systems, and its acquisition, use and transmission are extremely relevant to livelihoods in subsistence fishing over most of the world, especially in Southeast Asian Coastal Community. Presently community-based coastal resource management, particularly fisheries management is an alternative of sustainable development in coastal communities of Southeast Asia, especially in Bangladesh. In Bangladesh, traditional local knowledge and community-based participatory management are extremely successful for sustainable development in some localised area of coastal community. This management with scientific input is now expanding to other coastal communities of Bangladesh. The paper will analyse the successful of sustainable development in coastal communities of Bangladesh and identify the different factors behind this successful history. The key sustainable development planning and management issues are formal and informal education, awareness, community consultation, community participation and implementation of local community-based rules and legislation, which cover the nature conservancy as well. On the other hand, financial support and technical help including need-based education are the important factors to achieve the sustainability of the Southeast Asian coastal communities. Strong decision-making processes from local, national and international community will strengthen to the achievement of the coastal sustainable development. Institutional and research involvement is another factor to implement this process. Therefore, finally the paper will recommend a policy framework on how overall coastal Bangladesh and other Southeast Asian coastal community will enjoy the opportunity of sustainable development.

JSP11/08A/A10-005 — 1050

MONITORING DROUGHT OVER NORTH-EAST OF I. R. OF IRAN USING STANDARDIZED PRECIPITATION INDEX (SPI)

Javad BODAGHJAMALI[1], AliMohammad NOORIAN[2], Sohaila JAVANMARD[1], Abdolhossein MOGHADAM[1], Reza SHIRMOHAMADI[1] ([1]Climatological Research Institute (CRI), I. R. of Iran Meteorological Organization (IRIMO), P. O. Box 91735-491, Mashhad, I. R. of Iran, [2]President of IRIMO, I. R. of Iran Meteorological Organization, Meraj Ave., Tehran, I. R. of Iran)

Drought is the most complex of all natural hazards, that is so difficultto define, detect, and measure, and resaerchers have been striving to develop indices to accomplish these tasks. In 1993, researchers at Colorado State University developed a new drought index, the Standardized Prediction Index (SPI), which is based on precipitation alone. The SPI was designed to be a relatively simple, year-round index applicacble to all water supply conditions. Its fundamental strength is that it can be calculated for a variety of time scales from one month out to several years. This versatility allows the SPI to monitor short-term water supplies, such as soil moisture important for agricultuteral production, and longer-term water

resources such as grounwater supplies. Drought impacts are usually first apparent in agriculture, but gradually move to other water-dependent sectors. Recovery time for water stored in surface and subsurface systems can be quite long under severe drought conditions. Risk of drought is still a major conceren in parts of I. R. of Iran, where precipitation amounts are low extremly variable. The SPI is a relatively new index, and it has not been widely applied or tested. In this research, we tested the SPI for different climatic regions and investigated its potential use as a tool for monitoring drought in I. R. of Iran. SPI values have been computed for 100 synoptic stations of IRIMO network for 3-,6-, 12-, and 24-month scales, covering 1960-2002.The results of the research shows that at the 3-month scale drought frequency increases but its duration decreases. On the other hand, as the time scale increases, the index responds more slowley.

ECOLOGICAL POLICY AND RISK ASSESSMENT OF RADIOACTIVE CONTAMINATION IN THE BLACK SEA

Alexei Evgenievich KONTAR (Laboratory of Seismology and Geodynamics, P.P. Shirshov Institute of Oceanology, Russian Academy of Sciences)

Environmental problems in the Black Sea continue to be serious, even though governments have initiated a regional approach to the management and protection of the marine environment. Following the Chernobyl accident in 1986, the Black Sea riparian countries (viz., Bulgaria, Georgia, Romania, Russia, Turkey, and Ukraine) identified radioactive pollution as a serious problem. This paper presents some results of the project which is part of the fundamental research carried out by the P.P.Shirshov Institute of Oceanology of the Russian Academy of Sciences. The aim of the project is to develop the policy and methods for assessing the risk and fate of the Chernobyl radionuclides in the Black Sea.The risk assessment mathematical model has been designed to investigate the fate and distribution of the Chernobyl radionuclides in sediments of the Black Sea. One of the regions of intensive radioactive precipitation during the Chernobyl disaster was the nothwestern Black Sea region. There are some canyon systems in this region, where bottom sediments of the shelf zone are removed to the continental slope region and finally to the abyssal part of the sea. Occasionally there are dramatic velocity increases in the near-bottom current, the so-called ″bottom or benthic storms″. Different eddies above the area studied are supposed to be the cause of the observed events. In the following it is suggested that additional mechanisms are needed to explain some observations of bottom storms and mixing processes in the Black Sea. The importance of periodic bottom storms springs from the fact that they stir up bottom sediments with radionuclides incorporated, which are then captured and transported over large distances by weaker but stable currents. Some so-called ″warm″ bottom storms are connected with lutite flows, forming in the upper horizon of the slopes. This is due to bottom erosion, resulting from landslides and creeps of sediment, frequently shaken by local submarine earthquakes. As a result of this work scientifically provided recommendations have been elaborated for assessing risk of pollutants in the Black Sea and near-bottom dynamics interaction with the environment in natural and man-induced hazards and also suggestions for monitoring the near-bottom environment, aimed at minimizing negative ecological effects. The results of this work have confirmed once again by research that the Black Sea crisis calls for a concerted international approach and that it is critical for the future of the Black Sea that various programs addressing the Black Sea´s environmental problems be coordinated to work together. It will promote sustainable development of efforts towards improved environmental management and risk assessment in the Black Sea region. The results obtained for the Black Sea can be used in comparable regions of Russia for elaborating a policy, strategy and methodology of predicting the fate of pollution in the sea. Solution of these problems is particularly acute for the new social and economic conditions in Russia.

GUIDELINES FOR SUSTAINABLE PROVISION OF ARSENIC FREE WATER SUPPLY IN BANGLADESH

Md. SALEQUZZAMAN[1], Mostafa Md. KHALEQUZZAMAN[2] ([1]Associate Professor, Environmental Science Discipline, Khulna University, Bangladesh; and Ph.D. Candidate and Researcher, Institute for Sustainability and Technology Policy (ISTP), Murdoch University, Western Australia, Perth, WA 6150, Australia, email: salek@central.murdoch.edu.au / msalequzzaman@hotmail.com, [2]Paediatrics Consultant, General Hospital, Magura, Bangladesh.)

Ground water arsenic pollution becomes a serious environmental health issue of the people of Bangladesh. The issue has been taken a priority agenda by the government and many local, national and international organisations, but very few successes have been made for its remediation and sustainable management. A lot of recommendations have been suggested from many national and international seminars, symposia and conferences; and in the national and international journal as well. In a real sense, very few workable efforts have reached to the victims, most of whom are very poor people. The reasons include a lack of coordination among different organizations and selection of locally available, low-cost alternative solutions and treatment technologies. This paper will discuss the real barriers to solutions of this arsenic calamity. Finally, the paper will recommend sustainability guidelines for the management of arsenic calamity of Bangladesh.

MONITORING OF LANDSLIDE PHENOMENA BY USE OF INTEGRATED SURVEY SISTEM

Paolo RUTIGLIANO[1], Francesco SDAO[2], Francesco VESPE[3] ([1]Telespazio Spa, [2]Universita della Basilicata, [3]Agenzia Spaziale Italiana)

This paper summarises the geological and geomorphologic studies and the main results of the monitoring survey carried out on some landslides in some areas in Basilicata region (southern Italy). The landslide monitoring was done using an integrated approach: traditional survey systems and applications based on the GPS technique. The adoption of a ″mixed″ approach, with the contemporary use of classical techniques and GPS, has been introduced since the space geodesy tools become very effective for the monitoring of landslide movements. The success of GPS for landslide monitoring is due to its characteristics such as a relative easiness in the acquisition of data and a very high precision and accuracy in the measurements. In addition, the GPS allows an easy reconstruction of the velocity field of a landslide, which adds a really helpful information for the modelling of the phenomena. However the surface velocity obtained by GPS could be not representative of the deep movements of gravitational phenomena. This means that in the monitoring of landslides GPS can not be used in stand-alone mode: the use of classical methods is necessary to really understand the evolution of a landslide. One test site was at Lauria locality, an urbanised area interested by large and active landslides; the lasts are subject to frequent reactivation causing severe damage to the urban structures. Results of GPS survey, in good agreement with the information´s coming from geomorphologic studies, show that large part of the investigated area are affected by slow but continue deformations. Other results came from the survey (in progress) about slope instability processes observed in two areas of the *Parco*

Archeologico Storico Naturale delle Chiese Rupestri del Materano. In the investigated areas, the lithological defects and intense fracturing state of carbonate rocks cause it´s the cause of mass movements of blocks (rock falls, topples and rockslides) that could seriously damage some fine rupestrian heritages present in the area. The potentially unstable carbonate blocks have been defined by geological and geomorphologic studies and actually this sites are under monitoring with a survey system, made up by a traditional topographic survey, GPS measures and a deformation measurement system.

EFFECTS OF EARTHQUAKES AND VOLCANIC ACTIVITIES ON CITIES AROUND THE LAKE KIVU BASIN, WESTERN RIFT VALLEY OF AFRICA

Mifundu WAFULA[1], Kasereka MAHINDA[1], Mavonga TULUKA[1], Munyololowa YEMBA[2], Hiroyuki HAMAGUCHI[3] ([1]Department of Geophysics, C.R.S.N./ Lwiro D.S. Bukavu, D.R.Congo, [2]Lwiro station of C.R.G.M./ Kinshasa, D.R.Congo, [3]Graduate School of Sciences, Tohoku University, Sendai 980-8578, Japan)

The Western Rift Valley is the west branch of the East African Rift System. This rift valley is one of the most seismically and volcanically active region in the African Continent. The Western rift valley is characterized by the shallow seismic activities with normal faulting type. Volcanoes Nyiragongo and Nyamuragira standing at the north of Lake Kivu are characterized by frequent basaltic eruptions in the recent history. The most catastrophic disastrous eruption occurred on Jan. 17, 2002 and the thick lava flows covered over about 13 percent of Goma city, 80 percent of its commercial district and killed 100 people. The Bukavu and Goma (D.R.C.), and Gisenyi (Rwanda) are the main cities located around the lake Kivu margin. The whole population in these cities is more than one million. From the seismic and volcanic studies, field observations and testimonies of inhabitants in the basin, it is revealed that, since 1997 the lake Kivu basin had became more active than before. Several moderate earthquakes with local magnitude more than 4.0 accompanied with foreshocks and aftershocks have been recorded in basin every year. This seismic activity is supposed to be related partly to the reactivation of faults in the basin area and partly to volcano-magmatic activity. The last earthquake of Mw 6.2 occurred recently at the western escarpment of the Rift system near the lake Kivu on October 24, 2002. The damages caused by this event were recorded on houses in Bukavu, Lwiro, Kalehe, Nyabibwe, Kiroshe, Gisenyi and even in farther city like Kigali in Rwanda. The most heavily damaged zone was the territory of Kalehe where 90% of masonry D were destroyed and masonry C affected. In total 8 persons were killed and 1700 houses damaged. Very slight damages were observed in Goma and Bukavu. Landslides phenomenon, which has been already observed in Bukavu area since 1997, was accelerated by the occurrence of this earthquake. In addition to the seismic activity prevailing, some factors such as: the regressive erosion, the presence of aquifer nape, the deforestation, and parcelling on the steep slopes are contributing to the landslides phenomenon and inundation in Bukavu, where big catastrophic event may be expected in the future. Except some seismological and geological results available, no serious studies have been done on soil engineering; foundation soil, special treatment of slope instability and subsidence, modification of strong-motion parameters. Every year several people are killed directly by earthquake or by landslides and inundations. The earthquakes associated to the Nyiragongo eruption on January 17, 2002 killed 4 people, injured 18 and damaged more than 400 houses, most of masonry D in Gisenyi. Therefore, geophysical monitoring must be reinforced quickly around Lake Kivu region in order not only to understand what are occurring beneath the basin and volcanic regions but also to reduce the geophysical risk in future.

THE EFFECT OF SMAZE ON PRECIPITATION PROCESS OVER TEHRAN

Seyed Alireza SADEGHI HOSSEINI, Javad RAHELI SALIMI (Department of Meteorology, Space Group, Institute of Geophysics, Tehran University)

In recent decades, the problem of air pollution, specially particulate type in large cities as Tehran has created health problems to people. Here, from different perspective, the relationship between the precipitation process and the air pollution in Tehran have been investigated. The climatic changes in Tehran from 1950 to 2000 is considered to be mainly due to urbanization, as well as topographic setting of this city. This study shows that the annual mean maximum and minimum temperatures in Tehran are large than those of Karaj, a smaller city in west of Tehran. The same is true for the mean annual minimum temperature for Varamin, a city just east of Tehran. Although the annual maximum temperature in Varamin is larger than that of Tehran which is mainly due to topographic effect. The records indicate that the visibility in Tehran has a gradual decrease around 1975s, which is considered as the start of an accelerating city expansion, hence increase of air pollution. The frequency of smaze events has increased substantially since 1975s. The precipitation records also indicate that the mean annual precipitation has relatively increased over Tehran more than Karaj and Varamin, although local precipitation (based on sudden increase in local relative humidity) has been reduced that could be due to overseeding of the clouds by pollutant aerosols.

RHYTHMS OF RATS RESISTANCE TO HYPOXIA DEPEND ON GEOMAGNETIC ACTIVITY

Youry P. SIZOV[1], Maryam L. KHACHATURYAN[2] ([1]Geoelectromagnetic Research Institute of RAS, [2]Russian State medical University)

The objective was to find the influence of geomagnetic activity (GMA) on rhythms of rats resistance to acute hypoxia. METHODS. The resistance to acute hypoxia of rats-male Wistar was assessed by life time (LT) in sec after "raise" during 1 minute up to the "altitude" 11.5 km above sea level in the different seasons of one year from 13.00 to 21.00 h. GMA for an hour of LT determination was estimated by K-index for Moscow. Time rows of LT and K-indices values were studied by spectral analysis. The differences among periods (in percents of the value of the nearest largest period) of LT and GMA rhythms were determined. The periods of

one type of rhythms were compared. GMA rhythms number coincided with one LT rhythm (GMAC) for each type of rhythm was determined. Nonparametric methods of statistics were used: analysis of variance, correlation analysis, Dunn's method and X2. RESULTS. The same types of GMA and LT rhythms: circaseptal, circasemiseptal, infradian, circadian, ultradian were found. The majority of circa- and ultradian rats LT rhythms periods coincided with GMA rhythms periods. The basic rhythms of GMA and LT appeared to be either circadian ones, or multiple to them. Frequency of corresponding GMA and LT rhythms was practically equal and rose as periods decreased, i.e. it was the largest for ultradian rhythms (68 and 63% for the whole year) particularly at the first half of the year: max in spring and min in autumn (GMA), in summer (LT). At the same time the absolute number of GMA rhythms exceeded that of LT rhythms of corresponding rhythms types. The relative differences between periods of both GMA and LT rhythms diminished as the size of the periods decreased, i.e. were min for ultradian rhythms. The relative differences between periods of GMA and LT rhythms were more evident at the first half of the year. In rhythms with periods more than those of the basic rhythms amplitude increased as periods decreased. In rhythms with periods less than those of the basic rhythms amplitude also diminished as periods decreased. Apparently similarity of GMA and LT rhythms was stipulated by influence of GMA rhythms on LT ones by means of synchronization of rithms.

DROUGHT MONITORING USING NORMALIZED DIFFERENCES VEGETATION INDEX (NDVI) OVER I. R. OF IRAN

Javad BODAGHJAMALI[1], Sohaila JAVANMARD[1], Mehdi RAHNEMA[2], Sara ATTARCHI[2] ([1]Climatological Research Institute (CRI), I. R. of Iran Meteorological Organization (IRIMO), P. O. Box 91735-491, Mashhad, I. R. of Iran, [2]GIS and RS Department, Shahid Beheshti University, Tehran, I. R. of Iran)

Sever drought has been occured in most regions of I. R. of Iran in recent years.In order to the drought risk management, monitoring of drought using drought indices, such as Standardized Precipitation Index (SPI), Palmer Drought Severity Index (PDSI), Percent of Normal (PN), and Normalized Difference Vegetation Index (NDVI), should be applied for interested regions.Drought monitoring could be carried out using the remote sensing of vegetation status. During the periods of drought conditions, physiological changes within vegetation may become apparent. Satellite sensors are capable of discerning many such changes through specteral radiance measurments and manipulation of this information into vegetation indices which are sensetive to the rate of plant growth as well as to the amount of growth. Such indices are also sensitive to the changes in vegitation affected by moisture stress. The National Remote Sensing agency in Idia has developed NDVI to determine vigour of vegetation. In this research, the NDVI spatial distribution has been derived over I. R. of Iran, from AVHRR sensor of NOAA satellite images.In order to estimate the amount of rainfall using the satellite images, Kerr model has been applied. To test the model, the data of 115 synoptic stations of I. R. of Iran Meteorological Organization (IRIMO)have been used. The correlation shows good agreement between the estimated rainfall and NDVI value in most part of Iran.Based on the results of this research, it is going to use NDVI as an operational drought index in most regions of Iran.

NORTH ARMENIAN SEISMIC RISK ASSESSMENT

Edvard Grigori GEDAKYAN, Mkrtchyan MARIAM (Header Researcher, Institute of Geophysics and Ingineering Seismology NAS of Armenia)

Availability of a great number of mass inhabited and industrial objects, grouth of population and its dense setting on a comparatively limited territory increase the earthquake destructive effect. Lessons of the Spitak earthquake in 1988 (M=6,9) showed that absence of the complex of antiseismic programmes on the basis of seismic rosk assessment considerably increased the material and social damage.For the seismic risk assessment ot the North Armenian territory the modified approach to crreation of the following models was applied:a)the model of investidating of seismicity territory;b)the model of spatial distribution of intensity of ground shaking;c) the model of the effect, which the given object experiences from the shaking.On the basis of the above mentioned models and their combinations seismic risk parameters were calculated according to the discrets main points of the North Armenian territoty map.When constructing the territory seismiciti model the following task was set: to describe all the main seismicity parameters (the repetition law,average annual number of earthquakes according to calculated and quantutative descriptions of the straned-deformed state.For construction of the model of shaking intensity distribution over the earth surface and determination of the intensity macroseismic damping coefficients, maps of assists of the North Armenian strongest earthquakes were used.Among these msps one of the spetial importance due to its detailed and exact character the map of the Spitak earthquake macroseismic display. When creating the intensity distribution model some important factors were taken inti account, such as earthquake focal mechanisms, types of rupture-formation in the earthquake focus. This park of the work aims at determination of the isoseist parameters (such as area, ratio of semi-axes 1= a/b and azimuth A of the long axes) dependence on the magnitude, focal depth-H, focal mechanism type and the type of rupture-formation.The model of solitary earthquake effect was contracted according to the data about destructions and damages during the Spitak earthquake main shock and its strongest aftershocks.On the basis of the above mentioned models and their combinations seismic risk parameters were calculated according to the discrets main points of the North Armenian territoty map.They include: l - average of earthquakes threatening to the object of research,A - average effect, B P = 0,9 - the appear thressshold of the effect, Po - probability of the fact that the effect is equal to zero.Availability of these values of the seismic risk parameters serve as a basis for working out of a system of activities aiming at prevention and reduction of earthquake destructive consequences.

DETERMINATION OF SUBSURFACE STRUCTURE OF TOTTORI PLAIN USING SEISMIC METHOD AND GRAVITY EXPLORATION

Tatsuya NOGUCHI, Ryohei NISHIDA, Takuo OKAMOTO (Department of Civil Engineering, Tottori University)

Microtremor observations and a gravity survey were made to determine the subsurface structures of the Tottori Plain. This area was severely damaged during the 1943 Tottori earthquake (M7.2), damage being concentrated in the plain. Microtremors were recorded by seismic arrays (8 sites) and 3-component single-site observation (417 points). Gravity data were obtained at about 400 points. The microtremor data were analyzed by the spatial auto correlation (SPAC) method and the horizontal-to-vertical spectral ratio. The subsurface structures were determined by 1) S-wave velocity structure models obtained at the array observation sites, 2) a 3D bedrock configuration based on the horizontal-to-vertical spectral ratio and the residual gravity anomaly, 3) 2D density structures for three cross sections obtained using the gravity anomaly based on a depths of S-wave velocity structures. A shallow bedrock area extends over a belt-like zone along the coast. This bedrock suddenly

deepens from the eastern mountainous area to the plain.

PROBABILISTIC SEISMIC HAZARD ASSESSMENT IN ALBANIA

Betim MUCO[1], Anastasia KIRATZI[2], Shyqyri ALIAJ[1], Eduard SULSTAROVA[1], Siasi KOCIU[1], Veronika PECI[1], Emmanuel SCORDILIS[2] ([1]Seismological Institute, Tirana, Albania, [2]Geophysical Department of Aristotle University of Thessaloniki, Greece)

Albania is situated in the Alpine-Mediterranean seismic belt and accommodatespart of the deformation due to collision of the Adriatic micro-plate with theEurasian plate. Albania has repeatedly been the site of historical earthquakeswith considerable losses and as evidenced from the instrumental era the countrysuffers a lot of damage even from moderate size events. The fact is attributedmainly to the poor quality of the construction in rural areas. During Albania'spassing from an isolated and communist dictatorship to an open and democraticsociety in the beginning of 90's, a boom in the construction sector commencedwhich made imperative a modern seismic hazard assessment. In this work an evaluation of probabilistic seismic hazard in Albania ispresented based on an updated seismicity catalogue. For this reason Albania hasbeen subdivided in 8 seismogenic zones on the basis of seismotectonic criteriaas well as on the spatial and temporal distribution of earthquake epicenters. The earthquake catalogue adopted contains 553 earthquakes with M[3]4.5 for thetime period 58 AD ÅE2000. Ground Acceleration (PGA) for different probability levelsof exceedance are obtained for a grid (each element having dimensioned 10 kmx 10 km) over the territory of Albania. Respective maps are also presented.

JSP11/08P/D-007 Poster 1400-076

CRUSTAL UNDULATIONS IN RELATION TO COASTAL HAZARDS

Shigehisa NAKAMURA (Kyoto University (Ret'red))

There are several factors affecting to the human activities in the coastal zones. In this work, some typical cases of the interested natural processes are introduced with some geophysical consideration. One of the typical cases is sea level rising caused by the global warming of climate. In fact, some report informs us that several countries of the islands in the Pacific and in the Indian Ocean are threat to disappear under the sea surface by the increase of the sea level rising, especially when the every season of the annual local high tides. If the global warming process is surely affecting to the human activities on the coast, we should be active to clarify what effects could be expected for us in a scope of geophysical sciences. This sea level rising must be realized as a result of the climate change induced by the global warming as a trigger of the increased melting of the ice covers developed on the Antarctic and on the Green Land. Now, it is hard to give any direct answer how to predict and control the climatological processes. The author here would introduce a conceptual model in order to raise to start an urgent research project, even though there might be many of the projects running in the world. Now, it is noticed that an increase of the sea level rise could be a loading to the crust under the sea water. Then, we have to be careful to consider about some possible problems at set back of the coast line especially in the coastal zone facing an ocean. This notice could be reduced as a result of an equivalent thin plate model for considering an undulation of the earth's crust around the coastal zone. This undulation could possibly to give an understanding about an expected set back of the coast line. Adding to the above, it could be noted there might be a relation at considering a local co-seismic crustal upheaval with some assumptions in the scope of geophysical dynamics.

JSP11/08P/D-008 Poster 1400-077

ASSESSMENT OF LANDSLIDE HAZARDS USING GEOPHYSICAL TOMOGRAPHY

Simeon G. KOSTIANEV, P. STEFANOV, P. STOEVA (Dept. of Mathematical Geophysics, University of Mining & Geology)

Landslides and unstable slopes are among the major natural and man-made hazards affecting manking and yet their causes, their consequences for human life and property, and possible strategies for mitigating their effect are not very well understood. We will note, that only in Bulgaria there are over thousand active landslides on populated and health resort areas. The material and social losses have not been calculated yet. But in preliminary data they are enormous. Numerous and dangerous are thelandslides and unstable slopes in opencast coal-mines too. In this paper we offer methods for combined application of high resolution electrical (resistivity) tomography and seismic ray tomography for characteristic of landslide hazards and unstable ones. The major aim here is to predict where and when landsliding will occur, establishing their variability in space and time, and appraising their impact on the natural and socio-economical environment. The above methods are applied for studing of concrete landslide in Bulgarian Black Sea and on some unstable slopes in an opencast coal-mine of Maritza-Iztok area. This combined application of electrical and seismic tomography for assessment of landslide hazard is very usefull.

JSP11/08P/D-009 Poster 1400-078

DROUGHT MONITORING USING PALMER INDEX OVER NORTH-EAST OF I. R. IRAN

Sohaila JAVANMARD[1], Javad BODAGHJAMALI[1], GholamAli KAMALI[2], MohamadJavad AHMADIAN[1] ([1]Climatological Research Institute (CRI), I. R. of Iran Meteorological Organization (IRIMO), P. O. Box 91735-491, Mashhad, I. R. of Iran, [2]Atmospheric Science and Meteorological Research Center (ASMERC), IRIMO, P. O. Box 14965-114, Tehran, I. R. of Iran)

Sever drought has been occurred in most regions of Iran in recent years. In order to drought risk management, monitoring of drought using drought indices such as Standardized Precipitation Index (SPI), Palmer Drought Severity Index (PDSI), Percent of Normal (PN), Normalized Difference Vegetation Indes (NDVI) should be applied. A drought index calculated from known values of selected parameters enables us to evaluate the drought hazard over an area and assess the current extent and severity of drought over region. PDSI was specifically designed to treat the drought problem in semiarid and dry sub humid climates. The palmer drought index is widely used by a variety of people, such as hydrologist, foresters, field meteorologists, economists, policy decision makers, new media, private consultants, and researches, as a tool to monitor and assess long-term meteorological drought and wet spell conditions. As pointed out by National Drought Mitigation Center (NDMC), it is most effective measuring impacts sensitive to soil moisture conditions, such as in agriculture, and it has been used to start or end drought response actions. In this research, drougth monitoring using PDSI has been carried out in CRI over Khorasan province (Northeast of Iran), from 2000 to 2003 for 3 years as well as field measurement of soil moisture in 10 Agricultural Meteorological stations over there. There was a good agreement between the soil moisture situation and derived PDSI over the mentioned stations.

SEISMIC TOMOGRAPHY AND THE BOUNDARY BETWEEN UPPER AND LOWER MANTLE

Adam Marian DZIEWONSKI, Yu Jeffrey GU (Earth and Planetary Sciences, Harvard University)

It is difficult to think of a more controversial geophysical problem than the flow of the mantle materialacross the boundary between the upper and lower mantle. There is, however, strong evidence for strong impedance to flow across this boundary. It is based, in part, on the estimates of the patterns of large-scale velocity anomalies above and below the 660 km discontinuity. Gu et al. (2001) show that it is possible to satisfy a large and diverse set of traveltime data with a model that has distinctly differentspectral characteristics above and below the discontinuity. Even when the continuity is imposed,the velocity anomalies 100 km below and above the660 discontinuity are fully de-correlated, indicating a very steep change in the pattern of heterogeneity.Additional information comes from studies of thetopography of the 400 and 660 km discontinuities,using SS - SdS differential precursor times (Shearerand Masters, 1992). Simultaneous inversion formantle shear velocity and topography of the transitionzone discontinuities shows very little large wavelength topography on the 400 km discontinuity and much larger relief on the 660 km; the shape of the twosurfaces is de-correlated (Gu et al., 1998). However,the 660 topography is highly correlated with the velocity anomalies in the transition zone. A simple, although not unique, interpretation is that the negatively buoyant slabs pond in the transition zone.A shortcoming of the seismic tomography is that itprovides only a snapshot of the heterogeneity. Attempts to extrapolate it in time are uncertain. But the pondingof slabs does indicates the possibility that thismaterial could be, at least in part, recirculated in theupper mantle. At the same time, it is impossibleto ignore the correlation between the distribution ofsubduction zones and the circum-Pacific ring of high velocitiesin the lowermost mantle, whichmight indicate communication, perhaps episodic, between upper and lower mantle.

JSS06/07P/A04-002   1420

AVALANCHES REVISITED: EFFECTS OF THE PYROXENE-GARNET SYSTEM ON THE EXTENT OF MANTLE LAYERING AT 660 KM

Paul J. TACKLEY (Dept. Earth and Space Sciences and Inst. of Geophysics and Planetary Physics, University of California Los Angeles)

Much research in the early-to-mid 1990s was directed towards understanding the extent of mantle layering caused by the endothermic gamma-spinel to perovskite+magnesiowustite phase transition at around 660 km depth, and the consensus that emerged was that of basically whole mantle convection with some temporary inhibition and avalanching of downwelling slabs today, with a potentially much greater effect in the past. However, published models assumed that the mantle is made of 100% olivine and its high pressure phases, whereas it is well known that the garnet-pyroxene system accounts for at least 40% of the mantle. Phase changes in the latter system occur over a wider depth range, and the equivalent 660 transition was thought to have a neutral or even positive Clapeyron slope, leading to the expectation that it would dilute or even act against the dynamical effect of the endothermic olivine-spinel transition [Weidner and Wang, 1998]. However, recent measurements by Chudinovskikh and Boehler indicate a strongly negative Clapeyron slope (-6 MPa/K) for the ilmenite to perovskite transition, which is likely to be the relevant one at temperatures near the 660. Furthermore, when compositional effects are considered, subducted oceanic crust is likely to be buoyant in the depth range 660-740 km [Ringwood, 1994; Ono et al., 1991]. Thus, the situation warrants careful investigation. Here these matters are examined using high-resolution numerical convection calculations that incorporate both the olivine and pyroxene-garnet systems, and comparing to calculations with only the olivine system. The Clapeyron slopes of each phase transition are varied within the current range of uncertainty. Both isochemical models, and models that incorporate chemical differentiation, are considered. Preliminary results that include chemical differentiation indicate a substantial chemical stratification induced by the combined phase system even with a neutral Clapeyron slope in the Pyroxene-Garnet system. With a strongly negative slope, layering is enhanced compared to a purely olivine system.

JSS06/07P/A04-003   1440

SYSTEMATIC STUDIES OF THE MANTLE DISCONTINUITIES

Arwen DEUSS, John H. WOODHOUSE (Department of Earth Sciences, University of Oxford)

We report a systematic search for reflectors in the upper and lower mantleusing a global data set of SS-precursors. A bootstrap resampling algorithmis employed to determine robust reflectors (at the 95% confidence level).The results demonstrate that reflectors can be found from a large varietyof depths, and having substantial lateral variations. Such observations can beused as a probe for local mantle composition and temperature.To investigate the regional existence and lateral variations ofdiscontinuities, we search for robust reflectors within spherical caps of10 degree radius, and make comparisons with the corresponding stacks forsynthetic seismograms. The 410 and 660 km reflectors are global features andthe results can be used to map their variation in depth. The 520 kmdiscontinuity is confirmed in many regions but is absent in others. Thereare a number of regions in which we observe two discontinuities atapproximately 500 and 560 km depth, an effect that can be interpreted as´splitting´ of the 520 km discontinuity. Stacks for particular tectonicregions, for example North America or Indonesia, show additional reflectorsin both upper and lower mantle at depths of 220 km and 1000-1200 km. Thelocations in which discontinuities are found are correlated with features inthe shear velocity distributions in tomographic models. In addition to the transition zone discontinuities, the largest number ofrobust reflections comes from a depth of 220 km, showing that the Lehmanndiscontinuity is a major feature in the upper mantle. This discontinuity isobserved beneath both continental and oceanic areas, though the largestamplitudes occur beneath the continents. There is also evidence for weakdiscontinuities at approximately 260 and 310 km depth, for example in theregion of the South Pacific Superswell which could be related to processes inthe upwelling plume. There are also suggestions of lower mantle reflectors with a weak peak for800 km depth; deeper in the lower mantle there are reflections from acontinuous range of depths. Clear reflections from 1000-1200 km depth are foundbeneath North America and in the Indonesian subduction zone area, where otherstudies have also found reflections. The locations

correlate with fastfeatures in tomographic models.As we find discontinuities from a range of depths in different types oftectonic regions, we do not expect that only one mechanism is responsiblefor all reflections. We discuss different possible explanation for theseseismic discontinuities in terms of phase transitions and compositional andrheological changes.

OBSERVATIONS AND IMPLICATIONS OF MID-MANTLE SEISMIC REFLECTORS BENEATH THE MARIANA SUBDUCTION ZONE

Fenglin NIU[1], Hitoshi KAWAKATSU[2], Yoshio FUKAO[2] ([1]Department of Earth Science, Rice University,, [2]Earthquake Research Institute, University of Tokyo)

A clear later phase approximately 80 s after the direct P-wave is observed in most of individual seismograms recorded by a short-period seismometer network in Japan (J-array) from a cluster of deep earthquakes that occurred at the northern Mariana subduction zone. This phase 1) shows a P-wave particle motion; 2) arrives later from earthquakes with shallower focal depths; 3) has a steeper incident angle than that of P wave; and 4) shows a deviation of a few degrees in the arrival azimuth from that of P wave. We interpret it as an S to P converted wave which takes off downward from the source and is reflected at a velocity discontinuity (reflector) below the earthquakes. Applying an inversion technique to the data set shows that the seismic reflector dips toward southwest by about 20° at 24.25° N 144.75°E 1115 km with a lateral extension at least 100 x 100 km. The location corresponds to the lower edge of a high-velocity anomaly in global tomographic models. Amplitude and waveform analyses suggest a decrease of S-wave velocity by 2-6% and an increase of density by 2-9% within the reflector. There is almost no difference in P-wave velocity ($<$1%) between the reflector and the surrounding mantle. The estimated thickness of the reflector is about 12 km. These observations indicate that the observed seismic structure is more likely to be a chemical reservoir rather than a purely thermal anomaly. The seismic reflector might be a piece of subducted oceanic crust, as suggested by a previous study. It also could be related to the break down of the D-phase of dense hydrous magnesium silicates (DHMS) at mid-mantle pressure condition reported by recent mineral physics studies. Both scenarios imply that either mechanical or chemical segregation might occur within the subducted slab at mid-mantle condition.

THICK MANTLE TRANSITION ZONE BENEATH THE PHILIPPINE SEA AS INFERRED USING THE RECEIVER FUNCTION METHOD FOR DATA FROM THE LONG TERM BROADBAND OCEAN BOTTOM SEISMOGRAPH ARRAY

Daisuke SUETSUGU[1], Hajime SHIOBARA[2], Hiroko SUGIOKA[1], Shunichi KODAIRA[1], Yoshio FUKAO[1], Kimihiro MOCHIZUKI[3], Toshihiko KANAZAWA[2], Ryota HINO[3], Tomoharu SAITA[4] ([1]IFREE/JAMSTEC, [2]ERI/Univ. Tokyo, [3]RCEP/Tohoku Univ., [4]RCSV/Nagoya Univ.)

We analyzed broadband waveforms recorded by the broadband ocean bottom seismograph network in the Philippine Sea to investigate the mantle transition zone structure beneath the Philippine Sea. This is the first attempt to study the mantle discontinuities beneath the Philippine Sea using broadband ocean bottom seismographs. As a part of the Ocean Hemisphere network Project (OHP), fifteen Long-term Broadband Ocean Bottom Seismographs were deployed from November 1999 to July 2000 along a profile from the Saipan Island to the Amami island across the mid Philippine Sea. All of the stations were equipped with semi-broadband sensor (WB2023LP, PMD and 24-bit data loggers. The sensor has a flat velocity response from 0.03 Hz to 30 Hz, which provides high fidelity for the long-period P wave trains analyzed in the present study. We analyzed seismograms from recovered and selected 7 stations with low S/N ratios. We determined the depths of the 410 km and 660 km discontinuities and thickness of the mantle transition zone under the Philippine Sea region by the Velocity Spectrum Stacking Method, where we can take into consideration the three-dimensional velocity variation in determining the discontinuity depths. The 410 discontinuity is shallower than the global average by 17 km and the 660 discontinuity is deeper than the average by 37 km, resulting in the transition zone thicker than the average by 54 km. The western part of the Philippine Sea has the 660 km discontinuity at a depth of 703 km, which is deepest in the studied area. Existing tomographic models have high velocity anomalies there, which is interpreted as the cold stagnant Izu-Bonin slab, suggesting that the deep 660 km discontinuity is related to temperature anomalies associated with the stagnant Izu-Bonin slab. The Mariana trough has also the deep 660 km discontinuity at a depth of 691 km in spite that the Mariana slab seems to be subducted vertically into the lower mantle and no high-velocity anomalies are present in the tomographic models. This cannot be explained only by the cold temperature and compositional factors, e.g., influence of water dehydrated from the Mariana slab may contribute to the transition zone thickness.

MANTLE STRUCTURE AND COMPOSITION TO 800 KM DEPTH BENEATH SOUTHERN AFRICA AND SURROUNDING OCEANS FROM BROADBAND BODY WAVES

Rapelang E. SIMON[1], Cedric WRIGHT[2], M. Tarzan O. KWADIBA[3], Eldridge M. KGASWANE[4] ([1]Present address: Department of Physics, University of Botswana, Private Bag UB704, Gaborone, Botswana., [2]Bernard Price Institute of Geophysical Research, University of the Witwatersrand, Johannesburg, Private Bag 3, Wits 2050, South Africa., [3]Also: Department of Geological Survey, Private Bag 14, Lobatse, Botswana., [4]Present address: Council for Geoscience, Private Bag X112, Pretoria 0001, South Africa.)

Average one-dimensional P and S wavespeed models from the surface todepths of 800 km were derived for the southern African region usingtravel times and waveforms from earthquakes recorded at stations of theKaapvaal and South African seismic networks. The Herglotz-Wiechertmethod combined with ray tracing was used to derive a preliminary Pwavespeed model, followed by refinements using phase-weighted stackingand synthetic seismograms to yield the final model. Travel times combinedwith ray tracing were used to derive the S wavespeed model, which wasalso refined using phase-weighted stacking and synthetic seismograms.The presence of a high wavespeed upper mantle lid in the S model overlyinga low wavespeed zone between depths of 210 km and about 345 km that is notobserved in the P wavespeed model was inferred. The 410 km discontinuity showssimilar characteristics to that in other continental regions, but occursslightly deeper at 420 km. Depletion of iron and/or enrichment in aluminiumrelative to other regions is the preferred explanation, since the Pwavespeeds throughout the transition zone are slightly higher than average.The average S wavespeed structure beneath southern Africa within and belowthe transition zone is similar to that of the IASP91 model. There is noevidence for a discontinuity at 520 km depth. The 660 km discontinuityalso appears to be slightly deeper than average (668 km), although theestimated thickness of the transition zone is 248 km, similar to the globalaverage of 241 km. The small size of the 660 km discontinuity for P waves,compared with many other regions, suggests that interpretation of thediscontinuity as the transformation of spinel to perovskite andmagnesiowustite may require modification. Alternative explanations includethe presence of garnet-rich material or ilmenite-forming phase transformationsabove the 660 km discontinuity, and the garnet-perovskite

transformationas the discontinuity.

extinct subduction zones.

IMAGING THE MANTLE DISCONTINUITY STRUCTURE BENEATH THE SOUTH INDIA

K. SURYAPRAKASAM[1], B.K. BANSAL[2], T.J. OWENS[3], S.S. RAI[1] ([1]National Geophysical Research Institute, Hyderabad, INDIA, [2]Department of Science & Technology, New Delhi, INDIA, [3]Department of Geological Science, University of South Carolina, Columbia, USA)

We investigate the nature of seismic strain markers in the mantle beneath South India, analyzing the waveforms from teleseismic events recorded over a 32 station broadband temporary network operated during 1999-2002. The network encompasses largely Archean and Proterozoic terrains of South India. We apply a three-dimensional stacking method to the receiver function to determine the location of mantle discontinuities using the IASPI91 velocity model as the reference. The 410 and 660 km discontinuity are well defined at their respective depths except the depression in 660 km discontinuity by about 30 km in the Proterozoic Granulite terrain. The other transition zone discontinuity at 520 km is also observed at a few places. The images also reveal the presence of 8° and 220 km discontinuity in South India.

JSS06/07P/A04-008   1640

SEISMIC EVIDENCE FOR A THICKER-THAN-NORMAL TRANSITION ZONE AND SUBDUCTED OCEANIC CRUST BENEATH SOUTHERN AFRICA

John Anthony BLUM[1], Yang SHEN[2] ([1]Department of Physics, University of Michigan, [2]University of Rhode Island, Graduate School of Oceanography)

Observations of P-to-S conversions reveal the shoaling of the 410-kmdiscontinuity and the deepening of the 660-km discontinuity beneaththe oldest parts of the Archaean cratons in southern Africa; consequently,the mantle transition zone is 20 km thicker than beneath post-Archaeanregions and the global average. The thicker-than-normal transitionzone correlates strongly with surface geology and does not follow thetrack of plate motion as numerical simulations of small-scaleconvection beneath the cratons predict. Thus, the thicker-than-normaltransition zone suggests that the cold and mechanically strong cratonickeels penetrate into the transition zone. A negative-polarity P-to-S conversion is also found within the transition zone beneath southern Africa. The negative polarity of the converted phase indicates a ~ 2.2 ± 0.2% S-velocity decrease with depth at a seismic discontinuity near 570 - 600 km depth. The normal to low velocity contrast at the 660-km discontinuity beneath the study area requires an anomalously high velocity gradient near the base of the upper mantle. The exsolution of Ca-perovskite in former oceanic crust at depth greater than 600 km provides a plausible explanation for the apparent paradox between the significant negative velocity discontinuity and the normal to low velocity contrast at the 660-km discontinuity.

VP/VS AND MINERALOGY OF THE TRANSITION LAYER OF THE EARTH'S MANTLE

Hideyuki FUJISAWA (ABIKO Geoscience Laboratory)

Constituents of the mantle transition layer is discussed based on comparisonbetween the seismic Vp/Vs and those of mantle minerals. Vp/Vs means the ratio between a longitudinal wave velocity and a transverse wave velocity. At presenttwo different hypotheses are proposed on mineralogical composition of transitionlayer. An isochemical, olivine-phase change hypothesis has long been a standard model for the earth´s mantle. High pressure experiment on phase changes inmantle minerals has shown validity of this hypothesis. Until recently, however,elastic wave velocity measurements was technically difficult, and the data was not enough. In recent years the velocity measurement has been made extensively,and it brought controversy in mineralogy of the earth´s transition. The authormeasured the elastic wave velocity of forsterite and its beta-form, and found discrepancy between the seismic velocity jump at 410km discontinuity and thatobserved in the forsterite-beta spinel phase change. To explain this discrepancythe author introduced ˝eclogite˝ hypothesis on mineralogical composition of thetransition layer in the earth´s mantle. The ˝eclogite˝ model means that majorconstituents of the transition layer are high pressure versions of eclogite minerals. To judge these two hypotheses we need essentially new method of discussion of the problem. In this presentation the author discuss new aspectof elastic properties of olivine, spinels and eclogite minerals. Elastic properties of crystalline solid is mainly determined by its Crystal structure, if elements which constitute the solid are similar. Garnet type structure is more rigid compared to that of silicate spinels. Rigidity of crystalline solid is directly related to a transverse velocity (Vs) of the solid. So the ratioVp/Vs would reflect essential difference of elastic property among olivine-spinel group minerals and garnet-type minerals effectively, and could be a judgment standard for the problem. First of all, the author discuss the Vp/Vs ratio of the upper mantle. To estimate the ratio of the mantle, data of Vp andVs must be chosen very carefully, because, in most case, Vp and Vs distributionare determined independently using different observational data. At present the author used the Vp and Vs distributions, which were determined by the same author or the same group of authors using similar data. Values of this mantle ratio show steep increase in the depth range between moho and the 410km discontinuity, and in the transition layer the ratio dose not change with depth.Temperature and pressure dependence of the Vp/Vs ratio of peridotite and olivine-spinel group minerals is highly positive, and peridotite upper most mantle might be verified. The seismically determined Vp/Vs ratio in the transition layer,on the contrary, suggest a garnet type material in the layer.

JSS06/07P/A04-010   1720

THE ROLE OF A SLAB AVALANCHE IN THE RECENT EVOLUTION OF THE NEW HEBRIDES SUBDUCTION ZONE

Miaki ISHII[1], Russell N. PYSKLYWEC[2], Jerry X. MITROVICA[3] ([1]Department of Earth and Planetary Sciences, Harvard University, [2]Department of Geology, University of Toronto, [3]Department of Physics, University of Toronto)

The recent evolution of the New Hebrides subduction boundary exhibits a more complex deformation history than would be expected from simple plate-tectonic theory.In the late Miocene, highly oblique southwardconsumption of the Pacific plate along the Vitiaz trench ceased assubduction jumped across the New Hebrides arc and north-dipping subduction of the Australian plate commenced. Subsequent, rapid rotation of the New Hebrides arc away from the extinct Vitiaz trench was accompanied by substantial back-arc opening and the development of the North Fiji Basin. The mechanism responsible for this dramatic reorganization has remained elusive. We propose that an ongoing avalanche of cold slab material into the lower mantle, recently imaged by seismic tomographic methods, provides a unifying geodynamic framework for reconciling the recent evolution of the region. We present numerical models which satisfy disparate observational constraints, including the change in polarity of plate subduction, the rapid migration of the New Hebrides arc, opening of the North Fiji Basin, and the present-day geometry of slabs associated with both active and

CHEMICAL STRATIFICATION IN A NUMERICALLY MODELED TWO-DIMENSIONAL MANTLE WITH MAGMATISM AND MOVING PLATES

Masaki OGAWA (Department of Earth Sciences & Astronomy, University of Tokyo at Komaba)

A A self-consistent numerical model is presented for magmatism in a convecting mantle with moving plates. Mantle convection is modeled as a thermal-chemical convection of binary eutectic material with Newtonian rheology in a two-dimensional rectangular box internally heated by incompatible radioactive elements. Viscosity is assumed to depend on stress-history as well as temperature and pressure to self-consistently reproduce moving plates. The effects of solid-solid phase transitions at depths around 660 km on the convection is also taken into account. Magmatism is modeled as a permeable flow of basaltic melt produced upon decompression melting of the binary eutectic material through the coexisting matrix. Magmatism makes mantle chemically stratified with the shallower part occupied by chemically buoyant residue of magma depleted in radioactive elements and the deeper part occupied by hot but chemically dense materials enriched in basaltic component and radioactive elements. The magmatism is mostly induced by mantle overturn when internal heating is sufficiently strong or weak but is induced by moving plates (ridge volcanism) and hot plumes uprising from the 660 km phase boundary or the hot region enriched in basaltic component at depth in the lower mantle when the internal heating is moderate; plate motion is significant only when the internal heating is moderate. When plates move, subducting slabs penetrate deep into the lower mantle and induce broad thermal and chemical heterogeneity at depth in the lower mantle. The mantle with moderate internal heating is compared to the earth´s mantle.

WHAT DETERMINES ISOTOPIC AGE? CLUES FROM NUMERICAL MODELS OF MANTLE CONVECTION WITH EVOLVING GEOCHEMICAL HETEROGENEITY

Paul J. TACKLEY, Shunxing XIE (ESS and IGPP, UCLA)

Isotopic measurements on Mid Ocean Ridge Basalts and Ocean Island Basalts indicate effective ˝ages˝ (from e.g., Pb-Pb or Sm-Nd systems) in the range 1-2 billion years- much less than the age of the Earth, even though melting should have been much more vigorous early on, skewing the mean time since melting to older values. This relatively young ˝age˝ has generally been explained in terms of stretching of heterogeneities by mantle convection, which might reduce them to dimensions too small to be individually distinguishable in short timescales of less than 1 Gyr. On the other hand, published numerical models that use tracers to track differentiated material (Christensen and Hofmann, 1994, Davies, 2002) suggest that Earth-like ˝ages˝ can be obtained without taking stretching-induced erasure of tracer signatures into account, although this might effectively happen if the lengthscale for sampling the isotope systems was large enough. In those models, the only explicit mechanism for resetting isotope systems was re-melting, but for this to explain the isotopic ages observed for basalts, the global rate of melting in the recent past would have had to be very much higher than present-day values. To investigate stretching vs. re-melting we have conducted numerical experiments of a cooling mantle with plate tectonics, differentiation and evolution of important isotopic systems, as is fully described in another presentation at this meeting. The time of last melting and the total strain is tracked on each tracer (in addition to isotopic information). The results confirm that a model matching todays crustal production rate and with a reasonable secular cooling history generates ˝ages˝ that are substantially larger than those observed, with the extent of crustal settling above the CMB making some difference but not enough. The effect of sampling lengthscale on observed ˝age˝ is also tested and found to be insufficient to explain the data. Thus, these results reaffirm the importance of stretching as a key mechanism for effectively deleting older heterogeneities. From analysis of strain vs. age and matching of the observed ages, it is estimated that erasure of heterogeneities occurs at strains of 10^3-10^4, somewhat larger than has often been assumed.

HOTSPOT MOTION INFERRED FROM LARGE-SCALE MANTLE FLOW MODELS: IMPLICATIONS ON GLOBAL PLATE RECONSTRUCTIONS

Bernhard Maximilian STEINBERGER[1], Richard J. O'CONNELL[2] ([1]IFREE, JAMSTEC, [2]Dept. of Earth and Planetary Sciences, Harvard University)

The Hawaiian hotspot track predicted from a plate circuit, assumingthat the Hawaiian hotspot is fixed relative to African hotspots,does not fit the observed track: The divergence is steadily increasingback to 43 Ma, and the predicted track does not show a bend.Here we use a model of plumes distorted by global mantle flow tocompute hotspot motion, and test whether this motion can explain themisfit. Computations consistently predict a south-tosoutheastward motion of the Hawaiian hotspot, and a motion ofabout 1000 km southward during the past 80 Ma is within the rangeof model results. Thus, we find that our model of hotspot motion canaccount for the divergence from 0 to 43 Ma, but can not account forthe bend and the track prior to 43 Ma. For this, both a rather sharp change inhotspot motion at 43 Ma, and a westward component of hotspot motionprior to 43 Ma would be required, and neither is predicted in the model.However, a combination of modelled hotspot motion and a relatively modestmotion between W and E Antarctica - about 15 degrees clockwiserotation of W vs. E Antarctica - would permit a fit to the Hawaiiantrack from 80 to 43 My. The required deformation on the Antarcticplate could have beenaccomplished entirely within continental crust, with rates similarto e.g. present extension in the western U.S., andis not in conflict with, but actually supported by geologicevidence.

JSS06/08A/A04-003   0910

MANTLE DYNAMIC AND TRUE POLAR WANDER

Marianne GREFF-LEFFTZ (Departement de Geomagnetisme, Institut de Physique du Globe de Paris)

True polar wander (TPW), the coherent motion of Earth´s surface with respect to its rotation axis, is most likely controlled by internal mass redistribution within mantle. Recent paleomagnetic study find that true polar wander appears to be episodic in nature, with periods of quasi-standstill alternating with periods of faster TPW. The typical duration of these periods is on the order of a few tens of millions of years with wander rates during fast tracks on the order of 30 to 50 km/Ma. Here, we investigate mechanisms able to produce abrupt changes in the TPW. We first present some results about the influence of a plume crossing the mantle on the polar motion in order to explain fast excursion of TPW. In a

simple example where the upwelling plume is simply modelized by a sphere -with a radius variable as a function of the heatflux within the conduit- crossing the mantle at the Stokes velocity, we have investigated the influence of the phase change (physical or chemical) and of the viscosity contrast at the 670 km depth discontinuity.In some cases, fast changes may occur in the principal inertia direction but the weak amplitude of the inertia tensor perturbations involves that the rotation axis is not significantly affected by this upwelling plume. We extend these results to the study of the effects of two superswells, located one beneath Africa and the other one beneath Polynesia, on TPW. These superswells are modelised by two domes oscillating vertically within the mantle with periodicity of about 100 Ma.We find that such mantle mass anomalies can significantly pertub the TPW (with wander of about 0.5°/Ma) and involve polar motion with periods of slow velocity alternating with periods of faster TPW.

JSS06/08A/A04-004   0930

WHAT DRIVES PLATE TECTONICS? SLAB PULL, RIDGE PUSH OR GEOMAGNETIC TORQUE FROM THE CMB? A NEW LOOK AT THE OLD PLAYERS VIS-A-VIS AN EXCITING NEW ONE

Miles F. OSMASTON (The White Cottage, Sendmarsh, Ripley, Woking, Surrey GU23 6JT, UK: miles@osmaston.demon.co.uk)

Fundamental reappraisal of the mechanisms that drive plate tectonics suggests the remarkable conclusion that, for at least the past 130Ma, a major agent has been a CW-directed torque (probably of electromagnetic origin at the CMB) reaching the deep ($>$600km, e.g. Gu et al 1998 EPSL) tectospheric keel of the Antarctica craton, via the high-viscosity lower mantle. Major changes in spreading direction marked both ends of the 122-85Ma Cretaceous Superchron and started by forming the Ontong Java Plateau. Action of MORs as gearlike linkages has driven Africa and India CCW since Gondwana breakup and continues to drive the Pacific plate CCW. In the Arctic there is now no cratonic keel to pick up any corresponding polar torque, so northern hemisphere plate tectonics is far less active. My multifaceted study (over 25 years) of the subduction process has indicated that the rapid development of ´flat-slab´ interface profiles involves the physical removal of hanging wall material (beit lower crust or mantle) in front of the downbend by basal subduction tectonic erosion (STE). Historically this, and its active seismological manifestation known as seismic coupling, only occurs where the subducting plate was/is $<$70Ma old. Hence the requisite subducting plate buoyancy must be thermal and slab-pull an unlikely agent for such subduction - a conclusion reinforced by the abundant development of progressive foreland-directed thrusting during the STE process, which intermittently couples ridge push to the upper plate. Lots of ridge push is needed to drive that thrusting and the subduction of such buoyant plates. Accordingly, a redesign of the MOR process has incorporated the suboceanic LVZ as a physically integral part of the plate (Osmaston 2000 IGC Rio). This model not only generates much more (but still being quantified) ridge push, as required, but has turned out to be very successful in relation to MOR structures. The heat content takes the form of a superadiabatic gradient in the now-stiff LVZ, and is partially trapped (until subduction) by the much ($>$30%) lower thermal conductivity resulting from its (say 3%) interstitial melt. Perhaps surprisingly, this incorporated ocean-plate-heat is indeed evident as slab reheating during active subduction. Examples from among numerous circum-Pacific tomographic transects, kindly provided to me, all show that the ´slab´ high-Vp signature peters out at between 175 and 350km (plate age-dependent and even at 130Ma) and a second high-Vp signature then begins close to the top of the TZ and goes on into the lower mantle. This latter signature must be mineralogical, not thermal, and arguably is not mantle but is only a stream of dense stishovitic lumps residual from partial melting of subducted oceanic crust at TZ pressures. Where now is the slab pull beloved of modellers? A different cause exists for ´roll-back´. I conclude that CMB torque initiated the Atlantic and is probably the primary driver of plate tectonics, that ridge push comes second and slab pull a doubtful third. To generate such torque may require the presence of semiconductor properties in the CMB region.

JSS06/08A/A04-005   0950

IS TRUE POLAR WANDER IN THE LAST 200 MILLION YEARS A SIGNATURE OF EPISODIC INTER-HEMISPHERIC MOTION OF PRIMARY HOTSPOTS AND LOWER MANTLE CONVECTION?

Vincent E. COURTILLOT, Jean BESSE, Anne DAVAILLE (Institut de Physique du Globe)

Apart from a surge in true polar wander (TPW) in the last 5-10Ma, which could be related to the recent history of ice loading, there has essentially been no TPW back to 50 Ma ago. This standstill was preceded by a period of moderate, rather uniform TPW at a mean rate of 3 km/Ma. Although earlier data become more uncertain, a standstill prior to 130 Ma seems possible (though given uncertainties, some amount of rather jerky TPW is possible). These observations suggest that TPW is an episodic process (its second derivative can be approximated by a series of Dirac distributions separated by irregular intervals on the order of 50 Ma or more). There is however no convincing evidence for the episodes of super-fast TPW which have been proposed recently by a number of authors, though much additional paleomagnetic data is still desirable to analyze specific periods. One problem is that the TPW curve is derived from hotspot data restricted to the Indo-Atlantic hemisphere and is therefore not truly global. An independent (and methodologically distinct) determination using the far more limited Pacific plate database shows that, to first order, episodic and rather slow TPW with moderate amplitudes is a real feature of Earth dynamics. All current geodynamic models fail to account for the observed features. On closer inspection, the Pacific and Indo-Atlantic determinations of TPW fail to agree in the 50-100 Ma time window. Based on a set of five (geophysical, geochemical and geological) criteria, we have recently proposed that 7 out of 49 hotspots, 3 in the Pacific hemisphere, 4 in the Indo-Atlantic, which we have called primary, may have a very deep origin (this number might be somewhat higher but available data and the criteria we use do not allow to ascertain this yet). Hotspots in each hemisphere move at less than 5mm/a, whereas there has been significant (up to 50mm/a) episodic motion between the two hemispheres. These episodes coincide with those in TPW (over the limited range of the last 100 Ma when they are sufficiently well constrained). The primary hotspots passively trace the motions of quadrupolar lower mantle convection. The episode of TPW which may have started some 130Ma ago and stopped some 45-50Ma ago may have been triggered by an avalanche in the lower mantle (?) or by major change in plate boundaries. Another change at the time of generalized collision of India/Arabia/Africa with Eurasia and disappearance of huge subduction zones between these plates may be responsible for the 50 Ma halt in TPW and hotspot motion. In the last 50 Ma, Earth has mostly been in a quiescent stage.

JSS06/08A/A04-006   1010

MODELLING OF DYNAMICS OF DESCENDING SLAB AND TECTONIC STRESS IN THE EARTHQUAKE-PRONE VRANCEA REGION, SE-CARPATHIANS

Alik T. ISMAIL-ZADEH[1], Birgit MUELLER[2], Friedemann WENZEL[2] ([1]IIEPT, Russian Academy of Sciences, Moscow, and Geophysical Institute, University of Karlsruhe, Germany, [2]Geophysical Institute, University of Karlsruhe, Germany)

Repeated intermediate-depth large earthquakes of the SE-Carpathians (Vrancea) attract an attention of geoscientists to the region. Recent regional P-wave seismic tomographic images of the mantle revealed a high-velocity body in a nearly vertical position. The body is interpreted as a lithospheric slab descending into the mantle, and Vrancea seismicity is associated with the slab. To understand processes of stress generation in and around the descending slab, mantle flow and tectonic stress beneath the region are analysed by means of analytical and numerical modelling and on the basis of available geophysical data. An analytical model of corner flow predicts that the maximum shear stress migrates from the upper surface of the slab to its lower surface in the course of changes in slab dynamics from its active subduction through roll-back movements to sinking solely due to gravity. The changes in stress distribution can explain the location of hypocentres of Vrancea events at the side of the slab adjacent to the Eastern European craton. A 2D thermomechanical FE model of a sinking slab predicts lateral compression in the slab as inferred from the stress axes of earthquakes and its thinning and necking. The maximum stress occurs in the depth range of 80 km to 200 km, and the minimum stress falls into the depth range of 40 km to 80 km. The area of maximum shear stress coincides with the region of high seismicity, and minimum shear stress in the model is associated with the lower viscosity zone. Uplift of the crust starts before the slab detachment. Just after the detachment the tectonic stress in the slab is still high enough to lead to a seismic activity, and the stress decreases significantly in several Ma. Using recent experimental data on elastic parameters and anelasticity, we obtain a model of temperature at 50 to 350 km depth beneath the SE-Carpathians from the seismic tomography model of P-wave velocity anomalies. The modeled thermal structure beneath the SE-Carpathians predicts a cold area associated with the descending Vrancea slab and relatively hot mantle regions surrounding the slab. We analyse a mantle flow and tectonic stress induced by the sinking slab by means of 3D numerical modelling. Input model data are the geometry of the crust and slab, temperature-dependent density and viscosity. The crustal movements predicted by the numerical models are consistent with GPS data on the regional vertical motions. Modeled tectonic stress predicts a horizontal compression beneath the Vrancea region, and it coincides with the stress regime defined from fault-plane solutions for intermediate-depth earthquakes. The stress reaches maximum at depths of 70 to 110 km and 130 to 180 km and decays below being in a good agreement with the observed seismicity.

JSS06/08A/A04-007   1050

WAVEFORM MODELING OF MANTLE ANISOTROPIC ELASTIC STRUCTURE

Mark P. PANNING, Barbara ROMANOWICZ (Berkeley Seismological Laboratory, University of California, Berkeley)

Seismic tomography is a useful tool in determining structure anddynamics of the Earth´s mantle. While early models depended primarilyon short period travel times and surface wave phase velocities, usingfull seismic waveforms of both surface waves and body waves providesopportunities for improved resolution, especially in the lower mantle,when appropriate sensitivity kernels are used (e.g. Li and Romanowicz,1996). Our previous work in waveform modelling has focussed on isotropic shearvelocity structure of the mantle, but we have recently extended ourwaveform modelling method to a transversely isotropic model, ananisotropic medium with hexagonal symmetry and vertical symmetry axis,and applied it to the upper mantle (Gung et al., 2003), where theanisotropic structure is well documented both in terms of radiallysymmetric structure, as in PREM (Dziewonski and Anderson, 1981), andlateral variations (Montagner and Tanimoto, 1991; Ekström andDziewonski, 1998). However, there is also strong evidence forsignificant anisotropy in D´´ and, more recently, several studies havesuggested the presence of anisotropy near the transition zone betweenthe upper and lower mantle. Although transverse isotropy is often described by the five elasticparameters, A,C,F,L, and N, we reparameterize in terms of isotropic Pand S velocity, and three terms related to anisotropy. We furtherapply scaling relationships to invert only for our best-resolvedquantities, isotropic S velocity and ξ, an anisotropic parameterrelated to SH velocity over SV velocity. For the uppermost mantle, our results are quite consistent with our earlierwork (Gung et al., 2003), as well as regional studies. We see apositive ξ anomaly (SH$>$SV) under the oceanic basins in the depthrange 80-200 km, as well as deeper postive ξ anomalies beneath mostcontinental cratons from 200 to 400 km depth. We also see negative ξ anomalies (SV $<$ SH) in the transition zone thatcorrelate well with the locations of fast isotropic velocity anomaliesassociated with downwelling slabs. D´´ in our model is characterized by a predominantly positive ξ signature, extending to the entire globe results of regional studiesbased on the splitting of diffracted S waves. This SH $>$ SV signature maybe related to dominant horizontal deformation in a mechanical boundarylayer for mantle convection, although the mineral physics behind D´´anisotropy is still an area of active research (e.g. Karato, 1998).However, the low velocity areas corresponding to ˝superplumes˝ are anotable exception to the positive ξ dominance. These regionsappear to be more variable, and contain large regions with either verysmall positive or negative ξ anomalies, also generalizing someregional results.

GLOBAL UPPER MANTLE SHEAR VELOCITY AND ANISOTROPY FROM WAVEFORM ANALYSIS OF FUNDAMENTAL AND HIGHER MODE RAYLEIGH WAVES

Eric DEBAYLE[1], Alessia MAGGI[1], Anne SIEMINSKI[1], Sylvana PILIDOU[2], Maggy HEINTZ[3], Keith PRIESTKEY[2], Brian KENNETT[4], Jean-Jacques LEVEQUE[1], Michel CARA[1] ([1]CNRS and EOST, Universite Louis Pasteur, Strasbourg, France, [2]Bullard laboratories, University of Cambridge, United Kingdom, [3]Laboratoire de Tectonophysique, CNRS and Universite de Montpellier II, France, [4]RSES, Australian National University, Canberra, Australia.)

A collaboration between researchers from the University of Cambridge, the Australian National University in Canberra, the University of Montpellier and the Ecole et Observatoire des Sciences de la Terre in Strasbourg has allowed us to successfully match the waveforms of more than 40 000 fundamental and higher mode Rayleigh waves, using multi-mode synthetics seismograms computed for a path-average upper mantle elastic model. The selected waveforms are associated with relatively short epicenter-station paths ($<$ 10000 km) typical of regional surface wave tomography at the scale of a tectonic plate. They provide a quasi-global coverage of the Earth with an original dataset, less likely to beaffected by spurious effects such as multipathing or focusing/defocussing, compared to the longer R1 and R2 paths classically used in global tomography. The resulting tomographic model has a horizontal resolution smaller than 1000 km for the uppermost 500 km of the Earth and allows us to put new constraints on the upper mantle structure.In particular, our preliminary results show that well-resolved deep low velocities extending down to at least the transition zone are observed beneath some major hotspots, but also in other regions where they are not directly associated with hotspot volcanism at the surface. This would support in some oceanic regions a model of plume-fed asthenosphere. In addition, our model also suggests that the high velocity lid associated with cratonic roots is relatively thin and rarely exceed 250 km depth.

MAPPING 3D SEISMIC ANISOTROPY FOR UNDERSTANDING STRUCTURE AND THICKNESS OF THE MANTLE LITHOSPHERE

Jaroslava PLOMEROVA, Vladislav BABUSKA (Institute of Geophysics, Czech Academy of Sciences, Bocni II, 141 31 Prague 4, Czech Republic)

The alignment of olivine crystals is the dominant source of seismic anisotropy in the sub-crustal lithosphere and asthenosphere. Three-dimensional modelling of seismic anisotropy of the upper mantle, based on joint inversion and interpretation of body waves, revealed large anisotropic domains in the continental mantle lithosphere. The domains are often sharply bounded by sutures cutting the whole lithosphere. Different components of large-scale anisotropy can be traced in depth distributions of the radial and azimuthal anisotropy of surface waves. We proposed a global model of the lithosphere-asthenosphere boundary (LAB) as a transition between a ´frozen-in´ anisotropy in the lithosphere to anisotropy in the sub- lithospheric mantle related to the present-day flow. Base of the lithosphere, in this sense understood as the Lehmann discontinuity, plunges not deeper than down to 200 and 250 km even beneath the stable Precambrian shields and platforms. Due to different prevailing orientations of velocity maxima in the anisotropic subcrustal lithosphere and the asthenosphere, the velocity contrast related to the LAB can increase in particular directions. We model fabric of the anisotropic lithospheric domains by peridotite aggregates with hexagonal symmetry exhibiting dipping (a,c) foliation planes, or orthorhombic symmetry with dipping lineations (a-axes). The large-scale fabric, consistent on a scale of hundreds of kilometres, occurs due to preferred orientation of olivine - the most abundant mineral of peridotites - as a result of stress field acting during the formation, or later deformations of the mantle lithosphere. Subsequent continental break-ups and re-arrangement of micro-plates resulted in observed complicated structure of continental mantle lithosphere mostly retaining ´frozen-in´ anisotropy of mantle domains. Thus we observe, e.g., European Variscan Massifs formed by several microplates of different origin and development, large-scale structures in the stable lithosphere of northern Proterozoic/Archean Baltic Shield, and/or a shift/rotation between crust and mantle parts of the Phanerozoic and Proterozoic lithospheres around the Trans-Europen Suture Zone. Mapping the anisotropic structures of individual mantle domains contributes to our understanding how the present-day continents were formed and evolved.

ANISOTROPY UNDER CONTINENTS AND OCEANS: EVIDENCE FOR LATERALVARIATIONS IN THE DEPTH OF THE ASTHENOSPHERE

Yuancheng GUNG, Barbara ROMANOWICZ (UC BERKELEY)

We show that the lack of correlation between different global tomographicmodels of S velocity, in the depth range 200-400 km, can be explained bythe presence of anisotropy, with a strong Vsh >Vsv component, under mostcontinental cratons. To confirm the presence of this anisotropy, already pointed out by Montagner (1995), we have developed an inversion procedure for transverse isotropy using three component surface and bodywaveform data, in the framework of normal mode asymptotic coupling theory (NACT, Li and Romanowicz, 1995), which in particular, involves the use of 2D broadband anisotropic sensitivity kernels appropriate for higher modes and body waves. This method allows the inclusion of higher mode surface wave and body waveforms, which provide better depth resolution in the upper mantle than standard inversions based on fundamental mode surface waves. Our resulting degree 16 anisotropic model(SAW16AN) confirms the globalxi (=N/L) distribution found in previous studies in the depth range 100-200km, which is dominated by the striking positive dlnxi anomaly in the central Pacific and a similar one in the Indian Ocean. However, at depths greater than 250 km, the character of the distribution changes: positive dlnxi emerges under the Canadian Shield, Siberian Platform, Baltic Shield, southern Africa, Amazonian and Australian cratons. At 300 km depth, the roots of most cratons are characterized by positive dlnxi which extend down to about 400 km. Interestingly, the East Pacific Rise has a signature with dlnxi <0 down to 300km, indicative of a significant component of vertical flow. At 400km depth, we also note the negative dlnxi around the Pacific ring, consistent with quasi-vertical flow in the subduction zone regions in the western Pacific and south America. We propose that the Vsh >Vsv anisotropy, in the depth range 200-400km under cratons, and 80-200km under ocean basins are both related to shear in the asthenospheric channel, located at different depths under continents and oceans. The seismically defined tectosphere is then at most 200-250 km thick under old continents, in agreement with other geophysical observations.The Lehmann discontinuity, observed under stable continents in the depthrange 200-240 km, would then correspond to the top of the asthenosphere,and would mark a transition from the weakly anisotropic bottom of themechanical lithosphere to the strongly anisotropic asthenosphere, inagreement with early interpretations (Leven, 1984). One would not expectto observe this discontinuity at these depths under oceans, where thelithosphere/asthenosphere transition is much shallower.

JSS06/08A/A04-011 1210

HIGH RESOLUTION P-WAVE TOMOGRAPHY IN A GLOBAL MANTLE MODEL

Christian WEIDLE[1], Sri WIDIYANTORO[2], CALIXTO Group ([1]Geophysical Institute, Karlsruhe University, Hertzstr. 16, 76187 Karlsruhe, GERMANY, [2]Institut Teknologi Bandung, INDONESIA)

Many seismological tomography experiments with mobile stations and a local or regional focus have been carried out over the past 20 years. These experiments provided data sets which allow for a regional inversion of the seismic velocities in the upper mantle. Usually this inversion was done using a linearized inversion scheme where the resulting velocity model was linearized around a 1-D input model. This method proved to show reliable results, but only to a certain depth depending on the dimensions of the station network. To improve the resolution in depth we integrate regional data sets from experiments with mobile station networks into a global data basis and invert for the entire earth's mantle using a non-linear, iterative inversion scheme and a parameterization adjusted to the data density and the region of interest. In this way we can use the advantages of both global and teleseismic tomography: - by using a 3-D Ray tracing algorithm and an iterative, non-linear inversion scheme on the entire earth's mantle, heterogeneities in the velocity structure of the mantle can be localized and are therefore not mapped into the region of interest. In combination with the fact that the global data set has no frame dueto its global distribution of stations, we can expect a better resolution with depth as for teleseismic tomography alone, which is especially important in regions of deep structures, like subduction zones or mantle plumes. - On the other hand, the dense station coverage in the region of interest allowsfor a regional finer parameterization and therefore a regional higher resolutionof the velocity structure comparable to the resolution of teleseismic tomography. Additionally our result is not isolated but in the context of the larger scale velocity structure and can be interpreted in a greater frame than just the region of interest. We apply this approach to south-eastern Europe, where a high quality teleseismicdata set of first arrival times from the 1999 CALIXTO-Experiment (Carpathian ArcLithosphere X-Tomography) is integrated into an updated version of the widely used global data set by Engdahl et al. with recordings from 1964-1998.The CALIXTO data set includes 60 azimuthal equally distributed events which

wererecorded between May and November 1999 at around 120 stations in the Carpathians(Romania). One critical geodynamic problem of the area refers to the depth extend of a remnant slab (Vrancea slab) that is currently detached and hosts strong intermediate-depth earthquakes. The inversion results provide an improved resolution in depth compared to results of an inversion using the linearized ACH-method. The velocity models also show some amplitude exaggeration in the shallower parts of the model which can be ascribed to missing correction terms for station- and crustal effects (e.g. Moho topography). These results are supported by several synthetic resolution tests.

SLAB PENETRATION INTO THE DEEP MANTLE LAYERING: 2D VS. 3D

Takashi NAKAGAWA[1], Paul J. TACKLEY[2] ([1]Department of Earth and Space Sciences, University of California, Los Angeles, [2]Department of Earth and Space Sciences and Institute of Geophysics and Planetary Physics, University of California, Los Angeles)

Our previous study [Nakagawa and Tackley, 2003] focused on the possible thermo-chemical structure in the mantle that satisfies both seismological and geochemical constraints in two dimensional geometry. However, the model used in that study did not include three-dimensionality or tectonic plates, which may be generated by semi-brittle, semi-ductile yielding in the lithosphere, and are important for understanding seismic structure in the shallow mantle. In this presentation the interaction between subducting slabs and deep mantle layering, and its influence to the seismic structure in the whole mantle, are focused on using two- and three-dimensional models of mantle convection. The model assumes thermo-chemical convection of an anelastic and infinite Prandtl number fluid with temperature-, depth- and yield stress-dependent viscosity in a two- and three-dimensional rectangular box of dimensions 4x1 and 4x4x1. Cases that include either a thick chemical layer (30% of convective domain) or thin layer (10% of convective domain) will be presented in both 2D and 3D. We will show the fields of temperature, viscosity, chemical and seismic velocity anomaly, and compare spectral heterogeneity maps of seismic anomalies with those of actual tomographic models, in order to constrain the possible thermo-chemical structure in the mantle.

PHYSICAL DISPERSION WITH A REFERENCE FREQUENCY OF 2 HZ: BRIDGING BETWEEN SHORT- AND LONG-PERIOD S TRAVEL TIMES

Satoko OKI[1], Yoshio FUKAO[1], Masayuki OBAYASHI[2] ([1]Earthquake Research Institute, Univ. of Tokyo, [2]Institute for Frontier Research on Earth Evolution, JAMSTEC)

The P to S velocity ratio carries important information about the composition and state of the mantle. Comparison of the existing P and S tomography models, however, may not be always justified because of large differences in their accuracy and resolution. Our plan is to start from short-period S wave tomography consistent with P travel time tomography. At the present stage, we confirmed the validity of our method to measure S travel time with an unexpected finding about the reference frequency of the physical dispersion. Picking an arrival time of S wave is in general difficult, and waveform correlation is a method to solve this problem. With an assumption of a point source model, P and S waveforms at the source are identical, and so S waveform can be synthesized from observed P waveform by correcting attenuation effect. We take into account the physical dispersion which is characterized by two parameters t* and f0. The reference frequency f0 is conventionally set to 1 Hz. A search is made for the value of t* that gives the maximum cross-correlation for the first half cycle of waveform. Then S-P differential travel time is measured by cross-correlating synthetic and observed S wave. The measured S-P times have an advantage of being little affected by the uncertainty of origin time. Our method is justified for the consistency of measured travel times and those of AK135. To examine more detail, our cross-correlation method was checked against about 100 hand-picked S-P times. If the onset frequency were 1 Hz as conventionally regarded, the measured S-P with a reference frequency of 1 Hz and the hand-picked S-P should be close. We, however, found a systematic discrepancy of about 0.5 s between these two S-P times. This indicates a higher value for the reference frequency to be consistent with the onset frequency of short-period body waves. The 0.5 s discrepancy disappears when the reference frequency is taken to be 2 Hz. This result should be of great significance in bridging between long- and shot-period S travel times. The body wave models and associated travel time curves such as JB, IASP91 and AK135 should be those at a reference frequency of 2 Hz, not 1 Hz. If one wishes to combine these body wave models to those derived from normal mode data by taking physical dispersion into account, some correction is required for the Q model.

ESTIMATE OF ISOTROPIC AND ANISOTROPIC STRUCTURES OF THE EARTH BY SPECTRAL INVERSION INCORPORATING TOROIDAL-SPHEROIDAL COUPLING

Hitoshi ODA (Department of Earth Sciences, Okayama University)

The effect of isotropic and anisotropic velocity perturbations of seismic body waves on low-frequency multiplets of the earth's free oscillation was investigated using synthetic spectra calculated for an aspherical earth model, in which the velocity perturbations regionally vary. Hexagonal anisotropy of which the c-axes lie horizontally is assumed in the upper mantle. The influence of the velocity perturbations on the vertical component spectrum appears as amplitude anomaly, 'quasi-toroidal" mode resulting from toroidal-spheroidal coupling. Azimuthal dependence of the spectral amplitude of the quasi-toroidal mode excited by a vertical strike-slip fault is similar to the Love wave radiation pattern. In addition the free oscillation spectrum, especially the quasi-toroidal mode spectrum, is more sensitive to anisotropic velocity perturbation than to isotropic velocity perturbation. This means that the free oscillation spectrum may provide not only constraints on isotropic lateral structure but also those on anisotropic lateral structure. In order to retrieve the isotropic and anisotropic velocity perturbations from free oscillation spectra incorporating the quasi-toroidal mode, we presented an inversion method, 'mixed-coupling spectral inversion" where three kinds of splitting functions were defined for toroidal, spheroidal and mixed-coupling modes,

respectively. We confirmed that the isotropic and anisotropic lateral structures were correctly estimated from the free oscillation spectra and that mixed-coupling spectral inversion made it possible to estimate the odd order interior structure of the earth, which has been unable to be determined by the conventional spectral inversion with taking no account of the mixed-coupling. It was demonstrated that the mixed-coupling biases the estimate of higher order structure when the conventional spectral inversion is applied to the amplitude spectra incorporating the mixed-coupling.

INTERNAL STRUCTURES OF THE TERRESTRIAL PLANETS FROM GRAVITY AND TOPOGRAPHY CORRELATIONS: A STUDY OF OBSERVATIONAL CONSTRAINTS ON EVOLUTION MODELS OF PLANETS

Laramie Vance POTTS, C.K. SHUM (Laboratory for Space Geodesy and Remote Sensing Research, The Ohio State University)

The internal structures of terrestrial planets are commonly constrained by seismic data and geochemical considerations. Analysis of satellite-measured gravity and topography can provide crust-to-core mass variation models for considering the geologic evolution of terrestrial planets. These mass differentiated models facilitate developing new perspectives on the poorly understood crustal and subcrustal features of the terrestrial planets. We suggest that these constraints may be augmented by gravity drilling that focuses on interpreting satellite altitude free-air gravity observations for boundary undulations of the internal density layers related to mass flow. This approach involves separating the free-air gravity anomalies into terrain-correlated and -decorrelated components based on the correlation spectrum between the anomalies and the gravity effects of the terrain. The terrain-decorrelated gravity anomalies are largely devoid of the long wavelength interfering effects of the terrain gravity and hence provide enhanced constraints for modeling mass variations of the mantle and core. For the Earth, subcrustal interpretations of the terrain-decorrelated anomalies are constrained by radially stratified densities inferred from seismic observations. For other differentiated bodies like the Moon, Mars and Venus, seismic soundings are largely lacking so that geochemical and moments-of-inertia considerations must be invoked to constrain the radial density structures in interpreting the terrain-decorrelated free-air anomalies. These anomalies, with frequencies that clearly decrease as the density constrasts deepen, facilitate mapping mass flow patterns related to the thermodynamic state and evolution of the interior. Results for the moon obtained from inversions of the lunar subcrustal anomalies inferred boundary undulations of the lunar core-mantle boundary, asthenosphere-lithosphere, and middle-upper mantle during bombardment time. The elevated core beneath the Procellurm basin is consistent with the uplifting effects of the Imbrium impacts and the development of the great lunar hotspot. Topographic undulations inferred for the lower and middle mantle reflect a dichotomized thermal evolution of the lunar near-and farside. Our results further suggests that on the nearside, a relatively thinner and hotter lithosphere developed by mantle convection which facilitated the diapiric rise of magma and mare flooding of basins. Viscous entrainment of lower density material into the lower mantle on the farside developed a thicker and cooler lithosphere that may also have restricted basin flooding. We are currently extending our procedure for comparison of global gravity analysis for the Earth, Mars and Venus.

NUMERICAL STUDY OF EFFECTS OF CONTINENTAL PLATES ON MANTLE DYNAMICS

Yasuyuki IWASE[1], Satoru HONDA[2] ([1]Department of Earth and Ocean Sciences, National Defense Academy, [2]Earthquake Research Institute)

Numerical simulation of mantle convection with continental plates iscarried out to investigate the dynamic interaction between them.Three-dimensional spherical shell mantle convection model is used,in which mantle is assumed an incompressible and infinite Prandtl number fluid and Boussinesq approximation is adopted.The continental plates are modeled by high viscosity region of the mantle and are assumed to be moved by the horizontal averaged mantleflow velocity within the region. Numerical experiments are conducted for three cases, in which numberof the continental plates are one, two and four, respectively.In each case, the total areas of the continental plates are almost equal.Mantle temperature beneath the continents increases for all the casesdue to the blanket effect of the continents.Although the volume averaged mantle temperatures show small increasesand decreases with time, which is related to the locations of hotplumes and continents, the time averaged temperatures are almost thesame for all the cases.However, the amplitude of temperature difference between mantlebeneath continents and other part is larger, if the number ofcontinents is smaller, i.e., area of a continent is larger. For the single continental plate case, huge rising plume is generatedbeneath the continent and the continent is drifted away from the plumeby the horizontal flow accompanying with the plume generation.Then, the huge plume weakens and a new plume grows beneath thecontinent.As a result, spectrum of temperature field show that sphericalharmonic degree l=1 is dominant for almost all the time.In cases of two and four continents, when the continents are locatedclosely each other, plumes assemble beneath the continents and mergeinto a large plume.Flow associated with plume disperses the continents but they can beassembled again at the antipode due to the sphericity of the mantlesurface.Thus, the dominant wave length of the thermal structure alternatebetween l=1 and l=2 or 4 with time. The results of this study suggest that the thermal evolution of thewhole mantle is controlled by the total size of the continental areabut the magnitude of the super plume may be affected by the size ofeach continent.The generation of the super plume and the aggregation, breakup andseparation of continents may be explained by the dynamic thermalinteraction between mantle and continental plates.

THERMAL EVOLUTION OF THE EARTH WITH CONVECTION MODEL BASED ON MIXING LENGTH THEORY

Yasuko YAMAGISHI, Takatoshi YANAGISAWA (Institute for Frontier Research on Earth Evolution, JAMSTEC)

The thermal history of the Earth is supposed to have been essentially a cooling process. Convection is main mechanism for the process and plays a substantial role in the Earth´s structural evolution. Most of the thermal history models for the Earth take the convective heat transport into account by adopting the method of the parameterized convection. The convection occurring in the Earth´s interior, however, has some complicated aspects, including a large variation of the viscosity, internal heating and phase boundaries. Especially, the temperature dependency of the viscosity affects strongly on the efficiency of the convective heat transport and in the mantle, the viscosity should have strong dependency on the temperature and then have a large contrast. The parameterized convection needs to know the Rayleigh number of the convective region for the calculation of the efficiency of the heat transport. If the viscosity depends on the temperature, it inevitably differs with the position and the representative Rayleigh number of the convective layer should be decided arbitrarily. Therefore, the parameterized convection must treat the viscosity variation

artificially. There is an alternative method to calculate the efficiency of the convective heat transport, which we have developed based on the concept of ´mixing length theory´. This method needs only the local value of the various physical properties to calculate the efficiency of the convective heat transport. When using this method, the influence of the temperature dependency of the viscosity on the convective heat transport can be taken into account very easily, and the temporal change of the horizontally averaged temperature profile in the convective layer can be investigated by solving a mere thermal conduction problem. In this study, we firstly demonstrate that this method can calculate the efficiency of the convective heat transport correctly by comparison with the experimental results and 2D computational calculations. Next we actually calculate the one dimensional thermal history of the Earth by using this new method, taking account of the temperature dependency of the viscosity in the mantle and heat generation by the decay of the radiogenic isotopes and by the solidification of the inner core, and compare our models with the previous studies by using the parameterized convection.

DYNAMIC EVOLUTION OF PASSIVE FLOWS DUE TO LARGE-SCALE THERMAL ANOMALIES INSERTED INSTANTANEOUSLY WITHIN THE STATIC LAYERED MANTLE

Takao EGUCHI[1], Kiyoshi MATSUBARA[2], Mizuho ISHIDA[3] ([1]Dept. Earth and Ocean Sci., National Defense Academy, Yokosuka, JAPAN, [2]Fuji Research Institute, Tokyo, JAPAN, [3]N.I.E.D, Tsukuba, JAPAN)

To study three-dimensional unsteady mantle convection, we carried out numerical simulation on passive flows due to simplified local hot sources just above the CMB and/or large-scale cool masses beneath smoothed subduction zones. We utilized our individual numerical simulation code developed with the finite difference method. The basic three equations are for the continuity, the motion with the Boussinesq (incompressible) approximation, and the (thermal) energy conservation. The mantle viscosity in our model is sensitive to temperature. To obtain time integration with high precision, we followed the Newton method. The mantle velocity was initially set to zero throughout the layer. The temperature is 300K at the surface, ~ 2000K at the top of the lower mantle, 4,000K at the CMB. In the first model, the mantle viscosity has the temperature dependence which increases gradually from the CMB to the surface. The maximum and minimum values of the viscosity are 3.8E+24 (Pa s) at the surface and 1.6E+22 near the CMB, respectively. The second model has depth-fixed viscosity profile in which the averaged viscosity of the lower mantle is higher than that of the upper mantle. The maximum viscosity in the second model is 5E+22 (Pa s) at ~ 1,900 to 2,000 km depth and the minimum is 1E+21 at both regions of ~ 100 to 400 km and ~ 2,800 to 2,900 km depth. We in this study neglected the effect of surface plate motions, mineral phase changes and internal heating, etc. The Rayleigh number (Ra) is initially ~ 1E+7. To demonstrate numerically the viscosity dependence in the passive mantle flows, we input instantaneously a local cool mass (hereafter, case A) and great-circle cool ring (case B) as a finite negative buoyancy source near the top of the lower mantle, ~ 670 km depth. Also, as a finite positive buoyant source in the lowermost mantle layer, initial input of a local warm mass (case C) and great-circle warm ring (case D) were incorporated in the simulation. We describe the simulation result of cases A to D for the two viscosity models: In both the viscosity models, due to the negative or positive buoyancy of the thermal anomaly inserted initially at ~ 670 km depth or at the CMB, respectively, the mantle exerts gradually itself a large-scale viscous flow system. The passively excited flows in the second viscosity model show relatively higher velocities especially at distant regions from the buoyant source than those in the first model. For cases A and B, the angle distances for sites of major upwelling measured from the locus of the initial thermal anomaly input are ~ 30 deg. in the first model and ~ 35 deg. in the second model. For cases C and D, the angle distances measured from the site of the initial thermal anomaly to the place of the major down-welling are ~ 25 deg. in the first model and ~ 35 deg. in the second model.

THREE-DIMENSIONAL ELECTRICAL CONDUCTIVITY STRUCTURE BENEATH NORTH PACIFIC

Takao KOYAMA[1], Hisayoshi SHIMIZU[2], Hisashi UTADA[2] ([1]IFREE, Japan Marine Science and Technology Center, [2]Earthquake Research Institute, University of Tokyo)

In this paper, we present a model of three-dimensional electrical conductivity structure in the mid-mantle beneath the North Pacific by a semi-global three-dimensional inversion of EM data. We used data of voltage variations obtained by eight submarine cables and magnetic field variations at eight geomagnetic observatories/stations as well as C responses published Fujii and Schultz [2002]. We assumed that 3-D heterogeneous conductivity distribution can be separated into radially symmetric (1-D) structure and 3-D perturbation, in which the 1-D reference model beneath the North Pacific by Utada et al. [2003] is used. 3-D perturbation was inversely estimated so that the observation-calculation misfit is minimized with an additional mathematical constraint such that perturbation is smooth in space. For this analysis, a new three-dimensional inversion algorithm was developed by combining the steepest descent and the quasi-Newton methods. An integral equation solver using the modified IDM (e.g. Singer, 1995) was used as a forward solver. The 1-D reference model consists of 17 layers with 50 km thickness. Perturbation is assumed to exist in the depth range from 350 km to 850 km in a quarter of the Earth centered by the North Pacific, that is, in the horizontal range from 90 to 270 degrees of longitude and from 0 to 90 degrees of co-latitude. This region of perturbation is divided into 12 x 6 x 5 grids, i.e., total 360 grids of 15 degrees laterally and 100 km radially with unknown conductivity parameters, while the grid size for calculation is 3 degrees horizontally and 50 km in the depth. In the oceanic region, the ocean-land contrast makes a significant effect on EM responses, so we took into consideration the oceanic effect by including a priori ocean distribution with 3 S/m conductivity in the inversion.Total number of data parameters which are complex MT and GDS responses are 330. We have made a checkerboard test and found the spatial resolution depends on the distribution of observation sites (cables and magnetic stations). Considering this, following features can be pointed out that can be comparable to results of seismic tomography (e.g. Fukao et al., 2001; Megnin and Romanowicz, 2000): 1) There is a conducting zone in the transition zone beneath Hawaii with a conductivity perturbation of factor of three. 2) The uppermost lower mantle beneath Philippines is less conductive by a half. 3) The transition zone beneath Mariana is more conductive by three times. Assuming the heterogeneities purely of thermal origin, we found that they correspond to temperature anomalies of 200 - 300 degrees.

ISOTOPIC EVOLUTION OF THE MANTLE IN NUMERICAL CONVECTION MODELS

Shunxing XIE, Paul TACKLEY (Department of Earth and Space Sci., University of California, Los Angeles,USA)

To investigate dynamical mechanisms that have been proposed to explain geochemical observations, a model of mantle convection that combines a treatment of major and trace element geochemical evolution with a dynamically-consistent mantle convection-plate

---

tectonics is presented. Melting is simulated using a realistic solidus and is responsible for the generation of heterogeneity including the partitioning of trace elements between oceanic crust and residue; the subsequent hydrothermal alteration of element concentrations in the crust is also included. Trace elements studied are the U-Th-Pb and Sm-Nd isotope systems, helium and argon. Both olivine and pyroxene-garnet system phase transformations are included, with the relative density profiles of basalt, pyrolite, and harzburgite following those of Ringwood (1990) and Ono et al (2001) up to 800km depth, but varied in the deeper mantle to reflect present uncertainties. A suite of numerical experiments has been run to systematically investigate the sensitivity of the results to uncertain physical properties such as the density of subducted crust in the deepest mantle and elemental partition coefficients. In order to test whether the volumetric heterogeneities (associated with crustal differentiation and lower mantle segregation) obtained in our thermochemical models exist in Earth, we establish their observational signatures and compare to seismic observations. Statistical diagnostics such as field filtering, radial correlation functions and spectral heterogeneity map are used to characterize the observational signature of the thermochemical structures. Results indicate that the system can self-consistently evolve regions that have a HIMU-like signature (by segregation of subducted crust at the CMB) and regions with high He3/He4. Low He3/He4 ratios evolve in crustal material even though He may be more incompatible that U, due to outgassing of He to the atmosphere. Some parameter combinations simultaneously lead to Earth-like distributions of He3/He4 ratios, Pb-Pb and Sm-Nd ratio plots for erupted material, and ~50% outgassing of radiogenic Ar40 consistent with geochemical constraints. In the preferred model, helium is highly incompatible and crust is dense near the CMB. The Sm-Nd age is 1-2 billion years. Earth-like He3/He4 histograms are produced (in erupted material) when sufficient subducted crust mixes back into the shallow mantle to bring its Helium ratio down to the MORB-like range. Our results confirm that strong heterogeneities caused by crustal differentiation and subduction are in agreement with seismic tomographic models.

3D MANTLE P-VELOCITY MODEL BASED ON UNIFORMTETRAHEDRONIZATION OF THE EARTH AND THE NATURALNEIGHBOUR INTERPOLATION METHOD

Jianfeng PAN, Adam M. DZIEWONSKI (Harvard University)

Traditional parameterization of three dimensional (3D) Earth models consists of radial, and horizontal basis functions on aconstant lateral grid size independent of depth. As a result, the horizontal basis functions become more densely distributed with increasing depth. The nominal resolution thus becomes finer. For example, in the lower mantle and D′′ region, current whole-mantle models appear to be characterized by particularly short-wavelength structures and high gradients, which might not be real features. In this study, we use instead a 3D parameterization generated by an ``advancing front method´´ (NETGEN), given an initial triangulation on the surface of the Earth. The result is a number of tetrahedrons with optimal and, more or less, similar size making up of the Earth´s volume. We then utilize the natural neighbour interpolation technique to set up the whole mantle 3D inverse problem. The functional value (in our case, perturbation to the P-velocity) in any point within the Earth can be interpolated by the values of its natural neighbours (on the order of 10). The number of nodes decreases with depth as the volumedecreases. The basis function at each node is smooth, and dependent on the distances of other nodes around it. No separation of radial and horizontal basis functions is needed. Synthetic test with a 3D S-model S362 shows that most of the significant structures of S362 are recovered. The major differences exist: (1) at depth 2,500km and 2,800km, the recovered model is smoother and has less short-wavelength signal than S362; (2) at the surface and CMB, the recovered S-velocity perturbation tends to be larger. Currently we are deriving a whole mantle P-model. The preliminary result is promising. Compared to the traditional approach to employ both radial and horizontal basis functions in other studies, this parameterization allow a true 3D representation of the Earth´sseismic velocity perturbations. It is also straight-forward to build norm androughness damping matrices and apply them to the target model. Because of the ease of the grid generation and the grid-dependent basis function, it is also possible to introduce multigrid (denser grid points for some part but coarser for the rest) into the 3D seismic tomography to achieve multi-scale resolution.

3-D WAVEFORM SENSITIVITY KERNELS FOR SURFACE WAVES

Kazunori YOSHIZAWA (Division of Earth and Planetary Sciences, Hokkaido University)

With the assumption of scalar wave propagation in laterally heterogeneous structure, two-dimensional sensitivity kernels for surface-wave phase speeds for a single frequency can be efficiently constructed using the Born approximation linked to asymptotic ray theory [Yoshizawa and Kennett, 2002]. The combination of the two-dimensional sensitivity kernels for phase-speed structures and one-dimensional sensitivity kernels for the reference Earth model yields a representation of the three-dimensional sensitivity of travelling surface waves to shear wave speed structures. Using these time-dependent 3-D sensitivity kernels, suitably filtered seismograms can be inverted directly for 3-D shear wave speed structure without intermediary measurements of the phase and amplitude of surface waves as a function of frequency. The three-dimensional kernels generally exhibit sensitivity to wide areas around a geometrical ray path, which corresponds to a few orders of the Fresnel zones, with the maximum sensitivity near source and receiver locations. Source radiation patterns have significant influence on the sensitivity kernels, which suggests that the sensitivity kernels can be contaminated by errors in source parameters. Introducing differential waveforms between two nearby stations, we can construct 3-D sensitivity kernels for the differential waveforms by working with appropriate transfer functions with corrections for slight differences in both propagation distances and azimuths between two stations. Such differential 3-D kernels have nearly zero sensitivity to the source region, leaving high sensitivity to relatively small areas around the receivers. The use of the differential waveforms of two nearby stations as a secondary observable will enable us to investigate shear wave speed structures in and around regional seismic arrays taking the effects of finite frequency into account, and will be of great help in improving the reliability of regional surface wave tomography.

REFERENCE 3-D P-VELOCITY MODEL OF THE MANTLE BENEATH EURASIA AND FLANKED OCEANIC MARGINS: THE NEW TECTONIC AND GEODINAMIC VIEW

Valentin GEYKO, T. TSVETKOVA, L. LIVANOVA, K. GEYKO, L. SHUMLANSKAYA, I. BUGAYENKO, L. ZAYETS (Institute of Geophysics of NAS Ukraine)

An analysis of the model yields the following observations: The mantle of the explored subcontinent together with the flanked margins of the Pacific, Atlantic and Arctic falls into the two shells by the global boundary situated at 550-680 km depth. The upper shell (tectonosphere) is notably inhomogeneous laterally, while the lower one is more near to radial-symmetry (deeper than 750-780 km). The boundary of the upper and lower tectonosphere situated at depths 390-450 km - the asthenosphere - is not global. The former

is peculiar to the ancient and formed tectonic structures and later to those actively living at the present. The velocity anomalies correspond to known plate tectonic elements, but also reveal the presence of ancient tectonic features. Orogens seem to coincide with gently sloping subducted slabs. In some cases low velocity anomalies extend from the surface to large depths, perhaps relating spreading with rising asthenospheric material. The thickness of the tectonosphere is related to its age and genesis. The tectonic structures of the first order (plates) have 'roots' piercing full the tectonosphere, while those of higher order are clear-cut in the upper and unclear in the lower tectonosphere. Sutures and structural discontinuities are reflected in the mantle by large velocity contrasts. Thus, not only are major structural regions at the surface associated with velocity anomalies at depth, but the boundaries between them show anomalous velocities, perhaps reflecting the structural history of the region. Large tectonic structures have opposite velocity anomalies in the upper and lower tectonosphere. Seismic belts and regions of high seismicity are strongly connected with certain velocity anomalies.

MULTIMODE SURFACE WAVEFORM TOMOGRAPHY OF THE UPPER MANTLE UNDER THE SOUTH PACIFIC SUPERSWELL

Alessia MAGGI[1], Eric DEBAYLE[1], Keith PRIESTLEY[2], Guilhem BARRUOL[3], Fabrice FONTAINE[4], Dominique REYMOND[5] ([1]EOST, CNRS and Universite Louis Pasteur, Strasbourg, France, [2]Bullard Laboratories, University of Cambridge, United Kingdom, [3]Jeune equipe Terre Ocean, CNRS and universite de la Polynesie Francaise, Faaa, French Polynesia, [4]Laboratoire de Tectonophysique, CNRS and Universite de Montpellier II, France, [5]Laboratoire de Geophysique, CEA, Faa, French Polynesia)

The expanse of the South Pacific is punctuated by a swarm of volcanic island chains -- the Society Islands, Austral Islands, and Marquesas -- superimposed on a broad topographic high known as the South Pacific super swell (McNutt, 1998). The region is also characterised by a large-scale, low velocity anomaly in the lower mantle (e.g. Su et al., 1994) and anomalous converted phases from the 660 km discontinuity (Vinnik et al., 1997). We present preliminary results of a multimode surface wave tomographic study of the region. Except in its southernmost part, the Pacific plate is surrounded by subduction zones that provide an excellent azimuthal distribution of deep events with well excited overtones.The station distribution around the margins of the Pacific is also relatively dense, due to the high seismic risk of these regions. The resulting dense ray coverage, however, thins out in the South Pacific, and is insufficient for high-resolution imaging of an eventual Pacific super plume. As part of PLUME (Polynesian Lithosphere and Upper Mantle Experiment, funded by the French Ministry of Research), ten broadband stations have been deployed in French Polynesia, as far as -27 degrees South. The stations provide the necessary data to the south of the main location of the super swell to facilitate high-resolution imaging of its upper mantle expression.We initially analyse only Rayleigh wave seismograms, which constrain the isotropic SV structure of the upper mantle. Our preliminary results, obtained using the automated (Debayle, 1999) version of the Cara and Leveque (1987) method, will help answer questions about the possible existence and/or morphology of upper mantle upwelling (plume?) connecting with the Pacific super swell.

THERMO-CHEMICAL EVOLUTION OF THE CONVECTING MANTLE AND CORE: IMPORTANCE OF COMPOSITIONAL ANOMALIES IN THE CMB REGION

Takashi NAKAGAWA[1], Paul J. TACKLEY[2] ([1]Department of Earth and Space Sciences, University of California, Los Angeles, [2]Department of Earth and Space Scieces and Institute of Geophysics and Plantary Physics, University of California, Los Angeles)

The heat flow through the core-mantle boundary is the most important quantity for understanding the thermal evolution of the coupled core-mantle system, and it is strongly influenced by the presence and distribution of compositional anomalies above the core-mantle boundary. In a previous study [Nakagawa and Tackley, 2002 on AGU Fall Meeting] we showed how the thermal history of the convecting mantle-core system is affected by the presence of primordial compositional layering above the CMB. However, another proposed origin for the compositional anomalies in the CMB region is the build-up of recycled oceanic crust from subducted slabs. Here the thermal evolution of the coupled, convecting mantle-core system is studied using a two-dimensional cylindrical shell mantle convection model with self-consistently generated tectonic plates and material recycling. Thermal evolution histories are compared to previous models with primordial layering and to compositionally homogeneous models, and considered in the context of various constraints on heat budget. In order to understand how heat transfer through the CMB scales in the presence of dense compositional anomalies, an improved parameterized model, analagous to an upside-down version of a parameterized model used to treat the effects of continents [Gringe and Labrosse, 2001], will be considered and calibrated using the dynamical models.

DEEP STRUCTURE OF THE EURASIA—PACIFIC TRANSITION ZONE

Ludmila P. ZABARINSKAYA, Alexander G. RODNIKOV, Natalia A. SERGEYEVA (Russian Academy of Sciences, Geophysical Center)

The deep structure of the Eurasia-Pacific transition zone was investigated underthe Geotraverse International Project along the deep sections of the tectonosphere, including the lithosphere and the asthenosphere, based on the complex interpretation of geological and geophysical data. The first geotraverse, investigated in cooperation with Japanese geoscientists, crossed the region of the Japan Sea. The second geotraverse, investigated in cooperationwith Japanese and Chinese geoscientists, crossed the region of the Philippine Sea and the North China Plain. The third geotraverse crossed the region of the Okhotsk Sea. The total length of the geotraverses amounted to a few thousand kilometers with a depth of 100 km. The structure of the study region is distinguished by the fact that its upper mantle includes an asthenosperic layerwith its diapirs of hot anomalous mantle, responsible for the formation of a transitional zone. The asthenosphere has a depth of 50-80 km under the old Paleogene basins, such as the West Philippine Basin, a roughly 30-km depth underthe Neogene basins, such as the Parece Vela Basin of the Philippine Sea or the Kuril Basin of the Okhotsk Sea, and a merely 20-10-km depth under the Pliocene-Quaternary inter-arc basins, where it caused the break-up of the lithosphere, the formation of rifts, basalt magma flow, and hydrothermal activity. The sedimentary basins of the marginal seas are distinguished by an abnormal deep structure characterized by the localization of asthenospheric diapirs under these basins, the development of rifts and spreading centers at their bases, volcanic activity during the early phase of their formation, associated with hydrothermal processes and sulfidc formation, arid the high heatflow caused by the rise of the asthenosphere toward the surface. It appears thatthe asthenospheric diapirs with the partial melting of rocks represent channels by which hot mantle fluids from the asthenosphere penetrate to the sedimentary basins. Based on these geotraverses, researchers from the Geophysical Center ofthe Russian Academy of Sciences created a database including the deep geologicaland geophysical sections of the lithosphere under the

transition zone from Eurasia to the Pacific and the related primary geological and geophysical data,the results of the bathymetric, magnetic, and gravity surveys, heat flow measurements, deep seismic sounding, tomography, seismology, the results of studying the fine structure of the Bcnioff zone, some data on the chemistry and age of the rocks, and the results of deep-sea drilling and dredging. This work was supported by the Russian Foundation for Basic Research, projects 01-05-64400 and 01-07- 90233.

HIGH-RESOLUTION RECEIVER FUNCTION IMAGING OF THE CRUST AND THE MANTLE BENEATH THE JAPAN ISLANDS

Kazuro HIRAHARA[1], Makiko YAMAUCHI[1], Takashi TONEGAWA[1], Takuo SHIBUTANI[2] ([1]Graduate Shool of Environmental Studies, Nagoya University, [2]DPRI, Kyoto University)

In recent 5 years, we have obtained the detailed images of receiver function (RF) in the crust and the upper mantle beneath the Japan Islands. In this paper, we show our strategy and some of interesting results. Though the number of stations is still increasing now, we have so far processed data observed at 203 J-array (operated by universities and JMA) and 634 Hi-net (NIED) short-period stations and at 63 J-array and 64 F-net (NIED) broadband ones. We use data during a period from 1996 to 2000 for J-array and F-net, and from 2000 to 2002 for Hi-net. At present, for the crust and the uppermost mantle, we use both short-period and broadband data, retaining high-frequencies up to 1 Hz, while only broadband data are used with low-pass filtering of 0.3 Hz for the deeper upper mantle. We employ Singular Value Decomposition (SVD) filtering to enhance the coherent phases. With a reference velocity model of iasp91, we transform the time domain RFs to the depth domain ones, assuming that phases in radial RFs are P to S converted ones at depths. We stack the depth domain RFs to project onto 2-D cross-sections along several profiles. In the crust, we find the remarkable positive Moho Ps phases in RFs, whose amplitudes vary locally, and we obtain the distribution of the depth and converted amplitudes. Generally, the clearer Moho Ps phases are seen in southwest Japan than in northeast Japan. The Conrad Ps phases are not clearly seen all over the Japan, but locally seen in the Kinki and the Chugoku regions of southwest Japan. For Hi-net data, we try to execute the analyses retaining the higher frequencies up to 3 Hz. In southwest Japan, such higher frequency RFs observed at some stations show the prominent wave-packets between the Conrad Ps phases and the Moho ones, which are possible Ps phases converted at the lower crustal reflective layers. Beneath southwest Japan, the short-period RFs clearly delineate the 3-D configuration of the subducting Philippine Sea plate (PHS) from Kii Peninsula to the Shikoku regions, which is consistent with the hypocentral distribution and the previous tomographic results. Further down to depths of 60 to 80 km, we can trace positive RFs in the deeper extended regions which is the aseiscmic PHS. The Pacific plate (PAC) subducts westwards from the Japan trench to a depth of 600 km, which are estimated from the earthquake distribution and the tomographic studies, Correspondingly, we see the positive RF amplitudes down to a depth of 150 km or more. Almost all over the Japan islands, we can trace the 410 and the 660 km Ps phases, which are undulated due to the cold PAC. The 410 km discontinuity is locally elevated in the cold PAC by 80 km, and the 660 km one is downwarping in a larger scale toward the PAC. For these upper mantle discontinuities, also see the detailed discussion by Tonegawa et al. in this symposium.

RECEIVER FUNCTION IMAGE OF THE 410 AND 660KM SEISMIC VELOCITY DISCONYINUIYIESBENEATH THE JAPAN ISLANDS

Takashi TONEGAWA[1], Kazuro HIRAHARA[1], Takuo SHIBUTANI[2] ([1]Graduate School of Environmental Sciences, Nagoya University, [2]2)Disaster Prevention Research Institute, Kyoto University)

In the Japan Islands, several short-period and broadband seismic networks have recently been installed or are still under construction at present, which realize one of the highest densities of station spacing in the world. Among these networks, we apply Receiver Function (RF) analyses to teleseismic P-wave coda portions observed at 63 J-array and 64 F-net broadband stations and investigate the detailed structure of the upper mantle velocity discontinuities. We examine the observed waveforms from the teleseismic events with the magnitudes greater than 5.5, which occur during a period from 1996 to 2000. We discard almost 30,000 RFs with low signal-to-noise ratios, and finally keep a total of 5555 RFs from 153 events. Since such numbers of data and stations used in this study are largely augmented comparing with those in the previous RF analyses around the Japan Islands such as Li et al. (2000), we can reveal the far more detailed upper mantle structure. RFs are conventionally constructed through frequency domain division of radial components by vertical ones with a water level of 0.01. The low-pass Gaussian-filter of 0.3Hz is also applied. Assuming the phases in RFs are produced by Ps converted ones at depths, we transform the time domain RFs to the depth domain ones using a reference velocity model of iasp91. This process may be called migration. Then, SVD-filtering is applied to the depth domain RFs. We keep largest 6 eigenimages to construct filtered RFs. Finally, we construct 2-D stacked RF image projected on cross-sections along several profiles to see the detailed velocity discontinuity structure. Beneath the Japan Islands, the Pacific plate (PAC) is subducting westwards from the Japan trench to a depth of 600km, while the Philippine Sea plate (PHS) is subducting from the Nankai trough to a depth of 60-80km in southwest Japan. Beneath the whole Japan Islands, the dipping positive RF amplitude traces can be recognized to a depth of 150km or more, which coincide with the distribution of deep earthquakes occurring within PAC. In southwest Japan, however, we cannot clearly see the RF image of the descending PHS. In the deeper upper mantle, the remarkable positive RF traces corresponding to the 410 and 660km velocity discontinuities are recognized clearly all over the Japan Islands, while the 510km discontinuity can not be seen. The 410 and 660km discontinuities are undulated due to the subducting cold PAC slab. Beneath central to southwest Japan with the highest density of conversion points of these phases, RF images remarkably delineate that the 410 km velocity discontinuity is locally elevated by about 80 km within the subducting PAC, The 660km discontinuity is gradually downwarped westwards toward the PAC in a larger scale, whose deepest depth is about 690km.

LATERAL VARIATIONS OF THE D'' DISCONTINUITY BENEATH THE CENTRAL PACIFIC

Megan Sue AVANTS[1], Thorne LAY[1], Sara RUSSELL[2] ([1]Department of Earth Sciences, University of California, Santa Cruz, [2]Weston Geophysical Corporation)

The lowermost ~ 250 km of the mantle is characterized by a laterally heterogeneous thermal and chemical boundary layer, the D´´ Region. In many areas a strong velocity gradient or velocity discontinuity is found near the top of D´´, which is variously interpreted as being the result of a phase change, a chemical contrast, a transition in fabric to an anisotropic layer, or a relic subducted slab thermal/chemical anomaly. Seismic waves from events in the Tonga—Fiji region encounter the D´´ zone beneath the Central Pacific and are recorded by dense broadband seismic networks in western North America. Recent waveform stacking

---

efforts suggest the presence of coincident P and S velocity discontinuities at about 230 km above the core-mantle boundary under the Central Pacific. The velocity contrasts at the discontinuities are weaker (0.75% and 1.7%, respectively) than found in circum—Pacific regions. It is also found that the S wave velocity decrease below the D´´ discontinuity is abnormally strong with respect to the P velocity decrease in this region. Being far removed from present subduction zones, the existence of D´´ discontinuities in the low velocity mantle under the Central Pacific is particularly intriguing. Lateral heterogeneities within this zone, combined with complex crustal structure at the receivers, make the depth and magnitude of the velocity discontinuities difficult to resolve. We extend analysis of shear wave data from Tonga—Fiji earthquakes recorded by broadband networks in western North America to better resolve small scale features in D´´ under the Central Pacific. Our approach includes deconvolving reference source wavelets, binning and stacking localized subsets of data, and modeling features in the stacks to provide improved resolution of the nature of the D´´ discontinuity beneath the Central Pacific. Preliminary binning of data into subsets has shown that the depth and strength of this discontinuity vary widely across the region sampled by the events in our data set. The results of more refined binning as well as waveform modeling of observed features will better resolve the character of the D´´ discontinuity beneath the Central Pacific, allowing us to compare these results to D´´ structure in circum—Pacific regions, ultimately providing insight as to the cause of D´´ discontinuities.

WAVEFORM MODELING OF 3D STRUCTURE AT THE BASE OF THE MANTLE USING A COUPLED SEM/NORMAL MODE APPROACH

Akiko TO, Yann CAPDEVILLE, Barbara ROMANOWICZ (UC Berkeley)

The presence of strong lateral heterogeneity in D˝ is now well documented, and represents a problem for seismic modeling, when using standard ray or mode approaches, because of the theoretical limits of validity of these methods. Consequently, present tomographic models are only able to represent the large scale, smooth features of the structure. They may also not reflect the amplitudes of lateral variations accurately. We use a coupled normal mode/Spectral Element Method (SEM) to compute synthetic seismograms of Sdiff in the D˝ part of a 3D tomographic model (SAW24B16, Mégnin and Romanowicz, 2000) down to a corner frequency of 1/12s. This coupled method is much faster than standard SEM, as the numerical part of the computation is restricted to the D˝ region. The rest of the mantle is assumed 1D, and there the wavefield is computed using efficient normal mode summation. We compare the synthetics thus obtained with observed waveformsfor a collection of deep earthquakes in the Western Pacific and stations in North America. For deep earthquakes, the effect of strong heterogeneity in the crust and upper mantle is avoided. Observed and synthetic travel time trends are very consistent, although in most cases the observed residuals are significantly larger. Waveform amplitudes are less consistent. We also compare the predictions using SEM with those obtained by more approximate methods: ray theory on the one hand, NACT (Non-linear asymptotic coupling theory, a normal mode perturbation approach) on the other. The comparison with ray theory demonstrates that it generally over estimates travel times; the fit is somewhat better with NACT, but erratic discrepancies in amplitudes remain. Starting with the tomographic model, and correcting for mantle structure outside of D˝ using approximate NACT predictions, we next invert for perturbations to the tomographic model, using the coupled SEM/mode computation for the forward part of the modeling, in several regions of the D˝ under the Pacific which are well sampled by available Sdiff data. We present and discuss the inversion technique and the resulting models, and in particular explore whether the Pacific ˝superplume˝ structure requires sharp borders, as has been suggested for the African one.

TO THE QUESTION OF NEW INTERPRETATIONS OF MECHANISMS OF EVOLUTION OF THE TERRESTRIAL STRUCTURE AND SOME CONSEQUENCES THEREFROM

Eugeni Yakovlevich SMIRNOV (author)

The project ´Creation of a Computing Complex for the Study of Evolution of the Terrestrial Structure on the Account of Sciences of the Earth´ (see http://tspm.icape.ru/geya/eng/lab_e.htm) is described. In the project some non-traditional models of the terrestrial magnetic field generation mechanism are proposed that do not conflict with the available metrical information; of the mechanisms of tectonic forces action, earthquakes, dislocations of Earth´s crust, underground waters and magma; of the process of generation of ores of the volcanic and hydrothermal types.

PRINCIPLE OF THE EARTH GRAVITATIONAL ENERGY MINIMIZATION AND THE MECHANISMS OF ITS EMBODIMENT

Vladimir V. KUZNETSOV (JSS06)

The self-gravitational ball (star, planet, the major satellite) is treated as a self-regulating, self-organizing system in terms of the theory of self-organizing and optimum processes. The effect of the gravitational potential's minimization principle results in the Earth, as well as the other planets, to aspire to minimize its surface area. It means, that at the Earth there is a force, which aspires as to bring it to a state of a standing balance, and as to reduce the shape of the Earth into the equilibrium shape of sphere by minimization of the geoid height. This force initiates the shift tensions which involve the matter flow at the surface layer of the earth crust. This force is similar to force of the surface tension of liquid. The surface forces cause the motion of continents, the formation of mountains, seismicity and volcanicity through embodying of the Principle.

ANALYSIS OF BROADBAND SEISMIC ARRAY FOR THE INVESTIGATION OF THE TOP OF THE EARTH'S OUTER CORE BENEATH THE INDIAN OCEAN

Satoru TANAKA (Research Center for Prediction of Earthquakes and Volcanic Erupions, Graduate School of Science, Tohoku University)

The issues of stable stratification and possible heterogeneity at the top of Earth´s outer core are important to understand not only the core-mantle interaction but also the dynamics of the outer core. Previously some seismological studies had revealed vague features of the region using the seismological networks of the former generations, but their results were not consistent each other. The recent data accumulation under the modern seismic networks or arrays consisted of broadband seismographs makes it possible to try a further study. Here we show the examples of the analysis using the Kaapvaal broadband seismic array that was temporarily deployed in the South Africa since 1997 to 1999. The target of analysis is SmKS (m=1,2,3,4) seismic phases. Seismograms were deconvoluted using the instrumental response to displacement, and rotated the horizontal components into the radial ones. The

IA

relative times were corrected to align on the peak locations of S2KS or S3KS. We applied the phase-weighted stack to separate the SmKS phases in the time-slowness space. The peak location of SKS and S3KS were picked on the vespagrams from the original seismograms while the Hilbert transformed seismograms were used for picking S2KS and S4KS because of the phase shift of the SmKS. Until now, we have analyzed the array records of one intermediate-depth earthquake (1997/04/23 in Mariana, distance from 116 to 127 degrees), and two deep earthquakes (1997/09/04 in South Fiji, distance from 117 to 126 degrees; 1998/03/29 in Fiji, distance from 130 to 135 degrees). The ray paths are distributed under the Indian Ocean. Differential travel times and relative slowness were obtained for the combination of S(m+1)KS and SmKS. PREM was used for the calculation of the ray theoretical travel times and slowness as a reference. The residuals of differential travel times for T(S3KS-S2KS) and T(S2KS-SKS) were scattered from -1.6 to 1.6 s indicating no systematic geographic pattern. Since only small parts of the Fresnel zones of S2KS and S3KS coincide for the predominant period of 5-10 s, it is difficult to separate the effects of the D″ and the outermost core. Only the deep Fiji event shows clear S4KS seismic phases, and the residual of T(S4KS-S3KS) was 0.0 s while the residual slowness was 0.14 s/deg. Main parts of the Fresnel zones of S3KS and S4KS coincide and the ray paths cross the CMB regions with the small velocity perturbation. If this measurement is confirmed by the other combination of an event and array, the velocity gradient in the outermost about 50 km of the core should be slightly modified without the change of the average velocity.

JSS06a/08P/D-023   Poster   1400-101

SEISMIC OBSERVATION OF NARROW PLUMES IN THE OCEANIC UPPER MANTLE

X. LI[1], R. KIND[1], X. YUAN[1], S.V. SOBOLEV[1], W. HANKA[1], D.S. RAMESH[2], Y. GU[3], A.M. DZIEWONSKI[3] ([1]GFZ Potsdam, Germany, [2]NGRI, Hyderabad, India, [3]Harvard University, USA)

We have found seismic evidence for the existence of narrow (about 200 km diameter) and hot plumes in the upper mantle above the 410 km discontinuity. They are located mainly under ocean islands, not however, under the central parts of major continents. These results are obtained from comparing globally the observed travel time differences between Ps conversions and SS precursors from the discontinuity at 410 km depth, using published data and new observations from ocean island stations. Comparison of SS precursors and Ps conversions, however, leads also to indications of significantly fewer narrow plumes in the upper mantle transition zone between 410 and 660 km depth, than in the upper mantle above 410 km depth.

SEISMIC WAVE SPEEDS AND ATTENUATION IN THE UPPER MANTLE INTERPRETED THROUGH LABORATORY MEASUREMENTS

Ulrich FAUL, John D. FITZ GERALD, Ian JACKSON (Earth Materials Department, Australian National University)

The influence of a small basaltic melt fraction (0.004-0.037) on the seismic properties of fine-grained synthetic polycrystals of Fo90 olivine has been explored at seismic frequencies with torsional forced oscillation/microcreep methods. The presence of a broad dissipation peak superimposed on the monotonically frequency and temperature dependent background clearly distinguishes materials containing as little as ~ 0.5 % melt from their melt-free equivalents. In both types of material the observed dissipation is attributed to grain-boundary sliding involving a mixture of elastic and diffusional accommodation. The difference in mechanical behaviour is ascribed to the rounding of olivine grain edges at melt-bearing grain-edge tubules ? allowing sufficient localisation of dissipation in frequency-temperature space to produce a resolvable peak attributable to elastic accommodation. Empirical models have been developed that adequately describe the dependence of 1/Q upon period, temperature, average grain size and, for the melt-bearing materials, maximum melt fraction. These models have been extrapolated to the larger grain sizes and P-T conditions representative of the upper mantle. The inferred levels of attenuation for melt-free material are broadly consistent with those observed seismologically suggesting that the same grain-boundary diffusional processes thought to dominate the behaviour of the fine-grained materials tested in the laboratory might also account for much of the wave speed variability and attenuation in the mantle. For melt-bearing olivine, the extrapolated attenuation is generally somewhat higher than the highest seismologically measured attenuation, but the low spatial resolution of seismological studies means that the latter may average the properties of melt-free and partially molten parts of the upper mantle. The superposition of the melt-related dissipation peak upon the monotonic background is such that, for appropriate combinations of grain size, melt fraction and temperature, nearly frequency-independent attenuation is to be expected. Progress will be reported in the development of a procedure for the simultaneous inversion of laboratory dissipation and associated shear modulus dispersion data for the creep function that provides a complete description of the viscoelastic behaviour. Knowledge of the respective creep functions for melt-free and melt-bearing olivine-based materials will allow an interpretation of specific seismological velocity-attenuation models more closely guided than hitherto by laboratory studies.

STRUCTURE OF THE DISCONTINUITIES BENEATH TONGA SUBDUCTING ZONE AND ITS IMPLICATION

Yuan Ze ZHOU, Shao Xian ZANG (Department of Geophysics, Peking University)

Tonga subduction zone has caused a big attention from the geoscientists because there are the deepest Wadati-Benioff zone, a lot of big intermediate and deep earthquakes and complicated geodynamics processes. Some authors have utilized the abundant data to study mantle discontinuities in this region. In this study the discontinuities beneath the Tonga region are investigated with SdP converted phases near source. Short period vertical component data for the 58 events from 1988 to 2000 beneath Tonga region recorded by hundreds stations of PNSN and NCSN in the western USA are retrieved from IRIS and NCEDC. The data are processed with the N-th root slant stack method (Zang and Zhou, 2002) to pick out faint secondary phases from mantle discontinuities where the n is 4. Based on the differential slowness, differential travel time and relative amplitude of each possible phase, SdP phases are picked out and the corresponding position and depths of the converted points are calculated with the successive integration along ray paths with PREM. Those converted points are counted in the depth range. The results show that there are several depths where the converted points are concerted which appear before the pP. There are discontinuities possibly existed though the scale of discontinuity may vary. The discontinuity near the 660 km depth seems a multiple. There are 2 obvious peaks between the depths of 630 and 760km when the constraint of slowness difference (Δp) between the observed and theoretical differential slowness is less than 0.1 or 0.2 s/(º). The converted points existed between the depths of 630 and 760km whose related Δp is less than 0.1 s/(º) are projected to three profiles which are determined based on the configuration of Wadati-Benioff zone. There are clear double parallel layers at 640 and 680 km at the north part of Tonga and each layer depresses nearly 60 km; the middle part of Tonga shows a

complicated structure near 660 km and just a little depression near the subducted slab; the south part of Tonga also has double parallel layers near 660 and 720 km and each has 20 km depression. From the analysis above, the "660 km discontinuity" varies from region to region and is affected by the Tonga subducted slab. The complicated structure near 660 km is discussed.

SYNTHETIC SEISMOGRAM ASSOCIATED WITH AN EARTHQUAKE AT A SUBDUCTION ZONE

Arabinda ROY (Dept Of Applied Mathematics,Calcutta University)

The distributions of epicenter locations and focal depths of intermediate and deep Earthquake gives important and deep earthquakes give important evidences ofthe seismic processes active at a subduction zone. Comparison of the theoreticalsynthetic seismogram with actual seismogram for an earthquake in the subduction zone can provide a suitable model of the structure of the Lithosphere near the subduction zone as well as the seismic process.   In our model we choose the region near the subduction zone as a two layeredWedge shaped media with an inclined surface separating the media. The EarthquakeIs simulated by a source acting inside one of the media or at the interface i.e. on the plunging plate. We have computed theoretically the synthetic seismo0gram associated with the model considered.   Presently even for SH wave such solutions are not known for a two layered wedgeshaped medium. For a lateral inhomogeneous medium, such solutions are not known for SH wave in case of two quarter spaces in contact.. We have successfullydeveloped   an integral equation method to solve the problem in the general case.Iterative solutions of the integral equations give the ray picture in the two layeredWedge shaped media. Our method is equally applicable for both SH as well as P,SV cases. The synthetic seismogram can be generated by piecing together the Iterative solution of the integral equations. Comparing the synthetic seismogram so constructed with the actual seismogram of an Earthquake will help in bettermodeling of the structure near the Lithosphere.

THE MOBILITE OF THE EARTH'S INNER CORE AND PROCESS OF LATITUDE VARIATIONS

Yuri N. AVSYUK (Institute of Physics of the Earth of Academy of Sciences Of Russian Federation)

The Earth´s orbital motion around the Sun is the sum of the movements: the one-year motion of the center of the Earth-Moon system (barycenter) around the Sun and the Earth´s monthly motion around the barycenter. The lunar inequality L=6″.4356 is the parallax of the Earth´s orbit with respect to the barycenter. The solar attraction is dynamically balanced at the Earth-Moon center of mass (barycenter) rather than at the Earth´s center. The Earth motion around the barycenter is the exact motion of the Moon whose perturbation modulii are 81.3 times smaller than the modulus perturbations in the motion of the Moon. The tidal force from the real motion contains the Kepler term (the Laplace formula) plus perturbations of the Earth´s orbital motion around the barycenter; their modulus and periodicity depend on the Earth orientation relative to the direction to the Sun, i.e., on the difference between the longitudes of the Earth $\lambda\oplus$ and Sun $\lambda\Theta$ [Avsyuk, 1996]. The Earth longitude $\lambda\oplus$ is, in turn, related to the direction angles of the node Ω, perigee Γ, and anomaly W, as well as to their temporal variations having periods of 18.6 years, 8.85 years, and 27.5 days, respectively; i.e., we have $\lambda\oplus - \lambda\Theta = \Omega + \Gamma + W - \lambda\Theta = (\Omega + \Gamma - \lambda\Theta) + W$. Consequently, the analysis of the perturbations should resolve fortnightly and monthly (27.5 days) periodicities if a one-day sampling interval is used and a periodicity of 412-437 days $(\Omega + \Gamma - \lambda\Theta)$ if a one-month sampling interval is used. This can be confirmed by resolving the tidal force acting on the IC into three components: F_z along the rotation axis and F_x and F_y in the equatorial plane along the Greenwich meridian and 90°W, respectively. The resulting harmonics have periods of 13.6, 27.5, 365, and 412-437 days and 6 years [Avsyuk, 1980]. The comparison between the periodicities of the forces and those of the rotation axis motion within the Earth suggests that the IC experiences forced movements changing the coordinates of the origin $(X(T_i), Y(T_i), Z(T_i))$ and displacing the rotation axis within the Earth. With a modulus of the solar tide effect of about 50×10^{-6} cm/s² and a density difference between the inner core and outer core of 0.2-0.3 g/cm³, the IC displacements in the static approximation are estimated at about 10 m. The power associated with the IC motion in its surrounding melt is characterized by a value of 10^{19} erg/s. Based on the complete frequency correspondence between the force and response (axis variations observed at the surface), we state that the IC moves within the Earth.

MANTLE LATERAL VARIATIONS AND ELASTIC DEFORMATIONS

Laurent METIVIER, Marianne GREFF-LEFFTZ, Michel DIAMENT (Institut de Physique du Globe de Paris)

Earth strain and gravity responses to phenomenon such as tides or atmospheric loads, are generally calculated assuming earth models radially stratified, and at hydrostatic equilibrium. However, some local observations show unexplained perturbations on the tidal gravity signal.A possible cause for those perturbations may be the neglect of rheology and density lateral variations as well as the non hydrostaticity of the Earth.We have investigated a non radially symmetrical earth numerical model with the intent to study the earth response to low frequency forcings. This model has used a finite element method (spectral element) developed on the ˝cubed sphere˝ mesh (Ronchi et al., 1996), and has resolved gravito-elasticity equations. As a validation of our model, we have computed the effect of the hydrostatic ellipticity of the Earth and have compared, for simple model (homogeneous planet), our numerical results with the analytical solutions obtained using Maple computation.As a first application, we have investigated the influence of the lateral variations induced by the oceanic-continental crust distribution. Finally, the non hydrostaticity of the Earth has been taken into consideration by a first order perturbation theory, and we have investigated the possible influence of a mega-plume on gravity tide.

PRELIMINARY INVESTIGATION OF INHOMOGENEOUS VISCOUS STRUCTURE OF UPPERMOST MANTLE BENEATH JAPANESE ISLANDS: ITS IMPLICATION TO QUASI-STATIC DEFORMATION OF SUBDUCTION ZONE

Satoru FUJIHARA (Earth Simulator Center, Japan Marine Science and Technology Center)

Based on its known inhomogeneous-inelastic properties, it may be more suitable to assume the (regional scale) subduction zone as visco-elastic, at least for simulating (the cyclic property of) quasi-static earthquake generation [For example, Yoshioka and Suzuki, 1999; Hirahara, 1999]. In addition, a priori knowledge of rheological state of subduction zone is essential for visco-elastic modeling in that quasi-static response depends on whether the

region surrounding around the assumed seismic fault region is elastic or visco-elastic. Based on the better understanding of the spatial pattern of brittle-ductile transition, the realistic and complex boundary of elastic-visco-elastic media can be assigned more realistically in the visco-elastic modeling. Along with those effects of inhomogeneity within volume, it is also important to physically interpret the empirically-determined frictional parameters of Rate and state dependent frictional law (For example, [Tue and Rice, 1986]), and to understand the spatial variation of frictional parameters in horizontal and vertical direction. Hirahara and Earth Simulator Research Group for Earthquake Generation Process (2002) and Hirahara (1999) introduced the very realistic scheme that assumes 3-D visco-elastic medium and Rate and state dependent frictional law along the faults, numerically simulating the cyclic, quasi-static large earthquake generation. These studies emphasized the very importance of realistic, three-dimensional visco-elastic medium, instead of the homogeneous, half space-elastic model. Many efforts have been made for estimating a reasonable viscosity distribution for a various scale (For example, [Peltier 1998; Suito and Hirahara, 1999]). However, significant discrepancy in viscosity value can be often seen probably based on technical differences, nature of dataset, amount of noise, and rather many assumptions. Here, a preliminary model of uppermost mantle viscous structure of was discussed beneath the Japanese Islands, based on the empirical relationship (Sato, 1991) between viscosity and seismic attenuation factor that was derived by combining homologous temperature dependence of viscosity (Borch and Green, 1987) and attenuation factor of seismic wave (Sato, 1989), of high pressure and temperature conditions. Solidus temperature was referred to Takahashi (1986). The dominant rock type of upper mantle is assumed as peridotite. Based on assumption of thermal activation process and homologous temperature dependence of seismic attenuation factor (Sato, 1989), viscosity is expected to be largely dependent on temperature, as a first order estimation. The seismic attenuation structure beneath the Japanese Islands of (Fujihara .et al, 2001) was used, which was obtained by using many broadband waveform data of Freesia network of Japan. Scattering effect was assumed to be less dominant on attenuation of seismic wave amplitude than absorption effect.

EAST-WEST HEMISPHEICAL DICHOTOMY OF SEISMIC STRUCTURE AT THE TOP OF THE INNER CORE AND ITS IMPLICATIONS

Fenglin NIU[1], Lianxing WEN[2] ([1]Department of Earth Science, Rice University,, [2]Department of Geosciences, State University of New York at Stony Brook)

We collect a global data set of PKIKP and PKiKP phases recorded by the Global Seismic Network and many regional seismic arrays to study seismic structure in the top of the Earth´s inner core. The PKIKP and PKiKP observations show different characteristics between those sampling the ˝eastern˝ hemisphere (40°E-180°E) of the inner core and those sampling the ˝western˝ hemisphere (180°W-40°E). PKIKP phases (1) arrive about 0.4 s earlier than the theoretical arrivals based on Preliminary Reference Earth Model (PREM) for those sampling the eastern hemisphere of the inner core and about 0.3 s later for those sampling the western hemisphere (131°-141°); (2) bifurcate at smaller epicentral distances for those sampling the eastern hemisphere, compared to those sampling the western hemisphere; and (3) have smaller amplitudes for those sampling the eastern hemisphere. Waveform modeling of these observations suggests two different types of models for the two ˝hemispheres˝ of the top of the inner core, with a model in the eastern hemisphere having a P velocity increase of 0.765 km/s across the inner core boundary, a small radial velocity gradient of 0.000055 (km/s)/km, and an average Q value of 250, and a model in the western hemisphere with a P velocity increase of 0.633 km/s across the inner core boundary, a radial velocity gradient of 0.000533 (km/s)/km and an average Q value of 600. The hemispherical difference of seismic structures may be explained by different geometric inclusions of melt and/or different alignments of iron crystals with anisotropic properties in both velocity and attenuation. We speculate that this large-scale pattern of seismic heterogeneities may be caused by a large-scale heat flow anomaly at the bottom of the outer core and/or different vigorousness of convection in the top of the inner core between the two hemispheres.

INNER-MOST INNER CORE: A DISTINCT REGION AT THE CENTER OF THE EARTH

Miaki ISHII, Adam M. DZIEWONSKI (Department of Earth and Planetary Sciences, Harvard University)

Although the presence of anisotropy in the inner core is widely accepted, inferences of its strength and depth dependence vary considerably from model to model. We have recently shown that a significant fraction of inner-core sensitive data is reconciled by a model in which anisotropy does not vary with radius. This simple anisotropy model fits the absolute travel-time data well atall distance ranges except between 173° and 180°. This distance range correspondsto the inner-most 300 km of the Earth, where normal-mode constraints are weak, and where constraintsfrom differential travel times (AB-DF) are likelycontaminated by strong heterogeneity near the core-mantle boundary. When the travel times are inverted for anisotropic parameters of the inner-most inner core, we obtain a model with a slow direction orientered ~45° from the equator, in contrast to the bulk inner core where the slowest wave propagationoccurs when the rays are parallel to the equatorial plane. The existence of the inner-most inner core has significant consequences in ourunderstanding of the Earth´s evolution. This region may represent fossil evidence of two episodes of inner core development, changes in chemistry, or changes in the pattern of convection in the outer core. Furthermore, if the inner-most inner core represents a preserved region of the early Earth, then the development of subsequent anisotropy is limited to mechanisms acting close to the inner-outer core boundary.

PKP TRAVEL TIME DATA: COMPLEXITY IN INNER CORE ANISOTROPY STRUCTURE?

Barbara A. ROMANOWICZ, Aimin CAO (Univ. of California at Berkeley)

Twenty years ago now, Poupinet et al. (1983, Nature) observedthat PKP waves travelling on polar paths arrived earlier, by a few seconds,than those travelling on equatorial paths. Several years later, it was proposed that this was due to inner core anisotropy, as was anomalous splittingof core sensitive free oscillations (Morelli et al., 1986; Woodhouse et al., 1986). The orginally proposed model was simple: constant transverseisotropy with axis parallel to the axis of rotation of the earth, and couldconceivably be related to the alignment of iron crystals within the inner core. Since then, much data has been accumulated, in the InternationalSeismological Center (ISC) bulletins as well as high qualitybroadband and waveform data, and the models have become increasingly complex.When interpreted solely in terms of structure in the inner core, broadbanddata seem to require significant hemispherical differences in the strengthof anisotropy, a layer of isotropic structure at the top of the inner core,with strongly varying thickness, which is hard to reconcile with free oscillation data. Most recently, Ishii and Dziewonski (2002) proposed theexistence of a distinct innermost inner core. On the other hand, someauthors have suggested that the data may be biased by the uneven samplingof available paths through the inner core, and that a significant portion ofthe observed trends should be sought outside of the inner core, in thedeep mantle as well as, perhaps the outer core (e.g. Romanowicz et al., 2002). We have assembled a comprehensive dataset of absolute PKP(DF) traveltimesmeasured on high quality broadband and short period digital seismograms, including data at antipodal distances. This complements our previouscollection of differential PKP(AB-DF) and PKP(BC-DF) data (Tkalcic et al., 2002). We discuss the trends in these data, in particular to verify theplausibility of the existence of the innermost inner core and considerpossible alternative interpretations.

LONG-TIME ANGULAR MOMENTUM AND MASS TRANSPORTS IN THE CORE

Sergei V. STARCHENKO (Geoph. Observ. Borok of Russian Academy of Sciences)

Averaged (on a time-scale about million years) mass and angular momentum transports are investigated in the almost rigidly and rapidly rotating Earth's core, which inner rigid part is growing in expense of the outer liquid part. This results in an original 'momentum' torque with value between 1,000 and 10,000 TN m accelerating the rigid core's rotation relative to the mantle. Balancing this 'momentum' torque with viscous torques I get the rigid core's super-rotation of order one degree per year for the molecular viscosity, while sufficiently smaller super-rotation value appears for more realistic 'turbulent' viscosity in accordance with the modern seismic investigations and 3D MHD numerical models. The power connected with my 'momentum' torque is between 0.1 and 1 TW, that is enough to support all the convection and valuable geomagnetic field in the core, if one prescribe this torque only without any other driving force in the core.

JSS06/09A/A04-005   1040
PRODUCT SPECTRAL DENSITY OF THE TIDAL GRAVITY DATA OBSERVED WITH GLOBAL SUPERCONDUCTING GRAVIMETERS AT GGP STATIONS: A SEARCH FOR THE INNER CORE TRANSLATION TRIPLET

Jian-Qiao XU[1], He-Ping SUN[1], Bernard DUCARME[2] ([1]Institute of Geodesy and Geophysics, Chinese Academy of Sciences (CAS), [2]Belgium National Fund for Scientific Research, Royal Observatory of Belgium)

In recent years, a special attention was paid to the translational oscillations of the Earth's solid inner core. They are Earth's fundamental free modes (Slichter, 1961) which are usually called Slichter triplet or Slichter modes, as they include three modes: the equatorial prograde, the axial and the equatorial retrograde translational oscillations. In 1993, four long-term high-quality tidal gravity data, recorded with superconducting gravimeters (SG) in central Europe, have been used to form a product spectrum (Smylie et al 1993). Three weak resonance signals with central periods of 3.5820h, 3.7665h and 4.0148h were found, corresponding to the periods theoretically computed under the subseismic approximation (Smylie et al 1992). Similar results were obtained using six globally distributed SG observations (Courtier et al, 2000). However, Hinderer et al (1995) and Jensen et al (1995) are contradicting these results using the SG data from Strasbourg/France and Cantley/Canada. In our study, the 21 long SG series of the Global Geodynamics Project (GGP) network are used to investigate Slichter triplet. The original observations are pre-processed with identical technique in order to remove anomalous signals, instrumental drift, tidal gravity signal and barometric influence. The product spectral density of the tidal gravity residuals and station barometric pressure are estimated respectively. Three significant spectral peaks are found with central periods of 4.93438h, 4.42734h and 4.09269h, in close agreement with the eigenperiods of Slichter triplet theoretically computed by Smith (1976).

THE ELECTRICAL CONDUCTIVITY STRUCTURE OF THE EUROPEAN LOWER MANTLE

Pascal TARITS[1], Mioara MANDEA[2] ([1]UMR CNRS Domaines Oceaniques, IUEM/UBO, [2]Institut de Physique du Globe de Paris)

Monthly mean values of the geomagnetic field from about 120 observatories have been analyzed. We selected time windows of 30-35 years which are appropriate for most of the available observatory data. Transfer functions in the period range 2.5-24 months have been obtained at 24 European observatories that sample the mantle in the depth range 700-2000 km. Conductivity profiles obtained from the inversion of the transfer functions show that conductivity increases rapidly from less than 1 S/m to about 3-5 S/m from 700-1300 km and is about constant at greater depth. In the uppermost lower mantle, the conductivity would agree with Al-free perovskite while deeper, a conductive phase should be added. Possible petrological models include Al-bearing perovskite or connected magnesowustite. The conductivity beneath Europe seems to vary laterally as much as radially. Anomalous conductivity profiles - defined as the log-difference with respect to a one dimensional global conductivity model obtained from the analysis of all available observatories - are compared to velocity anomaly profiles and reveals a complex combination of correlation and anticorrelation with the seismic parameters. The results are discussed in terms of temperature and compositional variation in the lower mantle.

JSS06/09A/A04-007   1120
TOMOGRAPHIC EVIDENCE FOR SUBDUCTION INDUCED RIFTING OF THE NAZCA PLATE

Tom HILDE[1], Sri WIDIYANTORO[2], Yoshio FUKAO[3] ([1]Department of Geology & Geophysics, Texas A&M University, [2]Department of Geophysics and Meteorology, Bandung Insititute of Technology, [3]Earthquake Research Institute, University of Tokyo)

Mendana FZ (MFZ), a NE striking structure within the eastern Nazca Plate, intersects the Peru Trench at 10 deg 20'S. Previous bathymetric, magnetic and seismic reflection mapping and sonar imaging reveal that MFZ: 1) is 100km wide at the Peru Trench and narrows SW

IA

to 25km at 83 deg 30'W, 12 deg 00'S,2) consists of 5-10km spaced, FZ parallel, ridges and troughs, 3) has exposed igneous basement along the ridges, and 4) displays an associated set of NE striking magnetic lineations. The liner magnetic anomalies have been modeled and interpreted as seafloor spreading/magnetic field reversals. An axial Brunhes anomaly correlates with rift axis structure, and anomaly 2A (~3Ma) is observed near the MFZ margins from the Peru Trench seaward ~200km. These data suggest that MFZ is a seafloor spreading center, active for the last 3+Ma, that has propagated ~400km seaward at a rate of 115-130km/Ma which will divide the Nazca Plate into separate plates in 30-35Ma. Subsequent heat flow measurements across MFZ are anomalously low which appears inconsistent with the above observations and interpretation. We have employed seismic tomography to examine subducted Nazca Plate velocity structure beneath Peru. Our results show a generally complex upper mantle velocity structure. Included is an ~400km wide 2% low velocity gap, relative to subducted Nazca Plate velocities beneath Peru, which is located across the subduction projection of MFZ. Our results support the conclusion that the Nazca Plate is being rifted apart along MFZ by subduction related extensional stresses.

DISCONTINUITIES IN THE LOWER-MANTLE BENEATH WESTERN PACIFIC REGION

Shao Xian ZANG, Yuan Ze ZHOU (Department of Geophysics, Peking University)

Lower mantle discontinuities draw more attention nowadays because they challenge the traditional ideas on Earth's interior structure. Abundant inter-mediate and deep earthquakes occurred in Western Pacific subduction zone, which can be used to study the deep velocity structure beneath the region. Faint converted phases from the mantle discontinuities or heterogeneities can be observed from stacked data for single event recorded by arrays or networks or from stacked data for multiple events recorded by one permanent high quality broadband station. Beside the discontinuities at the depth of 410, 520 and 660 km, discontinuities or regional heterogeneities near the depths of 900, 1070 and 1170 km are also reported to be observed in certain places. In this paper, the interfaces in lower mantle are studied. Through carefully selection of the records for each events, short period vertical component data of 27 events beneath Okhotsk Sea from 1982 to 2001 and 10 events beneath Japan Sea from 1982 to 2000 recorded by hundreds of stations at western USA, United Kingdom and Germany and the data for the 58 events beneath Tonga from 1988 to 2000 recorded by hundreds of stations located at western USA were retrieved. All the data are processed by the N-th root slant stack method (Zang and Zhou 2002) and SdP phases are picked out. The depths of conversion points are inverted with the successive integration along ray paths with PREM. From analysis, it can be found that there are interfaces at 730, 810, 880, 950, 1020, 1090, 1130, 1370, 1450, 1610 and 1770 km beneath Tonga subduction zone, 900 km beneath Okhotsk Sea region and 760 and 1120 km beneath Japan Sea region. Compared the result obtained in this study with the others, there are two interfaces coincident with each other. They exist near the depths of 900 and 1170 km. The scale or horizontal extension of the interfaces is not able to constrain at the moment. More work should be done to make sure whether other interfaces are discontinuities or regional heterogeneities related to stagnant materials of subducted slab.

ESTIMATING THE PLAUSIBLE TEMPORAL CHANGE IN THE THERMAL STATE OF D'' LAYER DUE TO SUPERPLUME EPISODES

Upendra RAVAL (National Geophysical Research Institute)

The D" layer in the lowermost part of the mantle and within few hundred km from the core mantle boundary is the modulator of the heat received from the outer core. The seismically deduced ultra low velocity zone (ULVZ) in D" layer, with reduction up to 10% in P-wave and 30% in S-wave velocities, provides strong evidence for the thermal (or magmatic pumping) of this thermal boundary layer. Since these thermal inputs generate instabilities in form of mantle plumes it is apparent that the outward flow of heat from core acts as a major source for the development of these instabilities (or plumes). It is also noted in this context that the plumes (or more correctly the super-plume) events are episodic in nature which in turn indicates that during the interval a major instability originates, the thermal state of the D" would significantly change.Using the various parameters available from high pressure temperature studies and long period geomagnetic variation this study tries to model the diffusion of electromagnetic field through the D" during (1) Superplume formation and (2) inter Superplume period. The simulation also takes into account the laterally heterogeneous nature of the D". The theoretical experiment tries to estimate whether significant difference exists between the electrical and thermal characteristics of the two states and if it could be observed through temporal (or secular) geomagnetic variations.

ONSET OF SUBLITHOSPHERIC SMALL-SCALE CONVECTION AND ITS IMPLICATIONS FOR UPPER MANTLE STRUCTURE

Jinshui HUANG, Shijie ZHONG, Jeroen VAN HUNEN (Dept of Physics, University of Colorado)

The rich structures in the Pacific upper mantle suggested from recent seismicstudies with the body-wave and surface-wave techniques prompt us to re-examine the dynamics of small-scale convection by formulating numerical models with realistic mantle rheology. Our study is focused on the onset and consequences of sublithospheric small-scale convection. In our models, small-scale convection is mainly controlled by two parameters: activation energy E and the upper mantle viscosity, the latter can be recast as Rayleigh number Ra.Our numerical studies suggest that the onset time for small-scaleconvection for flows cooling from above scales as $E^{0.742}Ra^{-0.679}$ when the large-scale plate motion is absent. The E-dependence of onset time is significantly weaker than that predicted fromDavaille and Jaupart [1994]. We found that our results of onset time are rather insensitive to large-scale plate motion and initial perturbationwhose effects are generally less than 20%. Sublithospheric small-scale convection eventually causes surface heat flux Q to deviate from the predicted from a simple half-space cooling model. The elapsed time from the onset of small-scale convection to when Q significantly deviates from the half-space cooling scales as $E^{1.516}Ra^{-0.648}$, and this is controlled by thermal diffusion through the stable portion of lithosphere (i.e., stagnant lid), as evident from $E^{0.784}Ra^{-0.333}$ scaling for the thickness of the stagnant lid. Q during the period of a few onset times immediately after the onset scales as $E^{-0.529}Ra^{0.323}$. We found that thermal anomalies associated with fracture zones significantly reduce the onset times, implying that small-scale convection always first starts near fracture zones. We also found that a thin asthenosphere can significantly delay the onset.

JSS06/09P/A04-002   1420
LITHOSPHERIC STRUCTURE IN THE AUSTRALIAN REGION- A SYNTHESIS OF SURFACE WAVE AND BODY WAVE STUDIES

Brian L.N. KENNETT, Stewart FISHWICK (Research School of Earth Sciences, Australian National University)

The configuration of earthquake belts around Australia provides awealth of events at suitable distances to be used as probes into theseismic structure of the upper mantle. The limited number of permanenthigh-fidelity seismic stations on the continent have been supplementedwith extensive deployments of portable broadband stations for periodsof a few months at each site. The combination of long term recording at the permanent stations and the broad spatial coverage ofthe portable stations have been exploited in a range of studiesof the three-dimensional structure in the mantle. The large amplitude surface waves in the later part of the seismogramtravel nearly horizontally, and can be used in a tomographic inversionto determine the 3-D variations in shear wavespeed. This approachrelies on matching the waveforms on individual paths and then mappingthe path-specific constraints on shear structure into a 3-D model.In contrast, the higher frequency body wave arrivals are refracted backfrom the variations in structure in the mantle and are particularlysensitive to discontinuities in structure. Observations out to 3000 kmprovide coverage of the structures down through the transition zone andfor the region below northern Australia, the combination ofshort-period and broadband observations provides detailedinformation on both P and S wavespeeds and attenuation structure. The combination of the different classes of results reveal a complexpattern of 3-D structure beneath the Australian region. The cratonicregion in the centre and west of Australian is underlain by a thickmantle lithosphere extending to around 210 km depth with fastwavespeeds (especially for S waves). In the asthenosphere below the Swavespeeds diminish and there is significant attenuation and also somelevel of seismic anisotropy. Beneath the eastern zone with Phanerozoicoutcrop the lithosphere is generally thinner (less than 140 km) and theasthenosphere has a pronounced low velocity zone for S again with highattenuation. The variations in seismic wavespeeds extend through the upper mantlewith noticeable differences in the transition zone. There is alsoevidence for pervasive small scale heterogeneity (scale lengths of100-200 km) superimposed on the broader scale variations that can beimaged using tomographic methods.

JSS06/09P/A04-003   1440
ON NATURE OF SEISMIC FOCAL ZONE AND RELATED TO IT PROCESSESWITH REFERENCE TO THE KURIL-JAPAN REGION

Roman Z. TARAKANOV (Institute of Marine Geology and Geophysics, Russian Academy of Sciences)

The paper deals with simple interpretation of the seismic focal zone nature. From the theory of dislocations it has been known that if near-horizontal forcesof compression or extension affect the pattern, then maximum tangential stressesand the zone of disturbances are oriented at the angle 45 degree to the acting forces. Let us take the entire continent-ocean transition zone, which is constantly affected by near-horizontal compression forces caused by the interaction between continental and oceanic structures as a large-scale ˝pattern˝. In this case maximum tangential stresses will be also oriented at the angle 45 degree to the acting forces. The seismic focal zone as a system ofdeep faults will coincide with the zone of maximum tangential stresses and willbe one of the nodal planes defined by the theory of dislocations. Seismic focalzone crossing the layers of higher and lower strength-velocity characteristics is continuously fed up with maximum tangential stresses and irregular rotationalmode of the Earth. In the area of intersection with the layers of higher velocity this energy will be constantly accumulated and can reach extra valueswhich will lead to the movement of separate blocks, i.e. to the earthquake. Inasthenospheric layers of lower velocity (lower viscosity) this energy will be relaxed increasing the layer temperature and finally can lead its separate partsto the partial melting state, which can be the feeding medium for volcanoes. Itis remarkable that the Kuril-Kamchatka island arc and volcanic chains are located above the area, where the asthenospheric layer (120-150 km) is intersected with the seismic focal zone. Let us give some seismological data, which are not agreed with the plate tectonics concept: 1. We should expect an increase in seismicity manifestations as the plate would go deeper into the upper mantle. But in fact the deepest seismic events are typical for relativelyyoung island arcs (Kuril-Kamchatka, Idzu-Bonin etc.). 2.A correlation of vulcanite compositions with depths of occurrence of Benioff zones testifies to the fact that magma emerges to the surface from different levels of upper mantle, but is not the result of melting down from the lithospheric plate. 3. From the plate tectonics positions it is difficult to explain the reasons ofthe successive pushing forward of Benioff zones with the oceanic trenches towards the Ocean. By general movement of the lithospheric conveyer from the ocean to the continent it would be natural to expect that these structures willmove in the same direction (Vlasov, 1994). Geological objections against globaltectonics have been expounded in some G.M. Vlasov's papers (1981; 1994 etc.) andin papers of other geologists. Results of works on mathematical (Demin, Zharinov, 1986, 1988) and physical modeling (Guterman, 1987) showed plausibilityof the stated viewpoints on the nature of seismic focal zones.

COMPARISONS OF MODELLING RESULTS FROM TELESEISMIC P-WAVE TOMOGRAPHY IN PROJECT TOR

Soren GREGERSEN[1], Hossein SHOMALI[2], Peter VOSS[1], Tor Working Group[1] ([1]National Survey and Cadastre - Denmark, [2]Swedish Geological Survey)

Within Project Tor, which is about Teleseismic Tomography across the Tornquist Zone in Germany-Denmark-Sweden, we have detected very significant deep lithosphere differences and are able to compare results of various interpretations. In 1996-1997 our 120 seismographs constituted the largest seismic antenna ever in Europe. The Tor area was chosen along a well studied crustal profile of an earlier project, and the inversion efforts were concentrated on the deep lithosphere and asthenosphere differences to depths around 300 km. The Tor investigation can be called two-and-a-half dimensional, as it has a 900 km profile length with 100 km width plus a few seismographs off the profile. The Tor data have been subjected to P-wave travel time tomography, surface wave and receiver function analysis as well as anisotropy and scattering measurements. It was always considered an important goal of the project to make several independent inversions of the tomography data, and compare the results in an attempt to evaluate accuracy, resolution and uniqueness of these inversions. The present paper reports on these comparisons. The outcome is a substantiation of earlier statements like: "The transition is interpreted to be sharp and steep and abrupt in three places. It goes all the way through the lithosphere at the Tornquist Zone near the border between Sweden and Denmark, and here the lithosphere difference is large. Another less significant lithosphere difference is found near the border between Denmark and Germany. Also this transition is sharp and steep, and goes all through the lithosphere. These two sharp transitions divide the Tor region into 3 different lithosphere structures distinguishable in P-wave travel time tomography, surface wave dispersion, P- and S-wave

anisotropy and partly in P-wave scattering". In addition we have found a sharp and steep transition region 100 km into the shield in Sweden. Unfortunately a detail like the slope of the lower lithosphere transition right under the Tornquist Zone cannot be constrained even if this is where the resolution is best, and the curiosity largest.

STRUCTURE OF THE LITHOSPHERE-ASTHENOSPHERE AND VOLCANISM IN ITALY AND SURROUNDINGS

Giuliano PANZA[1], Antonella PONTEVIVO[2], Angela SARAO[2], Abdelkrim AOUDIA[1], Angelo PECCERILLO[3] ([1]SAND Group, Abdus Salam International Centre for Theoretical Physics & Dept. of Earth Sciences, University of Trieste, Trieste - Italy, [2]Dept. of Earth Sciences, University of Trieste, Trieste - Italy, [3]Dept. of Earth Sciences, University of Perugia, Perugia - Italy)

The Italian peninsula and the Tyrrhenian Sea are some of the geologically most complex regions on Earth. Such a complexity is expressed by large lateral and vertical variations of the physical properties as inferred from the lithosphere-asthenosphere structure and by the wide varieties of Plio-Quaternary magmatic rocks ranging from tholeiitic to calcalkaline to sodium- and potassium-alkaline and ultra-alkaline compositions.The integration of geophysical, petrological and geochemical data allows us to recognise various sectors in the Tyrrhenian Sea and surrounding areas and compare different volcanic complexes in order to better constrain the regional geodynamics. A thin crust overlying a soft mantle (10% of partial melting) is typical of the back arc volcanism of the central Tyrrhenian Sea (Magnaghi, Vavilov and Marsili) where tholeiitic rocks dominate. Similar lithosphere-asthenosphere structure is observed for Ustica, Vulture and Etna volcanoes where the geochemical signatures could be related to the contamination of the side intraplate mantle by material coming from the either ancient or active roll-back. The lithosphere-asthenosphere structure and geochemical-isotopic composition do not change significantly when we move to the Stromboli-Campanian volcanoes, where we identify a well developed low-velocity layer, about 10 km thick, below a thin lid, overlain by a thin continental crust. The geochemical signature of the nearby Ischia volcano is characteristic of the Campanian sector and the relative lithosphere-asthenosphere structure may likely represent a transition to the back arc volcanism sector acting in the central Tyrrhenian. The difference in terms of structure beneath Stromboli and the nearby Vulcano and Lipari is confirmed by different geochemical signatures. The affinity between Vulcano, Lipari and Etna could be explained by their common position along the Tindari-Letoianni-Malta fault zone. A low velocity mantle wedge, just below the Moho, is present in all the regions related to the inactive recent volcanoes (Amiata, Vulsini, and Cimino, Vico, Sabatini, Albani Hills) in the Tuscany and Roman regions. A very thick rigid body is found in the upper mantle beneath the Ernici-Roccamonfina province that exhibits very distinct geochemical and isotopic compositions when compared with the Roman province.

3D P-WAVE VELOCITY IMAGING OF THE TORNQUIST SUTURE ZONE USING MARKOV CHAIN MONTE CARLO INVERSION AND TELESEISMIC P-PHASE ARRIVALS

Peter VOSS[1], Klaus Teddy MOSEGAARD[2], Soren GREGERSEN[1] ([1]National Survey and Cadastre - Denmark, [2]Niels Bohr Institute, University of Copenhagen)

In this study we have applied the Markov Chain Monte Carlo inversion algorithm to the teleseismic tomographic problem, using teleseismic P-phase arrivals measured during the TOR-project.TOR was a 1000km long and 100km wide antenna of mobile broad band and shortperiod seismographs, that continuously collected data in Sweden, Denmark and Germany, for half a year from 1996 to 1997. Inversion is performed using the relative arrival time of 3510 P, PKiKP and Pdiff phases, from 51 earthquakes, in an area 1350km long and 750km wide and from 50km to 350km depth. The travel time data are corrected for the relatively well-known crustal and upper mantle structure to depth 50km. Synthetic travel time calculations for 3D forward modeling of teleseismic wavefronts are performed by a finite difference algorithm. Wavefront arrival times at 350km depth are computed using the IASP91 model. The transition between the Baltic Shield and the geologically younger lithosphere to the south west is found to be narrow, near vertical and more than 300km deep.

THE LITHOSPHERE AND ASTHENOSPHERE OF THE ICELAND HOT SPOT

Ingi Thorleifur BJARNASON (Science Institute, University of Iceland)

High resolution Love and Rayleigh waves [period 5-85 s] recorded onthe ICEMELT broadband network resolve a structural landscape of theIcelandic lithosphere. It has large lateral variation in velocity,anisotropy and thickness. The main characteristic variation in theasthenosphere is anisotropy. A large asymmetry is in the thickness of the lithosphere from east to west. The mantle lid part of thelithosphere under the Eastfjords is at least 40 km thicker than theWestfjords lid, adding up to over 100 km thick lithosphere in theeast. The thick east lithosphere deflects the mantle plume head to thewest. The highest observed S lid velocities (4.5 pm 0.1 km/s) arealso under these oldest (10-15 Ma) parts of Iceland. The asymmetry inthickness can not be explained by age (cooling) as the age is assumedby surface geology to be similar on both sites of the ridge. Startingat ~12 km depth the Eastfjords have 4-6% lower velocity than astandard gabbroic Icelandic lower crust down to the 30 km depth ofthe mantle lid there. The seismic structure of the Eastfjords from 12km depth down is thus very similar to a continental structure invitingthe hypothesis of a buried continental fragment under the basalticlava pile. The surface waves show a maximum of 5-7% lateral variationin the SH and SV velocities in the crust, excluding the top 2~km,where it can be higher. The lateral variation in the mantle lidvelocity is less, generally under 5% in SH and SV. The anisotropicvariation seen by the surface waves is larger. Up to 5-10% in the crust and up to 5-8% in the mantle lid. Some parts of the lithosphereseem isotropic, expecially the top half the Eastfjords lithosphere.All observations show anisotropic asthenosphere with between 3-7%anisotropy. Under central Iceland at 30-60 km depth the anisotropycan be so large (8%) that it is not straight forward to determine whatis lid and what is asthenosphere. There is some evidence that thiszone may be transverse isotropic and that these observations of SH >SV can be explained by a horizontal layer cake structure of partiallymolten soft layers and stiffer layers between in the mantle. Similaranisotropy feature in character and magnitude is observed with onsetat 5 km depth in the crust and at least 7 km thick in both rift zonesof Iceland. There the SV velocity is at least 6% lower than in normalIcelandic lower crust. Partial melt may be required to explain such alarge anomaly. At the same depth MT measurements find a goodconductor. The observed surface wave anisotropy in the asthenospherebelow 90 km depth agrees qualitatively with SKS derived azimuthalanisotropy with NNW fast direction under central Iceland and NNE fastdirection under west Iceland and the Westfjords.

IMAGING THE RESULTS OF ARCHEAN TECTONIC PROCESSES: EM AND TELESEISMIC STUDIES OF THE SLAVE CRATON, CANADA

Alan G. JONES[1], David SNYDER[1], Bill DAVIS[1], Wouter BLEEKER[1], Herman GRUTTER[2], Pamela LEZAETA[3], Alan D. CHAVE[3], Rob L. EVANS[3], Ian J. FERGUSON[4] ([1]Geological Survey of Canada, Ottawa, Canada, [2]Mineral Services Canada, Vancouver, Canada, [3]Woods Hole Oceanographic Institution, Woods Hole, U.S.A., [4]University of Manitoba, Winnipeg, Canada)

Geophysical (magnetotelluric and teleseismic) data from the sub-continental lithospheric mantle (SCLM) of the central Archean Slave craton, northern Canada, have imaged collocated electrical conductivity and seismic impedance interfaces that correlate spatially with a unique two-layer SCLM geochemical stratigraphy and with the distribution of low-Cr (G10) garnets in xenoliths. The ultra-depleted harzburgitic layer at 80-140 km is both highly conducting and lower impedance than the underlying lherzolitic lower lithosphere layer. Taken together, these geophysical and geochemical observations imply a three-part NE-SW to E-W zonation of the Slave's SCLM that is at a high angle to the north-south trending isotope boundaries between Mesoarchean and Neoarchean crustal domains. This NE-SW mantle zonation parallels the orientation of late geological structures, including an F1 fold belt and distribution of ca. 2.63-2.62 Ga plutonic rocks. Extensive Neoarchean plutonism, crustal melting and associated HT-LP metamorphism argue for widespread elevated mantle heat input to the crust, a feature most consistent with thin (<100 km) lithosphere. We propose that the present-day mantle lithosphere developed by tectonic imbrication of one or more slabs subducted beneath the craton at 2.63-2.60 Ga. Subsequent collision, possibly accompanied with partial delamination of some of the underthrust lithosphere, produced widespread deformation and granite plutonism throughout the province at 2.6-2.58 Ga. The consequence of this model is that the Slave's mantle lithosphere, model-dated to be, in part, Mesoarchean in age, is exotic to its crust, and that the existing tectosphere grew from about 2.6 Ga onwards by subcretion (early) and thermal cooling (later).

RAYLEIGH WAVE PHASE VELOCITIES BENEATH THE NORTHERN PHILIPPINE SEA DETERMINED BY DATA FROM LONG TERM BROADBAND OCEAN BOTTOM SEISMOGRAPHS

Takehi ISSE[1], Daisuke SUETSUGU[1], Hajime SHIOBARA[2], Yoshio FUKAO[2], Kimihiro MOCHIZUKI[2], Toshihiro KANAZAWA[2], Hiroko SUGIOKA[1], Shuichi KODAIRA[1], Ryota HI NO[3] ([1]Insutitute for Frontier Research on Earth Evolution, Japan Marine Science and Technology Center, [2]Earthquake Research Institute, University of Tokyo, [3]Research Center for Prediction of Earthquakes and Volcanic Eruptions Graduate School of Science, Tohoku University)

This study is the first attempt in the world to measure the dispersion curves of surface waves using long term broadband ocean bottom seismographs. The Philippine Sea, a marginal basin of the Pacific Ocean, has a complex tectonic history, which should be reflected in its upper mantle structure. In previous surface wave dispersion studies, events and seismic stations were restricted to the periphery of the Philippine Sea because there are no earthquakes and seismic stations in the Philippine Sea. This situation has limited the resolution in elucidating lateral heterogeneities of the relevant upper mantle structure. As a part of the Ocean Hemisphere network Project (OHP) a sea floor broadband seismic observation was conducted across the Philippine Sea in a period from November, 1999 to July, 2000 with eight Long Term Broadband Seismometers LT-BBOBS. We measured phase velocities of the fundamental Rayleigh waves over the northern Philippine Sea region sandwiched by the Japanese broadband network(FREESIA) to the north and the LT-BBOBS array to the south, using a two-station method in a frequency range from 0.01 to 0.05 Hz. Owing to the deployment of a broadband OBS array we were able to determine pure path Rayleigh wave dispersion curves across the old Pacific Sea floor, the young Shikoku Basin, the Parece-Vela Basin and the actively spreading Mariana Trough, respectively. The pure path phase velocities obtained by the present study for the Pacific Sea floor with ages older than 110 Ma are consistent to the result by Nishimura & Forsyth (1988). The average phase velocity across the young Shikoku Basin is slow as compared with the model velocity of the Pacific Sea floor of the same age, which may be related to the anomalously deep sea floor depth in the Shikoku Basin. The average phase velocity across the actively spreading Marian Trough is lowest in the analyzed area. The dispersion curves of the phase velocity across the Mariana Trough are consistent to the model velocity of the Pacific Sea floor of the same age. The observation by LT-BBOBS array enabled us to measure the pure path phase velocity even in a small marginal basin and determine the structural difference of the Philippine Sea precisely. The observed deviation of the dispersion from the age-dependant velocity model may indicate the presence of a compositional anomaly beneath the Shikoku Basin, which is an important subject in the future study.

SV-WAVESPEED HETEROGENEITY BENEATH ASIA

Keith F. PRIESTLEY[1], Eric DEBAYLE[2], Sylvana PILIDOU[1] ([1]Bullard Laboratories, [2]Ecole et Observatoire des Sciences de la Terre, [3]Bullard Laboratories)

We have inverted almost 17,000 fundamental and higher mode regional Rayleigh surface waveforms to built a high resolution Sv-wavespeed tomographic model for the upper mantle beneath eastern Asia and the surrounding regions. We construct the 3D upper mantle model by first determining the 1D path-average upper mantle velocity models compatible with the observed waveforms, and then combining the 1D velocity models in a continuous tomographic inversion to obtain the local Sv-wavespeed and azimuthal anisotropy at each depth. Depending on the signal-to-noise ratio, fundamental mode is analyzed in the period range between 50 and 160 s and up to the fourth higher modes are analyzed in the period range between 60 and 90 s. We evaluate the horizontal and depth reliability of our model using a series of synthetic experiments that reproduce both steps of theanalysis procedure. These synthetic tests confirm that the dense path coverage and rich higher mode content allow us to achieve a horizontal resolution of a few hundred kilometers down to at least 400 km depth. The well resolved features of the model include: (1) a high velocity lid with respect to PREM extending to about 200 km depth beneath most of the Siberian platform and the west Siberian basin, (2) a high velocity lid beneath the western Sino-Korean Craton but low upper mantle velocities beneath the eastern Sino-Korean Craton, (3) high velocities at depths below about 120 km beneath the the Hangai Dome of north-central Mongolia, and (4) high upper mantle velocities beneath southernTibet. There is a complex pattern of azimuthal anisotropy at shallow depths (< 175 km) but the amplitude of azimuthal anisotropy decreases and the patten becomes more uniform at deeper depths (> 225 km).

UPPER MANTLE ANISOTROPY BENEATH JAPAN FROM SHEAR WAVE SPLITTING

Maureen D. LONG[1], Rob D. VAN DER HILST[2] ([1]Department of Earth, Atmospheric, and Planetary Sciences, Massachusetts Institute of Technology, [2]Faculty of Earth Sciences, Universiteit Utrecht)

Shear wave birefringence is a consequence of seismic anisotropy and is oftenused to characterize the upper mantle. Together with constraints from mineralphysics, shear wave splitting can yield information on the pattern of uppermantle deformation. In the context of a subduction zone, however, therelationship between measured shear wave splitting parameters (Φ, Δt)and geodynamical processes is not straightforward. The three-dimensionalpattern of anisotropy in a subduction zone should reflect processes such assubduction itself, back-arc extension, corner flow in the mantle wedge, flowaround the slab edge, and motion of the overriding plate. This relationshipcan be further complicated by complex slab morphology, by the presence ofanisotropy in the slab itself, and by the presence of volatiles such as water,which can dramatically change the relationships between strain geometry andresulting anisotropy. Because a single shear wave splitting measurementrepresents a path-integrated picture of anisotropy, and because most splittingstudies use phases with near-vertical incidence angles, the complexities inanisotropic structure associated with subduction zones are difficult todetect. In this study, we take advantage of dense station coverage in Japanand use phases covering a wide range of incidence angles, incomingpolarization angles, and backazimuths. We avoid making the simplifyingassumption of a single, horizontal anisotropic layer, and take advantage ofthe good data coverage needed to consider complexities in structure such asmultiple anisotropic layers, dipping symmetry axes, and small-scale lateralvariations in anisotropic properties. We utilize data from the Japanese F-net network, which comprises 65 broadbandseismic stations. We analyze shear wave splitting parameters at each stationusing methods due to *Silver & Chan* [1991], *Levin et al.* [1999], and *Chevrot* [2000]. We use recordings of local and teleseismic direct S phases as well ascore-refracted SKS and SKKS phases. Because the purpose of this study is toinvestigate three-dimensional anisotropic structure, we search for variationsin measured splitting parameters (Φ, Δt) with incidence angle andincoming polarization angle at each station. As well as examiningcomplexities in anisotropic structure beneath individual stations, we map thelarge-scale spatial variations of shear wave splitting parameters over thearea of the network. These spatial variations of shear wave splittingpresumably reflect the pattern of mantle flow associated with subductionbeneath the Japanese islands.

ENHANCEMENT OF DECOMPRESSION MELTING IN THE PRESENCE OF CONTINENTAL ROOT IN PLUME- LITHOSPHERE INTERACTION MODELS

A. MANGLIK[1], U.R. CHRISTENSEN[2] ([1]National Geophyscal Research Institute, Uppal Road, Hyderabad 500007, India., [2]Institut fuer Geophysik, Herzberger Landstrasse 180, 37075 Goettingen, Germany.)

Global distribution of Large Igneous Provinces (LIPs) shows that in many of these provinces massive volcanic events associated with starting plume heads occurred at the margins of continental lithosphere. The contrast between the thick lithospheric root and adjacent thinner lithosphere affects the spreading of the plume head below the plate. In the present study, we analyse the effect of lithospheric roots on the pattern of plume flow and decompression melting in three-dimensional numerical models. We also incorporate horizontal shear due to plate motion. We assume the viscosity to be temperature- and depth-dependent and define the lithosphere as mechanically strong, high viscosity lid. Decompression melting is computed by using the batch melting model of McKenzie and Bickle. Presence of a root inhibits uniform lateral spreading of the plume. The plume material rising beneath the lithospheric root deflects away from the root and rises to comparatively shallow depth at its margin. Our results show that the deflection of plume material towards one side can facilitate a more than three fold enhancement in the total melt production rate in comparison to models without root. The model reproduces the characteristics of melting rates and melt volumes seen in flood basalt provinces without invoking an excessively high plume thermal anomaly. Our results also support juxtaposition of late-stage and main phase of volcanism in a flood basalt province.

JSS06/10A/A04-002   0850

GLOBAL DEVIATORIC STRESS IN THE LITHOSPHERE FROM GEOID HEIGHT, TOPOGRAPHY, AND STYLE OF FAULTING

David T. SANDWELL, Bridget SMITH (Scripps Inst. of Oceanography)

Stress in the Earth´s lithosphere is due to three forces: slab pull, swell-push, and asthenospheric drag. While the swell-push force can be measured from geoid height variations across seafloor spreading ridges, the global stress field of the Earth is still poorly determined because the dominant slab-pull force is largely unknown. Here we attempt to develop a 3-D global stress model of the lithosphere that is consistent with three key observations ; geoid height, topography, and style of faulting. Our method follows: 1) Part of long-wavelength ($>$ 400 km) 2-D global stress field can be estimated from geoid height. The geoid is decomposed into a ˝lithosphere˝ contribution and a ˝deep mantle˝ contribution by making plausible assumptions about the compensation mechanisms of the continents and the seafloor spreading ridges (i.e., ridges are weak). This "lithospheric" contribution is used to construct a partial global stress model. 2) The topography of the Earth is high-pass filtered to isolate wavelengths shorter than 400 km. We use a (3-D) semi-analytic solution for the loading of an elastic half-space from both surface topography and compensating Moho topography to calculate the stress in the crust and lithosphere. This short-wavelength stress field is added to the long-wavelength field to construct the trial global 3-D stress model. 3) Finally, we test the style of faulting predicted by this model (normal, strike-slip, or thrust) with the known active faults along plate boundaries. For example, the model predicts 12 MPa of extension, at 6 km depth, in the Transverse Ranges of the Big Bend area. Because the method of faulting through the Big Bend area is primarily strike-slip, there must be a 12 MPa tectonically-induced compressional stress that is not predicted by the model. We will explore the possibility of correcting the model by applying the appropriate tractions along the plate boundaries.
